As alluded to above, EPR and X-ray spectroscopies have also generously fed the debate on the valence state of the tetranuclear cluster during the catalytic cycle. Mn edge absorption spectroscopy has provided strong evidences for oxidation of an Mn atom during the S_0 to S_1 and S_1 to S_2 transitions. EPR and (less clearly) UV spectroscopies supported this view. Based on a kinetic analysis the S_4 is equivalent to the $[S_3Y_Z^{ox}]$ state. This seems to ground the accumulation of four oxidizing equivalents within the catalytic center (which would then include Y_Z as a partner), before water is oxidized. Yet, the assignment of the substrate of the oxidation associated with the S_2 to S_3 transition is still an open question. This ambiguity mainly comes from the fact that depending on the group involved in these studies, X-ray absorption spectroscopy shows either a shift in the absorption edge consistent with a Mn oxidation, or little, if any, shift in the absorption edges, ruling out this latter assignment and favoring the formation of a radical species. Unfortunately other spectroscopies such as EPR or UV absorption did not provide either unequivocal results. The disappearance upon S_3 formation of the EPR "multiline signal" arising from S_2 could be taken as a strong support for a Mn oxidation. However, this disappearance could be as well accounted for by a magnetic interaction between a radical species and the Mn cluster as argued by Styring, Rutherford, and Boussac.

The Mechanism of Water Oxidation

If indeed, the S_2 to S_3 transition involves the formation of a radical species, the possibility arises that a water molecule is oxidized during this step. If, on the contrary, the three successive steps leading to the formation of S_3 only involve Mn oxidation, an obvious conclusion is that water oxidation only takes place after the formation of S_4 (i.e., $S_3Y_Z^{ox}$). As just seen, this alternative could not be settled by spectroscopic approach. However, recent experiments on substrate binding tilt the scale toward

the latter and further constrain the inventiveness when attempting to draw possible mechanism for water splitting.

Substrate/Bulk Water Molecule Exchange

In a series of very elegant studies, Hillier and Wydrzynski have used isotopically labeled water ($H_2\ ^{18}O$) and measured the release of either O_2^{34} or O_2^{36} after a rapid mixing with PSII in the presence of unlabeled water. Most interestingly, they observed that substrate water may be exchanged with bulk water up to the S_3 state. This has been, until now, the strongest result in favor of a O–O bond-formation step occurring after S_3 is formed and thus during the S_4 to S_0 transition.

Proton Release during the Catalytic Cycle

The oxidation of two water molecules does not only release oxygen as a byproduct but also four protons. From the pioneering work of Fowler it is known that proton release accompanies the S_i to S_{i+1} transitions, which precedes the final S_4 to S_0 step during which O_2 is released. However, it is commonly agreed that these proton release events do not result from water chemistry. Indeed, proton transfers are often associated with redox changes either when the species which undergo the redox change is itself protonated or when the change in electrostatic potential resulting from the redox change shifts the affinity of a nearby acid group for proton. The two non-exclusive processes are likely to be at work, simultaneously or not, during the S_0 to S_1, S_1 to S_2, and S_2 to S_3 steps. The different groups which are deprotonated during these steps would be reprotonated by the protons produced during water oxidation. Although they most probably do not originate from water splitting, the proton release events occurring during the first three steps do play an important role in the overall water chemistry. They obviously compensate the charge accumulation which would otherwise result from three successive electron abstractions from a single catalytic unit. They control the thermodynamics of the enzyme by modulating the redox potential of the successive intermediate.

The Mechanisms for O_2 Formation

As discussed above, many issues regarding the catalytic cycle are still obscure. This may explain why there are almost as many mechanistic models for water splitting as groups studying this fascinating enzyme. It is beyond the scope of the present overview to present them all. As described Mn atoms are oxidized during some, if not all, transitions between S states. Obviously many models have incorporated these results and are based upon Mn-centered redox chemistry. There is a trend toward mechanisms in which only two among the four Mn atoms really participate in the water chemistry. The oxo or μ-oxo bridges which are thought to link the Mn atoms may also participate to the formation of the final O–O product. Last, the tyrosine Y_Z could play a crucial catalytic role. As discussed above, the S_4 state is equivalent to the $[S_3Y_Z^{ox}]$ state so that Y_Z may be considered as a full member of the catalytic center. The close proximity between Y_Z and the Mn cluster supports this view. Furthermore the phenolic oxygen of the tyrosine side chain is protonated when Y_Z is in the reduced state, whereas EPR spectra shows Y_Z^{ox} is deprotonated. Its reduction must thus be accompanied by its reprotonation. This led G. Babcock to propose that Y_Z could act as H atom abstractor undergoing a simultaneous reprotonation and reduction at the expense of water molecule. Although it seems to be agreed that this process does not occur on each step, as previously proposed, this model is largely resorted to for the higher S-states transitions.

Perspective

Obviously important questions such as when and how does water oxidation chemistry come into play are still unsettled. However, as illustrated by the recent release of new structural models by Shen or Iwata and Barber, the expected improvement in our knowledge of PSII at the atomic level should clarify if not solve some of the remaining ambiguities. Yet, it will not put an end to the sparkling development of models and concepts since identifying the different intermediate states during the overall reaction is a constantly renewed challenge, which is likely to be taken up by the field.

Glossary

chlorophyll excited state State that is formed after absorption by a chlorophyll molecule of a light quantum. At the molecular orbital level it corresponds to the hopping of an electron from the highest occupied molecular orbital to the lowest unoccupied molecular orbital.

oxidation De-electronation reaction or abstraction of an electron from a molecule.

reduction Electronation reaction. An electron transfer reaction occurs between an electron donor (which is oxidized) and an electron acceptor (which is reduced). In the case of photosynthetic water oxidation, two molecules of water (H_2O) are oxidized into molecular oxygen and serve as an electron source.

S_i states Successive states, as defined by B. Kok, formed during the accumulation in the catalytic center of the water-splitting enzyme of the oxidizing power required to split water into dioxygen. The transition from state S_i to state S_{i+1} reflects the abstraction of one electron from the catalytic center.

Biography

Fabrice Rappaport joined Pierre Joliot's Lab in 1990 and holds a permanent position in the Centre National De La Recherche Scientifique. His principal interests are in proton and electron transfer in photosynthetic bioenergetic chain.

Pierre Joliot is a Professor Honoraire at the Collège De France And member of the French And United States Academies Of Science. He has developed tools to study the photosynthetic process *in vivo* and is mainly interested in the photosynthetic electron transfer chain with an emphasis on its supramolecular organization.

Plant Signaling: Peptides

Clarence A. Ryan and Gregory Pearce
Washington State University, Pullman, Washington, USA

Peptide hormones are extracellular signaling molecules that are found in animals, yeast, and plants. In animals, many physiological processes are regulated by peptide signals including, for example, metabolism, cell division, growth, pain, well-being, reproduction, and immunity. Before 1991, plants were thought to utilize small, non-peptide organic molecules called phytohormones, to regulate all physiological processes. Since then, over a dozen peptide hormones have been isolated from plants, or identified by genetic approaches, that regulate physiological processes, such as defense, cell division, growth and development, and reproduction.

Many similarities exist between some animal and plant peptide hormones, their receptors, and their signaling pathways, indicating that they may have evolved from common ancestral origins. Several plant peptide hormones and their precursor are shown in Figure 1. Plant peptide hormones and their receptors provide new approaches for improving crop yields and for the production of phytochemicals for industry and medicine.

Systemins

Tomato Systemin

The tomato systemin peptide $^{+}$AVQSKPPSKRD PPKMQTD^{-} is composed of 18 amino acids and is derived from a 200 amino acid precursor protein. The precursor, called, prosystemin, differs from animal peptide hormone precursors in that it lacks a signal sequence at its N terminus and is not synthesized through the secretory pathway. The potency of systemin is similar to animal peptide hormones, being active in the nanomolar range. The function of systemin as a primary signal for the activation of defense genes was confirmed by producing transgenic tomato plants that constitutively express an antisense prosystemin gene. The plants do not exhibit a systemic induction of proteinase inhibitors in response to *Manduca sexta* larval damage or to other mechanical wounding, and the larvae rapidly consume the plants in contrast to the less palatable wild-type plants.

Prosystemin genes are present in various solanaceous species, but not all, and its gene has not been identified in any other plant family. Why and how systemin evolved as a systemic wound signal only in some solanaceous species is not known. The mechanism for the release and transport of systemin through the plants is also not understood, but its long range signaling effects in response to wounds caused by attacking insects are thought to involve a mechanism for amplification of the signal. The presence of prosystemin in vascular bundle cells suggests that its localization there is important for long distance signaling. The proteolytic processing of prosystemin does not involve the typical dibasic sites usually found for processing of animal secretory prohormones. Processing enzymes that convert prosystemin to systemin have not been identified, nor have the initial cleavage sites.

Systemin exhibits only weak structural features in aqueous solutions, which reflect a poly(L-proline) II, 3_1 helix secondary structure that is due to the two proline doublets in the central region of the peptide. The resulting kinks in the peptide appear to be important for recognition by its receptor. The systemin receptor is a 160 kDa membrane-bound protein. It is a leucine-rich repeat (LRR) receptor kinase with a K_d of about 10^{-10} M, which is generally similar to many peptide-LRR receptor kinase interactions found in animals.

Systemin activates a complex signaling pathway that is analogous to the inflammatory response in animals. Early events following the systemin-receptor interaction include the activation of a MAP kinase and a phospholipase that cleaves linolenic acid from membranes, in much the same manner as arachidonic acid is released from animal membranes in response to cytokines. In plants, linolenic acid is converted to the oxylipin, jasmonic acid, a powerful inducer of defense genes, while in animals arachidonic acid is converted to the oxylipin prostaglandins, a mediator of inflammation.

Tomato and Tobacco Hydroxyproline-Rich Glycosylated Defense Signals

Other peptide signals have been associated with the activation of defense genes in response to herbivore attacks; two in tobacco leaves and three in tomato leaves. These peptides range from 15 amino acids to

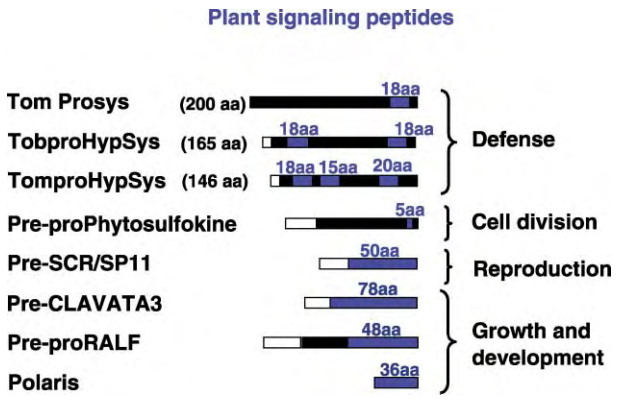

FIGURE 1 Box representations of plant peptide hormones and, where known, the precursor proteins from which they were derived. The locations of the peptides within the precursor are designated by the blue boxes.

20 amino acids in length and are structurally different from systemin in that they are hydroxyproline-rich and are glycosylated. This suggests that they are synthesized through the secretory pathway. The peptides activate proteinase inhibitor genes when supplied to plants at nMolar levels. Because of their sizes and their biological activites in signaling the activation of defense genes, they have been assigned to the systemin family, which is now a functionally defined family of peptide defense signals that are derived from plants.

The tobacco peptides are called Tobacco Hydroxyproline-rich Systemins, abbreviated to TobHypSys I and TobHypSys II. Wounding tobacco leaves results in a strong local response but a very weak systemic response, and these peptides are thought to be involved in signaling that is localized within the wounded leaves. The two tobacco systemins are derived from a single precursor protein of 165 amino acids that includes a signal sequence, with TobHypSys I sequence near the N terminus and TobHypSys II sequence near the C terminus.

The three tomato peptides, called TomHypSys I, II, and III, may also be localized signals, since prosystemin antisense tomato plants do not respond systemically to wounding but do generate a substantial localized wound response. As in tobacco, the localized defense response may result from the release of the TomHypSys peptides near the wound sites. The three TomHypSys peptides are derived from a single 146 amino acid precursor that has a leader peptide at its N terminus. Multiple peptide signals derived from a single precursor, as found with both TobHypSys and TomHypSys peptides is a scenario that is often found among precursors of peptide hormones in animals.

Standard protein–protein and nucleotide–nucleotide searches for cDNAs and pre-proproteins with homologies to the systemin precursor genes did not reveal homologues in other plant species, but short regions (less than 10 amino acids) in the N and C termini of the TomHypSys and TobHypSys precursors exhibit identity, suggesting that their genes may have evolved from a common ancestor.

Peptide Signals for Growth and Development

Phytosulfokine

A sulfated pentapeptide, called phytosulfokine (PSK), with the structure Tyr(SO_3H) -Ile-Tyr(SO_3H) -Thr-Gln, regulates plant cell proliferation. The peptide was initially found to cause low-density suspension cultured cells to proliferate rapidly. PSKs with identical structures are found in many plants, where they are derived from larger precursor pre-proproteins. The rice (*Orizae sativa) PSK* gene, for example, is a single-copy gene consisting of one large intron and two exons. The gene codes for a PSK pre-prohormone precursor of 89-amino acids including a leader peptide, suggesting that it is synthesized through the secretory pathway, where sulfation and processing occur. Sulfated tyrosines are often found in animal proteins, but to date PSK is the only example of a post-translational sulfated tyrosine in plants.

PSK is the ligand for a 150 kDa membrane-bound LRR receptor kinase with a K_d in the nMolar range. It plays *in vivo* functional roles in differentiation of cell cultures of zinnia into tracheary elements, in somatic embryogenesis in carrot, in the induction of adventitious root and bud formation in *Antirrhinum* callus, and in the formation of adventitious roots on cucumber hypocotyls. These effects of PSK require the presence of various levels of two small phytohormones, auxin, and cytokinin, indicating that PSK is part of a complex, but integrated, signaling network.

Clavata3

Clavata3 (CLV3) is an extracellular signaling polypeptide composed of 96 amino acids of which 18 residues comprise an N-terminal leader peptide. CLV3 and its receptor CLV1 have been studied extensively in *Arabidopsis thaliana*. CLV3 helps determine the fate of cells in shoot apical meristems (SAM). The identity and position of aerial organs in plants is initiated and established in the SAM, where a balance between the division of stem cells and differentiation is maintained as the plant grows. The stem cells divide slowly while the surrounding cells divide and differentiate.

No evidence is available to support any further processing of CLV3 after removal of the signal peptide, but dibasic or monobasic residues are present internally

that could be candidates for processing sites to produce smaller peptides that may have a role in signaling.

The CLV3 receptor, CLV1, is an 980 bp LRR receptor kinase that is associated with a 720-amino acid LRR receptor-like protein lacking a kinase domain. The CLV3-receptor complex results in autophosphorylation, leading to the binding of downstream signaling proteins as an early step in stem cell differentiation.

SCR/SP11: Signals for Self-Incompatibility

A family of intercellular signaling peptides of 47–60 amino acids in length play a central role in pollen self-incompatibility in the Brassicaceae family. The peptides are cumulatively called S-locus Cysteine Rich proteins (SCR) or S-locus Protein 11 (SP11), and are signals from the pollen that determine incompatibility when recognized by the appropriate receptor. During pollination, as pollen comes in contact with the papilli of the stigma, a self-recognition occurs that results in dehydration of the papilli and cessation of the pollenation process. SCR/SP11 peptides are found as a large gene family of 28 members that are derived from cysteine-rich pre-proteins of 74–83 amino acids in length that include leader peptides. In contrast to animal and plant leader peptides, the amino acid sequences of the SCR/SP11 leader peptides are highly conserved, while the mature SCR/SP11 peptides share only weak identities except at the eight cysteine positions that are conserved among most of the family members.

SCR/SP11 interacts with an S-locus Receptor Kinase (SRK). The receptor in Arabidopsis is composed of 858 amino acids including a 31 amino acid leader peptide. It is localized in membranes associated with the cell walls of stigma papillae. The SRK has a functional serine/threonine kinase at its C terminus with a transmembrane region in the middle and an extracellular cysteine-rich domain at its N-terminal region. An abundant soluble 60 kDa S-Locus Glycoprotein (SLG) appears to be associated with SRK and is often present in a 100-fold excess and appears to facilitate a functional SCR/SRK/SLG complex that results in signaling intracellular events leading to dehydration and incompatibility.

RALF, a Signal for Root Growth

The rapid alkalinization factor, called RALF, is a 49 amino acid peptide that is derived from the C terminus of a 115-amino acid precursor that contains a 25 amino acid leader peptide at its N terminus. RALF was named because of its ability to cause a rapid alkalinization of suspension cultures of tomato, tobacco, and alfalfa. Databases revealed the existence of RALF homologues in more than 15 plant species from nine families, present in a variety of tissues and organs. Two binding proteins of 120 and 25 kDa are thought to be part of a receptor complex that recognizes RALF to initiate a signaling pathway. The addition of micromolar solutions of tomato RALF to germinating tomato and Arabidopsis seedlings caused root growth to immediately cease. RALF inhibits both cell elongation and cell division. While its specific biochemical role in plants is not known, the ubiquity of the RALF peptides suggests that they have a fundamental physiological role in different organs and tissues of the plants. Nine RALF genes are present in Arabidopsis that contain highly conserved RALF sequences. The N-terminal amino acid sequences of each RALF precursor are much less conserved than the C-terminal sequences encoding the RALF peptide. The presence of two Arg residues just upstream from the putative N termini may be a recognition site for processing enzymes. The region just upstream of the dibasic site is rich in polar residues that are highly conserved among RALF precursors from different species and, as in animals, may be part of a recognition site for a RALF-processing proteinase.

Other Signaling Peptides

Several other peptides have been suggested to be hormone-like signaling molecules in plants with various roles related to growth, development, and differentiation. A small peptide of 36 amino acids lacking a signal peptide is translated from a 450 bp mRNA in Arabidopsis seedlings and root tips. This peptide, called POLARIS, is required for cytokinin and ethylene signaling during root growth, but its specific role in signaling is not known.

Several laboratories have looked for homologues of animal peptide hormone genes in plants, but none have been found.

Concluding Remarks

Since the discovery of insulin in 1922, hundreds of peptide hormones have been found in animals that regulate fundamental physiological processes. Over a dozen peptide hormones have now been identified in plants, establishing a new frontier for studies of plant growth, development, reproduction, defense, and responses to the environments. In many respects the properties of plant peptide hormones resemble those of animals, but several plant peptides have unique properties, indicating that the diversity of properties of peptide signals in plants may be the rule, rather than the exception. It is not clear whether all peptide signaling traces back to a common ancestral signaling system, or if

peptide signaling was reinvented many times by nature during the evolution of plants and animals. It is clear that peptide signaling has conferred a distinct advantage to the organisms, whether animal or plant. The recent discovery of peptide signals has laid to rest the long held hypothesis that all plant processes are regulated by small phytohormones.

To date, the receptors for peptide hormones appear to be either LRR receptor kinases or cysteine-rich receptor kinases (SRK). Although only a small number of plant peptide hormones and their receptors have been identified, peptide signaling in plants has become a focus of inquiry to gain a better understanding of plant signaling. Peptide signaling is a new area of research for the discovery of fundamental knowledge about plants. Such knowledge holds promise to reveal novel regulatory systems that can be used for biotechnological approaches to improve man's environment, to increase crop yields, and to provide nutraceuticals and medicines for human health.

Plasma-Membrane Calcium Pump: Structure and Function

Emanuel E. Strehler
Mayo Clinic College of Medicine, Rochester, Minnesota, USA

Plasma-membrane calcium pumps, also called plasma-membrane calcium ATPases (PMCAs), are integral membrane proteins responsible for the expulsion of ionized calcium (Ca^{2+}) from the cell interior to the extracellular milieu. They use adenosine triphosphate (ATP) as energy source to pump Ca^{2+} "uphill" against a large concentration gradient, thereby ensuring that the resting free intracellular Ca^{2+} concentrations remain low and that Ca^{2+} signaling can occur with fidelity and spatial precision.

Plasma-Membrane Calcium Pump Abundance and Isoforms

Plasma-membrane calcium pumps are ubiquitous in eukaryotic cells, although there are differences in expression during development in various tissues and even among different membrane domains within the same cell.

Isoforms

In mammals, multiple plasma-membrane calcium pumps are generated from multigene families and via alternative RNA splicing, giving rise to pump isoforms with distinct regulatory and functional properties. Humans, rats, mice, and other mammals express four distinct genes (human genome database nomenclature ATP2B1–ATP2B4) coding for PMCA isoforms 1–4. Alternative RNA splicing of the primary gene transcripts occurs at two major sites (called splice sites, A and C) and involves multiple exons that can either be spliced out or wholly or partially retained in the final mRNA (Figure 1). Combinatorial alternative splicing produces multiple splice variants of each PMCA isoform.

Expression

Development

Plasma-membrane calcium pumps are differentially expressed during mammalian development, though mouse embryonic stem cells express all four PMCA genes. In mice, PMCA1 is expressed from the earliest embryonic stage identified, and is ubiquitously present in all tissues. PMCA 2, 3, and 4 are first detected at ~12 days postcoitum and show a changing and restricted tissue distribution during embryonic development. PMCA2 is essentially confined to neuronal tissues, PMCA3 initially shows widespread expression but eventually becomes restricted to the nervous system and muscle, and PMCA4 is transiently expressed at high levels in the liver but then becomes less abundant and more evenly distributed in multiple tissues including the brain, heart, and intestine.

Tissues

In the adult, PMCA1 and PMCA4 are expressed in virtually all tissues, with PMCA1 normally being the most abundant isoform. PMCA2 is largely confined to nervous tissue as well as to epithelia of the breast and kidney, and PMCA3 is expressed at generally low levels and restricted to specific areas in the brain and to skeletal muscle.

Cells

Differential distribution of PMCA isoforms in different plasma membrane domains has been demonstrated in many cell types, notably in highly polarized cells such as retinal photoreceptors, auditory, and vestibular hair cells, cerebellar Purkinje cells, and epithelial cells. In cochlear hair cells, for example, PMCA2 is exclusively and highly expressed in the apical stereocilia, whereas PMCA1 may be concentrated along the basolateral membrane and close to synaptic terminals.

Plasma-Membrane Calcium Pump Structure

The overall structure of plasma-membrane calcium pumps resembles that of the calcium pump of the

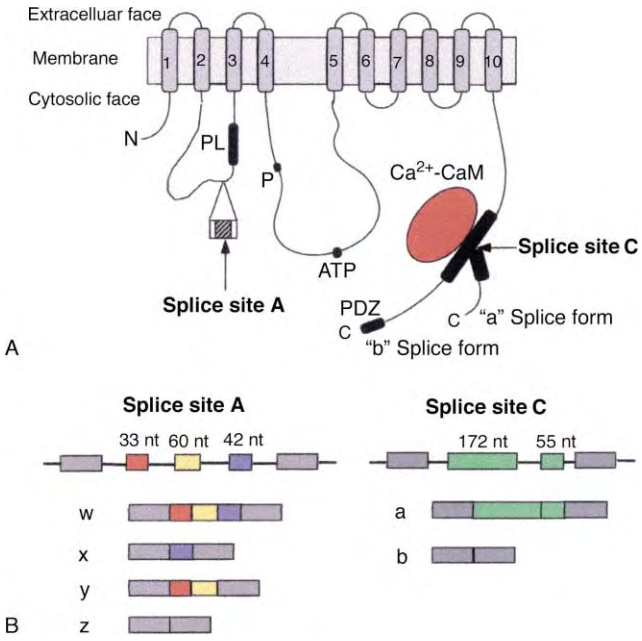

FIGURE 1 (A) Schematic model of the plasma membrane calcium pump, showing the major domain substructure. The ten transmembrane regions are numbered and indicated by shaded boxes. The cytosolic amino- (N) and carboxyl-terminal (C) ends are labeled, and a phospholipid-sensitive region (PL), the calmodulin-binding region and the C-terminal PDZ domain binding sequence of the "b" splice forms are shown as black boxes. P is the site (aspartate residue) of the obligatory aspartyl-phosphate formed during each Ca^{2+} transport cycle, and ATP denotes the specific residues involved in nucleotide (ATP) binding. The PMCA is shown in its active form, with Ca^{2+}-loaded calmodulin (Ca^{2+} -CaM, red oval) bound to the regulatory C-terminal tail. Arrows labeled "splice site A" and "splice site C" denote the regions affected by alternative splicing. At site A, the peptide segment encoded by alternatively spliced exon(s) is indicated by a hatched box, and at site C, the two major splice variants (a and b splice forms) created by alternative splicing are drawn as separate carboxyl-terminal tails. (B) Major alternative splicing options for the generation of PMCA splice variants. The example given is that of human PMCA2. At splice site A, three exons (shown as red, yellow, and blue boxes) can be all excluded or variably included to generate splice variants w, x, y, and z. At splice site C, two exons (green boxes) are either included or excluded to generate splice variants a or b, respectively. The sizes of the exons in human PMCA2 RNA are indicated in nucleotides (nt). Constitutively spliced exons are shown as dark gray boxes. Note that the combinatorial use of splicing options at sites A and C can generate a large number of different PMCA variants.

sarco/endoplasmic reticulum membrane. Major features include intracellular amino- and carboxyl-terminal ends, ten membrane-spanning domains, and three distinct intracellular domains involved, respectively, in ATP binding (N-domain), formation of an obligatory phosphorylated intermediate (P-domain), and actuating large conformational movements (A-domain) to complete the catalytic cycle that links ATP hydrolysis to transmembrane movement of Ca^{2+} (Figure 2).

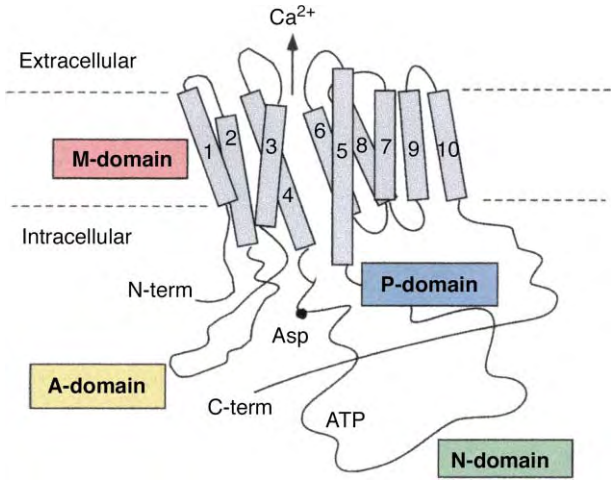

FIGURE 2 Folding and domain model of the PMCA based on structural homology to the sarco/endoplasmic reticulum calcium pump. The ten membrane-spanning regions are numbered and shown as gray cylinders forming the M-domain. The invariant aspartate residue (Asp) undergoing phosphorylation during the reaction cycle is indicated, as is the ATP-binding site (ATP). The three major cytosolic domains are labeled A (actuator), P (phosphorylation), and N (nucleotide-binding). The amino (N-term) and carboxyl ends (C-term) are indicated; the arrow shows the direction of Ca^{2+} pumping. The extended C-terminal tail is drawn to indicate its intramolecular interaction with other cytosolic domains as found in the autoinhibited state of the pump.

Mechanistic Aspects

The plasma-membrane calcium pumps belong to the superfamily of P-type ion-motive ATPases, where they are classified into the type II subfamily that also includes organellar Ca^{2+} ATPases, Na^+/K^+ ATPases, and H^+/K^+ ATPases. The salient feature of the P-type ATPases is the formation of a phosphorylated intermediate during the reaction cycle, whereby the γ-phosphate of ATP is transferred to an invariant aspartate residue in the central catalytic domain of the pump (see Figures 1 and 2). The basic reaction scheme for the stepwise cycling of the pump between conformational states which link ATP hydrolysis and ion translocation across the membrane is described by the E1–E2 model (Figure 3). In this scheme, the pump alternates between the E1 and E2 conformations, where the E1 state describes the pump with its ion (Ca^{2+}) sites facing the cytoplasmic side and the E2 state that of the pump having its ion sites facing the extracellular side. The energy of hydrolysis of one ATP molecule is required for each Ca^{2+} ion transported by the plasma membrane calcium pump. The Ca^{2+} transport cycle is accompanied by large conformational changes in the pump protein, whereby the reactions occurring at the cytoplasmic ATP binding and phosphorylation sites are coupled to the rearrangement of the membrane-spanning domains corresponding to the Ca^{2+} transport site. The positive charge

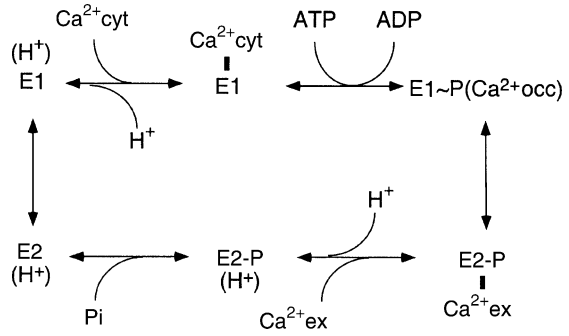

FIGURE 3 Reaction scheme of the plasma membrane calcium pump. The pump adopts two major states E1 and E2. The E1 state shows high affinity for Ca^{2+} on the cytosolic side of the membrane (Ca^{2+} cyt). Ca^{2+}-binding stimulates the ATPase activity of the pump, leading to the formation of the phosphorylated intermediate E1 ~ P and "occlusion" (occ) of the bound Ca^{2+} ion. Translocation of the Ca^{2+} ion across the membrane occurs concomitantly with the release of stored energy during the conformational transition from the E1 ~ P to the E2-P state. The Ca^{2+} affinity of the pump in the E2-P state is low and Ca^{2+} dissociates on the extracellular side of the membrane (Ca^{2+} ex). This is followed by hydrolysis of the phosphoenzyme and rearrangement of the E2 to the E1 state. The charge movement during Ca^{2+} transport is at least partially neutralized by countertransport of protons (H^+).

movement accompanying the transport of Ca^{2+} from the intracellular to the extracellular side of the membrane is at least partially compensated by countertransport of H^+ ions. When fully active, the turnover number of the PMCA is of the order of 50–100, i.e., a single PMCA molecule can pump about 50–100 Ca^{2+} ions per second across the membrane.

Domain Structure

The plasma-membrane calcium pumps can be divided into an N-terminal cytoplasmic domain followed by a first membrane-spanning hairpin loop, an intracellular loop making up most of the A-domain, a second membrane-spanning hairpin loop, the major cytosolic catalytic loop containing the nucleotide-binding and phosphorylation domains, three additional membrane-spanning hairpin loops and a final, cytosolic C-terminal domain containing multiple regulatory sequences (Figures 1 and 2). Based on structural homology to the sarco/endoplasmic reticulum calcium ATPase (SERCA) for which a high-resolution three-dimensional structure is available, the PMCAs consist of a compact membrane-embedded domain comprising the ten membrane-spanning regions, and of a large cytoplasmic domain that can be subdivided into the three well-separated A, N, and P domains (see Figure 2). The P (phosphorylation) domain of the PMCA assumes the structural-fold characteristic of haloacid dehalogenase. The three-dimensional structure of the C-terminal regulatory domain unique to the PMCAs is not yet known, but chemical cross-linking and proteolysis studies indicate that this domain is involved in extensive intramolecular interactions with the A and the N/P domains.

Plasma-Membrane Calcium Pump Regulation and Function

Plasma-membrane calcium pumps function to maintain and reset the low (~100 nM) intracellular Ca^{2+} concentrations required for effective Ca^{2+} signaling. Through multifaceted regulation, these pumps also participate in spatio-temporal Ca^{2+} signaling by restricting the spread of Ca^{2+} signals and reducing noise in local signal transduction.

Regulation

The calcium sensor protein calmodulin is a major regulator of the plasma-membrane calcium pumps. In general, the PMCAs are autoinhibited at very low cytosolic-free Ca^{2+} concentrations ($[Ca^{2+}]_i$ < 50–100 nM). Upon a rise in $[Ca^{2+}]_i$, Ca^{2+}-calmodulin activates the PMCAs by releasing the autoinhibition. Calmodulin binds to a specific binding site of varying length in the C-terminal tail of the PMCAs (Figure 1). Different PMCA isoforms and alternative splice variants show different affinities for Ca^{2+}-calmodulin, and hence are differently sensitive to rises in $[Ca^{2+}]_i$. The PMCAs are also regulated by phosphorylation. Protein kinases A and C phosphorylate specific residues in the C-terminal tail of various PMCAs downstream of and/or overlapping the calmodulin-binding domain. The effects of phosphorylation on PMCA activity are complex, involving both direct activation (by deinhibiting the pump) as well as interference with calmodulin regulation. Different PMCA isoforms and splice variants react differently to Ser/Thr phosphorylation in their C-terminal domains, depending on the specific sites of phosphorylation and the surrounding sequence context. Tyrosine phosphorylation also has been observed in some PMCAs and may lead to changes in the cellular distribution of the pumps. Additional regulatory mechanisms for the PMCAs involve activation by dimerization or oligomerization and stimulation by various acidic phospholipids (such as phosphatidic acid, phosphatidylinositol-phosphates). A phospholipid-sensitive region has been identified near the third membrane-spanning region in the A-domain (Figure 1). PMCA splice variants ending with the C-terminal amino acid sequence … GluThrSerVal or … GluThrSerLeu ("b" or CI splice variants, see Figure 1) bind directly to the PDZ (*PSD95/Dlg/ZO-1*) protein–protein interaction domain found in many scaffolding,

anchoring, and signaling proteins. These interactions may anchor the PMCAs to the submembraneous actin cytoskeleton and recruit them into multiprotein complexes with other membrane receptors, transporters, and signaling molecules.

Function: Resetting and Maintenance of Resting Calcium Levels

The primary function of the PMCAs has been traditionally linked to the maintenance of low resting levels of intracellular Ca^{2+}. In cell types such as human erythrocytes where the PMCA is the sole system for Ca^{2+} expulsion from the cytosol, the function of this pump is essential for Ca^{2+} homeostasis and normal cell physiology. Because of its low capacity (turnover number < 100) and low abundance in most membranes, the PMCA is not well suited to the mass evacuation of high Ca^{2+} loads that may occur after global Ca^{2+} influx (such as happens with every beat of a heart muscle). In these cases other, low-affinity but high-capacity systems such as the Na^+/Ca^{2+} exchangers are responsible for the bulk export of Ca^{2+} from the cell. However, with their high Ca^{2+} affinity in the fully activated state ($Kd_{Ca^{2+}} < 0.2\ \mu M$), the PMCAs are the only transport system of the plasma membrane capable of reducing cytosolic Ca^{2+} levels down to the required submicromolar and even nanomolar levels. The specific PMCA isoform and splice variant expression pattern enables each cell to fine-tune and maintain its $[Ca^{2+}]_i$, and to reset $[Ca^{2+}]_i$ to the resting level following transient increases generated by Ca^{2+} signals.

Function: Vectorial Calcium Transport And Local Calcium Signaling

In epithelia involved in transcellular Ca^{2+} transport, e.g., in the intestine and the distal kidney, the PMCAs are concentrated in the basolateral membrane of the cells where they play an important role in vectorial Ca^{2+} transport from the apical (intestinal lumen, kidney urinary lumen) to the basal (blood) side. In other tissues and cell types, e.g., in the choroid plexus and cochlear hair cells, specific PMCA isoforms are uniquely expressed in the apical plasma membrane where they are responsible for local Ca^{2+} transport into the cerebrospinal fluid and the endolymph, respectively. An important function of the PMCAs thus consists in their participation in localized Ca^{2+} transport to allow the selective enrichment of Ca^{2+} in a specific extracellular compartment. Besides their role in the maintenance of overall Ca^{2+} homeostasis, PMCAs also participate in Ca^{2+} signaling. Specific PMCA isoforms and splice variants are concentrated in multiprotein complexes localized in distinct membrane domains (e.g., in caveolae or at the neck of dendritic spines of hippocampal and cerebellar neurons). As part of "Ca^{2+} signalosomes," the PMCAs are involved in the spatial and temporal regulation of Ca^{2+} signaling. By preventing the spread of a local increase in Ca^{2+}, they contribute to the spatial resolution of Ca^{2+} signaling and suppress signaling "noise." By counteracting the local rise in Ca^{2+} following the temporary opening of influx channels, they also contribute to the termination of Ca^{2+} signaling and thus to its temporal regulation.

Diseases Linked to Plasma-Membrane Calcium Pumps

Specific human diseases linked to PMCA mutations or the lack of a particular PMCA isoform are not yet known. However, spontaneous mouse mutants called "deafwaddler" and "wriggle mouse Sagami" have been described in which mutations in the PMCA2 gene lead to a defective PMCA2 protein. Homozygous mutant mice are deaf and show an unsteady gait, underlining the importance of PMCA2 function in the auditory and vestibular hair cells. The same phenotype is observed in homozygous PMCA2 "knockout" mice, which are profoundly deaf and severely ataxic. By contrast, homozygous knockout mice lacking PMCA1 are embryonic lethal, as might be expected given the ubiquitous expression pattern of this PMCA. On the other hand, numerous disease conditions have been linked to abnormal expression of PMCAs. These include diabetes where a significant decrease in PMCA activity in erythrocytes has been described, and neurodegenerative disorders such as Alzheimer disease and stroke, where complex changes in PMCA isoform expression accompany or precede neuronal malfunction and death. Because of their large size (average > 100 kb), the human PMCA genes almost certainly suffer relatively frequent mutations. Many familial and "spontaneous" diseases with an incompletely understood etiology are therefore likely to be linked at least in part to abnormal PMCA expression and function.

Biography

Emanuel E. Strehler is a Professor in the Department of Biochemistry and Molecular Biology at the Mayo Clinic College of Medicine in Rochester, Minnesota. His principal research interest is in the molecular mechanisms of calcium regulation and calcium signaling, including calcium transport systems of the membrane and calcium sensor proteins. He holds a Ph.D. from the Swiss Federal Institute of Technology (ETH) in Zurich, Switzerland, and received his postdoctoral training at Harvard Medical School in Boston. He was involved in the first molecular cloning of a human plasma membrane calcium ATPase, and his laboratory has made seminal contributions to the characterization of the human plasma membrane calcium pump and calmodulin gene families.

Plastocyanin

Elizabeth L. Gross
Ohio State University, Columbus, Ohio, USA

The photosynthetic electron transport chain of higher plants, algae, and cyanobacteria consists of two light reactions (photosystem II (PSII) and photosystem I (PSI)) which act in series to produce molecular oxygen, reduce $NADP^+$ to NADPH, and synthesize ATP. The cytochrome b_6f complex is a large multi-subunit complex involved in the transfer of electrons from PSII to PSI. Plastocyanin is a ~10 kDa Cu-protein which acts as a mobile electron carrier, located in the lumen of the chloroplast thylakoid, which shuttles electron from cytochrome *f* (Cyt *f*) in the cytochrome b_6f complex to P700 in PSI. It can be replaced by an Fe-containing cytochrome (cytochrome c_6) in some green algae and cyanobacteria under conditions of copper deficiency.

Plastocyanin Structure

The Copper Center

Plastocyanin (PC) is a β-sheet protein (Figure 1) with a Cu atom that acts as the redox center. The Cu atom is coordinated to four amino acid residues (H87, H37, S84, and M92) in a distorted tetrahedral geometry. The distorted tetrahedral geometry of the Cu center together with the protein matrix promotes efficient electron transfer between Cyt *f* and P700. Electrons enter and leave PC via the H87 ligand to the copper which is located on the surface of the PC molecule (Figures 1 and 2A).

The Surface of the PC Molecule

Higher Plant and Green Algal PCs

Figure 2A depicts the surface of spinach PC which is a typical representative of higher plant and green algal PCs. There are two important features. The first is the patch of hydrophobic residues (green in Figures 2A and 2B) that surround the H87 ligand to the copper. These residues – including G10, L12, G34, F35, P36, L62, P86, G89, and A90 – are either conserved or replaced with similar residues in all PCs. They provide a hydrophobic binding surface for both Cyt *f* and PSI (see below). The second feature consists of two patches of negatively charged residues surrounding Y83 (yellow in Figures 2A and 2B). Negatively charged residues are shown in red and positively charged residues are shown in blue in Figure 2. The lower patch consists of anionic residues #42–44 and either #45 or #79. The upper patch consists of anionic residues #59–61 in most higher plant PCs. In a few higher plant species and in all green algae, one of the anionic residues in the upper patch is deleted and is replaced by a glutamate at position #85. Also, all higher plant and green algal PCs contain an additional anionic residue at either position #51 or #53. Thus, there are a total of eight anionic residues that contribute to large negatively charged electrostatic field surrounding Y83.

Cyanobacterial PCs

Cyanobacterial PCs are similar to those from higher plants and green algae in that a patch of hydrophobic residues surrounds the H87 ligand to the Cu (Figure 2B) (residues from cyanobacterial PCs are numbered so as to be consistent with those from higher plant PCs). However, the distribution of charged residues on their surface of cyanobacterial PCs is quite different than observed for higher plants and green algae. The only conserved anionic residue is D42. Instead, there are a series of positively charged residues on PC including R88, K44, and K51 that contribute to a positively charged electrostatic field surrounding Y83.

The Interaction of PC with Cyt *f*

The Structure of Cyt *f*

Cyt *f* is also a β-sheet protein with two domains. The heme is located on the large domain. The sixth ligand to the heme is the amino group of Y1 which may provide a pathway of electron transfer from the heme to H87 on PC. Y1 and the heme are surrounded by a patch of highly conserved hydrophobic residues. Cyt *f*s from higher plants and green algae have a highly conserved basic patch consisting of five residues (K58, K65, K66, K187, and R209 in turnip Cyt *f*). The negatively charged residues on higher plant and algal PCs are attracted to the positive patch on Cyt *f*. In contrast, Cyt *f* from

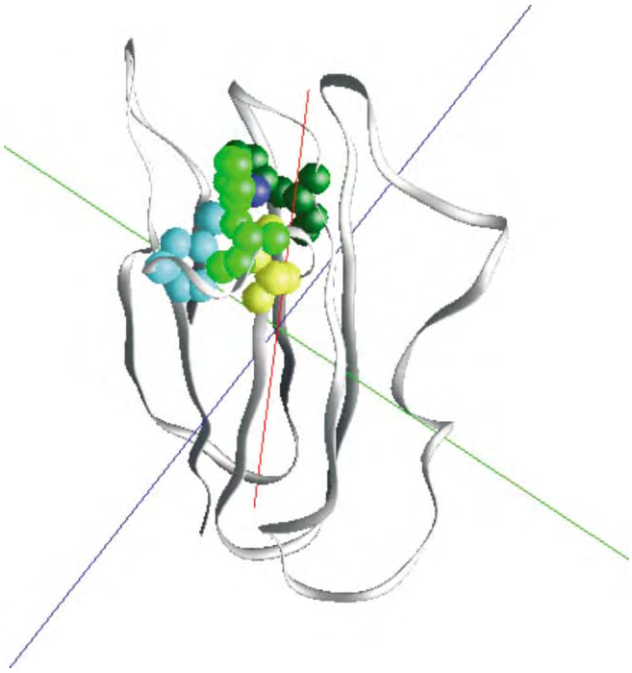

FIGURE 1 The structure of spinach plastocyanin: the copper center. The copper atom in PC (dark blue) is coordinated to two histidines (H87 – light green and H37 – dark green), C84 (yellow) and M92 (cyan). PC structures are taken from the Protein Data Bank from Berman H. M., Westboro, J., Feng, Z., Gilliland, G., Bhat, T. N., Weissig, H., Shindyalou, I. N. and Baume, P. E. (2000). A rapid finite-difference algorithm, utilizing successive over-relaxation to solve the Possion-Boltzmann equation. *J. Comp. Chem.* 435–445).

the cyanobacterium *Phormidium lamanosum* has a large number of negatively charged residues on its surface that attract the positively charged residues on cyanobacterial PCs.

Complex Formation between PC and Cyt *f*

Figure 3 depicts a complex between spinach PC and turnip Cyt *f* determined by NMR. Two types of interactions are observed. First, there is an electrostatic attraction between cationic residues on Cyt *f* (blue) and the anionic residues surrounding Y83 on PC (red). These electrostatic interactions serve to bring the two molecules together and to orientate them properly. Evidence for electrostatic interactions come from cross-linking, chemical modification, and mutagenesis experiments. Second, hydrophobic residues surrounding the heme and Y1 on Cyt *f* interact with those surrounding the H87 ligand and the Cu on PC. These hydrophobic interactions anchor the two proteins in the proper orientation for efficient electron transfer from the heme and Y1 on Cyt *f* to H87 and the Cu on PC. Complexes formed between *Phormidium* Cyt *f* and *Phormidium* PC show a greater influence of hydrophobic as opposed to electrostatic interactions.

The Interaction of PC with PSI

The Structure of PSI

Recently, the structure of PSI from *Synechococcus elongatus* has been determined at a resolution of 2.5Å by X-ray crystallography. A simplified model of PSI is presented in Figure 4. Two regions of PSI have been implicated in PC binding. The first region includes the two largest subunits, PsaA and PsaB. These two subunits form a heterodimer containing P700 as well

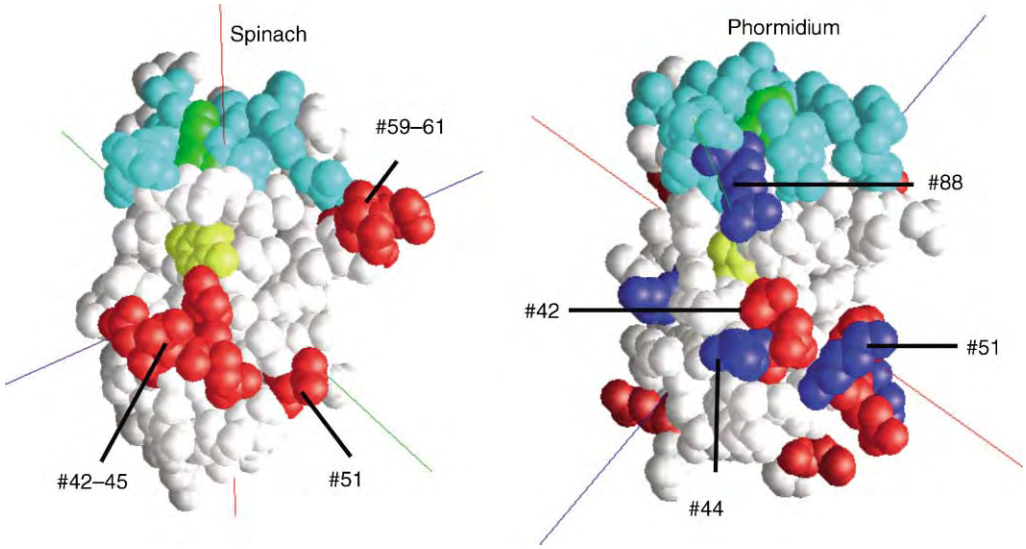

FIGURE 2 Surface residues on PC. H87, green; Y83, yellow; hydrophobic, cyan; cationic, blue; anionic, red: (A) spinach PC; (B) cyanobacterial PC from *P. lamanosum*. Other conditions were the same as for Figure 1.

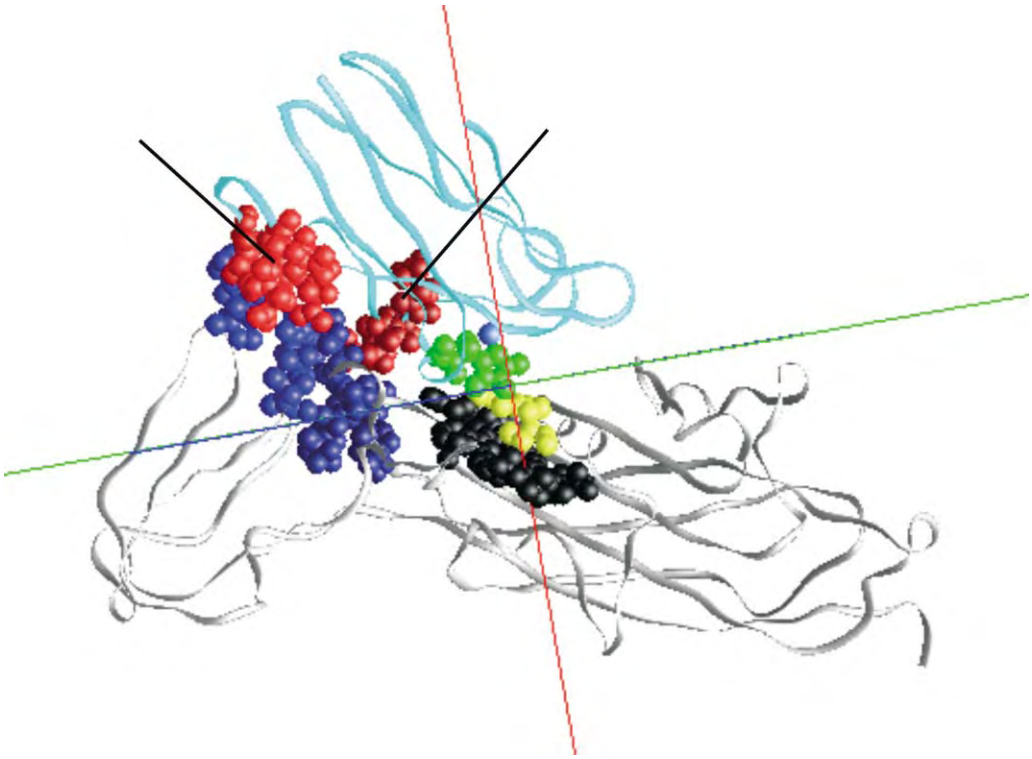

FIGURE 3 Complex formed between turnip Cyt *f* and spinach PC. Model 1 taken from Ubbink *et al.* (1988) *Structure* **6**, 323–335. Backbone of Cyt *f*, gray; backbone of PC, cyan. Other colors are the same as for Figure 2.

as the early electron acceptors A_0, A_1, and F_x. The second region includes the small subunit PsaF.

The Involvement of the PsaA and PsaB Subunits in Hydrophobic Interactions with PC

The PsaA–PsaB heterodimer has a 10Å depression which has been postulated to form a binding pocket for PC and cyt c_6 (Figure 4). Two surface-exposed hydrophobic helices line the binding pocket. One is part of PsaA and extends from residue #646 to residue #664; the second is located on PsaB and extends from residue #Y621 to residues #N639. Also, W655 on PsaA and W631 on PsaB are located in these helices and point toward the binding pocket. It has been postulated that these residues may be involved in the transfer of electrons from PC to P700. The observation that two mutants of residues located in the surface-exposed PsaB helix (W627F and E613N) caused significant inhibition of electron transport from PC to P700, support the hypothesis that these helices participate in the binding of PC to PSI.

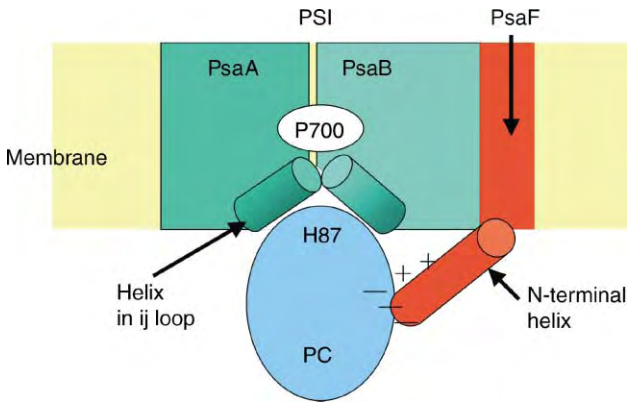

FIGURE 4 Model of the interaction of PC with PSI in higher plants and algae. The interactions of PC (blue) with: (1) the PsaA and PsaB subunits of PSI (green) and (2) the N-terminal positively charged helix of PsaF (red) are shown. The hydrophobic helices in the ij loops of PsaA and PsaB that have been postulated to be part of the binding pocket are also shown.

Involvement of the PsaF Subunit in Electrostatic Interaction between PC and PSI in Higher Plants and Green Algae

The PsaF subunit in green plants and algae has been implicated in PC binding to PSI (Figure 4). The evidence for this is as follows. First, removal of PsaF by either detergent treatment or mutagenesis inhibits the fast phase of electron transfer from PC to P700. This rapid phase has a half-time of ~11 ps and represents electron transfer from PC to P700 in preformed PC–PSI complexes. Second, mutagenesis of residues #42–45 in

the lower patch of PC inhibited the fast phase of electron transfer. In contrast, mutagenesis of the upper patch (residues #59–61) had very little effect. The N-terminal portion of PsaF consists of an amphipathic helix in which six lysine residues are lined up on one side of the helix. Third, mutagenesis of the lysine residues in this region of PsaF inhibited cross-linking and electron transfer from PC to P700; the greatest effect was observed for K23Q. Fourth, PC can be chemically cross-linked to PsaF. It was found that residues from the lower acidic patch of PC (#42–45) were cross-linked to residues #10–24 on PsaF, and residues from the upper acidic patch (#59–61) were cross-linked to residues #24–51 on PsaF.

The situation is different in cyanobacteria. Cyanobacteria show no rapid phase of electron transfer from PC to P700. In fact, the rate of electron transfer in cyanobacteria is approximately 2 orders of magnitude lower than that observed in green plants or algae. Also, removal of PsaF has no effect. An examination of PsaF in cyanobacteria shows that it lacks the N-terminal lysine-rich helix found in higher plant and green algae. However, when a chimeric PsaF, made up of the N-terminal sequence from *Chlamydomonas* PsaF and the C-terminal sequence from the cyanobacterium *Synechococcus*, was placed in *Synechococcus* cells, rapid electron transfer was observed between *Chlamydomonas* PC (and cyt c_6) and P700 which had the same characteristics as observed in *Chlamydomonas* cells. However, there is some evidence for electrostatic effects in cyanobacteria since removal of the negative charge of D42 on a cyanobacterial PC increased the rate of electron transfer to P700, whereas removal of the positive charge of R88 decreases it.

In conclusion, binding of PC to PSI in green plants and algae is similar to its binding to Cyt *f* in that electrostatic forces steer PC (and cyt c_6) to the hydrophobic binding sites on PSI (Figure 4) where electron transfer to P700 occurs in a rapid and efficient manner.

Biography

Dr. Elizabeth L. Gross is a Professor of Biochemistry and former Head of the Interdisciplinary Biophysics Graduate Program at the Ohio State University. Her research includes a study of chloroplast electron transport in general with an emphasis on plastocyanin using both experimental and computational methods. She has authored over 70 articles on the subject. She holds a Ph.D. in biophysics from the University of California, Berkeley and did postdoctoral work at the C. F. Kettering Research Laboratory in Yellow Springs, OH.

Platelet-Activating Factor Receptor

Katherine M. Howard and Merle S. Olson
University of Texas Health Science Center, San Antonio, Texas, USA

The platelet-activating factor (PAF) receptor is a member of the G protein-coupled seven transmembrane receptor superfamily. PAF receptor stimulation and the subsequent intracellular signaling events are involved in both physiological and pathophysiological processes but mainly participate in transcellular communication during inflammatory events. PAF receptor activation is instigated by the binding of PAF (1-*O*-alkyl-2-acetyl-sn-glycero-3-phosphocholine), a potent lipid mediator which produces biological responses at very low molar concentrations (10^{-10} M).

Platelet-Activating Factor

Although PAF was first identified in the 1970s as a soluble mediator responsible for platelet aggregation when IgE-sensitized basophils were challenged with antigen, researchers have since established that PAF has diverse and potent biological activities. In addition to platelet aggregation, PAF can activate monocytes/macrophages, induce hypotension and bronchoconstriction, stimulate glycogenolysis and participates in ovulation and ovoimplantation. In addition, PAF has a profound role in acute inflammation, allergic disorders, and endotoxic and anaphylactic shock. Unlike other cytokines and inflammatory mediators, PAF is not synthesized and stored in a preformed state; rather, it is rapidly synthesized in response to specific stimuli. Cells that participate in inflammatory reactions including monocytes/macrophages, polymorphonuclear neutrophils, eosinophils, basophils, and platelets all rapidly produce PAF upon stimulation. Most cells that produce PAF also express PAF receptors. Therefore, PAF can operate in an autocrine, paracrine, or juxtacrine fashion. For instance, stimulated monocyte/macrophages release a majority of the PAF synthesized into the fluid phase and this PAF can interact with PAF receptors on its own cell surface (autocrine) or can bind to PAF receptors on other inflammatory cells in the immediate vicinity (paracrine). In the case of endothelial cells and leukocytes, synthesized PAF remains partially cell associated. For endothelial cells, this PAF is presented on the cell surface for the juxtacrine activation of infiltrating leukocytes. The biological responses resulting from PAF receptor activation occur as a consequence of direct interactions of the mediator with receptors on target cells or through indirect secondary signaling effects.

In 1979, Hanahan and colleagues defined the chemical structure of this novel ether phospholipid and the chemical structure of the lipid is presented in Figure 1. The PAF molecule contains several specific structural features which are necessary for its potent biological activity. PAF contains an *O*-alkyl ether residue at the sn-1 position of the glycerol backbone. The ether-linked side chain can vary in chain length and degree of saturation but the 16:0 moiety is predominant. 18:0-, 17:0-, and 18:1-containing molecules also occur naturally but these molecules exhibit several orders of magnitude less biological activity. There is an acetyl moiety at the sn-2 position of PAF and removal of this acetate group by the enzyme PAF acetylhydrolase generates lyso-PAF which is biologically inactive. In addition to the strict structural requirements at the sn-1 and sn-2 positions, PAF requires a polar head group containing choline at the sn-3 position for specific PAF-binding and functional activation of the PAF receptor. Both PAF synthetic and degradative enzymes recognize these unique structural features of PAF.

There are two distinct synthetic routes for PAF production, a remodeling and a *de novo* pathway. The *de novo* pathway produces low levels of PAF and has been attributed to the formation of constitutive levels of PAF for normal physiological actions. The remodeling pathway is the predominant route of PAF production by cells and tissues in response to systemic or local injury and trauma. Such stimulants for PAF generation can be microbial agents like lipopolysaccharide (LPS) and zymosan or biological agents such as cytokines, chemotactic peptides, thrombin, and calcium ionophores.

Stimulating the remodeling pathway generates PAF in a two-step process. PAF synthesis begins with the activation of cytoplasmic phospholipase A_2 ($cPLA_2$). This enzyme preferentially cleaves membrane ether phospholipids with arachidonate at the sn-2 position. This reaction releases arachidonic acid during the formation of lyso-PAF. The arachidonic acid is converted

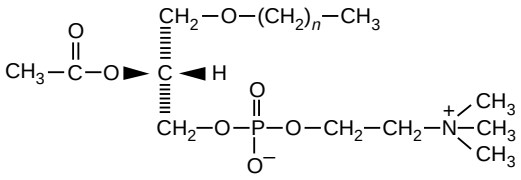

FIGURE 1 Chemical structure of PAF.

to eicosanoids via the lipoxygenase or cyclooxygenase pathways while the lyso-PAF is further converted to PAF by the actions of acetyl-CoA-lysoPAF acetyltransferase. Therefore, production of PAF occurs concomitant with the production of the eicosanoids which also contain far-reaching biological activities. The essential role of $cPLA_2$ in the synthesis of PAF has been confirmed from $cPLA_2$ knockout animals but little is known about the regulation of acetyl-CoA-lysoPAF acetyltransferase.

While the synthesis of PAF is tightly controlled, PAF-like species capable of binding and activating the PAF receptor can arise from the oxidation of unsaturated phosphatidylcholine. These ligands of the PAF receptor arising from oxidative damage of membrane phospholipids contribute to dysfunctional PAF receptor signaling and to the pathophysiological events associated with numerous disease entities.

Many of the biological and pathophysiological actions of PAF were initially investigated using specific PAF receptor antagonists. These PAF receptor antagonists include compounds with structural resemblance to PAF such as CV-3988 (phospholipid analogues) and nonstructural antagonists such as WEB 2086 and BN 50739. Classical ligand-binding experiments demonstrated specific PAF binding in numerous tissues and cells including platelets, neutrophils, macrophages, mononuclear leukocytes, eosinophils, Kupffer cells, epithelial cells, and endothelial cells.

The unique structural features of PAF, the existence of PAF receptor antagonists, and direct binding data utilizing radiolabeled PAF, as well as biochemical evidence for the diverse activation of second messenger signal cascades, all provided evidence for the existence of specific PAF receptors. Confirmation that PAF signaling occurs through receptor-mediated mechanisms was affirmed in 1991 with the molecular identification of the first receptor cloned for a lipid mediator by Shimizu and colleagues.

PAF Receptor Structure

Numerous attempts by investigators to isolate the PAF receptor proved unsuccessful. The eventual cloning of the PAF receptor was accomplished in an elegant strategy involving expression cloning of a guinea-pig lung cDNA library in *Xenopus laevis* oocytes. The initial cDNA library, constructed from size-fractionated poly (A) RNA, was converted *in vitro* into cRNA using the phage DNA as a template. Pools of cRNA were introduced into oocytes and a PAF-induced electrophysiological detection of G protein-coupled phosphatidylinositol (PI) turnover was assayed. A single PAF-receptor cDNA sequence isolated by the cloning strategy predicted a protein of 342 amino acids and a calculated molecular mass of ~39 kDa. However, immunological detection of the PAF receptor on Western blots revealed an apparent MW of 69 kDa suggesting the presence of posttranslational modifications of the receptor. In fact, two potential N-linked glycosylation sites were identified in the PAF receptor cDNA sequence. Hydropathy plot analyses of the deduced PAF receptor amino acid sequence predicted the presence of seven transmembrane-spanning domains within the PAF receptor. A schematic representation of the PAF receptor is presented in Figure 2. Through site-directed

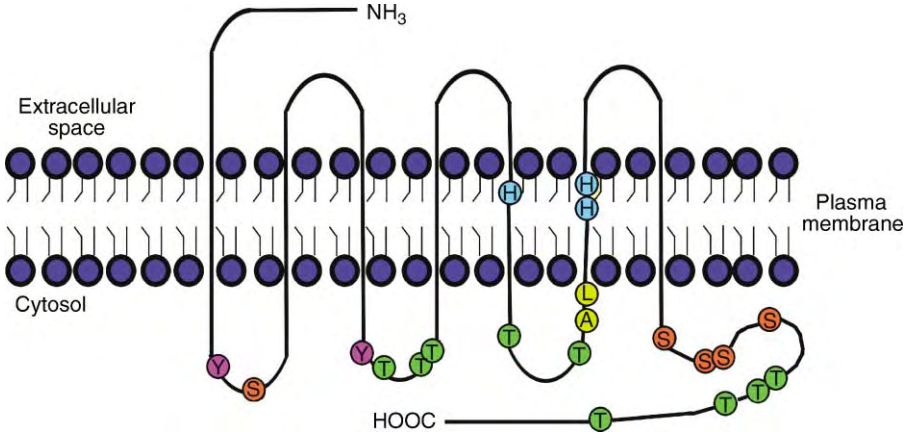

FIGURE 2 Schematic representation of the seven transmembrane spanning PAF receptor.

mutagenesis studies, several key features of the PAF receptor have been determined. Similar to other G protein coupled receptors, the ligand-binding site is defined in three dimensions by amino acids from several of the transmembrane-spanning regions. Mutations in membrane-spanning segments II (N58A, D63A), III (N100A, T101A, S104A), and VII (D289A) increased affinity of PAF binding while mutations in V (H188A), VI (H248A, H249A, Q289A), and VII (Q276A, T278A) lowered the affinity of PAF for the receptor. The third intracellular loop of the receptor is coupled to phosphatidylinositol turnover. The C-terminal cytoplasmic tail of the receptor containing a cluster of serine and threonine residues are candidate sites for phosphorylation by G protein receptor kinases, and are critical for agonist-induced desensitization.

Subsequent to the isolation of the guinea-pig cDNA, cDNA for numerous other species were isolated by cross hybridization. The PAF receptor maintains ~74% sequence identity between the various species identified to date. Because the PAF receptor mRNA is present in only subsets of cells, Northern blot hybridizations have limitations in detecting PAF receptor expression in some tissues. The relative tissue abundance among different species varies but in general lung, neutrophils, monocytes, macrophages, placenta, small intestine, heart, liver, kidney, brain, and spleen have detectable PAF receptor expression.

The isolation of human PAF receptor cDNAs identified two unique 5′-noncoding regions designated transcript 1 and transcript 2. The tissue- and cell-type distribution of these two transcripts are disparate. Transcript 1 can be found ubiquitously but is expressed abundantly in leukocytes, eosinophils, and monocytes/macrophages. Conversely, transcript 2 is found predominantly in heart, lung, spleen, kidney, and skin epithelial cells but not in leukocytes, eosinophils or monocyte/macrophages. Analysis of human genomic DNA sequence localized the PAF receptor to chromosome 1 and revealed other features of the PAF receptor gene. The PAF receptor gene contains no introns within the coding sequence of the gene (exon 3). Many G protein-coupled receptor genes also lack introns within their open reading frame. The first two exons of the PAF receptor gene are located entirely within 5′ -non-coding sequences and were identified by sequence comparisons to the human cDNAs. These two exons reside more than 20 kb upstream of exon 3 and each exon is spliced to the common exon encoding the PAF receptor protein thus creating PAF receptor transcript 1 and 2 (Figure 3). The two transcripts are controlled by distinct promoters immediately 5′ of the exons. Because transcript 1 was identified first, the exon further upstream was designated exon 2. Neither PAF receptor promoter region contains canonical TATA or CCAAT box regulatory sequences commonly found in the promoter regions of eukaryotic genes. Each PAF receptor promoter contains distinct regulatory features that reflect the requirement for PAF receptor expression in different target cells and tissues.

The promoter for transcript 1 contains three consensus transcription factor binding sites for nuclear factor-κB (NF-κB) and one for Sp1. The transcript 1 promoter also contains a pyrimidine-rich initiator sequence (Inr) which includes the transcriptional start site. Inr sequences aid in positioning the start site of transcription in many TATA-less genes. Functional analysis of the promoter region demonstrated that PAF and phorbol 12-myristate 13-acetate (PMA) increased PAF receptor transcript 1 levels through these three NF-κB sites. The NFκB transcription factor plays a crucial role in the regulation of many inflammatory response genes and is activated by various cytokines, PMA, and lipopolysaccharide (LPS).

The promoter for PAF receptor transcript 2 contains consensus sequences for AP-2 and Sp-1 that were demonstrated to control basal promoter activity. In addition to the basal promoter activity, a hormone responsive element (HRE) and a TGF-β inhibitory element function in regulating transcript 2 levels. Retinoic acid and thyroid hormone increase transcript 2 expression levels while TGF-β suppresses promoter activity. Thus, it is apparent that PAF receptor promoter 1 responds to inflammatory stimuli, whereas

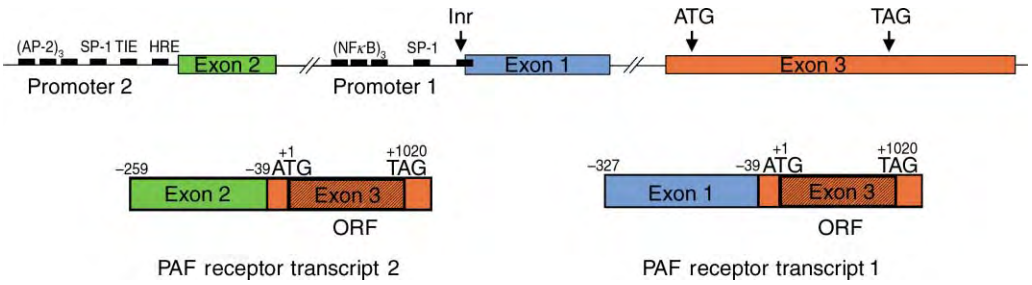

FIGURE 3 PAF receptor gene structure and transcript organization.

the PAF receptor transcript 2 expression is controlled by differentiation signals.

PAF Receptor Regulation

Because of the crucial role that PAF and PAF receptor activation plays in numerous physiological and pathophysiological events, PAF-instigated signaling is tightly controlled. The first manifestation of PAF receptor regulation is the expression in specific cells and tissues as already discussed. Another mechanism for tightly controlled regulation of PAF receptor signaling is controlling the availability of PAF. This mechanism includes regulation of both PAF synthesis and release, and the rapid inactivation of PAF by PAF acetylhydrolases. Other mechanisms of regulation of this signaling system are intrinsic to the PAF receptor and include homologous desensitization to repeated or sustained administration of PAF. Desensitization of the PAF receptor leads to decreased PAF-induced cellular responses in GTPase activity, IP_3 production, and calcium mobilization. The carboxy terminus of the PAF receptor is the target for phosphorylation required to desensitize the receptor. PAF receptor desensitization may occur by uncoupling of the receptor to G proteins and by ligand-induced internalization of the receptor.

As opposed to the fairly rapid process of controlling PAF availability and PAF receptor responsiveness, long-term regulation of the PAF receptor includes alterations in PAF receptor expression. Transient elevation of cyclic AMP (cAMP) reduces expression of the PAF receptor. This down-regulation is accompanied by a decreased responsiveness to a prolonged exposure of PAF. Conversely, priming of macrophages with low levels of LPS can induce a threefold increase in PAF receptor transcript levels thereby amplifying subsequent response to stimulation.

PAF Receptor Signal Transduction

The wide range of biological responses instigated by PAF receptor activation can be attributed to complicated intracellular signaling mechanisms. Calcium, cAMP, IP_3, and diacylglycerol (DAG) are all proven second messengers for PAF signaling. Figure 4 presents an overview of PAF receptor-mediated signaling pathways. Heterotrimeric G proteins are intricately involved in the signal transduction events generated by PAF receptor occupancy. G proteins bind guanine nucleotides, are activated by GTP and possess intrinsic GTPase activity. Binding of PAF activates the associated G protein by exchanging guanosine triphosphate for guanosine diphosphate. The PAF receptor is linked to more than one G protein because some processes are sensitive to pertussis toxin treatment while others are resistant. In fact, this G protein utilization also can differ in different cell types. The activated G proteins, in turn, activate polyphosphoinositide turnover mediated by phospholipase C (PLC). The subsequent generation of inositol 1,4,5-triphosphate (IP3) and diacylglcerol mobilizes intracellular Ca^{+2} and activates protein kinase C (PKC) respectively. PAF receptor associated G protein activation also leads to the activation of cytoplasmic phospholipase A_2 with the subsequent cleavage of arachidonic acid (AA) and the formation of leukotrienes (LT), prostaglandins (PG) and thromboxanes (TX). More recently, investigators demonstrated broader activation of kinases and phospholipases following PAF receptor activation. For instance, PAF receptor activation has been shown to activate mitogen-activated protein kinase (MAPK), phosphatidylinositol 3-kinases (PI3K), protein tyrosine kinases, and G protein receptor kinase.

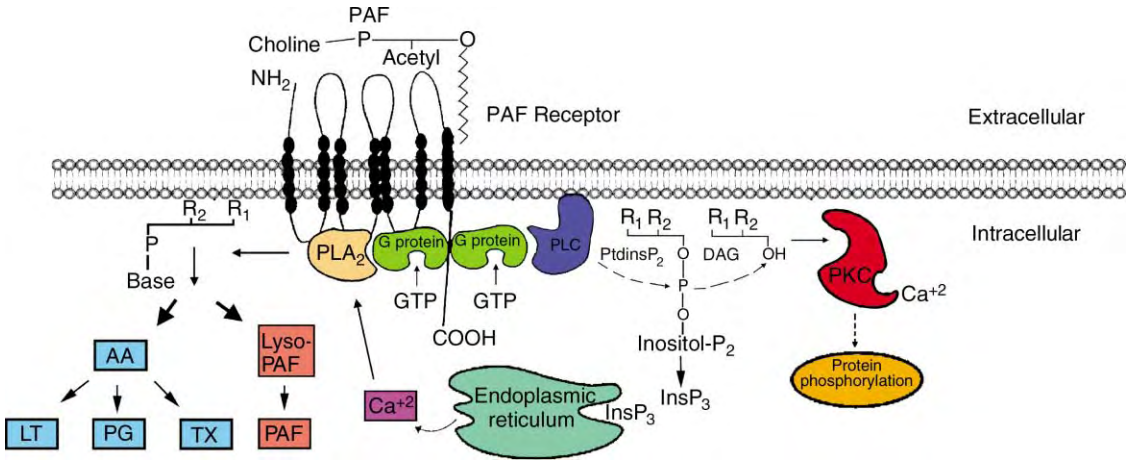

FIGURE 4 PAF receptor intracellular signaling pathways. See text for abbreviations.

Experiments in both PAF receptor knockout animals and transgenic animals overexpressing PAF receptors support the pathophysiological role attributed to PAF receptor signaling. Deletion of PAF receptors in mice drastically attenuates systemic anaphylactic responses after antigen challenge; whereas mice overexpressing PAF receptors exhibit hypersensitivity to bacterial endotoxin. It is not surprising then that PAF receptor activation is being investigated as a contributing factor in numerous disease entities including asthma, atherosclerosis, inflammatory bowel disease, ischemia-reperfusion injury, endotoxemia, and allergic disorders.

Glossary

autocoid Autopharmacologic substance that has potent local activity.

G protein-coupled receptor A class of receptors for a diverse set of ligands including hormones, lipid inflammatory mediators, and chemokines that use associated trimeric G proteins for intracellular signal transduction.

lipopolysaccharide A component of the cell wall of gram-negative bacteria containing both lipid and carbohydrate moieties that instigates many innate immune responses such as secretion of cytokines, activation of macrophages, and expression of leukocyte adhesion molecules. Synonymous with endotoxin.

platelet-activating factor (PAF) Lipid autocoid.

zymosan An insoluble protein–carbohydrate complex from the cell wall of yeast.

Platelet-Derived Growth Factor Receptor Family

Marina Kovalenko and Andrius Kazlauskas
Harvard Medical School, Boston, Massachusetts, USA

Platelet-derived growth factor (PDGF) is a potent mitogen, chemoattractant, and survival factor for cells of mesenchymal origin (such as fibroblasts, smooth muscle cells (SMC), or glial cells). PDGF exists as a number of isoforms that initiate signaling via two closely related receptor tyrosine kinases (RTKs) named α- and β-receptors. PDGFs and their receptors (PDGFRs) are important for embryonic and postnatal development. Knockout mice lacking either PDGFs or receptors develop severe defects in various tissues and organs, and die before or shortly after birth. In adult organisms, PDGFs participate in wound healing, regulation of blood vessel tonus, and maintenance of the interstitial fluid pressure. PDGF signaling is also involved in the pathogenesis of various proliferative diseases (certain tumors, atherosclerosis and restenosis, fibrotic conditions). PDGFs and their receptors have been best characterized in mammals. However, there is evidence that PDGFR-like proteins are expressed in lower vertebrates, and PDGF-like growth factors have been found in molluscs, annelids, sea urchins (*Lytechinus pictus*), and *Drosophila*. Taken together, these findings indicate that PDGFs and their receptors play an important role in a variety of biological processes throughout eukaryotic species.

PDGF Isoforms

At present, four genes encoding different PDGF chains are known: A, B, C, and D. Biologically active PDGFs exist as disulfide-bonded homodimers designated AA, BB, CC, and DD. A and B chains form a heterodimeric PDGF AB (Figure 1). The history of the discovery of PDGFs dates back as early as 1974, when mitogenic activity of whole blood serum was linked to the presence of platelets. PDGF AB was the first to be purified and biochemically characterized a few years later, followed by PDGF BB and AA. Cloning of PDGF A and B cDNAs and determination of the structure of corresponding genes were completed in the 1980s.

New members of the PDGF family, PDGF C and PDGF D, were found only recently by searching the database of human-expressed sequences. PDGFs C and D have a 2-domain structure with N-terminal CUB domain and C-terminal PDGF/VEGF (core) domain, separated by a hinge region (Figure 1). No heterodimers involving C or D chains have been detected. The unique feature of these two new PDGFs is the requirement for proteolytic cleavage of the CUB domain upon secretion in order to achieve biological activity. Thus, latency may be the reason why these growth factors were not originally detected by functional assays.

PDGF Receptors

PDGFs exert their biological functions by binding to two isoforms of PDGF receptors, α and β, with different degrees of affinity. Both receptors are transmembrane tyrosine kinases, composed of extracellular, transmembrane, and intracellular parts. The extracellular part consists of five immunoglobulin-like domains that are involved in ligand binding (domains I–III) and receptor dimerization (domain IV). The intracellular kinase domain of the PDGF receptors is split into two by ~100-amino acid insert (Figure 1).

PDGF A chain binds specifically to α-receptor, and PDGF B can bind to both α and β. PDGF C was originally described as a ligand for PDGF α-, but not β-receptor, however, later it was shown to bind PDGF β-receptor in cells expressing both α- and β-isoforms. PDGF D has been reported to be a β-receptor ligand, but its ability to bind α-receptor in α/β-expressing cells remains controversial. Interactions of PDGFs with α- and β-receptors are summarized in Figure 1. A bivalent dimer, PDGF molecule binds to two receptor subunits causing them to dimerize. Upon dimerization, PDGF receptors become rapidly phosphorylated on multiple tyrosine residues. One of them ("regulatory tyrosine") is located in the second part of the kinase domain and is important for receptor kinase activity (Tyr857 in β-receptor and, by homology, Tyr849 in α-receptor). Most of other phosphorylation sites lie in noncatalytic parts of the receptor (Figure 2). The exact sequence of events during receptor activation and formation of signaling complex is unknown. By analogy to other RTKs, it is likely that

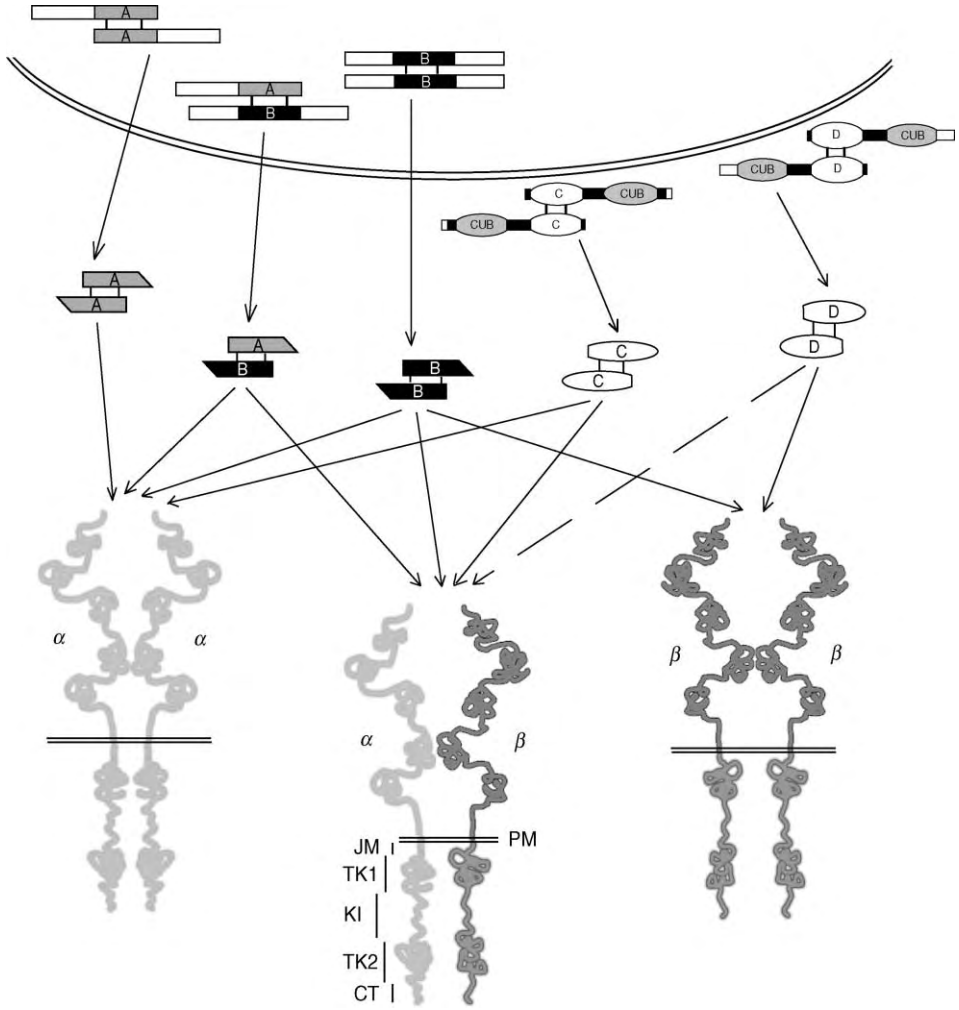

FIGURE 1 Platelet-derived growth factors and their receptors. PDGFs A and B are synthesized as precursors that are proteolytically processed before secretion. PDGFs C and D are secreted in latent form and activated by proteolytic cleavage of the CUB domain. All PDGF isoforms dimerize prior to the proteolytic cleavage. Specificity of binding of mature active PDGFs to their receptors is shown; dashed arrow indicates the lack of consensus regarding the ability of PDGF DD to cause the formation of a heterodimeric receptor. Domain structure of the PDGF receptor α-subunit (identical to that of β-subunit) is presented. The extracellular part of the receptor consists of 5 Ig-like domains. PM, plasma membrane; JM, juxtamembrane domain; TK1 and TK2, proximal and distal parts of tyrosine kinase domain; KI, kinase insert; and CT, carboxyl-terminal tail.

ligand binding and subsequent dimerization of the receptor induces a conformational change that facilitates transphosphorylation of regulatory tyrosine residues within the dimer. Importantly, the regulatory tyrosine lies within activation loop, the region that is conserved among receptor tyrosine kinases. As shown for the insulin receptor, the activation loop blocks the catalytic site in nonphosphorylated receptor, whereas upon ligand-induced phosphorylation it moves away providing access for substrate. It is possible that the PDGF receptor activation occurs via similar mechanism, although there is no direct evidence for this in the absence of crystal structure of the PDGF receptors.

Recently, ligand-bound dimerized PDGF β-receptor was found to be less susceptible to dephosphorylation by protein tyrosine phosphatases (PTPs) than the monomeric receptor. It is suggested that this "phosphatase protection" may contribute to maintenance of activated (phosphorylated) state of the receptor.

Proteins Associated with the PDGF Receptors and PDGF-Driven Signaling Pathways

A total of 13 tyrosine residues in β-receptor and 11 in α-receptor get phosphorylated upon PDGF stimulation. Phosphorylation of most of the tyrosines within PDGF receptors results in the creation of docking sites for a variety of proteins many of which in turn get phosphorylated upon association with the

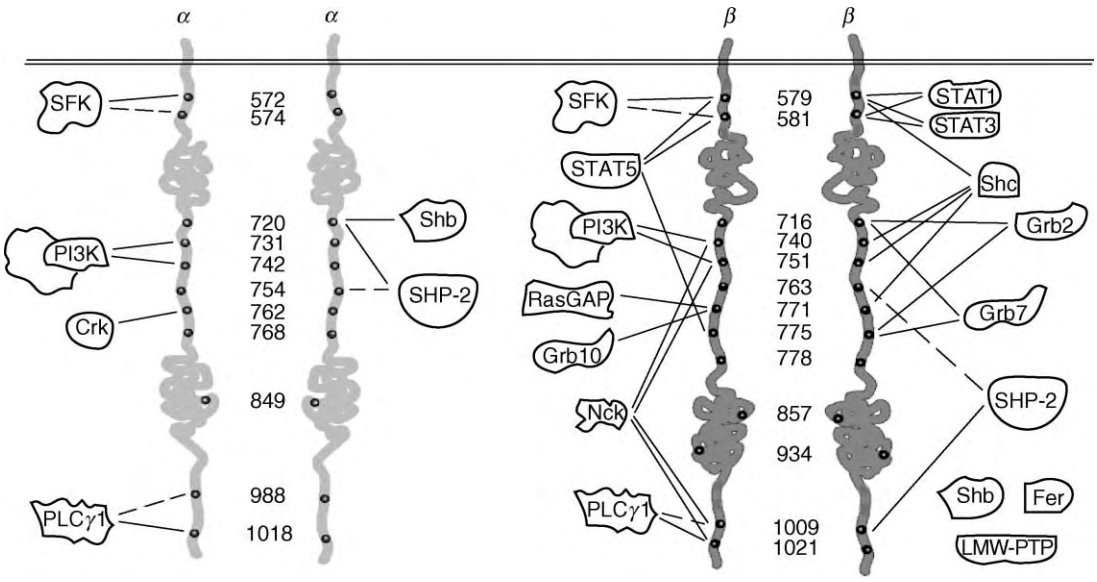

FIGURE 2 Intracellular domains of $\alpha\alpha$ and $\beta\beta$ homodimers of the PDGF receptor. Phosphorylated tyrosine residues are shown (dark circles). Numbers indicate their positions in the human PDGF receptor sequence. Association of signaling proteins with phosphorylation sites of the activated PDGF receptors is shown by solid lines (major binding sites) or dashed lines (additional sites). Proteins binding with high affinity (e.g., PI3-kinase, PLCγ1, RasGAP) bind to the receptor via one or two phosphotyrosine residues on the receptor, whereas low-affinity binding (e.g., Nck, Shc, or Shb binding to β-receptor) involves multiple sites. Shb was found to bind to most of the phosphorylated tyrosines on the PDGF β-receptor. Fer and LMW-PTP bind to as yet unidentified sites on the PDGF β-receptor.

receptors (Figure 2). These proteins include enzymes (phosphatidylinositol 3′-kinase (PI3-kinase), phospholipase C-γ1 (PLCγ1), SH2 domain-containing protein tyrosine phosphatase-2 (SHP-2), GTPase-activating protein of Ras (RasGAP), Src family kinases (SFKs), transcription factors (members of STAT family), or adaptor proteins, such as Grb2, Grb7, Shc, Shb, Nck, or Crk, linking the receptor to signaling proteins further downstream. Some proteins that are recruited to the PDGF receptors are both adaptors and enzymes, e.g., tyrosine phosphatase SHP-2 is able to recruit Grb2 via its phosphorylated C terminus. Association is mediated in most cases by SH2 (Src homology 2) domains of these proteins and is remarkably specific, each phosphorylation site having its own binding partner(s). This specificity is based on the ability of SH2 domains to differentially recognize amino acid sequence following the phosphorylated tyrosine. Many receptor-binding proteins also contain SH3 (Src homology 3), PTB (phosphotyrosine binding), or PH (pleckstrin homology) domains that may facilitate recruitment of other yet unidentified signaling molecules to the complex.

Cellular Responses Mediated by the PDGF Receptors

Assembly of the PDGF receptor complex initiates a number of signaling pathways leading to cellular responses (Figure 3): chemotaxis, proliferation, differentiation (in certain cell types), and protection from apoptosis. One pathway may lead to several different responses, whereas some of the pathways are redundant and converge on the same cellular effect.

Proliferation

Proliferation is the major and most well studied cellular effect induced by PDGFs. Virtually all signaling proteins binding to the receptors have been implicated in proliferation, but not all of them have to be present in the signaling complex at the same time to induce the response.

Ras-Dependent Pathway

The mitogenic pathway that involves Ras, a small GTPase, can be activated through multiple ways in response to PDGF. The complex of Grb2 (adaptor protein) and Sos1 (nucleotide exchange factor for Ras) can bind to the β-receptor either directly or via phosphorylated Shc or SHP-2. This association brings the complex to the plasma membrane where it activates Ras. Activated Ras GTPase interacts directly with Raf-1 serine/threonine kinase, in turn activating it. Raf-1 is the first kinase in MAP kinase cascade. Elevation of its activity is followed by sequential activation of MEK and MAP kinases Erk1 and 2, which are translocated to the nucleus and phosphorylate a number of transcription factors.

As for the PDGF α-receptor, Grb2 is able to bind to it via SHP-2, but there is no evidence of its involvement in

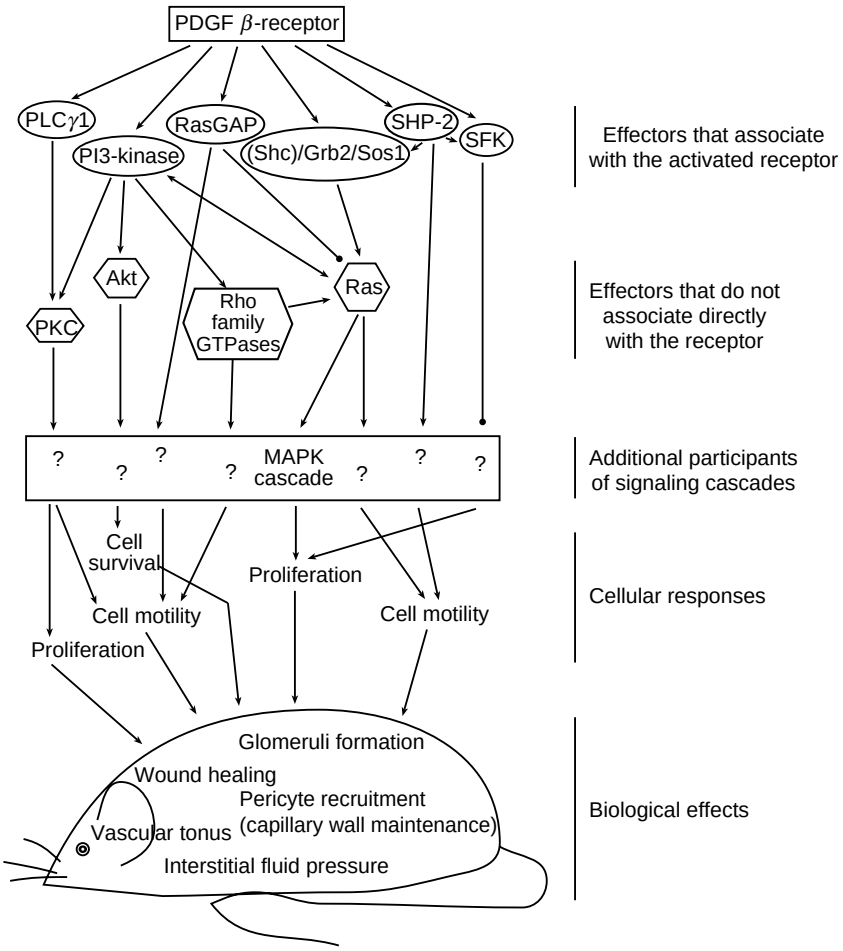

FIGURE 3 Major events initiated by the PDGF β-receptor and culminating in biological responses. Upon ligand binding, activated PDGF β-receptor recruits enzymes and adaptor proteins that start a number of distinct signaling pathways, some of which are shown on the figure. Note that not all of them are initiated by the same receptor dimer or in the same cell. Arrows represent either physical or functional interactions along the pathways. The least defined part of the signaling cascade is the one that bridges the receptor-proximal events with proteins that carry out cellular responses. PDGF is necessary but not sufficient to achieve biological effects. In a living organism, other growth factors and hormones, as well as cell–cell and cell–matrix interactions within tissues and organs make indispensable contributions.

Ras activation. Therefore, pathways other than the Ras-mediated one are likely to contribute to α-receptor-mediated proliferation.

The Ras pathway is believed to be counteracted by RasGAP that binds to the PDGF β-receptor (but not to α-receptor) and is able to enhance GTPase activity of Ras, thus converting it from active (GTP-bound) to inactive (GDP-bound) state. The extent to which this negative signaling affects proliferation may depend on many factors (cell type, environmental conditions).

Src

Src ($p60^{c\text{-}src}$) has been shown to be important for PDGF-driven mitogenesis. However, its association with the PDGF receptors and early PDGF-induced elevation of activity are dispensable for proliferative response and may have a different function. Yet, Src is required at multiple time points during PDGF-dependent cell-cycle progression. Thus, elevation of Src activity early in G1 leads to increase of *c-myc* expression, which is required for transition through G1. Importance of Src also has been confirmed for late G1 and for the exit from M-phase of the cell cycle.

PLCγ1

PLCγ1 binds to the PDGF receptors upon ligand stimulation and becomes phosphorylated and activated. Increasing the catalytic activity of PLCγ1 leads to production of inositol 1,4,5-trisphosphate (IP3) and diacylglycerol (DAG). IP3 is involved in regulation of cytoplasmic Ca^{2+} levels, which, together with direct action of DAG, can contribute to activation of certain members of the PKC family. In particular, DAG has been shown to activate protein kinase C-ζ (PKC-ζ) which then activates Raf-1 and, consequently,

the rest of MAP kinase cascade, leading to proliferation. PLCγ1 is involved in PDGF-stimulated proliferation mediated by β-receptor, whereas in the case of α-receptor, it is important mostly for the motility response.

PI3-Kinase

PDGF-dependent PI3-kinase activation is critical for mitogenesis in most cell types. Prolonged exposure to PDGF, needed to induce cell-cycle progression in quiescent cells, causes two distinct peaks of PI3-kinase activity, one within minutes and another following a delay of several hours. Only the second peak was found to be important for the cell-cycle progression, whereas the early increase of activity is required only for immediate responses to PDGF such as chemotaxis.

How this biphasic increase of PI3-kinase activity is linked to the cell-cycle machinery still remains an open question. Continuous treatment with PDGF can be substituted by two separate pulses of the growth factor, the first getting cells out of G0 to early G1 and the second pushing them through late G1 and into S phase. Early elevation of *c-myc* and sustained activation of the MAP kinase pathway can replace the first pulse of PDGF, but is not sufficient to drive the cell through late G1. To complete cell-cycle progression, a properly timed second peak of PI3-kinase activity (second pulse of PDGF or just the addition of PI3-kinase lipid products) is required. It is hypothesized that early *c-myc* and Erk activation trigger expression of new protein(s) whose interaction with the late PI3-kinase products is critical for S phase entry.

Chemotaxis

Most receptor-expressing cells exhibit chemotaxis upon exposure to PDGF. Migration of pericytes in response to SMC-released PDGF plays a critical role in capillary formation, which is particularly important during embryonic development. In the process of wound healing, PDGF causes chemotaxis of neutrophils and macrophages, as well as fibroblasts and SMC.

α- and β-PDGF receptors differ in their ability to mediate chemotaxis. PDGF β-receptor homodimer as well as α–β heterodimer potently stimulate it. However, the ability of α–α homodimer to drive chemotaxis remains controversial and may depend on the cell type. This difference may be explained by variations in composition of the signaling complex assembled by different receptor dimers, which may be cell-type specific.

PI3-Kinase and Ras Pathways

Chemotaxis involves dynamic remodeling of cytoskeleton, including rearrangement of actin filaments and microtubules, changes of focal adhesions, and formation of lamellipodia or filopodia. These processes are controlled, in part, by the Rho family of small GTPases (RhoA, Rac1 and Cdc42), that are activated by the PDGF receptors via different pathways. The PI3-kinase pathway is considered to be the major one. Activation of the Rho family of small GTPases is dependent on PI3-kinase lipid products. The Ras pathway that can be initiated by the PDGF receptor independently from PI3-kinase pathway, leads to chemotactic response via activation of Rac1, another small GTPase Ral, and in some cell types, MEK1 and stress-activated kinase p38. Interestingly, PI3-kinase is able to interact directly with Ras and activate it, whereas both Ras and Rho family GTPases can activate PI3-kinase, forming a positive feedback loop. Thus, reciprocal regulation of Ras and PI3-kinase provide an example of interaction between different PDGF-dependent pathways.

RasGAP, a negative regulator of Ras, has been shown to inhibit chemotaxis. However, in some cell types, RasGAP has also been shown to have a positive impact on motility that is most likely independent from Ras.

PLCγ1

PLCγ1 promotes chemotaxis in many cell types, but the knowledge about what happens downstream of PLCγ1 is only starting to emerge. Upon PDGF stimulation, PLCγ1 activates sphingosine kinase through IP3 formation and subsequent release of Ca^{2+} from intracellular stores. Sphingosine kinase product, sphingosine-1-phosphate (SPP), is a ligand for EDG-1, a G-protein coupled receptor (GPCR). Stimulation of EDG-1 by SPP leads to activation of Rho family GTPases, which, in turn, results in remodeling of actin cytoskeleton and cell–matrix adhesion sites. This is a new example of receptor crosstalk, where an RTK requires activation of a GPCR to achieve a cellular response.

PKC isoforms that are activated via both PI3-kinase and PLCγ1 pathways, are also involved in chemotactic signaling, as chemotaxis is reduced when PKCs are inhibited or downregulated.

SHP-2 and Low Molecular Weight Phosphatase (LMW-PTP)

Two other positive mediators of PDGF-induced chemotaxis are tyrosine phosphatases SHP-2 and LMW-PTP, both directly associated with the phosphorylated PDGF receptor and activated by PDGF-dependent phosphorylation. Involvement of SHP-2 in chemotactic signaling may occur via the Ras pathway, since SHP-2 can serve as

an adaptor protein for Ras binding. LMW-PTP is likely to act through dephosphorylating and inactivating one of its cellular targets, p190RhoGAP, a negative regulator of Rho GTPase, thus leading to increased activation of Rho and subsequent cytoskeletal rearrangements.

SFKs

The role of Src family kinases in PDGF-induced chemotaxis is not clear. A pathway leading to chemotaxis is initiated at SFK-binding sites in the juxtamembrane domain of the PDGF α-receptor, since mutating these tyrosines to phenylalanine residues results in chemotaxis inhibition. However, it is not yet clear whether it is Src family kinases or other signal transduction molecules binding to the same sites that are responsible for cell migration, since in triple SFK knockout cells PDGF-AA-dependent cell migration is intact.

It is necessary to note that $\alpha\alpha$- and $\beta\beta$-homodimers of the PDGF receptor cause different, although partially overlapping, cellular responses, due to the differences in their ability to bind signaling proteins (Figure 2). For instance, α-receptor homodimer has been found to send a less potent mitogenic signal than the β-receptor homodimer. Additionally, in some cell types (SMC, human foreskin fibroblasts), it fails to mediate a chemotactic response to PDGF AA and inhibits chemotaxis induced by other agents. PDGF β-receptor homodimer formation generally results in higher mitogenicity and chemotaxis. The heterodimeric $\alpha-\beta$ receptor is believed to have unique signaling properties, due to altered phosphorylation pattern of both α- and β-subunits, which results in recruitment of a different subset of signaling proteins. In particular, the heterodimer mediates a stronger mitogenic response than either $\alpha-\alpha$ or $\beta-\beta$ complexes. Distinct signaling properties of different PDGF receptor dimers are based not only on different intrinsic properties of receptor isoforms, but also on the type of cells where these receptors are expressed and on varying experimental conditions.

Negative Regulation of the PDGFR Signaling

Down-regulation mechanisms described for the PDGFR include internalization, ubiquitin-mediated proteolysis (degradation), and dephosphorylation by PTPs. Their relative contribution to the termination of signaling appears to be different.

Internalization and Degradation

Internalization of the PDGF receptors, mediated by clathrin-coated pits, occurs shortly after ligand stimulation and is dependent on the receptor kinase activity. Intracellular trafficking of the PDGF β-receptor involves PI3-kinase but is not entirely elucidated yet. Internalized receptors can be recycled and go back to the cell surface or can be directed to lysosomal degradation, which actually results in receptor down-regulation. However, before they are degraded, internalized receptors remain associated with downstream proteins and continue to signal. For this reason, internalization and subsequent trafficking can be considered a late signaling stage rather than the way of receptor inactivation only.

Additionally, PDGFRs can be targeted for cytoplasmic degradation in proteasomes via polyubiquitination. Ubiquitination of the receptors occurs upon ligand binding and is strictly dependent on receptor autophosphorylation. Generally, multi-ubiquitin chain is added to proteins by E3–E2 ubiquitin ligase system and after that ubiquitinated proteins are recognized by the 26S proteasome and degraded. c-Cbl, a E3 ubiquitin ligase, has been shown to be phosphorylated upon PDGF stimulation and is therefore likely to contribute to the PDGFR ubiquitination and subsequent proteolysis. Proteolytic degradation can be considered a true mechanism of receptor down-regulation that terminates signaling through decreasing the number of the PDGF receptor molecules.

Dephosphorylation by PTPs

PTP-dependent dephosphorylation of the PDGF receptors represents another level of regulation of PDGF-induced signaling. Thus, dephosphorylation of the regulatory site or non-specific removal of phosphate from all tyrosine residues would shut down all signaling, whereas site-specific dephosphorylation would selectively block corresponding signaling pathways. LMW-PTP, for instance, has been shown to act both ways. This PTP selectively interferes with two pathways initiated by the PDGF β-receptor: Src-dependent induction of *c-myc* and STAT1/3 mediated *c-fos* expression. It can also affect kinase activity of the PDGF β-receptor by dephosphorylating Tyr857, providing a general negative regulation of all downstream signals.

Unlike LMW-PTP that acts on membrane-bound PDGF β-receptor, PTP1B was found to dephosphorylate the receptor upon its internalization on the surface of the endoplasmic reticulum, shutting down signaling at a later time point, yet before the receptor gets degraded or recycled to the plasma membrane.

The ability of SHP-2 to act as both positive and negative regulator of PDGFR signaling puts it apart from other receptor-directed PTPs. It is able to dephosphorylate selectively, tyrosines 771 and 751 on the β-receptor, potentially turning off RasGAP and PI3-kinase pathways. On the other hand, SHP-2 can

serve as an adaptor for Grb2 binding, therefore initiating Ras-mediated signaling. Additionally, SHP-2 has been implicated as a positive regulator in the stimulatory effect of integrins on PDGF receptor signaling.

An increase of intracellular reactive oxygen species (ROS) is an early PDGF-dependent event mediated by PI3-kinase and Rac1, and it was shown to be important for mitogenic signaling. Since ROS reversibly inhibit PTPs, it is likely that this event helps to prevent the negative effect of PTPs on early stages of PDGF signaling.

Developmental Role of the PDGF Receptors

At very early stages of embryonic development (before gastrulation), both PDGF α-receptors and PDGF A chain are expressed throughout the embryo, suggesting that PDGF AA may be acting in autocrine manner to stimulate cell proliferation. At later stages, PDGF β-receptor and PDGF B chain appear, and both receptors and growth factor chains start to show distinct expression pattern. The expression of PDGF C largely overlaps with that of PDGF A, and information about PDGF D expression in embryo is still incomplete. PDGF receptors are found mainly in cells of mesodermal origin, with some exceptions (e.g., central nervous system), whereas PDGFs are present in adjacent ecto- and endodermal derivatives. This distribution indicates that, during morphogenesis, PDGFs act in a paracrine manner to induce migration of receptor-expressing mesenchymal cells.

As shown by genetic analysis in mice, interruption of PDGF signaling leads to morphogenic defects and embryonic or perinatal lethality. PDGFR α-null mice die before birth, many (but not all) at a very early stage. Those available for analysis have myotomal abnormalities, rib fusions, defects in neural crest derivatives, and incomplete cephalic closure. PDGF A knockouts demonstrate an emphysema-like lung condition characterized by the absence of mature alveoli. This defect originates due to a lack of migration of PDGF α-receptor expressing alveolar SMC progenitors in the walls of alveolar sacs. Both PDGF A and PDGFR α-null mice also display hypoplasia of skin mesenchyme and abnormal intestinal villi formation. The most pronounced phenotypic features of the PDGF B and PDGF β-receptor knockout mice are defects in kidney glomeruli and capillary microaneurisms. Both result from failure of capillary branching and dilation of capillary walls in the absence of PDGF-dependent recruitment of pericytes and kidney mesangial cells. Other abnormalities include dilation of heart and large arteries, thrombocytopenia, and anemia.

Glossary

adaptor A protein linking together proteins that are otherwise unable to interact.

autocrine signaling Type of signaling in which the cell responds to a stimulus (e.g., growth factor) that is produced by the same cell.

cell cycle Tightly regulated sequence of events exhibited by dividing cells. Consists of the following phases: Gap 0 (G0; temporary or permanent quiescence), Gap 1 (G1; growth and preparation of the chromosomes for replication), S (synthesis of DNA), Gap 2 (G2; growth and preparation for mitosis) and M (mitosis).

chemotaxis The ability of cells to migrate toward a gradient of chemoattractant.

growth factor A substance that needs to be present in the environment of responsive cells in order for them to divide.

ligand A molecule (or ion) that can interact with a receptor.

mitogen A substance (e.g., growth factor) that can initiate cell division.

paracrine signaling Type of signaling in which the cell responds to a stimulus (e.g., growth factor) that is produced by a nearby cell.

pericytes Pluripotential cells surrounding blood vessels.

receptor A molecule (mostly of protein nature) able to detect the presence of a specific stimulus (ligand) and give rise to signaling events leading to physiological response(s).

transphosphorylation A phosphorylation event in which two protein kinases phosphorylate each other (e.g., within the dimer).

Biography

Andrius Kazlauskas is currently a Senior Scientist at the Schepens Eye Research Institute, and Associate Professor at Harvard Medical School. He studies signal transduction pathways used by receptor tyrosine kinases to drive cell proliferation. He graduated from Cleveland State University with a Ph.D. in Chemistry in 1986, and

then studied signaling by tyrosine kinases as a postdoctoral fellow at the Fred Hutchinson Cancer Research Center from 1986 to 1990. He has held an independent research position from 1991.

Marina Kovalenko is a postdoctoral fellow in the lab of Andrius Kazlauskas. After graduating from Moscow State University, she earned her Ph.D. in Biochemistry from Friedrich Schiller University in Jena, Germany, in 1996. Then, she studied PDGF receptor-directed tyrosine phosphatases as a postdoctoral fellow at the Ludwig Institute for Cancer Research in Uppsala, Sweden. Both her thesis work and postdoctoral research were devoted to antagonists of the PDGF receptor tyrosine kinase.

Polysialic Acid in Molecular Medicine

Frederic A. Troy II
University of California School of Medicine, Davis, California, USA

Molecular medicine is an emerging new science that seeks to understand the complex interaction between genes (genomics), proteins (proteomics), carbohydrates (glycomics), and lipids (lipomics) in health and disease. Studies in this field are directed at elucidating the structure, synthesis, and function of these major classes of molecules in both normal and abnormal processes, including disorders in all organ systems of the human body. A major impact of molecular medicine is in the field of cancer metastasis, which is discussed in this article, with focus on the polysialic acid (polySia) molecule.

The cell surface of normal and cancer cells is decorated with a remarkable array of information-rich sugar molecules, usually attached to proteins (glycoproteins) and lipids (glycolipids). Surface expression of many of these complex sugars changes dramatically during the developmental life of a cell and with the onset of cancer. Importantly, these sugars carry specific information that determines the cell behavior at different stages in their life cycle, for example, when to detach and move to different locations and when to stop dividing and become adherent. A specific example of one class of these surface carbohydrates is "polysialic acid" (polySia), the focus molecule of this article.

The emerging importance of polySia in molecular medicine has given rise to a new sub-discipline of glycobiology, termed sialobiology. When polySia chains are attached to surface proteins designated neural cell adhesion molecules (N-CAMs), they help direct in a controlled way this "stop–go" signaling during development. During neural development, for instance, polySia is normally expressed on N-CAM during the embryonic stage, when cells need to avoid sticking together and must migrate to where their "zip code" has programmed them to go. When cells have reached their correct address and need to adhere, other molecular events signal the removal of the embryonic or polysialylated form of N-CAM (polySia-N-CAM) from the cell surface, thus facilitating N-CAM-mediated cell–cell adhesion. In this sense, polySia is an "anti-adhesive glycotope" that forbids cell adhesion and allows cell movement. But polySia is also an oncodevelopmental or oncofetal, tumor-associated antigen, which means that it can be re-expressed on the surface of adult cancer cells. When this re-expression occurs, polySia becomes a metastatic factor that promotes tumor cell detachment, invasion, and colonization at distant sites. Indeed, many human cancers that express polySia have a predilection for metastasis to the brain. How this re-expression occurs is not well understood, but the hereditary information or genes containing the "blueprint" for building the protein catalysts or enzymes required for synthesizing polySia (the polysialyltransferases (polySTs)) are reactivated in cancer cells, having been silenced at the end of embryonic development. The up-regulated polyST genes now allow the adult cancer cell to again synthesize the embryonic form of polySia-N-CAM, thus facilitating cell detachment and migration. This fundamental event may be key in allowing a number of polysialylated human cancer cells to detach from their original site and to spread or metastasize throughout the body. It is this metastatic property of cancer cells that is so feared and deadly, and that is the hallmark of malignancy.

In humans, the pathogenic neuroinvasive bacteria *Escherichia coli* (*E. coli*) K1 and *Neisseria meningitidis* (*N. meningitidis*) that cause meningitis express a surface capsule of polySia acid that is structurally identical to the polySia chains expressed on N-CAM. In this case, the capsule coats the entire surface of the bacterium and as such is a neurovirulent determinant that allows for the invasion and colonization of the brains (meninges) of neonates. Accordingly, the polySTs in both pathogenic bacteria and human cancer cells have become important targets for chemotherapeutic agents directed at treating meningitis and in slowing or stopping cancer cells from metastasizing. This article summarizes information related to the structure,

occurrence, function, synthesis, and glycopathology of polysialic acid in mammalian cells.

The Importance of Molecular Medicine in Health and Disease

The field of molecular medicine is important in human biology and medicine because of the new information it is providing towards the discovery, diagnosis, and treatment of known and emerging diseases. The discipline uses contemporary methodologies of biochemistry (molecular genetics, and molecular cell developmental and structural biology), to identify and analyze new information on the "molecule signature" and interaction of molecules, which are key molecular players in all aspects of health and disease. The outcome of studies in molecular medicine is already leading to a new generation of synthetic and biotechnology-based approaches for the diagnosis and treatment of a variety of health-related diseases.

Natural Occurrence and Structure of Oligo-Polysialic Acids

As shown in Figure 1, the polySia are linear sugar chains usually composed of one of the two most common sialic acid residues, N-acetylneuraminic acid (Neu5Ac) or N-glycolylneuraminic acid (Neu5Gc). Shorter chains of KDN (2-keto-3-deoxy-D-*glycero*-D-*galacto*-nonoic acid), the newest member of the class of sialic acids, occurs in some fish egg sialoglycoproteins and bacterial capsule polysaccharides. The sialic acids are unusual 9-carbon sugar acids that are joined internally by α2,8-, α2,9-, or alternating α2,8/α2,9-ketosidic linkages. The α2,8-linked chains are the most common, and are the principal polySia synthesized by mammalian cells. Their chain length, or degree of polymerization (DP) exceeds 200 Sia residues in *E. coli* K1 and 100 residues in some mammalian tissues. A striking feature of these chains is the bewildering degree of structural diversity and wide range of expression on the surface of both prokaryotic and eukaryotic cells. The operative paradigm is that this diversity in both structure and DP is related to the myriad of cellular functions regulated by polySia, including cell–cell adhesion, cell migration, neuronal development and regeneration, synaptic plasticity, neurotropism, and the possible activation of cell proliferation by initiating second messenger-related signaling pathways. A review of the structural and functional features of oligo-polySia has appeared in *Biology of the Sialic Acids*.

Polysialylated Neural Cell Adhesion Molecules

Embryonic and Adult Forms of N-CAM

N-CAMs are morphoregulatory glycoproteins that are members of the immunoglobulin gene superfamily. They represent a class of high-molecular-weight cell surface sialoglycoproteins that affect a number of cell adhesive and cell migration processes, including neurite fasciculation and neuromuscular interactions. N-CAMs are the most prevalent carrier proteins of polySia chains in mammalian cells and, as such, are the most thoroughly characterized. There are four different isoforms of N-CAM, which arise by alternative mRNA splicing. These include polypeptides with molecular masses of 180, 140, 120, and 110 kDa. The 180- and 140-kDa isoforms are linked to the plasma membrane via a transmembrane spanning domain, and each has a cytoplasmic domain. In contrast, the 120-kDa protein is attached to the membrane via a glycosylphosphatidylinositol anchor and thus lacks a cytoplasmic domain. The 110-kDa N-CAM is a secreted isoform. The 180-kDa isoform is expressed primarily on neurons but not on muscle cells, while the 140-kDa protein is expressed on both neural and muscle cells. A unique structural feature of N-CAM is the presence of α-(2,8)-linked polySia (polyNeu5AC) chains that posttranslationally modify the protein during embryonic development. These chains are attached to both N- and O-linked oligosaccharides that are located on the extracellular domain of N-CAM. No α2,9-ketosidic linkages, which characterize the polySia capsule in neuroinvasive

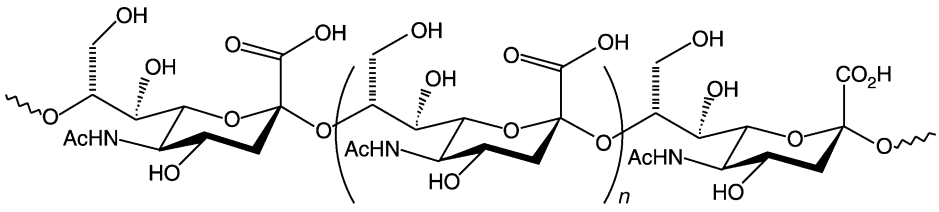

FIGURE 1 Structure of α2,8-polysialic acid.

N. meningitidis Gp. C, nor Neu5Gc or KDN residues have been reported as constituents of N-CAM. The covalent attachment of polySia chains to N-CAM, which characterizes the embryonic form of the molecule, decreases N-CAM-dependent cell adhesion in a variety of tissues, thereby acting as a negative regulator of cell–cell interactions. In contrast, cells expressing relatively low levels of polysialylated N-CAM, which characterizes the adult form, aggregate much more readily than those with high levels of polySia. Thus, polysialylation of N-CAM is an essential reaction that mediates cell recognition events that modulates cell migration and cell adhesion. As such, polysialylation plays a central role in regulating mammalian developmental processes, including neural cell differentiation, migration, and synaptic plasticity.

Temporal Expression of Polysialic Acid during Embryonic Neural Development

Maximal expression of the polysialylated form of N-CAM usually occurs in embryonic neural tissue, when cells are migratory, and is greatly reduced in adult tissue, where little cell migration occurs. The embryonic form of N-CAM has a high Sia content that undergoes a postnatal conversion to the adult form with a low Sia content. During development, the presence of polySia is closely correlated with axon pathfinding, synaptogenesis, and neuron–muscle formation. As the embryo develops, most of the N-CAM changes from the embryonic, or high-polySia form, to the adult, or low-polySia form. The adult form is postulated to help stabilize mature tissues. In this way, N-CAM plays a role in both facilitating two adjacent cells to form regions of contact and in inhibiting such contacts. If neighboring cells express the adult form of N-CAM, strong cell adhesion is promoted. In contrast, if cells express the polysialylated forms of N-CAM, cell adhesion is reduced. Thus, the polySia moiety on N-CAM is an anti-adhesive glycotope that has a regulatory effect on adhesion between living cells. The amount of this carbohydrate is important for normal development, and while the DP of polySia chains on N-CAM changes during embryonic chick brain development, the significance of this change is unknown.

Expression of Polysialic Acid in Adult Human Brain

Although polySia expression is most abundant during early stages of embryonic development in both neural and non-neural tissues, polysialylated N-CAM is also expressed in restricted parts of the adult brain that exhibit synaptic plasticity, and may be required for the rearrangement of neural cells or their interconnections. In rat brain and spinal cord, polysialylated N-CAMs are expressed in discrete regions of the hypothalamic and thalamic nuclei, the hippocampal dentate gyrus, mesencephalic central gray matter, the supraotic nucleus, and the olfactory bulb. It is also expressed on neurohypophysial astrocytes and on mesencephalic dopaminergic cells in the brain that persist throughout development. Functional studies on the role of polySia in adult brain suggest that its primary role is to promote plasticity in cell interactions, thus facilitating changes in the structure and function of the nervous system. PolySia therefore represents one of the few defined carbohydrate structures with an identifiable role in a morphogenic pathway.

Expression and Function of Polysialic Acid on Extraneural Cells

Roth and colleagues first showed that expression of the embryonic form of N-CAM was developmentally regulated in rat and human kidney, a mesodermally derived tissue. The polySia chains in kidney are maximally expressed early in development and, like brain, may regulate cell–cell adhesive interactions during kidney differentiation and development. The polySia chains are re-expressed in Wilms tumor, a highly malignant tumor of the kidney. Polysialylated N-CAM is also expressed on newborn heart and muscle tissue. In human, rat and chicken embryos polySia-N-CAM is expressed on cells derived from mesoderm (mesenchymal cells) and endoderm (pancreas, lung epithelium), and on neuroectoderm cells (neural or lung endocrine cells). In the thyroid gland, calcitonin-producing cells, which are endocrine derivatives of the neural crest, also express the embryonic form of polysialylated N-CAM. During the early stages of rat heart development, polySia-N-CAM is expressed on myocardial, endocardial, and some atrioventricular cells in the epicardium. Later during development, its appearance in the epicardium decreases. In the adult heart, the only significant expression of polysialylated N-CAM is during innervation. Polysialylated N-CAM is transiently expressed in developing chicken osteoblasts during osteogenesis and on dermal and smooth muscle cells in the chick during feather development. In *Drosophila melanogaster*, expression of α2,8-linked polySia chains is developmentally regulated, and occurs only during the early stages of development. The possible function of the polySia glycotope in prokaryotic and eukaryotic cells is summarized in Table I.

TABLE I

Possible Functions of the Polysialic Acid Glycotope

Bacterial polysialic acid capsules
- In neuroinvasive *E. coli* K1 and *N. meningitidis*, functions as a neurotropic determinant; facilitates invasion of the blood–brain barrier and colonization of the meninges of neonatal brains
- Polyanionic shield that masks the somatic O-antigen chains of lipopolysaccharide and renders cell resistant to immune detection and phagocytosis
- Receptor for binding K1-specific bacteriophages

Fish egg polysialoglycoproteins
- Implicated in regulating cell–cell interactions and cell migration during oogenesis
- May function as recognition markers for mediating egg–sperm interaction
- May protect the embryo from osmotic lysis, artificial activation, mechanical destruction, and bacterial infection by retaining Ca^{2+} around the embryo (KDN-gp has affinity for Ca^{2+} ions)
- *O*-Acetylation and KDN cosylation render polySia chains resistant to depolymerization by sialidases; consequence unknown (protective?)
- Expression of an $\alpha 2 \rightarrow 8$-polysialyltransferase is developmentally regulated

Polysialic acid-containing glycoproteins in the jelly coat of sea urchin eggs
- May mediate cell–cell interactions during gastrulation when endodermal cells interact with ectodermal cells
- May be involved in inducing the acrosome reaction in sperm
- Expression of an $\alpha 2,8$-polysialyltransferase is developmentally regulated

Polysialylated neural cell adhesion molecules (N-CAMs)
- Implicated in embryonic neural development and neuronal plasticity; mediates cell adhesive interactions including neurite fasciculation, neuromuscular interactions, and cell migration. Expression of polySia usually decreases N-CAM-mediated cell adhesion
- The amount of polySia on N-CAM is critical for normal morphogenesis and neural development
- Influences cell–cell apposition and regulates contact-dependent cell interactions. PolySia "shield" may simply increase the intercellular space between cells
- Participates in the establishment of neuronal connections and in modulating neurite outgrowth. May activate a second messenger pathway in primary neurons
- May influence the formation of new neural circuits in the dentate gyrus, and in reorganization of the piriform cortex in the adult rat
- Proposed to regulate intramuscular nerve branching during embryogenesis
- Implicated in the normal separation of secondary myotobes from primary myotobes during muscle development
- Influences the interaction of cells of the preimplantation mammalian embryo
- May couple the morphogenic effects of adhesion and synaptic activity-dependent processes
- In bone formation, may mediate the interaction of osteoblasts and regulate skeletogenesis
- May mediate the formation of fiber cell gap junctions and adherence junction during lens cell differentiation
- May control the migration and maturation of dopaminergic cells of the developing mesencephalon
- Participates in the internalization of the Antennapedia homeobox peptide involved in late expression of some homeogenes in the CNS

Expression on tumors
- In developing human kidney, brain (neuroblastomas), and plasma cells, polysialylated N-CAM is an oncodevelopmental antigen
- On some human cancers, e.g., natural killer-like and T-cell malignant lymphomas, acute myeloid leukemia, multiple myeloma, and some head and neck tumors, polySia expression may enhance neuroinvasive potential and metastases
- May protect malignant cells from immune surveillance

Sodium channel glycoproteins
- Function unknown. By analogy with bacterial polySia capsules, the polyanionic surface charge over the channel may maintain a solute reservoir and shield channel from toxins

Expression and Function of Polysialic Acid in Cancer

Prokaryotic-Derived Reagents for the Detection and Analysis of PolySia

α-(2,8)-Polysialylated N-CAM expression on a number of human cancers was revealed using anti-polySia and anti-N-CAM antibodies in combination with Endo-N-acylneuraminidase (Endo-N), a diagnostic enzyme specific for catalyzing the depolymerization $\alpha 2,8$-linked polySia chains. The ease with which these reagents can be used to discover and confirm the presence of polySia chains in mammalian cells and human cancers provides a way to study polysialylation that had not been previously possible. Using these specific molecular probes, α-(2,8)-polysialylated N-CAM expression was identified on a variety of human cancers, including high-grade tumors, e.g., medulloblastomas, neuroblastomas, pheochromocytomas, medullary thyroid carcinomas, small cell lung carcinomas, pituitary adenomas, and congenital

TABLE II

Human Tumors Expressing the $\alpha 2 \rightarrow 8$-Linked Polysialic Acid Glycotope

Neuroblastomas
Nephroblastomas (Wilms' tumor)
Medulloblastomas
Pheochromocytomas
Medullary thyroid carcinomas
Small-cell lung cancers
Lung carcinoid tumors
Pituitary adenomas
Congenital mesoblastic nephroma
Multiple myelomas
T-cell malignant lymphomas
Leukemias (AML)
Head and neck tumors (principally squamous cell carcinomas)
Malignant melanomas
Human tumor expression $(\rightarrow 9Neu5Ac\alpha 2 \rightarrow)_2$
Ovarian teratocarcinoma (PA1 embryonal carcinoma cells)

mesoblastic nephromas. Table II summarizes human cancers that have been shown to express the polySia glycotope. The human breast cancer cell line, MCF-7 and rat basophilic leukemia (RBL-1) cells are unique in that the $\alpha 2$,8-linked polySia chains are attached to O-linked oligosaccharides, suggesting that polysialylation of glycoproteins on tumor cells may be more prevalent than heretofore recognized. While few studies have been carried out to determine the length of polySia chains on cancer cells, polySia chains containing >55 Sia residues are expressed on human neuroblastoma cells. Because of methodological limitations, accurate DP values are difficult to obtain. Reported values thus represent minimum estimates, as some pre-hydrolysis of the polySia chains occurs during isolation and purification and/or derivitization procedures that are required for most chromatographic separation and detection methods.

Polysialic Acid as an Oncodevelopmental Antigen and its Relationship to Tumor Metastasis

Extended chains of polySia were first shown to be expressed on human neuroblastomas, some of which were metastatic to bone and brain. Concurrent studies showed that polySia was temporally expressed in human embryonic kidney, but not in adult kidney, and was re-expressed in malignant Wilms' tumors. These findings led to the important conclusion that polySia was an oncodevelopmental (oncofetal) antigen in human kidney and brain because the long-chain forms of polySia, which characterized the embryonic form of N-CAM, were infrequently expressed in adult brain. An exception to this paradigm, as noted above, is the hypothalamo-neurohypophysial system in the adult brain, where polySia-N-CAM is postulated to function in plasticity.

Evidence for the Role of Polysialic Acid in Cancer Metastasis

Several independent *in vivo* studies reveal a specific role for polySia in tumor metastasis. First, mice injected subcutaneously with polysialylated mouse leukemia cells develop tumors that are metastatic to the spleen. All of the metastatic tumors express polySia. Second, a significant correlation between the level of polySia-N-CAM expression and growth rate, invasion, hormone secretion, and metastasis occurs in rat pituitary tumors. Tumors showing the highest level of polySia-N-CAM expression show the highest level of metastasis. Third, human rhabdomyosarcoma cells expressing polysialylated N-CAM are able to form lung metastases in nude mice. Metastasis is decreased in mice receiving injections of Endo-N, the endo-sialidase that specifically removes polySia from the surface of the cancer cells.

Role of PolySia in Lung Cancer (Small-Cell Lung Carcinoma (SCLC) and Non-SCLC)

There is a positive correlation between polysialylated N-CAM expression and malignant behavior in SCLC and non-SCLC. This finding suggests that polySia functions to reduce cell–cell adhesion and cell–matrix interactions leading to tumor cell detachment, aggressive behavior, and a higher incidence of metastases. The overall survival of SCLC patients with polySia-negative cancers is higher than in patients with polySia-positive tumors. Thus, the polysialylated state of N-CAM may be a prognostic indicator in SCLC patients, corroborating earlier studies in which polySia-N-CAM is associated with poor differentiation and aggressive clinical behavior in patients with SCLC and other neuroendocrine lung tumors. The role of polySia in SCLC was confirmed by an analysis of surgically resected SCLC tumors. Patients with polySia-N-CAM-positive tumors have a significantly lower probability of survival than patients with polySia-negative tumors, again showing the prognostic value of polySia-N-CAM in SCLC. PolySia expression is also an important clinical marker in non-SCLC carcinomas, as patients with polySia-positive tumors have a poorer prognosis for survival. In non-SCLC patients, polySia expression shows a positive correlation with nodal and distant metastasis.

Biosynthesis of Polysialic Acid

The Polysialyltransferases

Molecular insight into the problem of how polySia is synthesized and how surface expression of oligo/polySia-containing glycoconjugates is controlled is currently an active area of investigation. These studies use a combination of biochemical, molecular genetic, and biophysical techniques. Two closely related polyST genes have been cloned, sequenced, and their encoded proteins shown to catalyze the biosynthesis of polySia chains. They are the CMP-Sia:α2,8-polySTs designated STX (ST8SiaII) and PST (ST8SiaIV). Both polySTs catalyze the transfer of sialic acid from the activated sugar nucleotide precursor, CMP-sialic acid, to endogenous or exogenous acceptor substrates. In mammalian cells, N-CAM is the most common endogenous acceptor. The catalytic domains of STX and PST are located in the lumen of the Golgi complex. The amino acid sequence of the human PST is 97% homologous with the hamster and mouse, and is encoded by a single gene (2.0 kb) that codes for a protein with a predicted molecular mass of 41.2 kDa. PST and STX show $\sim$60% homology at the protein level. The genomic structures and promoter activities of the mouse PST and STX genes have been reported, although there is little information about how transcription and translation of these genes are regulated. While the overall structure and genomic organization of STX and PST genes are similar, the 5′-flanking regions of PST and STX are distinctly different. The STX gene is about 80 kb long and consists of six exons, whereas the PST gene is $\sim$60 kb long and contains five exons. PST and STX can independently polysialylate N-CAM in transfected cell lines, where there are reports that the two enzymes may act cooperatively.

Autopolysialylation of the Polysialyltransferases

Soluble constructs of STX and PST both undergo "autopolysialylation" in cell lines transiently transfected with V5 epitope-tagged PST and STX cDNAs. The question of whether autopolysialylation is required for N-CAM polysialylation remains a point of some controversy, although it does not appear to be an obligatory requirement. STX is not autopolysialylated during neuronal development in embryonic chick brain, and it may not be so in cell lines that express no or low levels of N-CAM. It is possible that soluble constructs do not have the same catalytic properties as their membrane-bound counterparts, particularly in the presence of N-CAM. Soluble constructs of polySTs show reduced activity compared with the activity of the membrane-bound form, indicating that N-CAM may modulate polyST activity, and hence the extent and DP of N-CAM polysialylation.

How many Sialyltransferases does it take to Polysialylate?

Results from transfection experiments have been interpreted to support the hypothesis that only one enzyme is required for polySia chain synthesis, since individual cDNAs encoding for polySTs induce polySia expression in cell lines previously shown to be polySia negative. However, some transfected cell lines have pre-existing disialyl (Siaα2,8-Siaα2,3-) terminal residues that can serve as initiating sites for polySia chain polymerization. The presence of diSia in an acceptor substrate would obviate the need for an α2,8-monoST, or "initiase." Thus, while the transfection studies support the necessity of a PST or STX for polySia chain synthesis, they do not exclude the possibility that more than one enzyme may be involved. An alternative theory to the single-enzyme hypothesis is that more than one sialyltransferase is required to catalyze both chain initiation and polymerization. This hypothesis is based on structural studies of the cognate di-, oligo-, and polySia chains that are expressed at different stages of development in the rainbow trout. These studies show that at least two α2,8 sialyltransferases are required. The first, an "initiase," transfers the first α2,8-Sia residue to Siaα2,6/3Gal-acceptors forming the disialyl derivative, Siaα2,8Sia-. A separate polyST or "polymerase" is required to complete polySia chain elongation, based on the later appearance in the development of polysialylated glycoproteins.

Rationale for Chemotherapeutic Inhibition of PolySia Biosynthesis

The studies described above show that surface expression of polySia is positively correlated with increased metastasis in a number of human tumors. Accordingly, the design and synthesis of compounds that selectively inhibit the synthesis of polySia is an important area of research with direct impact on cancer metastasis and treatment of meningitis. The rationale for this idea is that if the oncofetal expression of polySia on the surface of human cancers can be inhibited, then the detachment and anti-adhesive properties of these cells may be diminished, and tumor metastasis may be slowed or stopped. The same rationale holds for treating neuroinvasive meningitis caused by the polysialylated *E. coli* K1 and *N. meningitidis* pathogens.

Selectivity of the PolySTs as Chemotherapeutic Targets

The specificity of chemotherapeutics to selectively inhibit the polySTs and not the monoST, which could have an effect on other tissues, is based on the fact that the two classes of enzymes are structurally and functionally distinct. They differ in the following key properties:

1. The polySTs, in contrast to the monoSTs, are oncodevelopmental enzymes that are selectively re-expressed in cancer. An exception, as noted above, is expression of polySia in the hypothalmo–neurohypophysial region of adult brain, the function/consequence of which is not known.
2. At the protein level, the two classes of enzymes are distinct and have different kinetic properties (K_m and V_{max} values). This is a key feature that favors the design of inhibitors to selectively target the polySTs.
3. The polySTs and monoSTs show limited structural homology and exhibit different structural properties. The polySTs, but not the monoSTs, contain a uniquely extended basic amino acid domain of 31 residues upstream of sialylmotif S. This cationic domain is essential for polysialylation, and thus provides a selective target for the polySTs.
4. The two classes of enzymes show differences in response to thiol reagents, thiol-directed alkylating reagents, and metal ion requirements. The polySTs contain a cystinyl residue required for polysialylation, while the monoSTs do not, and;
5. The polySTs catalyze a processive mechanism of synthesis while the monoSTs catalyze a distributive mechanism of synthesis.

The significance of these differences is two-fold. First, they provide new insight into the enzymatic basis of polysialylation. Second, they reveal for the first time structural features unique to the polySTs that are essential in the design of chemotherapeutic inhibitors to selectively target this class of glycosyltransferases. To our knowledge, no other family of mammalian glycosyltransferases exhibit such marked differences. As such, to use this new information to selectively target the polySTs represents a paradigm shift from the more conventional approaches and targets currently underway in the "glyco-drug" discovery field.

Glossary

endo-N-acylneuraminidase (Endo-N) An endosialidase that catalyzes the depolymerization of polysialic acid chains and is a diagnostic enzyme for identifying **α**2,8-linked polysialic acid.

malignant Describing or referring to a tumor or cancer cell that is invasive and undergoes metastasis.

metastasis The process whereby malignant cancer cells spread from one location in the body to another.

monosialyltransferases (monoSTs) A family of sialyltransferases distinct from the polySTs that catalyze the addition of a single sialic acid residue to acceptor substrates.

neural cell adhesion molecules (N-CAMs) Cell surface glycoproteins that control cell adhesion and cell migration and are the major protein carriers of polysialic acid in mammalian cells.

oncodevelopmental/oncofetal antigens Glycoproteins or glycolipids that are most often expressed during embryonic development and are usually undetected in the differentiated adult. Many are then re-expressed in malignant cancer cells.

polysialic acid (polySia) Complex sugar molecules containing sialic acid that decorate the cell surface of neuroinvasive bacteria causing meningitis and some non-mammalian and mammalian cells. They are oncodevelopmental, tumor-associated antigens that regulate cell–cell interactions and allow some cancer cells to metastasize.

polysialyltransferases (polyST) A family of glycosyltransferases (enzymes) that catalyze the polymerization of multiple sialic acid residues forming polysialic acid.

sialobiology A sub-discipline of the field of glycobiology that focuses on the chemistry and biology of sialic acids in the molecular life sciences.

Biography

Frederic A. Troy II is professor and past chairman of the Department of Biochemistry and Molecular Medicine, University of California School of Medicine, Davis, California and a member of the UC Davis Cancer Center. His major area of research is glycoscience, cancer biology, and membrane chemistry. He received his Ph.D. in biological chemistry from Purdue University and carried out postdoctoral studies at Johns Hopkins University School of Medicine. He was a visiting professor in tumor biology at Karolinska Institute and has coedited two major texts in the field of Sialobiology.

Porphyrin Metabolism

Mark Shepherd and Harry A. Dailey
University of Georgia, Athens, Georgia, USA

Porphyrins are cyclic tetrapyrroles that perform critical roles in a variety of biological systems. Examples of important tetrapyrroles include heme and siroheme (both with chelated iron), chlorophyll (with chelated magnesium), coenzyme B_{12} (with chelated cobalt), and factor F_{430} (with chelated nickel). All of these are derived from a common precursor, δ-aminolevulinic acid (ALA). Heme, as a prosthetic group to various hemoproteins, is necessary for oxygen transport and storage as part of hemoglobin and myoglobin. It is essential for electron transport as part of various cytochromes and is also required by mixed function oxidases as a part of cytochrome P450. Additionally, heme is needed for the decomposition and production of hydrogen peroxide as a cofactor of catalase and peroxidase, respectively. Siroheme is the cofactor in both nitrite and sulfite reductases, and hence is not synthesized by mammals.

Several types of chlorophyll exist which differ with respect to the substituents on the tetrapyrrole ring. Chlorophylls are employed by photosynthetic organisms to absorb energy for photosynthesis. This process harnesses the vast majority of energy consumed by living organisms, and only chemolithotrophic bacteria are independent of this energy source. Chlorophylls are required in the first stage of photosynthesis, whereby visible radiation excites an electron in the porphyrin that, upon returning to a lower energy state, provides the energy needed for the synthesis of ATP and NAD(P)H.

Coenzyme B_{12} consists of cobalamin (vitamin B_{12}), a corrin ring, which is linked to dimethylbenzimidazole and 5′ deoxyadenosine via its central cobalt atom. The bond between the cobalt and the latter substituent is a weak cobalt–carbon bond, the only example known in biology, which catalyzes intramolecular rearrangements by cleaving homolytically to generate a free radical. Examples include methylations in methionine synthesis and the reduction of ribonucleotides to deoxyribonucleotides. Finally, there is a nickel (II) tetrapyrrole, factor F_{430}, which is found in methanogenic bacteria and is involved in methane metabolism.

Biosynthesis of Porphyrins

Figure 1 illustrates the first three steps of tetrapyrrole biosynthesis, which is common to all the tetrapyrroles mentioned above. All these molecules have a core structure of four pyrrole rings, designated A–D, as shown on the structure of heme in Figure 1. The carbon atoms are numbered 1–20 starting in ring A and ascending in a clockwise direction around the perimeter of the porphyrin ring.

Formation of δ-Aminolevulinic Acid

The first common intermediate in tetrapyrrole biosynthesis is δ-ALA. Two pathways for its synthesis are found in nature: the C_4 pathway in animals and some bacteria including *Rhodobacter sphaeroides*, and the C_5 pathway in plants, algae, and other bacteria including cyanobacteria. In the C_4, or Shemin pathway, ALA is formed by the condensation of glycine and succinyl coenzyme A in a reaction catalyzed by the enzyme ALA synthase. In the C_5 pathway an NADPH-dependent glutamyl-tRNA reductase produces glutamate 1-semialdehyde (GSA) from glutamyl-tRNA, which is subsequently converted to ALA by the replacement of the aldehyde moiety with an amide group. The C_5 pathway is thought to be ancestral to the Shemin pathway as bacteria with the former lack the α-ketoglutarate–dehydrogenase complex to make succinyl CoA. This group includes cyanobacteria such as *Synechocystis*, which may explain why plants today retain the C_5 pathway.

δ-Aminolevulinic Acid to Uroporphyrinogen III

In all organisms studied to date, the conversion of δ-aminolevulinic acid to uroporphyrinogen III proceeds via exactly the same steps. This process is summarized in Figure 1. The first step involves the condensation of two ALA molecules to form porphobilinogen with the release of two molecules of H_2O. This reaction is catalyzed by porphobilinogen synthase, also known as ALA dehydratase. Hydroxymethylbilane synthase, also known as porphobilinogen deaminase, catalyzes the condensation of four molecules of porphobilinogen in the order A, B, C, D

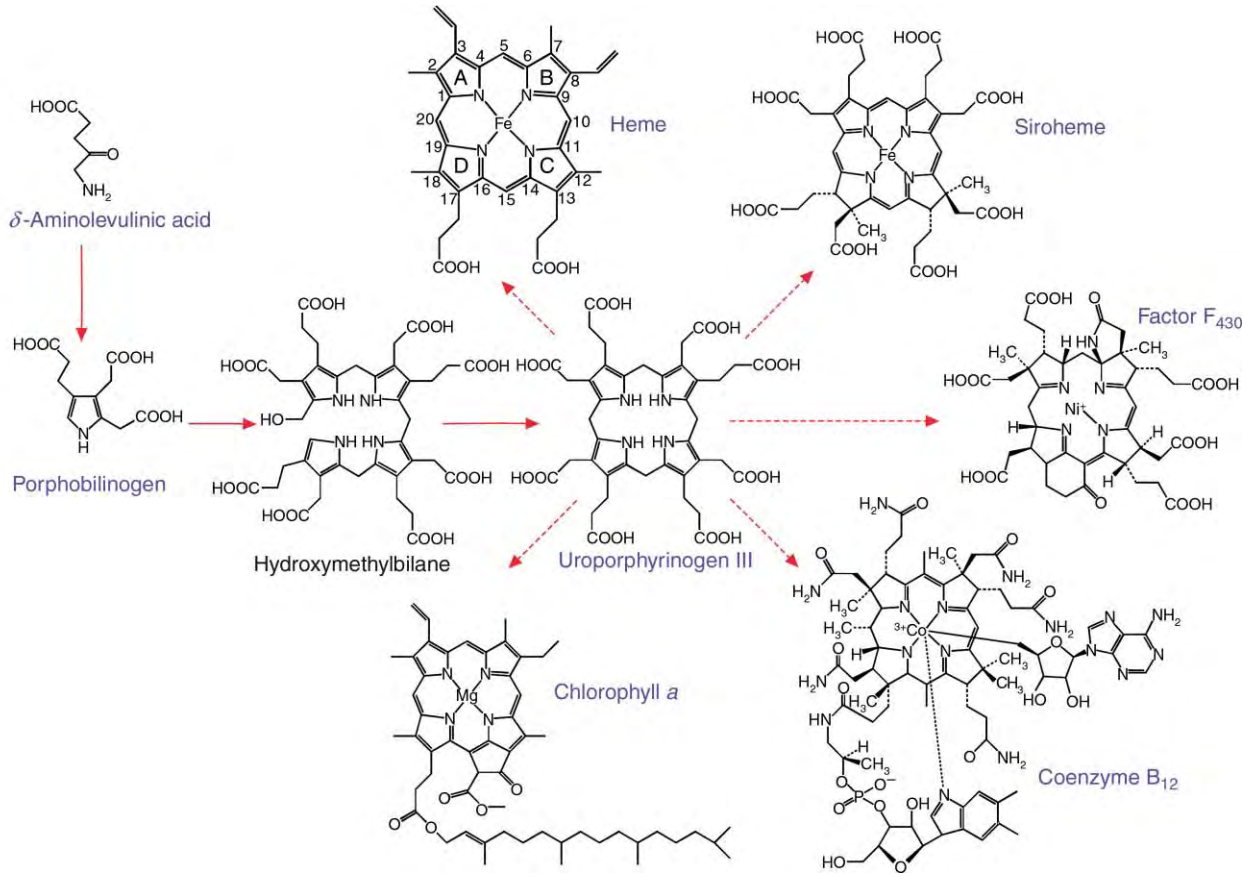

FIGURE 1 The porphyrins. The first three steps common to all porphyrin biosynthesis and the ultimate products of this branched metabolic pathway.

(the letters representing the rings of the ultimate tetrapyrrole product). This condensation gives rise to the first tetrapyrrole, hydroxymethylbilane, also known as preuroporphyrinogen, which is unstable and can close spontaneously, forming the biologically inactive isomer uroporphyrinogen I.

Several enzyme–substrate intermediates exist that are linked via a dipyrromethane cofactor (a modified dipyrrole). The dipyrromethane cofactor is posttranslationally attached to a cysteine residue of the enzyme. The first porphobilinogen molecule condenses with the cofactor and further porphobilinogen molecules are subsequently added to form hydroxymethylbilane. The enzymatic formation of the first macrocyclic tetrapyrrole, uroporphyrinogen III, is catalyzed by the enzyme uroporphyrinogen III synthase. During this reaction, the D pyrrole ring of hydroxymethylbilane undergoes an inversion, via a *spiro* intermediate. As free hydroxymethylbilane spontaneously reacts to form the biologically inactive isomer, uroporphyrinogen I, the enzyme must be present during or immediately after the release of hydroxymethylbilane from hydroxymethylbilane synthase to ensure that the correct isomer is formed.

Heme and Chlorophyll Biosynthesis

The biosynthesis of heme and chlorophyll proceeds along a common pathway until a branchpoint is reached at protoporphyrin IX (Figure 2). This pathway is conserved for almost all organisms studied, except *Desulfobrio vulgaris*, in which coproporphyrinogen III is formed from uroporphyrinogen III indirectly via precorrin-2. The formation of protoporphyrin IX from uroporphyrinogen III is achieved via a series of decarboxylation and oxidation steps. Uroporphyrinogen decarboxylase catalyzes the removal of a carboxyl group from each pyrrole ring to form coproporphyrinogen III. This is converted to protoporphyrin IX via the action of two enzymes, coproporphyrinogen oxidase and protoporphyrinogen oxidase. During aerobic growth both enzymes use oxygen as the terminal electron acceptor. However, anaerobic organisms have been shown to possess oxygen-independent isozymes and some facultative anaerobes encode both types of coproporphyrinogen oxidase.

The next step involves the insertion of a divalent cation into the porphyrin ring. Ferrochelatase catalyzes

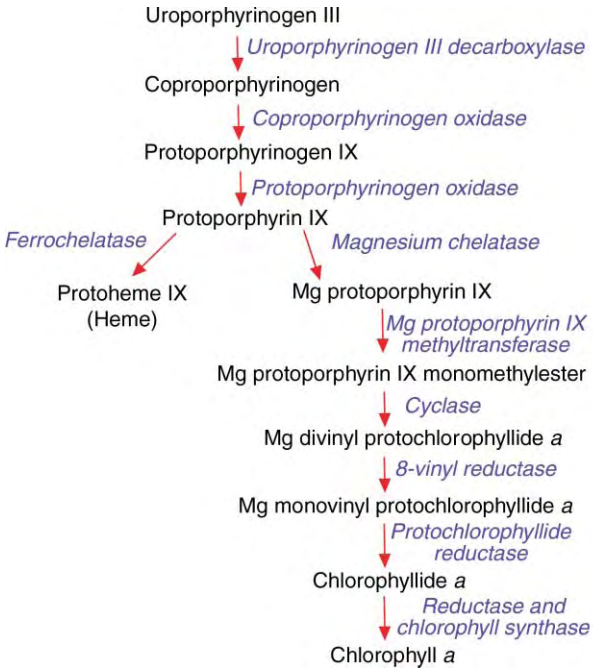

FIGURE 2 Heme and chlorophyll biosynthesis. The branching of the heme and chlorophyll biosynthetic pathways. The enzymes that catalyze the individual steps are shown in blue.

the insertion of an iron (II) ion whilst magnesium chelatase, as its name suggests, catalyzes the insertion of a magnesium (II) ion. It is thought that ferrochelatase distorts the porphyrin ring in such a way that allows the spontaneous insertion of iron (II). The insertion of magnesium requires the presence of MgATP and the participation of all three subunits of the heterotrimeric magnesium chelatase.

Subsequent steps of the chlorophyll biosynthetic pathway involve methylation and cyclization of the propionate group on ring C. After the reduction of the vinyl group on ring C, a light-dependent reaction takes place. This is catalyzed by protochlorophyllide reductase (POR) and is one of only two reactions known to be light dependent, the other being DNA photolyase. This reaction can also proceed via a light-independent reaction, catalyzed by dark protochlorophyllide reductase (DPOR). The formation of chlorophylls requires the addition of a hydrophobic tail to the propionate group on ring D via an esterification reaction. In the cases of chlorophyll and bacteriochlorophyll, these long chain alcohols are phytol and geranylgeraniol, respectively.

Coenzyme B_{12} and Factor F_{430} Biosynthesis

Figure 3 summarizes the synthesis of coenzyme B_{12} and factor F_{430} from uroporphyrinogen III. The first step

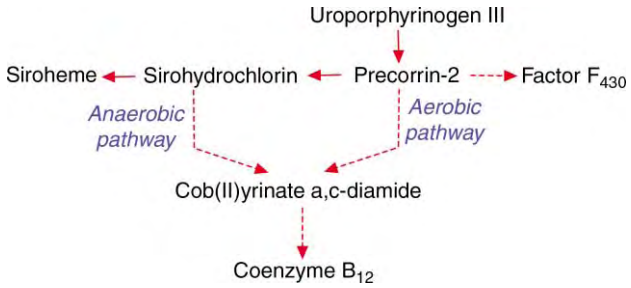

FIGURE 3 Coenzyme B_{12} and factor F_{430} biosynthesis. The branching of the coenzyme B_{12} and factor F_{430} biosynthetic pathways. The enzymes that catalyze the individual steps are shown in blue.

involves the methylation of uroporphyrinogen on rings A and B to form precorrin-2. Reduction to form sirohydrochlorin and subsequent ferrochelation yields siroheme, the prosthetic group for both nitrite and sulfite reductases. Factor F_{430} synthesis requires the cyclization of substituents on rings B and D and the chelation of nickel (II), which is bound to the pyrrole nitrogen on ring C. This final step is thought to be catalyzed by an ATP-dependent nickel chelatase.

The formation of coenzyme B_{12} involves a branched pathway consisting of several reactions. Figure 3 shows that the synthesis of cob(II)yrinate a,c-diamide can occur by either an anaerobic or an aerobic pathway. Both pathways involve the methylation, reduction, and isomerization of precorrin-2, along with the insertion of a central cobalt atom. The anaerobic chelatase has been compared to ferrochelatase as it is encoded by a single gene and does not require MgATP. The aerobic cobalt chelatase is similar to the magnesium chelatase involved in chlorophyll biosynthesis, as it is heterotrimeric and requires MgATP for catalysis. Coenzyme B_{12} is then formed via various alkylations, phosphorylation, an internal rearrangement, and the coordination of an adenosyl group to the central cobalt atom.

Regulation

As δ-ALA is the universal precursor for porphyrin synthesis, the supply of this metabolic intermediate ultimately governs whether or not porphyrin synthesis may take place. However, there are several examples where other key points in the pathway are subject to regulation. Heme plays a key role as a cofactor for many redox reactions in several different cell types and requires iron as a cofactor. From this it is clear that the regulation of heme biosynthesis must be dealt with on a global scale amongst different cell types and subcellular compartments. The model of negative feedback regulation mediated by a single regulator (heme) at a single site (ALA synthase) remained dogma for many years. Only after compelling evidence was generated to

support regulation at other sites, was it accepted that heme biosynthesis is subject to more complex control.

The biosynthesis of cofactor B_{12} or Factor F_{430} is more poorly understood. As mammals do not synthesize these cofactors, little work has been performed on the regulation of these pathways.

Regulation of Heme Biosynthesis

Role of ALA Synthase

In animal cells two ALA synthase (ALAS) genes exist that are classified by their histological localization. ALAS-E (or ALAS-2) is induced during erythroid differentiation and ALAS-1 encodes ALA synthase in other tissues. ALAS-1 is also referred to as ALAS-H (housekeeping) or ALAS-N (non-erythroid). The primary sequence of both ALAS proteins is highly conserved. However, significant differences exist between the regulatory regions of the genes and the untranslated regions of their respective mRNAs, which are manifested by the tissue-specific expression of the two enzymes.

Regulation at Sites Other than ALAS

Although it is accepted that ALAS is the major site of regulation, several examples of pathway control exist at the level of gene expression. In mammals, all the genes that encode heme biosynthetic enzymes possess both housekeeping and erythroid-specific promoter elements, although only ALAS is represented by two distinct genes.

A good example of regulation in response to an external stimulus is exhibited by the coproporphyrinogen oxidase of the nitrogen fixing bacterium *Azorhizobium caulinodans*. The enzyme responsible for nitrogen fixation, nitrogenase, requires the absence of oxygen to convert dinitrogen into ammonia. This organism is thought to possess both aerobic and anaerobic coproporphyrinogen oxidases and switches to the anaerobic isozyme in response to falling oxygen levels. Furthermore, the respiratory electron transport chain has been shown to act as the electron acceptor for protoporphyrinogen oxidase in anaerobically grown *E. coli*. This reaction is thought to be catalyzed by an enzyme distinct from the oxygen-dependent protoporphyrinogen oxidase.

Deficiencies in Porphyrin Synthesis

Porphyria

Porphyria is a mammalian disease caused by point mutations or deletions in the genes encoding heme biosynthetic enzymes. Individuals with this disorder are usually able to synthesize normal amounts of heme, but accumulate pathway intermediates that cause the clinical symptoms of porphyria. The disease can be divided into three groups: (1) cutaneous porphyrias, characterized by photosensitization; (2) acute porphyrias, where individuals experience abdominal pain, psychiatric disorders, constipation, vomiting, and paralysis; and (3) mixed porphyrias, which manifest themselves as a combination of both. Figure 4 illustrates the porphyrias that result from deficiencies in specific parts of the pathway.

Herbicides

The porphyrin biosynthetic pathway has been targeted for inhibition by certain herbicides to curtail the production of chlorophyll. Diphenyl ether-type herbicides, acifluorfen in particular, have been shown to act as potent inhibitors of protoporphyrinogen oxidase, the last enzyme before the branchpoint of heme and chlorophyll biosynthesis. These molecules compete for the tetrapyrrole-binding site on the enzyme, which impedes the binding of protoporphyrinogen. Hence, protoporphyrinogen production is inhibited, leading to reduced levels of heme and chlorophyll. As a result, plants treated with such herbicides appear chlorotic (yellow colored) due to their ability to produce

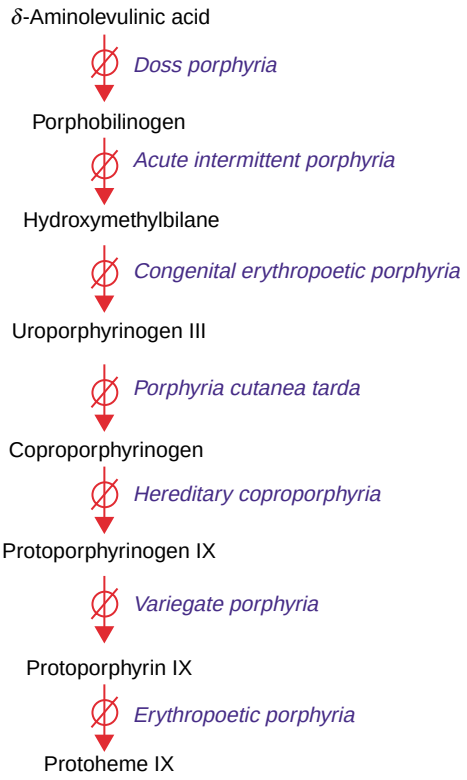

FIGURE 4 The porphyrias. The porphyric disorders that characterize deficiencies in specific parts of the heme biosynthetic pathway are shown in blue.

carotenoids but not chlorophylls. The action of these herbicides is characterized by the accumulation of protoporphyrinogen IX. This diffuses out of the plastids/mitochondria and is oxidized to protoporphyrin IX, either via non-enzymatic means or catalyzed by peroxidase. This mislocation of protoporphyrin IX leads to phototoxicity through the evolution of singlet oxygen species.

Biography

Harry A. Dailey received a B.A. (bacteriology) in 1972 and a Ph.D. (microbiology) in 1976 from UCLA. He joined the Department of Microbiology at the University of Georgia in 1980 as an Assistant Professor following postdoctoral studies at the University of Connecticut Health Center. He served as Head, Department of Microbiology at UGA (1987–1996) and was appointed Director of the Biomedical and Health Sciences Institute in 2001. His research interests involve heme biosynthesis and the genetic diseases named porphyrias.

Mark Shepherd received a B.Sc. (1999) (Biochemistry) and a Ph.D. (2003) from the University of Sheffield. He then moved to the University of Georgia to perform postdoctoral research in the laboratory of Harry A. Dailey. His research interests involve the enzymology of heme and chlorophyll biosynthesis.

Pre-tRNA and Pre-rRNA Processing in Bacteria

Sidney R. Kushner
University of Georgia, Athens, Georgia, USA

In bacteria, tRNAs and rRNAs represent the large majority of RNA molecules found inside cells. rRNAs along with a variety of ribosomal proteins are the structural components of the ribosomes, the macromolecular complexes that carry out protein synthesis. In an exponentially growing bacterium such as *Escherichia coli*, there are 30 000–45 000 ribosomes per cell. tRNAs are also required for protein synthesis, being the molecules that bring individual amino acids to the ribosome for the process of peptide bond synthesis. Both of these types of RNA molecules are very stable and are essential for cell viability.

Interestingly, tRNAs and rRNAs are synthesized as parts of larger precursor molecules that must be processed to generate the mature forms that are either incorporated into ribosomes or that can be charged with amino acids. The processing of these RNA molecules is carried out by a series of ribonucleases that have very specific functions. These processing reactions, as described, have been studied extensively in *E. coli*, but may be significantly different in other bacteria.

tRNAs

Mature tRNAs are relatively small molecules that can range in length from 73 to 94 nucleotides (Figure 1). In order for them to be functional, they must contain the trinucleotide CCA at their 3′ termini (Figure 1) to which specific amino acids can be covalently attached. In some bacteria such as *E. coli* the CCA is encoded in the DNA. In others, the CCA has to be added posttranscriptionally to some of the tRNAs transcripts. In addition, there can be multiple tRNAs that can be charged with the same amino acid. For example, in *E. coli* there are 86 tRNA genes even though there are only 21 amino acids. Each tRNA folds into a characteristic cloverleaf structure (Figure 1), most likely during or even prior to the various processing events.

Primary Structure of tRNA Genes

Although there are large numbers of tRNA genes in each bacterium, they are not clustered in one specific region of the genome. Rather, they may exist as independent genes (Figure 2A), in a group of tRNA genes that are all transcribed from a single promoter (Figure 2B), in a group of genes that also include mRNAs or embedded in an operon that contains rRNA genes (Figure 2C). In all cases, the tRNA transcripts contain extra nucleotides (Figure 2, black lines) that must be removed to generate the mature, functional tRNAs that can be recognized by their respective aminoacyl transferases, the enzymes that specifically charge each of the tRNAs with the appropriate amino acid.

Enzymatic Processing of tRNA Precursors

Some features of tRNA processing have been universally conserved, while others may be specific to certain classes of bacteria. For example, the mature 5′ terminus of every tRNA is generated by an endoribonuclease called RNase P. This enzyme is composed of a catalytic RNA and a protein subunit, and is found in both prokaryotes and eukaryotes. However, at least in *E. coli*, RNase P cleavage requires prior processing at the 3′ terminus. Thus, in the initial processing step for most, if not all, *E. coli* tRNAs, RNase E cleaves endonucleolytically near the mature CCA sequence (1–3 nucleotides downstream, Figure 3, blue arrows). Cleavage by this enzyme is required whether the tRNA is a monocistronic transcript (Figure 3A) or exists as part of a polycistronic operon (Figure 3B).

Following RNase E processing, RNase P cuts at the 5′ end (Figure 3, red arrows), generating the mature terminus. Subsequently, the few extra nucleotides found at the 3′ terminus are removed exonucleolytically by a combination of RNase T, RNase D, RNase BN, RNase II, RNase PH, and possibly polynucleotide phosphorylase (Figure 3, dashed orange arrows). Based on the substrate preferences of these various 3′ → 5′ exonucleases, RNase T appears to be the most important of the various enzymes. In the case of organisms where the 3′ CCA nucleotides are not encoded in the DNA, an enzyme called tRNA nucleotidyltransferase is capable of

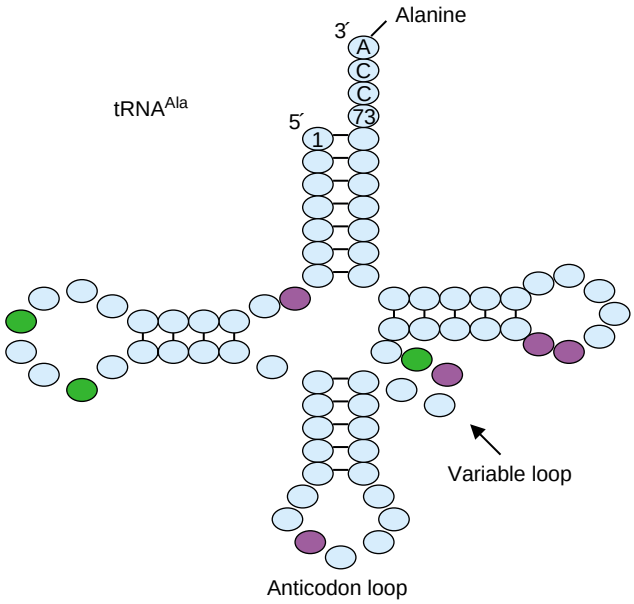

FIGURE 1 Schematic drawing of *Escherichia coli* alanine tRNA. This particular tRNA contains 76 nucleotides. The green ovals indicate positions at which one nucleotide may be deleted yielding tRNAs between 73–75 long or additional nucleotides can be added, yielding species up to 94 nucleotides in length. The magenta ovals indicate the locations of bases that are modified posttranscriptionally in this tRNA. Each tRNA has a unique pattern of base modification. The anticodon loop, used for reading the messenger RNA, as well as the CCA at the 3′terminus are indicated. The short black lines indicate positions of Watson–Crick base pairing.

adding the two Cs and one A, using CTP and ATP as substrates, to generate the mature 3′ terminus. Most bacteria contain this enzyme, which can also be used to repair 3′ termini that have been partially degraded during the exonucleolytic processing reactions (Figure 3A).

Modification of Individual Bases in tRNAs

Although tRNAs are synthesized using the standard nucleoside triphosphates containing either adenine, uracil, guanine or cytosine, each tRNA contains a number of modified bases that are generated posttranscriptionally (Figure 1). For example, a common modification involves the replacement of an oxygen atom at the 3 position of uracil with a nitrogen atom, generating a new base called pseudouracil. Additional alterations arise by the addition of methyl groups at specific locations. Some modifications occur through a single enzymatic step (methylation), while others require a series of biosynthetic steps (1-methylinosinic acid). Research has shown that only some of the modified bases are required for normal tRNA function. Many of the modifications are found not only in bacteria but in eukaryotic organisms as well.

rRNAs

rRNAs provide the structural core to which ribosomal proteins bind to form both the 30S and 50S bacterial ribosomal subunits. The 16S rRNA is found in the 30S subunit while the 23S and 5S species are located in the 50S ribosomal subunit. Numerous ribosomal proteins are associated with each subunit but recent crystallographic data suggest that it is the RNA component of the 50S subunit that catalyzes peptide bond formation. In bacteria all three rRNA species are transcribed as part of a single polycistronic transcript (30S) in the order of 16S, 23S, and 5S (Figure 2C). In addition, the rRNA genes are duplicated in most bacteria (seven copies in *E. coli*) and generally contain one or more tRNAs (Figure 2C).

Primary Processing

The primary 30S rRNA transcript is cleaved during its synthesis by the endoribonuclease RNase III. This enzyme recognizes specific stem-loop structures that are generated by inverted repeats within the RNA transcript. In bacteria, the 16S and 23S rRNAs form two adjacent stem-loop structures (Figure 4). RNase III

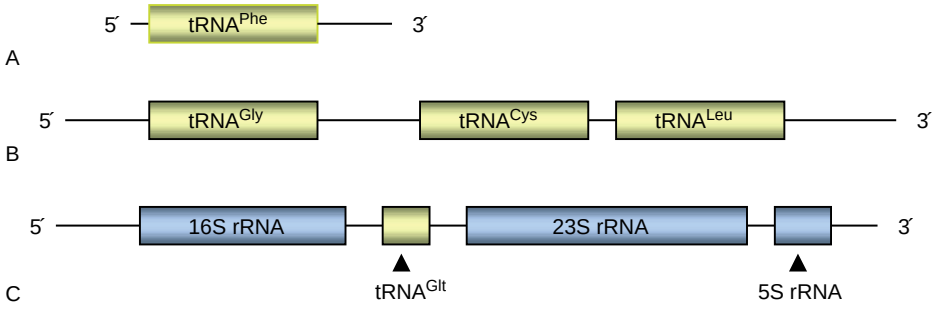

FIGURE 2 Organization of tRNA and rRNA genes. (A) The monocistronic phenylalanine tRNA gene from *E. coli*. (B) The polycistronic operon from *E. coli* containing glycine, cysteine, and leucine tRNA genes. (C) One of seven *E. coli* rRNA operons (*rrnB*) containing the sequences for 16S, 23S, and 5S rRNAs, as well as a glutamine tRNA. Colored boxes (yellow for tRNAs and blue for rRNAs) represent what will become the mature sequences. Black lines indicate sequences that will be removed by nucleolytic processing reactions.

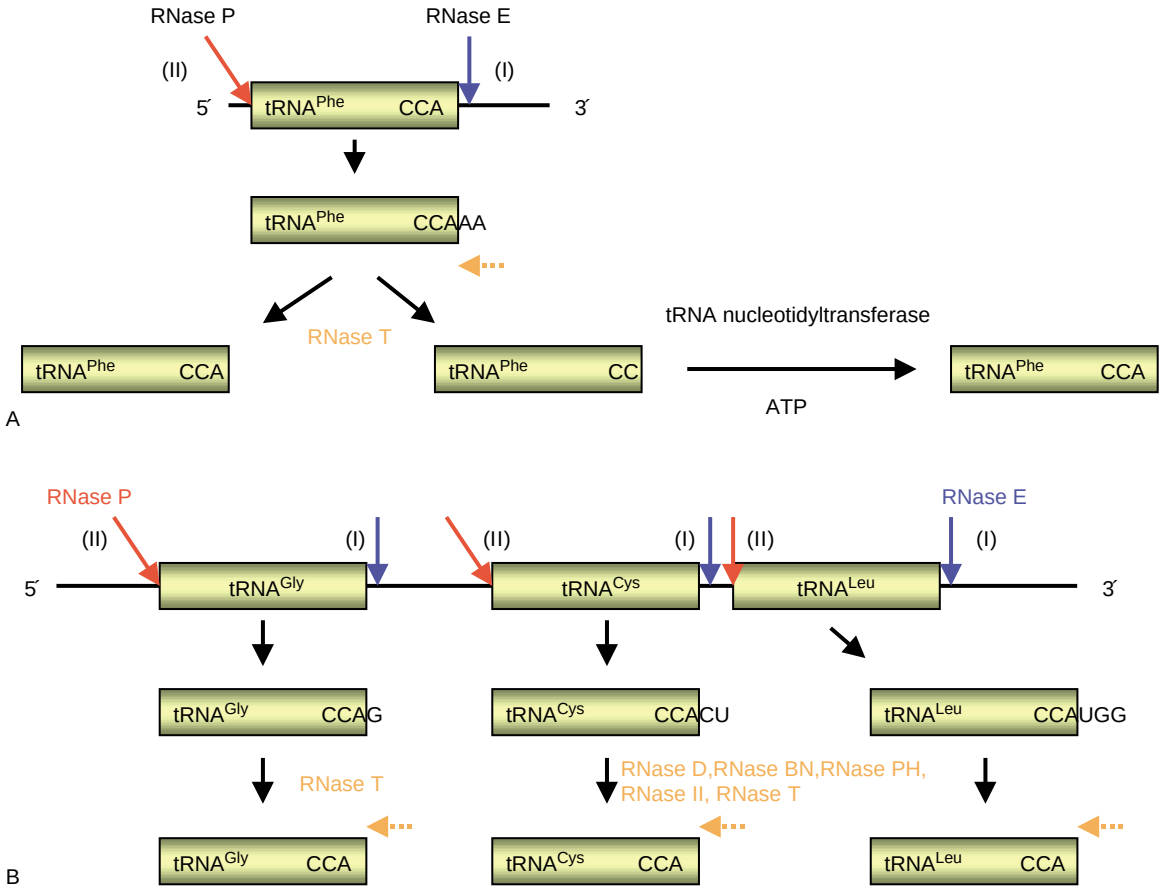

FIGURE 3 Processing of tRNAs in *E. coli*. (A) With a monocistronic operon, the initial cleavage (I) at the 3′ end is catalyzed by RNase E (blue arrow), followed by RNase P processing (red arrow) at the 5′ end (II). While RNase P cleavage generates the mature 5′ terminus, RNase E cleavage leaves a small number of extra nucleotides at the 3′ end. Based on extensive analysis of the various 3′ → 5′ exonucleases found in *E. coli*, it appears that RNase T (dashed orange arrow) is primarily responsible for processing the phenylalanine tRNA. If, however, RNase T removes one too many nucleotides, the A residue can be restored by the action of tRNA nucleotidyltransferase. (B) In the case of a polycistronic operon, the first series of cleavage reactions is again carried out by RNase E (blue arrows) (I). Subsequently, RNase P cuts (red arrows) at the 5′ end (II). Final processing normal involves RNase T (dashed orange arrow). In some cases, additional riboexonucleases, as indicated, are also required.

cleaves on both sides of each stem (Figure 4, magenta arrows). In one case, a 17S precursor of what will become the mature 16S rRNA is released. This molecule contains an extra 115 nucleotides at its 5′ terminus and 33 nucleotides at the 3′ terminus. In the case of the 23S rRNA, RNase III cleavage leaves an extra 3 or 7 nucleotides at the 5′ terminus and 7–9 nucleotides at the 3′ terminus. The RNase III cleavages release the 5S rRNA as part of a 9S precursor.

Generation of Mature rRNAs

16S rRNA

Recent studies have shown that the mature 5′ terminus of 16S rRNA is generated as a two-step process in which RNase E initially cuts endonucleolytically to remove 49 nucleotides from the immature 5′ end (Figure 4, blue arrow). Following this step RNase G cleaves to generate the mature 5′ end (Figure 4, green arrow). Removal of the extra 33 nucleotides at the 3′ end is thought to also occur endonucleolytically, even though the actual enzyme responsible for this processing event has not yet been identified (Figure 4, brown arrow).

23S rRNA

For the 3′ end of the immature 23S rRNA, experiments have indicated that a combination of polyadenylation and the activity of several exoribonucleases serve to generate the mature terminus (Figure 4, dashed orange arrows). In particular, RNase T appears to be the primary exonuclease involved in this process, but additional RNases such as RNase PH, RNase BN, RNase D and RNase II probably also participate. It is not known at this time how the extra nucleotides are removed from the 5′ end (Figure 4, brown arrow).

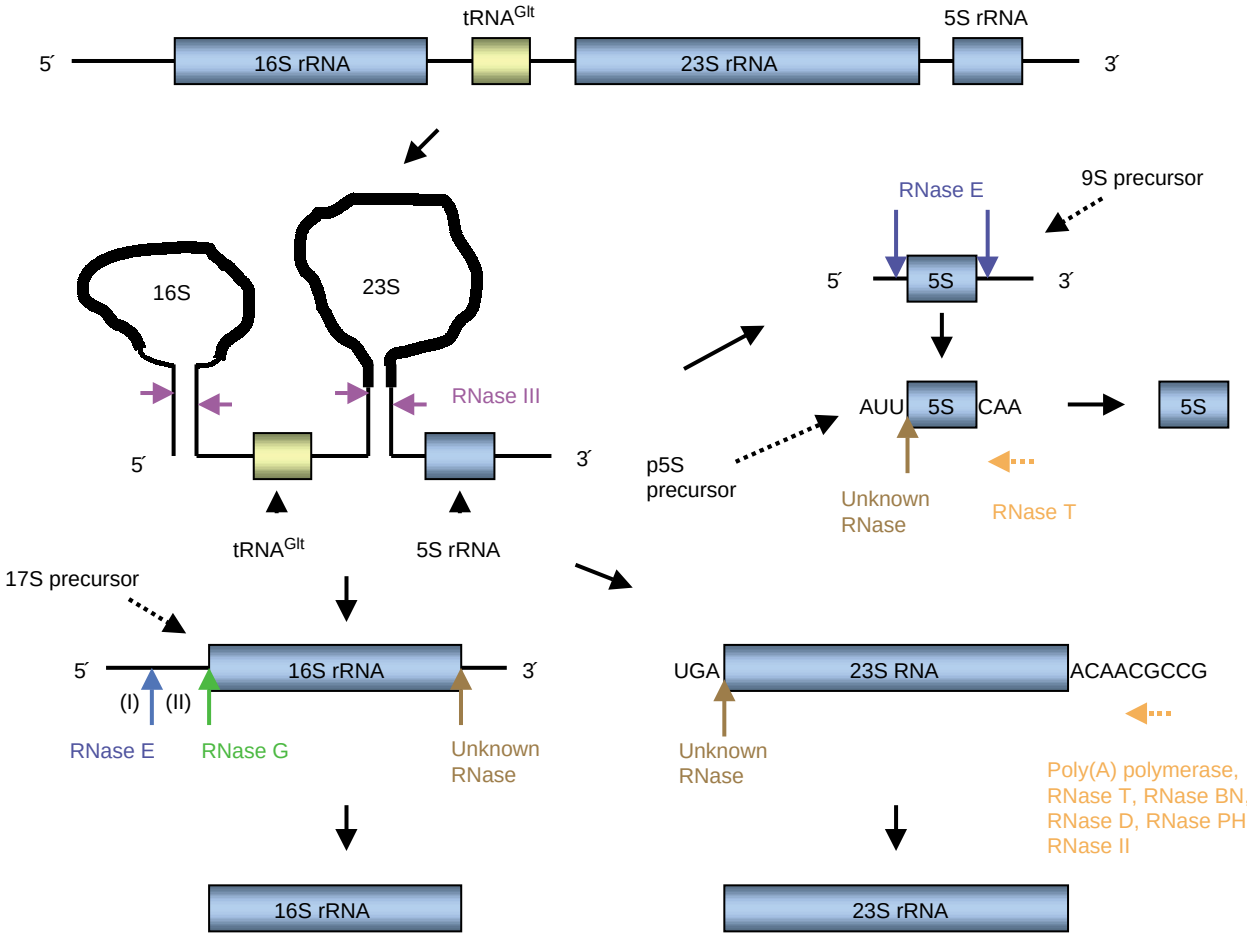

FIGURE 4 Processing of rRNA in *E. coli*. The polycistronic rRNA operon is shown initially in a linear form. Because of the presence of inverted repeats two double-stranded stems form, which loop out both the 16S and 23S rRNA sequences (thick lines). These stem-loop structures are recognized by RNase III (magenta arrows), which cuts on both sides of each stem to release pre16S (17S), 23S, and 9S species. The 17S species contains 115 extra nucleotides at the 5′end and 33 nucleotides at the 3′end. Processing at the 5′end involves a sequential series of reactions involving RNase E (blue arrow) first (I) followed by RNase G (green arrow) (II) to generate the mature 5′ end. An unknown endoribonuclease (brown arrow) is thought to generate the mature 3′ terminus. With the 23S rRNA, there are a few extra nucleotides at the 5′ end that are removed by an unidentified as yet RNase (brown arrow). At the 3′ end the extra 7–9 nucleotides are removed by a combination of polyadenylation and 3′ → 5′ exonucleases (dashed orange arrow). To generate 5S rRNA, RNase E (blue arrows) cuts the 9S precursor at both the 5′ and 3′ ends to release a p5S form that has three extra nucleotides at either end. RNase T (dashed orange arrow) processes the 3′ end, while the 5′ end is matured by an unknown ribonuclease (brown arrow). Processing of the glutamine tRNA is as described in Figure 3B.

However, since no 5′ → 3′ riboexonucleases have been identified in *E. coli*, it is presumed that this processing is carried out by an endoribonuclease.

5S rRNA

The 9S precursor, formed by RNase III cleavage of the 30S transcript, is cut twice by RNase E to release a p5S molecule (Figure 4, blue arrows). The p5S form contains three additional nucleotides at either end. In *E. coli*, RNase T has been shown to be essential for the removal of the extra nucleotides at the 3′ end (Figure 4, dashed orange arrow). It is not known how the 5′ end is processed (Figure 4, brown arrow).

Processing Differences among Various Bacterial Species

While the general genomic organization of the rRNA operons and tRNAs is conserved among bacterial species, it is not clear whether the processing reactions are identical in all organisms. For example, while certain enzymes such as RNase III and RNase P are highly conserved in large numbers of prokaryotes, others such as RNase G, RNase E, and RNase T, are found only in a limited number of bacteria. For example, RNase T homologues have been identified in gram-negative bacteria but have not been found in gram-positives. In addition, neither RNase E, RNase

G, nor RNase II exists in the Gram-positive organism *Bacillus subtilis*. Thus, while some aspects of processing are highly conserved in bacteria (RNase III cleavage of the 30S rRNA precursor and 5′ end processing of tRNAs by RNase P), there is probably considerable variation in the other aspects of processing.

What Happens when Processing is Defective?

Since mutations in either RNase E or RNase P lead to cell death, tRNA processing is essential for cell viability. This is not overly surprising because an immature 3′ terminus of a tRNA cannot be charged with the appropriate amino acid. Without charged amino acids, protein synthesis will not take place. This presumably is the reason for the presence of redundant enzymes (RNase T, RNase PH, RNase BN, RNase D, and RNase II) capable of removing the few remaining nucleotides at the 3′ terminus following RNase E cleavage. Loss of any one of these exoribonucleases does not compromise cell viability, as long as the others remain active. In addition, if processing happens to remove the 3′ terminal A, tRNA nucleotidyltransferase functions to restore a functional 3′ terminus (Figure 3A).

In contrast, the requirements for rRNA maturation are not as strict. Immature forms of 16S rRNA, 23S rRNA, and 5S rRNA can be incorporated into ribosomes that are biologically active. In addition, there are probably backup processing pathways for rRNA. For example, in RNase III mutants of *E. coli*, full-length 30S rRNA precursors are observed, but the cell is still viable. Under these circumstances, it is quite likely that alternative processing is carried out by either RNase G or RNase E. In *B. subtilis*, which lacks both these enzymes, RNase III is essential for cell viability.

Glossary

polarity RNA molecules have 5′ and 3′ ends (termini) which are named for the orientation of the 5′ and 3′ carbon atoms of the ribose rings in the sugar/phosphate backbone.

riboendonuclease An enzyme that degrades a RNA molecule at internal locations.

riboexonuclease An enzyme that degrades an RNA molecule, one nucleotide at a time. If the enzyme initiates the degradation from the 3′ terminus it is called a 3′ → 5′ riboexonuclease.

sedimentation coefficient (*S*) Named after the Swedish scientist Svedberg, the *S* value is an indication of the size of a large macromolecule. It is based on the mobility of large molecules in a centrifugal field. Thus, the higher the number the larger the molecule.

Sidney Kushner is a Professor and former Head of the Department of Genetics at the University of Georgia. His research focuses on understanding the molecular mechanisms of RNA processing and decay, as well as polyadenylation in bacteria. He holds a Ph.D. from Brandeis University and was a Postdoctoral Fellow at the University of California, Berkeley and Stanford University. He is a Fellow of the American Association for the Advancement of Science and the American Academy of Microbiology.

Pre-tRNA and Pre-rRNA Processing in Eukaryotes

Hendrik A. Raué
Vrije Universiteit, Amsterdam, The Netherlands

The two most abundant stable RNA species in eukaryotic cells, tRNA and rRNA, are synthesized in the form of precursor molecules containing extra sequences not present in the mature molecules. By processing the ordered removal of these extra sequences by exo- and/or endonucleases is meant and, in the case of tRNA, covalent linkage of the fragments arising from removal of an internal region (splicing). In a wider sense, processing also encompasses various types of modification of particular nucleotides, as well as addition of nucleotides that are not encoded in the DNA (editing). This article describes the present knowledge of the mechanisms responsible for pre-tRNA and pre-rRNA processing. The emphasis is on the yeast *Saccharomyces cerevisiae*, where this processing has been studied in greatest detail. However, the general principles, and even many of the details, apply to most other eukaryotes as well.

Pre-tRNA Processing

Eukaryotic tRNAs are generally synthesized as individual precursor molecules that contain extra sequences at both the 5′- and 3′-end, called leader and trailer, respectively. Some, though not all, pre-tRNAs also contain an intron, which is always located directly downstream (i.e., 3′) from the anticodon. Consequently, the conformation of the mature domain of the tRNA is largely conserved in its precursor and structural features of this mature domain are in fact the major recognition elements for the various processing enzymes (Figure 1A).

Processing of eukaryotic pre-tRNA takes place in the nucleus and only fully processed tRNAs are recognized by the export machinery that transfers them to the cytoplasm (Figure 1B). However, there does not seem to be an obligatory order of the different steps leading from the pre-tRNA to the mature molecule.

Removal of Precursor-Specific Sequences

5′-End Processing

Removal of the 5′-leader region is normally the first event in eukaryotic pre-tRNA processing. It is carried out by the nuclear endonuclease RNase P, a ribonucleoprotein complex that has orthologues in eubacteria and archaebacteria, as well as in mitochondria and chloroplasts. RNase P contains a single, small RNA molecule the conformation of which, though not the sequence, has been strongly conserved from bacteria to man. This RNA molecule is associated with a variable number of proteins, depending on the organism, that show a lesser degree of conservation.

The substrate for RNase P is a complex of pre-tRNA and the La protein which binds to the 3′-end of the precursor immediately after termination of transcription. Substrate recognition is mainly based upon the consensus tertiary structure of the mature domain of the pre-tRNA, but the 3′-trailer region also contributes to efficient cleavage by RNase P.

In yeast 5′-end maturation of pre-tRNAs takes place mostly in the nucleolus, a specialized region of the nucleus not bound by a membrane that is also involved in the first stages of pre-rRNA processing (Figure 1B). However, 5′-end maturation can also occur in the nucleoplasm, though it is as yet unclear whether this applies to a small portion of all pre-tRNAs or only to a few specific pre-tRNA species. All subsequent steps in yeast pre-tRNA maturation occur in the nucleoplasm. In mammalian cells, the situation seems to be reversed with most 5′-end processing occurring in the nucleoplasm.

3′-End Processing

Removal of the 3′-trailer sequence follows cleavage by RNase P and is performed by, as yet, an unidentified endonuclease that acts upon the precursor/La-protein complex. In the absence of bound La-protein both the timing and the mechanism of 3′-end processing are altered. The naked pre-tRNA is first attacked by 3′ → 5′ exonucleases that remove the portion of the 3′-trailer not base-paired to the leader. Removal of the latter by RNase P, then exposes the remainder of the trailer to further exonucleolytic digestion.

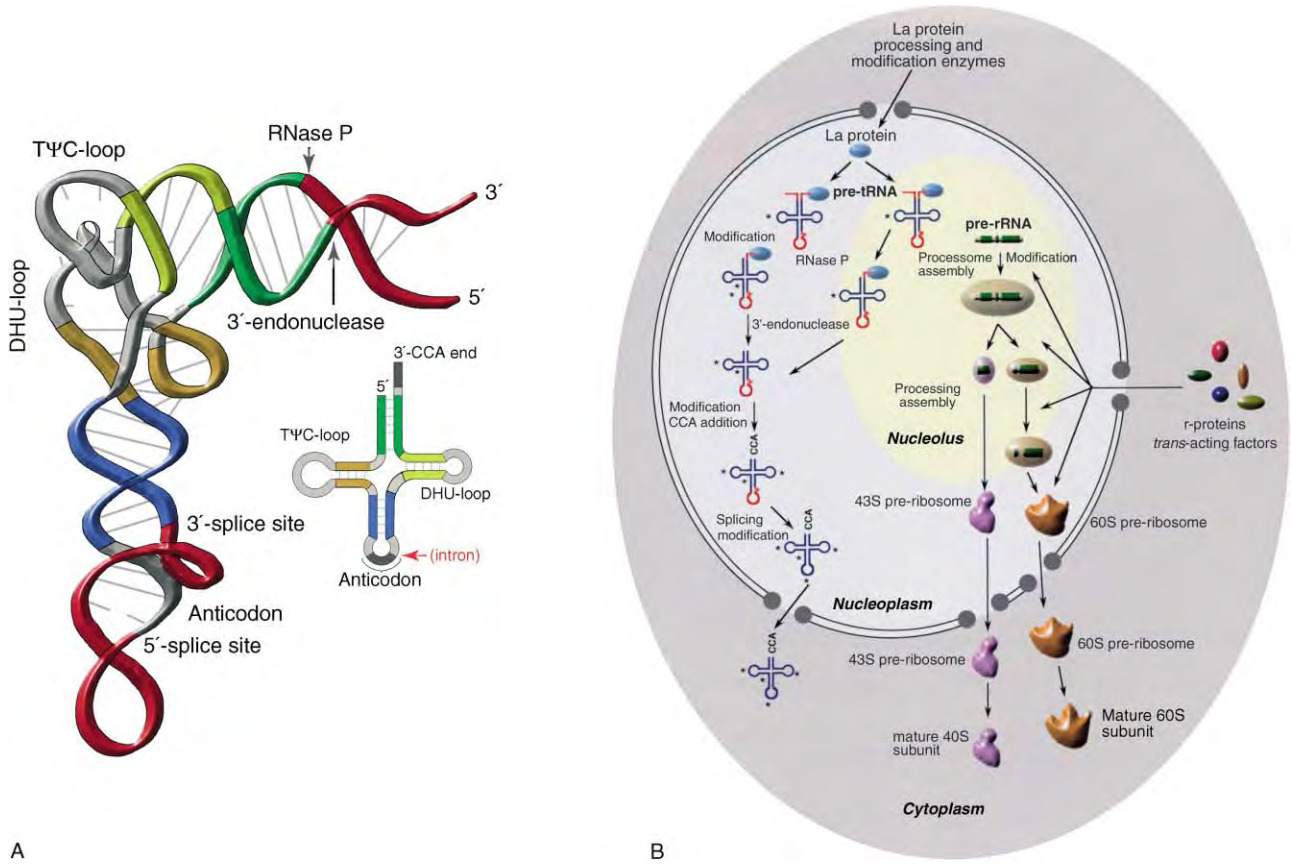

FIGURE 1 Overview of pre-tRNA processing and pre-rRNA processing/assembly in eukaryotic cells. (A) Conformation of pre-tRNA. The various regions are color-coded in the same manner as in the 2D model. Leader, trailer, and intron are in red. The mature domain of the precursor has essentially the same conformation before and after processing. (B) Subcellular localization. As discussed in the text pre-tRNA processing takes place in both the nucleolus and the nucleoplasm. Note that nucleotide modifications (indicated by asterisks) occur – in a specific order – at various stages. Pre-rRNA processing and its assembly with ribosomal proteins starts in the nucleolus with later stages taking place in the nucleoplasm. The finishing steps in formation of functional ribosomal subunits occur in the cytoplasm. In yeast this includes the final processing of 20S pre-rRNA into mature18S rRNA. In other eukaryotes the latter also occurs in the nucleoplasm. Export of tRNA and each of the two types of ribosomal subunits to the cytoplasm occurs by different pathways, which, however, do share some components. Note the nuclear pores are not selective for either the type of macromolecule to be transported or the direction of transport.

Removal of the Intron (Splicing)

Splicing is normally a late step in pre-tRNA processing, although under particular conditions it can occur prior to end maturation. Splicing involves the consecutive action of three enzymes. First, a splicing endonuclease cleaves the phosphodiester bonds at both ends of the intron. The yeast enzyme is a multi-subunit, integral membrane protein that may be located in the inner nuclear envelope. It contains two distinct active sites, one for each of the two splice sites. The enzyme selects the splice sites primarily by measuring their distance from specific structural features in the mature domain, using different features for each site. The intron, however, also contributes to this specific recognition.

The two, base-paired tRNA fragments left by the endonuclease are converted into a contiguous molecule by tRNA ligase in a complex three-step reaction that leaves a 2′-phosphate at the junction. This phosphate is removed by the third enzyme, an unusual NAD-dependent phosphotransferase.

Changes in Nucleotide Sequence of the Mature Domain

Addition of the 3′-CCA End

In contrast to their eubacterial counterparts, eukaryotic tRNA genes do not encode the 3′-CCA-end essential for tRNA function. These three nucleotides are added to the 3′-end formed after removal of the trailer by ATP[CTP]:tRNA nucleotidyltransferase. A cytoplasmic version of this enzyme is probably involved in repair of damaged CCA-ends.

Modification

tRNAs contain ~80 different types of modified nucleotide. All modifications are carried out by specialized

proteinaceous enzymes, that, depending upon their nature act on the primary precursor transcript, on one of the processing intermediates or possibly even on the cytoplasmic tRNA. Since in yeast most of the tRNA modifications studied are nonessential the presence of modified nucleotides probably serves to fine-tune tRNA function.

Pre-rRNA Processing

Each eukaryotic, cytoplasmic ribosome contains single copies of four different rRNA species. The18S rRNA (1500–2300 nucleotides, or nt) is part of the small (40S) subunit, while the large (60S) subunit contains 5S (~120 nt), 5.8S (~150 nt), and 25/28S rRNA (3400–5000 nt). The 18S, 5.8S, and 25/28S rRNAs are encoded by one or more sets of tandemly repeated rDNA units, each of which is transcribed by RNA polymerase I into a single long pre-rRNA molecule (35–45S), containing external transcribed spacers (ETS) at both ends (5′- and 3′-ETS) as well as two internal transcribed spacers (ITS1 and ITS2) that separate the coding regions (Figure 2). In *S. cerevisiae*, a single 5S rRNA gene is embedded in the DNA that separates two consecutive rDNA units, whereas in higher eukaryotes the 5S rRNA genes are scattered throughout the genome, often in clusters. All 5S rRNA genes are transcribed individually by RNA Polymerase III into a precursor carrying a short 3′-ETS.

Removal of the transcribed spacer sequences from the primary precursor transcript occurs in an ordered series of endo- and exonucleolytic steps, which, in the case of the 35–45S precursor, is preceded by modification.

Pre-rRNA transcription, a large portion of its maturation, i.e., modification and processing, as well as ordered association of the intermediate precursor species with most of the ribosomal proteins (r-proteins), takes place in the nucleolus. Later stages occur in the nucleoplasm and formation of functional ribosomal subunits is completed in the cytoplasm (Figures 1 and 3).

Modification of Pre-rRNA

Modification of pre-rRNA is limited to the mature 18S and 25/28S rRNA sequences and consists mostly of two types: conversion of U residues into Ψ (pseudouridylation) and 2′-*O*-methylation of the ribose moiety of nucleotides. A few nucleotides are base-methylated. The number of modified nucleotides increases with increasing complexity of the organism but most of the modifications found in lower eukaryotic cells (e.g., yeast) are conserved in higher eukaryotes, including man. 2′-*O*-Methylation and pseudouridylation take place on the primary pre-rRNA transcript and are carried out by two classes of small nucleolar ribonucleoprotein particles (snoRNPs). A collection of box C/D snoRNPs is responsible for methylation, whereas a similar collection of box H/ACA snoRNPs perform the U → Ψ conversions. The names refer to common primary and secondary structural features present in the RNA component of each member of that class. Each box C/D or box H/ACA snoRNA also contains at least one, and sometimes two, specific "guide" sequence(s) that are complementary to the rRNA region(s) containing the modification site. The specific rRNA/snoRNA base-pairing guides the modifying enzyme, which is an integral part of the snoRNP, to its target nucleotide. Base-methylation, occurs at later stages of ribosome formation and is carried out by conventional proteinaceous enzymes.

Experiments with yeast cells indicate that rRNA modification is not essential for ribosome formation or function but does strongly enhance functional efficiency of the ribosome.

Removal of the Spacer Regions

The Processing Pathway

In *S. cerevisiae*, the first detectable precursor of 18S, 5.8S, and 25S rRNA is called 35S pre-rRNA. This precursor has already lost most of the 3′-ETS due to endonucleolytic cleavage that occurs before its transcription has been terminated. The pathway by which the 35S precursor is subsequently converted into the mature rRNAs is depicted in Figure 2A.

Maturation of 35S pre-rRNA starts with the removal of the 5′-ETS by two successive cleavages, which produce first the short-lived 33S and then the 32S species. The latter is cleaved within ITS1 separating the small subunit 20S pre-rRNA from the 27SA2 large subunit intermediate. Processing of 20S pre-rRNA is completed in the cytoplasm by endonucleolytic cleavage at the mature 3′-end of 18S rRNA. So far none of the nucleases involved in these processing steps have been identified.

Processing of yeast 27SA2 pre-rRNA is more complicated and occurs via two separate pathways that produce the same 25S rRNA, but two distinct species of 5.8S rRNA whose 5′-ends differ by 6 nucleotides, in ratio of about 10:1 (Figure 2A). The physiological relevance of this phenomenon remains unclear.

As would be expected for such a vital process pre-rRNA processing shows considerable plasticity, which is revealed in cells in which a particular processing step is disturbed by a mutation in either the pre-rRNA or in an accessory factor. The 5′-ETS can be removed in a single step by cleavage at the 5′-end of the 18S rRNA sequence. Initial cleavage within ITS1 can occur at A3 instead of A2 giving rise to an aberrant 21S small subunit pre-rRNA that is still efficiently converted into 18S rRNA. When cleavage at A3 is prevented almost all of the 27SA2 pre-rRNA is processed via the "long" pathway

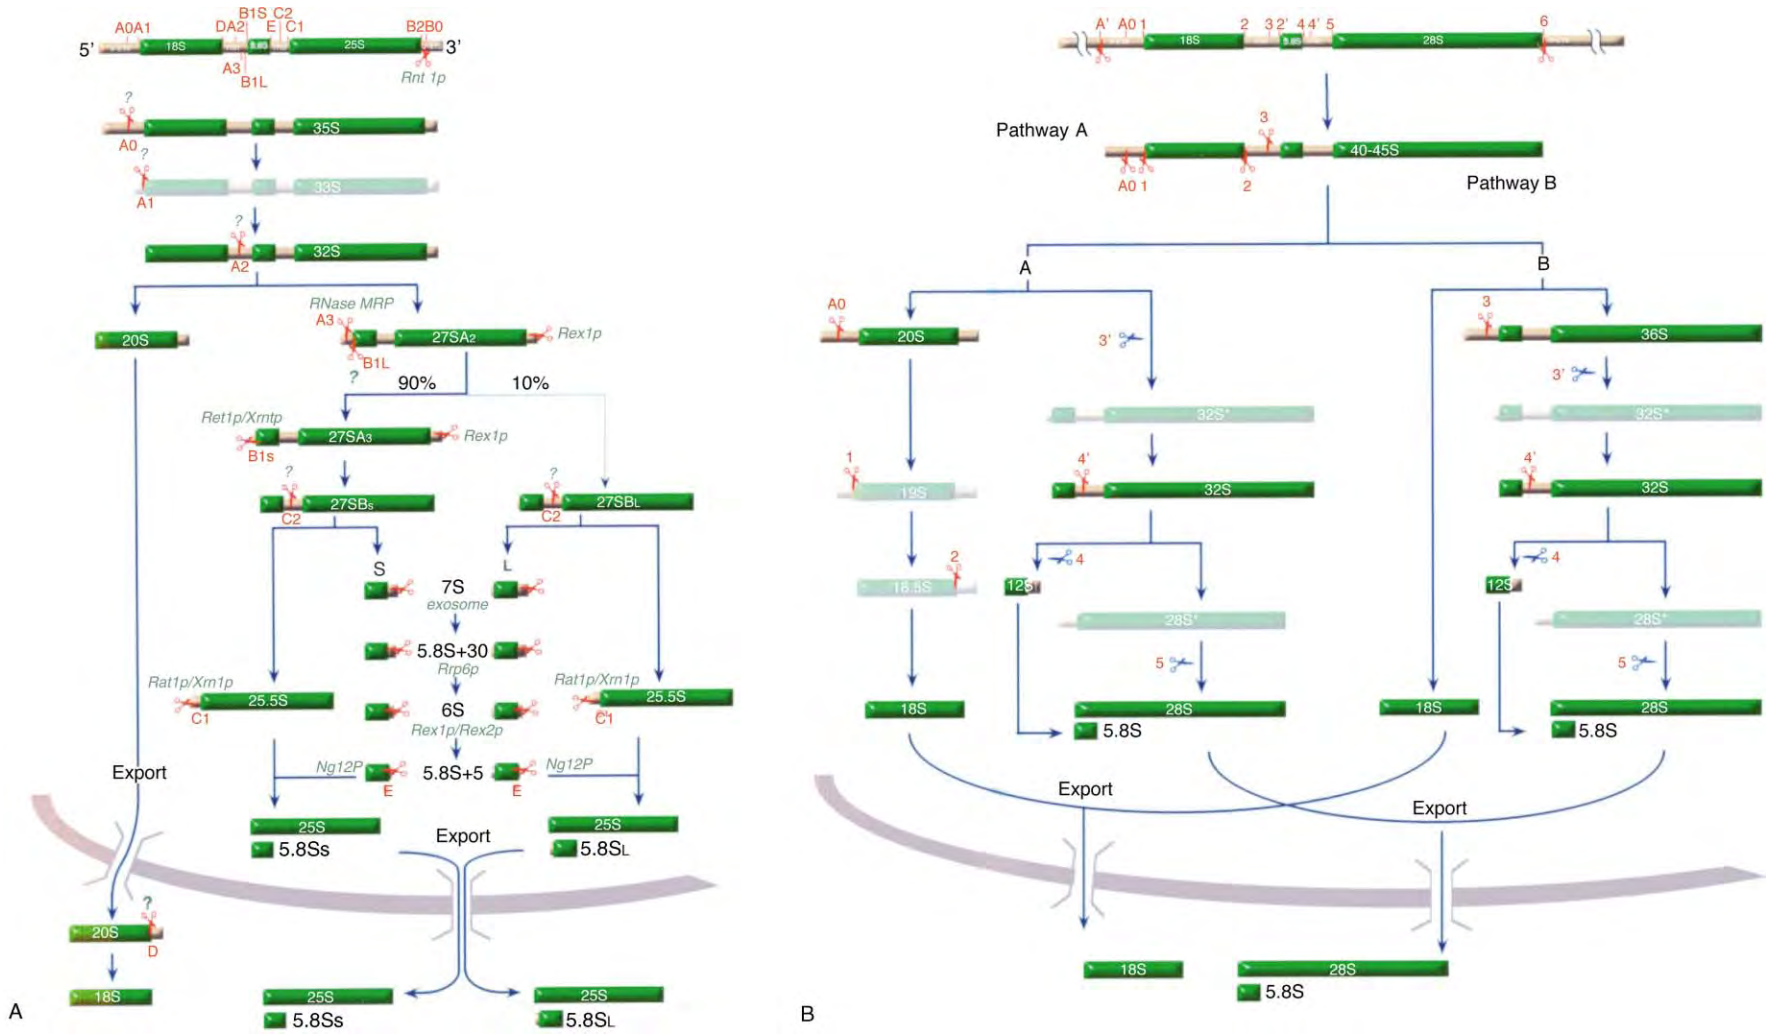

FIGURE 2 Pre-rRNA processing pathways in lower (panel A; *S. cerevisiae*) and higher (panel B) eukaryotic cells. The structure of the primary transcript including the processing sites is depicted at the top with the processing intermediates below. Regions encoding the mature rRNAs are in green, spacer regions are in brown. Light-colored intermediates are short-lived and not detectable under normal conditions. Vertical and horizontal scissors indicate endonucleolytic cleavages and exonucleolytic trimming, respectively. Blue scissors in panel B indicate that the nature of the processing step is unknown but, by analogy with yeast is likely to be exonucleolytic. Where known the enzyme(s) involved in a particular processing step is (are) identified. A question mark indicates that the enzyme is still unknown.

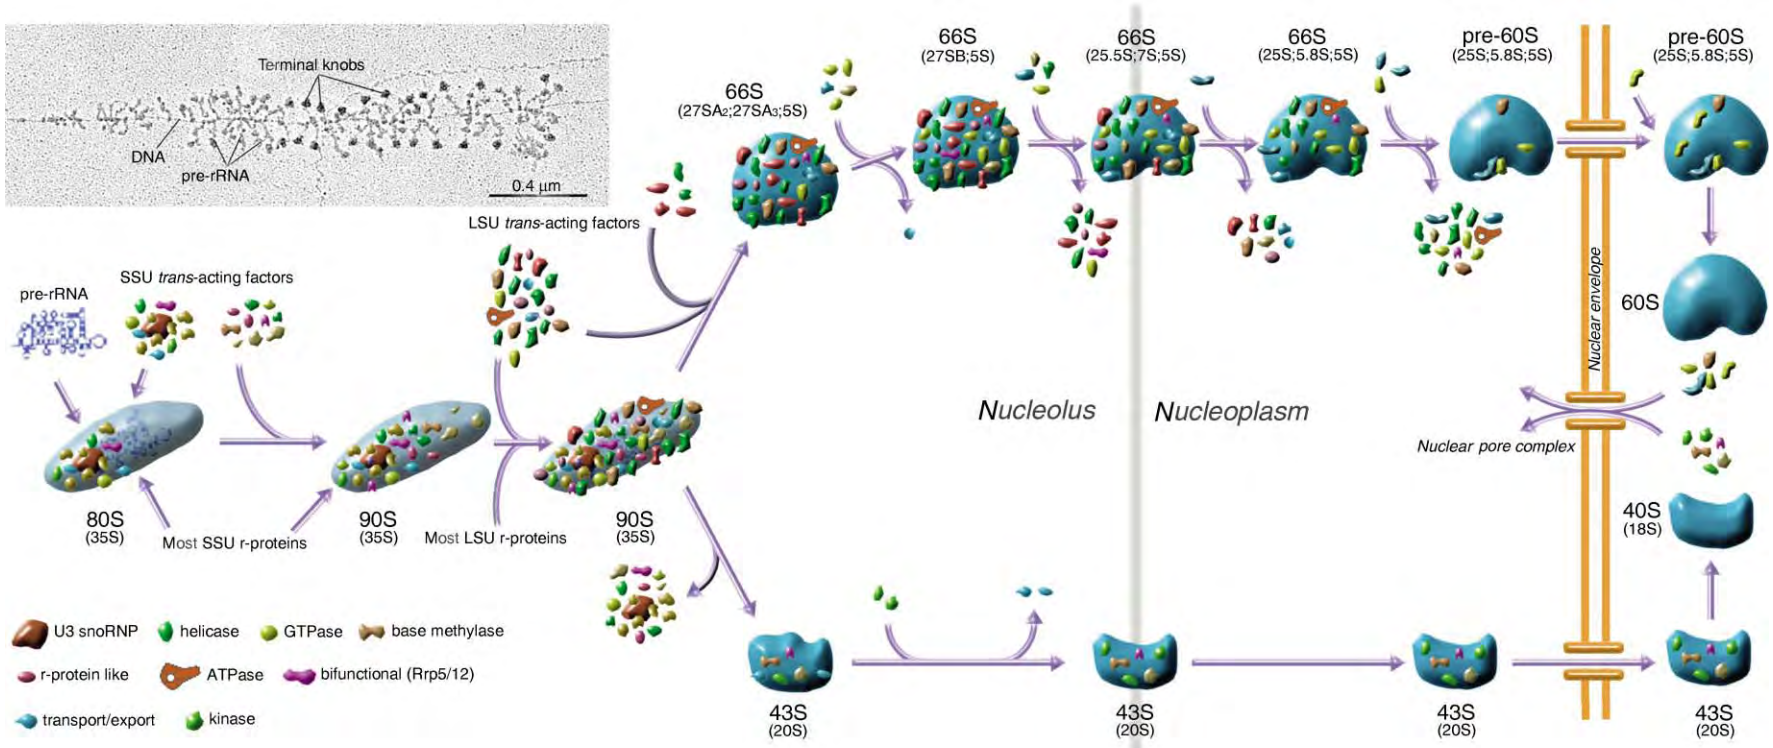

FIGURE 3 The pre-rRNA processing/assembly machinery in *S. cerevisiae*. The different intermediate pre-ribosomal particles so far identified are shown with their S value and, in parentheses, their pre-rRNA constituents. Note that the number of intermediates is tentative as is the nature of the components that associate or dissociate at the various stages. The inset shows an EM picture of the 'terminal balls' thought to correspond to the early stage in assembly of the 80S particle (photograph by Dr. Yvonne Osheim, University of Virginia).

producing 5.8S_L rRNA with little or no adverse effects on cell growth or maintenance.

Cleavage at site C2 is essential to initiate removal of ITS2 from either 27SB precursor but there is considerable redundancy among the exonucleases that remove the spacer nucleotides from the resulting 7S and 25.5S precursors.

Studies on pre-rRNA processing in other eukaryotes are limited mostly to *Drosophila*, *Xenopus laevis*, mouse and human and have not reached the same level of detail as those performed in *S. cerevisiae*. As shown in Figure 2B two pathways have emerged, of which the one labeled B is very similar, though not identical, to that of yeast. This pathway operates in *Xenopus* somatic cells, mouse and *Drosophila*. In *Xenopus* oocytes pre-rRNA processing can follow either pathway, even in the same cell, whereas pathway A occurs in human cells. In this pathway, cleavage at sites A0, 1, and 2 follows, rather than precedes processing at site 3.

Cis-Acting Elements

Correct and efficient processing of eukaryotic pre-rRNA is critically dependent upon structural features of the pre-rRNA (*cis*-acting elements). Such elements have been identified by *in vivo* mutational analysis, in particular in yeast, in both the mature and the spacer regions of the pre-rRNA. Some consist of short sequence elements, whereas for others their conformation, rather than their sequence, appears to be important. In only a few cases, the precise role of the element is known, e.g., the sequence spanning site A3, which constitutes the recognition element for RNase MRP.

Trans-Acting Factors

A large body of biochemical and molecular genetic studies, carried out mostly in yeast, have demonstrated that eukaryotic pre-rRNA processing and its assembly into functional ribosomes, apart from the ribosomal proteins, also requires a multitude of non-ribosomal factors. These *trans*-acting factors, whose number presently stands at ~200, include the modifying snoRNPs discussed before, a small number of additional snoRNPs (5 in yeast, including RNase MRP) and a large variety of proteins. Most have orthologues in other eukaryotes ranging from *C. elegans* to human, which underscores the strong evolutionary conservation of eukaryotic ribosome biogenesis.

Recent advances in the purification of large (ribonucleo) protein complexes by affinity chromatography (tandem-affinity-purification or TAP) and the identification of their constituents have clearly established that the *trans*-acting factors are the parts of two, essentially independent processing/assembly machineries (processomes) that govern formation of the small and large subunit, respectively. Both machineries are dynamic in nature, i.e., they lose particular components and acquire others in an ordered manner as subunit biogenesis progresses (Figure 3). Only two proteins have been found that are constituents of both the small and large subunit machinery.

Assembly of the small subunit (SSU) processome and the association of many of the SSU r-proteins on the pre-rRNA starts well before its transcription has been completed. The U3 box C/D snoRNP (which has no modification activity) plays a central role in the formation of the resulting 80S/90S pre-ribosome, the initial stages of which can be visualized as "terminal knobs" at the ends of the nascent transcripts by electron microscopy of an actively transcribed rDNA unit (inset in Figure 3). Actual processing is deferred, however, until the transcript has been released. Assembly of the large subunit (LSU) machinery starts a little later, immediately before cleavage at site A2 separates the 90S pre-ribosome into a 43S and a 66S particle, and many of the components of the LSU machinery may join only after this separation. Current, but definitely still incomplete, data indicate that the yeast 43S particle goes through at least two more stages before being exported to the cytoplasm, where cleavage at site D converts the 20S pre-rRNA into mature 18S rRNA. This final step requires several *trans*-acting factors that are coexported with the 43S particle and, after their release, are re-imported. The 66S pre-ribosome goes through at least five stages before an export-competent particle emerges that does contain the fully mature rRNA species but still has to undergo some structural rearrangement in the cytoplasm to acquire functionality. Again, some *trans*-acting factors needed for these finishing touches are already added in the nucleus and move back after having completed their task. Others may associate in the cytoplasm.

Studies on the specific function of the various *trans*-acting factors are still in their infancy. Comparative analysis, however, has identified several functional classes, whose role can at least be inferred (Figure 3). Nucleases constitute the most obvious, but also the most elusive, of these classes (Figure 2A). Remarkably, only one of the known processing nucleases (the $5' \rightarrow 3'$ exonuclease Xrn1p) has so far been detected in pre-ribosomes. A second class (19 members in yeast) is formed by proteins containing the signature motifs of RNA helicases. These proteins, therefore, could be involved in structural rearrangements of the pre-rRNA necessary for processing and assembly. Additional structural rearrangements may be carried out by a third class of proteins that show similarity to known GTPases or ATPases. A fourth class consists of proteins that may assist the association of particular r-proteins with the pre-ribosome. Circumstantial evidence points to the existence of at least two such assembly

chaperones for both the small and large subunit. Biochemical experiments have also identified several proteins involved in translocation of either the 43S or 66S pre-ribosome from the nucleolus to the nucleoplasm, while a considerable number has been implicated in export of either subunit to the cytoplasm. The latter include components of the generic nuclear export machinery as well as subunit-specific export factors. Four *trans*-acting factors have a structure strongly resembling that of a particular r-protein. It has been suggested that these rp-like proteins may play a role in timing the order of processing/assembly events by associating first and later giving way to their r-protein counterpart. A recent addition to this inventory are several protein kinases required for the final cytoplasmic step in 40S subunit formation.

This necessarily brief article leaves out the large majority of *trans*-acting factors for which little or no functional information is yet available. Obtaining this information and integrating it into a working model for the course of events in pre-rRNA processing/assembly is one of the major tasks for the future investigations into eukaryotic ribosome biogenesis.

Biography

Hendrik A. Raué is a Professor of Biochemistry in the Faculty of Sciences at the Vrije Universiteit in Amsterdam, The Netherlands. He obtained his Ph.D. in Biochemistry at Groningen University, The Netherlands, and received his postdoctoral training at the National Institute of Child Health and Human Development in Bethesda, Maryland. His primary research interest is in eukaryotic ribosome biogenesis, using the yeast *S. cerevisiae* as a model organism.

Prions and Epigenetic Inheritance

Reed B. Wickner
National Institutes of Health, Bethesda, Maryland, USA

Just as nucleic acids can carry out enzyme reactions, it has now been found that proteins can be genes. The nonchromosomal genes [URE3], [PSI], and [PIN] of *Saccharomyces cerevisiae* and [Het-s] of the filamentous fungus *Podospora anserina* are self-propagating amyloid forms of normal cellular proteins Ure2p, Sup35p, Rnq1p, and HET-s, respectively. The phenotypes produced are due to the absence of the soluble forms in the [URE3] and [PSI] cases, but due to the presence of the amyloid forms in [PIN] and [Het-s]. The portions of the Ure2p, Sup35p, and Rnq1p molecules primarily responsible for prion formation and propagation (prion domains) are very rich in asparagine and glutamine residues, unlike the HET-s prion domain or the PrP molecule that plays a central role in the mammalian transmissible spongiform encephalopathies. The [Het-s] prion is of particular interest because it carries out a normal function for *Podospora*, namely, heterokaryon incompatibility. Chaperones play a critical role in prion propagation, by generating seeds for formation of the amyloid filaments.

Yeast and Fungal Prions: Genetic Criteria

The word "prion" means an infectious protein, by whatever mechanism. This idea arose from studies of the transmissible spongiform encephalopathies (TSEs) of mammals, believed to be due to an infectious form of a protein called PrP. Two nonchromosomal genes of *Saccharomyces cerevisiae*, called [URE3] and [PSI^+], were identified as prions because their unusual genetic properties were inconsistent with their being nucleic acid replicons, but were just what one would expect for a prion (Figure 1). First, each could be efficiently eliminated (cured) from cells, but from the cured cells could again arise at low-frequency cells carrying the nonchromosomal gene. Second, overproduction of the normal form of the protein was shown to increase the frequency with which the prion form arose *de novo*. And it was the protein whose overproduction induced the appearance of the nonchromosomal gene, not the RNA or the gene in high copy number. Finally, the chromosomal gene encoding the protein was of course necessary for the propagation of the prion, but the phenotype of mutants in the chromosomal gene was the same as that of the presence of the prion.

Known Prions of Yeasts and Fungi

[URE3] has each of these properties as a prion of the Ure2 protein, a regulator of nitrogen catabolism in yeast. Similarly, [PSI] has the properties expected of a prion of the Sup35 protein, a subunit of the translation termination factor. A prion of *Podospora anserina*, called [Het-s], is unique in performing a function for this fungus, being required for an antiviral defense mechanism called heterokaryon incompatibility. A third *S. cerevisiae* prion, called [PIN^+], was discovered by its ability to promote the *de novo* development of the [PSI^+] prion and is an altered form of Rnq1p. While [URE3] and [PSI^+] make their presence known by the absence of the normal form of Ure2p and Sup35p, respectively, both [Het-s] and [PIN^+] produce a phenotype by the presence of the abnormal forms of HET-sp and Rnq1p, respectively, similar to the case with the mammalian TSEs.

Prion Domains and Functional Domains

In Ure2p and Sup35p prion proteins, the C-terminal part of the protein carries out the normal function of the protein and the N-terminal segment is responsible for the prion properties (Figure 2). The prion domain can propagate the prion completely independent of the functional domain, and can even confer prion properties to a suitable unrelated reporter protein. The HET-s protein and Rnq1p also have special domains responsible for their prion properties. The Ure2p, Sup35p, and Rnq1p prion domains are all rich in asparagine or glutamine residues, and these runs of N or Q are important for the prion properties of the proteins. However, neither the HET-s protein nor mammalian PrP have regions rich in N or Q (Figure 2). The N-, Q-rich prion domains of Ure2p, Sup35p, and

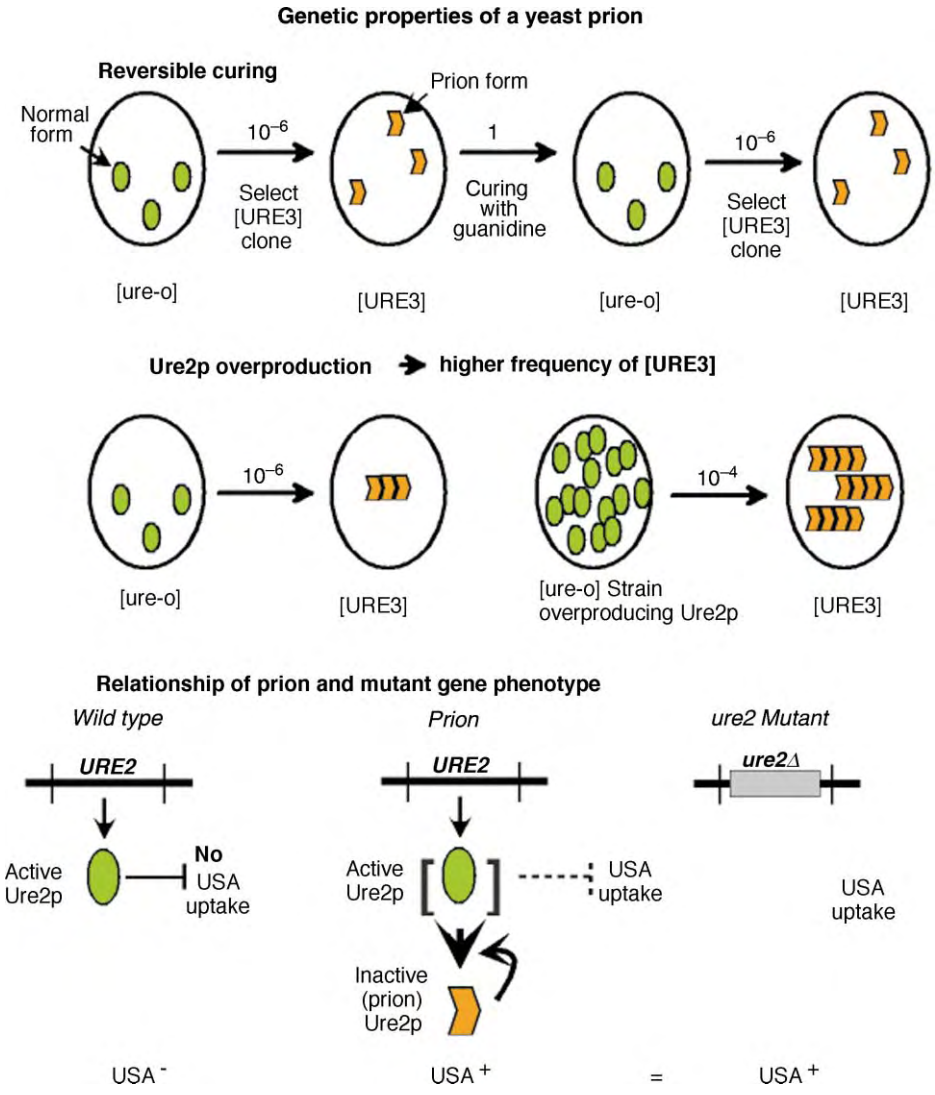

FIGURE 1 Genetic properties identify prions.

Rnq1 resemble the polyQ of Huntingtin whose amyloid formation is the central event in Huntington's disease.

In Ure2p, Sup35p, and HET-sp, the prion domain is stabilized by the rest of the molecule and largely prevented from converting into the prion form. This suggests that there is an interaction between the prion domains and the remainder of the molecule. In Ure2p, the prion domain helps with the nitrogen regulation function of Ure2p, although it is not essential for this activity.

Yeast, Fungal Prions [PSI$^+$], [URE3], and [Het-s] are Self-Propagating Amyloidoses

Amyloid is a special form of protein structure that is characteristic of a number of human diseases. Amyloid is a filamentous structure which is high in β-sheet structure, and which displays a characteristic yellow–green birefringence on staining with the aromatic dye Congo red. Amyloid filaments are partially resistant to protease digestion, probably reflecting their very stable β-sheet structure. Demonstration of aggregation is always simpler than that of amyloid structure, but it is evident that not all aggregates are amyloid. Amyloid formation by the Aβ peptide is the central event in Alzheimer's disease, while amyloid of amylin is a prominent feature of late-onset diabetes. Parkinson's disease features intracellular amyloid formation by α-synuclein, and amyloid of serum amyloid A protein is a complication of many long-term infectious and inflammatory processes.

Sup35p, Ure2p, and HET-sp each form amyloid *in vitro*. Moreover, the characteristics of the amyloid formed and the requirements for its formation closely reflect the corresponding properties and conditions of

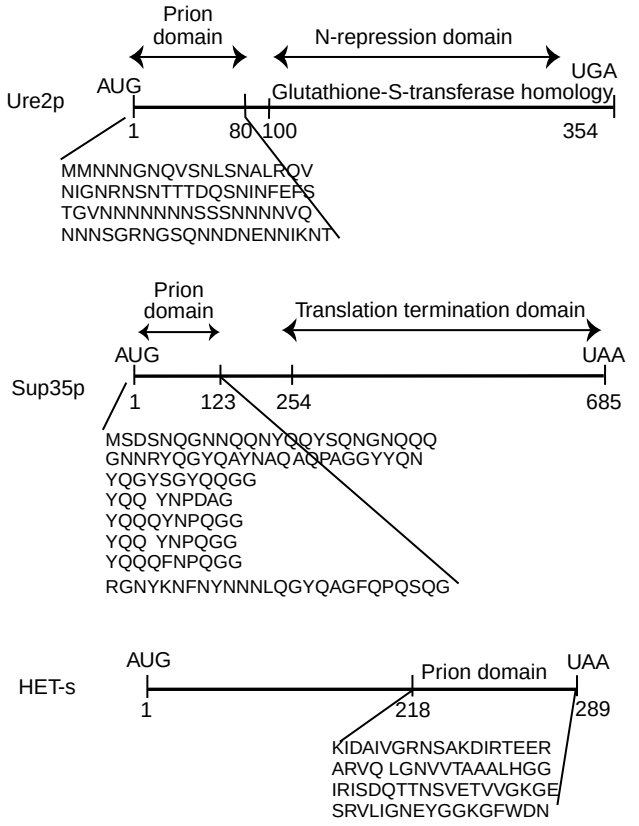

FIGURE 2 Prion domains of Ure2p, Sup35p, and HET-s. While the prion domains of Ure2p and Sup35p are rich in N and Q, that of HET-s is rich in neither.

prion formation *in vivo*. For example, extracts of [PSI$^+$] cells can prime the formation of amyloid by Sup35p much better than can extracts of normal cells. The prion domain of Ure2p induces amyloid formation by the full-length native Ure2p *in vitro* just as the prion domain produced *in vivo* induces *de novo* generation of the [URE3] prion (Figure 3). Indeed, filaments of the Ure2 protein have actually been visualized specifically in [URE3] cells.

Recombinant HET-s protein converted into amyloid *in vitro* efficiently transmits the [Het-s] trait to *Podospora* colonies when introduced by the "gene gun." The same protein, aggregated by heat denaturation or acid, or in its soluble form, has little or no such effect. This is a dramatic demonstration of the prion nature of [Het-s] which has not yet been accomplished in any of the yeast or mammalian systems.

The mechanism by which amyloid formation inactivates Ure2p is apparently not by a conformational change of the functional domain of the molecule. Fusion of the Ure2p prion domain to any of several enzymes shows no loss of their activity, but suggests that being in the amyloid filament sterically blocks access to binding Gln3p (the target of Ure2p action) or imposes a diffusion limitation.

The [HET-s] Prion Carries Out a Normal Function

Amyloidoses of humans are all associated with disease states, and the TSEs, in particular, are uniformly fatal. The [URE3] prion is associated with slow growth under most culture conditions. [PSI$^+$] and [PIN$^+$] do not confer any consistent phenotype on otherwise normal cells, although [PSI$^+$] is lethal in cells carrying a strong tRNA suppressor mutation. Searches by two groups for [PSI$^+$] in wild strains have failed to find it, supporting the notion that it is a disease, like the mammalian counterparts.

A colony of a filamentous fungus is not a pile of cells (as in yeast), but rather a syncytium – cells connected by cytoplasmic bridges. When two compatible colonies of *Podospora* or other filamentous fungi grow together, they fuse cellular processes (hyphae) thereby joining the two colonies into one, called a heterokaryon. This allows the colonies to share nutrients, but has the danger that a virus infecting one will spread by cytoplasmic mixing throughout the other. To minimize this risk, filamentous fungi have a system, called "heterokaryon incompatibility" which tests for identity between the partners at about a dozen polymorphic chromosomal loci. Nonidentity of alleles at a single locus is sufficient to abort the fusion process and a barrier to further fusion is formed. Most of these *het* loci are genetically unremarkable. The *het-s* locus of *Podospora* can have either of two alleles, *het-s* or *het-S*. A colony with the *het-s* allele is only incompatible with a *het-S* colony if the HET-s protein is in an amyloid form. This amyloid form is infectious and is the [Het-s] prion. The HET-S, which differs by only 14 amino acid residues from the HET-s protein, does not form amyloid, and residue 33 is critical in this difference.

Thus, the [Het-s] prion is the (so far) unique case of a prion that is necessary for a normal function, heterokaryon incompatibility. Consistent with this view is the fact that most wild strains of *P. anserina* with the *het-s* allele carry the [Het-s] prion.

Prion Generation

[PIN$^+$] was discovered as a nonchromosomal gene whose presence was necessary for the efficient induction of the *de novo* appearance of [PSI$^+$] by overexpression of Sup35p. [PIN$^+$] was found to be a prion of the Rnq1 protein, which had already been shown capable of a self-propagating aggregation *in vivo*. In fact, [URE3] was also capable of [PIN$^+$]-like activity. This showed that one prion could promote the generation of another. This may be because all of these prions ([PSI$^+$], [PIN$^+$], and [URE3]) are based on amyloid of asparagine-glutamine

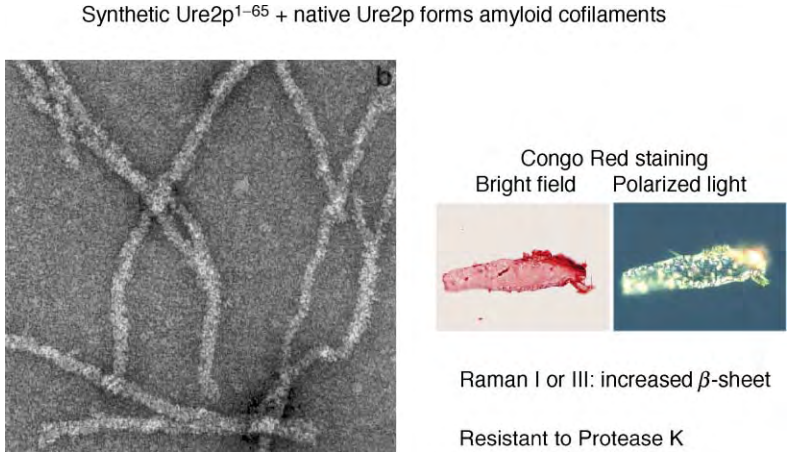

FIGURE 3 Amyloid and prions. The prion domain of Ure2p (for example) can form amyloid and can induce amyloid formation by the full-length native protein *in vitro*, just as overexpression of the prion domain *in vivo* induces prion formation by Ure2p.

rich segments. Although cross-priming of polymerization is not as efficient as self-priming (the usual propagation reaction), it is far more efficient than the truly spontaneous development of a prion. A similar, though weaker, effect of [PIN$^+$] on [URE3] generation has also been observed.

[URE3] has a very strong requirement for the Mks1 protein for *de novo* generation. Increasing or decreasing Mks1p levels dramatically increase or decrease the frequency of [URE3] arising. Although *mks1*Δ cells are nearly incapable of generating a new [URE3] prion, propagation of [URE3] is normal in such cells. Mks1p was discovered as a protein whose strong overproduction slows cell growth, but is inhibited in this activity by the Ras-cAMP pathway. Indeed, activation of Ras, like deletion of *MKS1*, dramatically diminishes [URE3] generation. Mks1p is also a regulator of glutamate biosynthesis, but the effects on [URE3] generation appear not to be mediated via glutamate levels. The detailed mechanisms of these effects remain to be elucidated.

Chaperones and Prion Propagation

Chaperones play a central role in the propagation of yeast prions (Table I). Hsp104 is a disaggregating chaperone critical in the cellular reaction to heat shock, and either increasing or decreasing its level adversely affects propagation of [PSI$^+$]. Overexpression of Hsp104 probably blocks propagation by completely disaggregating the Sup35p aggregates allowing return of the protein to its normal form. Elimination of Hsp104 interferes with seed formation. Amyloid aggregates are clumpy and may all remain in one of the daughter cells if they form a single lump in the mother cell. Modest levels of Hsp104 carry out the partial fragmentation of these filaments insuring that both daughter cells receive one or more seeds. [URE3] likewise requires Hsp104 for propagation, but unlike [PSI$^+$] is not cured by Hsp104 overproduction. Guanidine cures all the yeast prions and it has recently been shown that guanidine works by inhibiting Hsp104.

Different Hsp70s and Hsp40s have positive and negative functions with different prions as summarized in Table I. For example, overexpression of the Hsp40 protein, Ydj1, can cure [URE3]. Clearly, the detailed interactions of each prion with chaperones will be different, and this remains an important area to investigate. There is circumstantial evidence for a role of chaperones in the mammalian TSEs, but direct evidence has so far been limited to the yeast systems.

The importance of the discovery of the role of chaperones in yeast prions goes far beyond these systems and even the mammalian prion diseases. Amyloidoses are common (almost universal) diseases of old age, and one suspects that one of the primary roles of the heat-shock proteins is to defend against amyloid formation. It will be critical to learn how these systems can be marshaled to contend with the otherwise largely intractable human amyloidoses.

TABLE I

Chaperones and Prions

Chaperone	[PSI$^+$]	[URE3]	[PIN$^+$]
Hsp104	↑ → lost	↑ → OK	↑ → OK
	↓ → lost	↓ → lost	↓ → lost
Ssa1p (Hsp70)	↑ → OK	↑ → lost	
	↓ → lost		
Ssa2p	↑ → OK	↑ → OK	
Ydj1p (Hsp40)	↑ → OK	↑ → lost	
Sis1p (Hsp40)			↓ → lost

Conclusions

The ability of proteins to bear hereditary information recalls the earlier discovery by Sonneborn of cortical inheritance in *Paramecium*, in which the surgically altered arrangement of cilia on the surface of the cell was shown to be faithfully inherited by the progeny of the original cell. Self-propagating protein structures in the former case are closely analogous to self-propagating organellar structures in the latter. Efforts to find other self-propagating organellar structures have not yet met with any clear successes, and the mechanisms operating in the cortical inheritance phenomenon have not yet been elucidated.

All of the prions discussed here appear to be based on self-propagating amyloid of the corresponding protein. Of course, most amyloidoses are not prions, although nearly all have been shown to be self-seeding *in vitro*. Prion propagation requires both expansion of amyloid within one individual cell or compartment, but also a mode of transmission. There are indications that mature amyloid fibers may not be the infectious form of prions, and it is evident that the shorter the fiber, the higher the ratio of growing ends to mass of material. However, the *Podospora* studies show that amyloid itself can serve as the infectious material, and most infectivity assays with scrapie material show that the infectious material is relatively rapidly sedimenting.

The direct parallels between these yeast, fungal, and mammalian prions and amyloidoses have opened new areas for investigation of these very difficult human diseases.

A new prion (infectious protein) based on an enzyme whose active form is necessary *in trans* for activation of its inactive precursor has been described. This is the vacuolar protease B of *S. cerevisiae*. It is not news that a protease can activate its inactive precursor, but it is remarkable that such a protease can be a gene. Moreover, this suggests that other protein-modifying enzymes may prove to be prions under some circumstances.

Biography

Reed B. Wickner, M.D. is Chief of the Laboratory of Biochemistry and Genetics in the National Institute of Diabetes Digestive and Kidney Diseases of the National Institutes of Health in Bethesda. He is interested in nonchromosomal inheritance, and has long studied yeast RNA viruses. He discovered yeast prions based on their unusual genetic properties and has studied the mechanisms of generation, propagation, and curing of the [URE3] prion, and the structure of the Ure2p amyloid that forms its basis.

Prions, Overview

Cedric Govaerts and Fred E. Cohen
University of California, San Francisco, California, USA

Prions are transmissible pathogens responsible for a series of fatal neurodegenerative diseases including, in humans, Creutzfeld–Jacob disease (CJD), Gerstmann–Straussler–Scheinker disease (GSS), fatal familial insomnia (FFI), and kuru. Other mammals succumb to prion diseases including sheep scrapie, bovine spongiform encephalopathy (BSE, also known as mad-cow disease), chronic wasting disease (CWD) in mule, deer, and elk, feline spongiform encephalopathy (FSE), and transmissible mink encephalopathy (TME). In each case the emergence of a misfolded form of the prion protein, PrP^{Sc}, is pathognomonic for the disease.

Misfolding Diseases

More than 20 human pathologies, including Alzheimer's, Parkinson's, Huntington's, and prion diseases, are associated with the "misfolding" of specific proteins or protein fragments. Under normal conditions, some newly synthesized proteins are folded and post-translationally modified in specific cellular compartments, called endoplasmic reticulum (ER), in an effort to deliver the protein to the appropriate cellular location in its native (physiologically relevant) conformation. However, occasionally, proteins can adopt an aberrant conformation either during the initial folding process or through a "conformational transition" from the native state. A misfolded protein, if not cleared by cellular or extracellular machinery, can cause disease. Two mechanisms of disease must be considered: loss of function and gain of function/dominant-negative effect. With loss of function, the misfolded protein cannot serve the biological function normally achieved by the native protein. Cystic fibrosis is a useful example where the quality control machinery prevents the misfolded mutant CFTR protein from reaching the cell surface. Conversely, pathology can arise from gain of function, when the aberrant conformation leads to a new and potentially harmful function of the protein. The prion diseases follow this paradigm. Invariably, misfolded forms of proteins have a strong propensity to aggregate into insoluble material. In several diseases, these aggregates adopt a fibrillar structure called "amyloid" and can form large deposits or plaques which are found in the affected tissue. Following proteolytic fragmentation, prions can form amyloid fibers and plaques. As with other amyloid-forming diseases, it remains unclear whether oligomers of the misfolded protein or much larger polymeric aggregates (or fibrils) injure cells and cause neurodegeneration.

Prion Protein and Diseases

PrP^{C} and PrP^{Sc}

The prion protein, or PrP, is a membrane anchored protein, expressed predominantly in neurons and lymphocytes. The biological function of the normally folded prion protein (cellular PrP, PrP^{C}) has yet to be identified, but PrP^{C} is known to bind copper and could be involved in its homeostasis. Prion diseases are associated with the emergence of a misfolded form of PrP^{C} called PrP^{Sc} (for scrapie form, the oldest known prion disease). A wealth of data suggest that PrP^{Sc} is the etiologic agent in the disease. While PrP^{C} and PrP^{Sc} have the same amino acid sequence, they differ in their structural characteristics, PrP^{C} is rich in α-helical structure while PrP^{Sc} has substantially more β-sheet structure. While PrP^{C} is monomeric and protease sensitive, PrP^{Sc} is resistant to degradation by protease and is multimeric.

Replication Cycle

The global mechanism of PrP^{Sc} production is fairly well understood. It involves the presence of an initial PrP^{Sc} multimer which can either be exogenous (infectious forms of the diseases) or endogenous (inherited or sporadic forms). This first prion will initiate PrP^{Sc} accumulation by sequentially converting PrP^{C} molecules, following a "replication cycle" (see Figure 1). As illustrated, PrP^{C} is thought to exist in equilibrium with a transient intermediate, PrP^{*}, which is normally in low abundance compared to PrP^{C}. Binding of a PrP^{Sc} molecule to PrP^{*} may lead to its conversion into a new PrP^{Sc} molecule, through structural templating. This newly formed PrP^{Sc} molecule can in turn convert neighboring PrP^{*} molecules and therefore amplify the replication cycle. Importantly, PrP^{C}, PrP^{*}, and PrP^{Sc} are

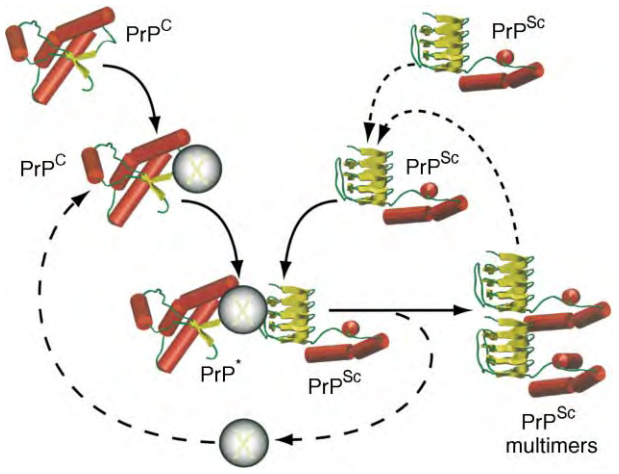

FIGURE 1 Exogenous or endogenous PrP^{Sc} initiates PrP^{Sc} synthesis by binding to a $PrP^{C/*}$/X complex. Facilitated by protein X and directed by the PrP^{Sc} template, PrP^{*} changes conformation and forms PrP^{Sc}. When PrP^{Sc} forms, the heteromultimeric complex dissociates, yielding recycled protein X and endogenous PrP^{Sc}. The newly generated PrP^{Sc} can then facilitate two replication cycles leading to an exponential rise in PrP^{Sc} formation.

not the only molecules involved in prion replication, as it has been demonstrated that at least one other protein is required for $PrP^{C} \rightarrow PrP^{Sc}$ conversion. This auxiliary protein remains to be identified and has been termed "protein X" (see Figure 1). Such additional complexity is probably responsible for the difficulties investigators have faced in building *in vitro* conversion protocols, leaving cell-based assays and animal systems (such as transgenic mice) as the only suitable experimental systems for the study of prion disease.

Transmission and Inheritance

Prion diseases are rare neurodegenerative disorders which affect approximately one person per million. Sporadic disease is the most common mechanism in humans and represents 85% of all cases. Individuals present in the sixth or seventh decade of life with a variety of cognitive defects. A rapidly progressive course leads to death in less than a year. Familial prion diseases (like GSS or FFI) represent 15% of all cases and are caused by mutations in the PrP gene. These mutations appear to favor the transition from the cellular form to the pathological form of PrP. PrP^{Sc} accumulates and neurodegeneration results.

In humans, infectious diseases are rare but have been a source of great concern, given the nature of the transmissible agent and its resistance to typical disinfection strategies. In the laboratory, disease can be readily transmitted to mice or hamster by intracranial injection of brain homogenate taken from prion-infected animals. Propagation of kuru disease in New Guinea Highlanders was due to ritualistic cannibalism involving ingestion of contaminated brain. Recently, it has been discovered that BSE had been transmitted to humans in Europe after consumption of infected beef, producing a variant of the CJD called vCJD (variant CJD). This constitutes a rare violation of the "species barrier," a term coined after observing that infectious material from one species inefficiently transmits to another species (this has presumably protected the human population from infection by scrapie-infected sheep).

Prion Strains

The various prion diseases are characterized by different incubation times and neuropathologic profiles, although in all cases the same misfolded protein (PrP^{Sc}) is responsible. This phenomenon has been attributed to the existence of various "prion strains." Although PrP^{Sc} molecules from different strains are chemically identical, they differ in their exact conformations. The structural characteristics of individual prion strains are propagated via the replication cycle. These characteristics appear to direct the precise tissue targeting, incubation time, and pathogenesis of the strain. For example, it has been established that consumption of BSE-infected meat has led to prion disease in over 100 people. Affected individuals suffer from a new form of CJD called vCJD, are drawn from a younger cohort and exhibit distinct clinical characteristics from CJD patients. The PrP^{Sc} molecules found in patients with vCJD can be conformationally distinguished from those of classical CJD, and have been shown to resemble PrP^{Sc} molecules from BSE-infected cattle. Therefore, vCJD is a different strain of prion from CJD, and is probably the human form of the bovine prion strain from BSE.

Physiopathology of Prion Diseases

Prions are neurodegenerative diseases, that induce neuronal dysfunction accompanied by neuronal loss with no inflammatory response. In most cases, the pathogenic process is characterized by vacuolar degeneration of the gray matter, which correlates with abundance of PrP^{Sc}. This vacuolation process creates spongiform change in the cerebral tissue. Prion diseases are therefore often referred to as transmissible spongiform encephalopathies (TSE). The precise location of tissue damage (e.g., cerebral cortex versus cerebellar cortex) may vary between the different prion diseases, but always correlates with the presence of PrP^{Sc}. In some forms, such as GSS, the disease is also characterized by the presence of amyloid plaques composed of PrP^{Sc} molecules. Although technological advances in medical imaging provide promising tools for the near

future, the definitive diagnostic for prion disease is currently achieved postmortem by histological analysis of brain tissue.

Structural Studies

As for any misfolding disease, the pathological form of the prion protein differs from the cellular one in its conformation. While no chemical difference is observed, biophysical and immunological measurements reveal important structural differences between the two isoforms. Notably, only a fraction of the specific antibodies targeted against PrP^{C} molecules are able to recognize the PrP^{Sc} isoforms. This suggests that the molecular structures of the two isoforms are significantly different.

The PrP^{C} molecule is soluble and its three-dimensional structure can be solved by classical techniques such as solution nuclear magnetic resonance (NMR). These experiments reveal that PrP^{C} fold is dominated by α-helices, tight helical structures found in a vast number of proteins with very little β-sheet, extended structures also commonly found (see Figure 2). While the structure of PrP^{Sc} cannot be probed by NMR due to its insolubility, biophysical measurements such as Fourier transform infrared spectroscopy (FT-IR) have deciphered important structural properties of PrP^{Sc}. These techniques have shown that the fold of PrP^{Sc} is composed of both β-sheet structures (40%), and α-helices (30%). Enrichment in β-sheet structure is commonly observed in proteins associated with misfolding diseases. This has led many to speculate that there are mechanistic similarities in the misfolding diseases. For a variety of technical reasons, resolving the atomic structure of PrP^{Sc} is extremely challenging. Recent advances include the discovery of two-dimensional crystals of PrP^{Sc} suitable for electron microscopic analysis. These data have led to the development of new models of the structure of PrP^{Sc}.

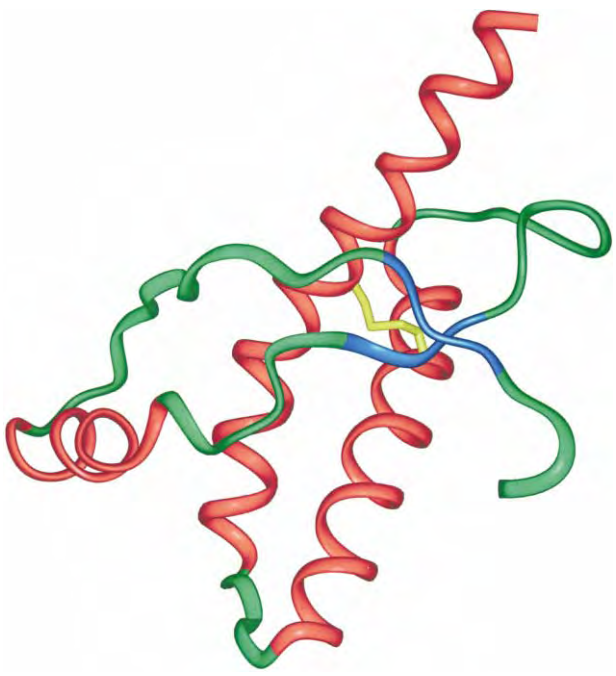

FIGURE 2 NMR structure of PrP^{C}. Ribbon representation of the globular structure of human PrP resolved by NMR, comprising residues 125–228. The three α-helices are colored in red and the small β-sheet is in blue.

Therapeutic Strategies

Currently, prion diseases are uniformly fatal illnesses. Diverse approaches are being taken to develop therapeutics for prion diseases. Compounds can be designed to specifically disrupt the replication cycle (illustrated in Figure 1), either by stabilizing the PrP^{C} conformation versus PrP^{*}, or by blocking interaction with the auxiliary partner protein X. Design of such compounds has proven successful in cell-based models of prion diseases but must now be extended to animal models and human clinical trials. Screenings of existing drugs that are known to penetrate the blood–brain barrier (and therefore potentially reach prion-infected tissues) have identified the drug quinacrine as being effective against PrP^{Sc} replication in cells. Quinacrine is currently approved for the treatment of giardiasis and has been used historically to treat malaria. Clinical trials are underway to determine its therapeutic utility in CJD patients. Similar approaches have identified a number of other potentially interesting compounds, but more efforts will be required to assess their therapeutic utility. Hopefully, one of these efforts will lead to potent antiprion drugs in the foreseeable future.

He holds a B.S. from Yale University, a D.Phil. from Oxford University and an M.D. from Stanford University. His fields of investigation include protein structure, protein folding, prion diseases, drug design against prions disease and parasitic diseases, and various aspects of computational biology.

Cedric Govaerts holds a B.S. and a Ph.D. from the Free University of Brussels. He is currently a postdoctoral fellow in the group of Fred Cohen and works on structural studies of prions.

Processivity Clamps in DNA Replication: Clamp Loading

Megan J. Davey and Mike O'Donnell
The Rockefeller University, New York, USA

DNA processivity clamps are ring-shaped proteins that encircle and slide freely along the DNA. These clamps tether replicative DNA polymerases to the DNA ensuring that they remain attached to the template for the many thousands of base pairs necessary to copy genomes. The stable toroidal structure of processivity clamps necessitates specialized machinery, termed a clamp loader, to open the clamp and place it onto DNA. Clamp loaders are hetero-oligomeric protein complexes that use the energy of ATP binding and hydrolysis for their function.

DNA Processivity Clamps

Chromosomal replicases are multi-subunit machines that use ATP to maintain a tight grip on DNA and thus are highly processive. Study of the T4 bacteriophage, *Escherichia coli*, and eukaryotic replisomes has demonstrated that these replicases consist of a polymerase and two accessory factors. Work on the *E. coli* system has identified the two accessory factors as a clamp and a clamp loader (Figure 1).

The first clue that one accessory protein acted alone as a ring-shaped sliding clamp was provided in the *E. coli* system. Biochemical experiments have shown that the *E. coli* DNA processivity clamp, β, binds tightly to circular DNA, yet slides freely along the duplex. Linearizing the DNA results in β sliding off the ends. This behavior led to the prediction that the clamp forms a topological link with DNA, independent of sequence and that it is shaped like a ring and encircles the duplex like a donut. This prediction was fulfilled by the crystal structure, which confirmed that β is ring shaped (Figure 2). Since that first structure, ring-shaped DNA processivity clamps have also been demonstrated in archaea, bacteriophage, and eukaryotes (Figures 1B and 2). These clamps share a common chain-fold; however, they employ slightly different strategies to achieve this structure. The *E. coli* β-clamp is composed of two crescent-shaped molecules that form a head-to-tail dimer. Each of the subunits is composed of three globular domains that lack sequence similarity yet have the same chain-folding pattern and are nearly superimposable. Thus, each β-clamp is composed of six globular domains arranged in a circle around a central channel (Figure 1A). The diameter of the central channel is $\sim$35 Å and is large enough to fit double strand DNA. The outside diameter of β is $\sim$80 Å. The structure contains 12 α-helices that are all positioned on the inside of the ring, lining the central channel. Although β has an overall negative charge, the helices carry a positive charge and are thought to contact the DNA phosphate backbone through nonspecific, water-mediated interactions, allowing the clamp to slide along DNA.

In eukaryotic cells the clamp is proliferating cell nuclear antigen (PCNA). PCNA shares very little sequence similarity with the β-clamp, yet the overall structure of PCNA is very similar to that of β (Figures 2A and 2C). The two structures have similar inner and outer diameters, and the domains have the same chain-folding pattern, making the molecules nearly superimposable. However, there is one major difference between the two clamps: PCNA is a trimer rather than a dimer. PCNA has two rather than three domains per monomer and trimerizes to form a six-domain ring. Eukaryotic PCNA is homologous to PCNA in archaea and, as expected, they share similar structures (Figure 2D). The replicase of bacteriophage T4 and the related phage RB69 also utilize a clamp and clamp loader. The T4 gene protein (gp) 45 has no sequence similarity with PCNA or β, but is a trimer, like PCNA, and the overall structure is quite similar to all the other clamps (Figure 2B).

Processivity Clamp Loaders

β and PCNA appear to be tightly closed rings. On circular DNA, β and PCNA remain associated with a half-life of 0.5–1 h at 37 °C, demonstrating that the interfaces between the protomers remain tightly associated. This tight association, while important for processivity, necessitates the use of a clamp loader to rapidly open and close the clamp.

B

FIGURE 1 Components of a replicase. (A) Cellular replicases are composed of a ring-shaped clamp that is placed on DNA by a clamp loader. The clamp is utilized by DNA polymerase to remain tightly linked to DNA for highly processive replication. (B) Table of clamps and clamp loaders from different organisms.

Clamp loaders, both prokaryotic and eukaryotic, are hetero-oligomeric protein complexes, usually hetero-pentamers, that use the energy of ATP binding and hydrolysis to drive the loading of processivity clamps onto primed DNA. The loading process includes opening of the clamp, bringing the clamp to the DNA, and closing of the clamp around double-strand DNA. The different subunits within clamp loaders share sequence and/or structural homology. In addition, most of the clamp loader subunits from bacteria, T4 phage, eukaryotes, and archaea share sequence homology with each other, particularly within the sequences necessary for ATP binding and hydrolysis. Because of these similarities, clamp loaders from different systems are thought to function similarly. The clamp-loading mechanism has been most extensively studied in *E. coli*.

E. Coli Clamp Loader, γ-Complex

The clamp loader in *E. coli* is composed of five different subunits, γ, δ, δ', χ, and ψ. A complex composed of γ, δ, and δ' is sufficient for clamp loading and replication *in vitro*; χ and ψ are not absolutely required for clamp loading and their role will be discussed later in this entry.

The δ Subunit Opens the β Clamp

δ is the clamp loader subunit that binds β the tightest and is also capable of opening β on its own. Neither β nor δ can bind ATP, δ must open the clamp using the energy of protein–protein interaction. Only one δ subunit binds to one β dimer, suggesting that only one interface of β_2 is opened by δ. Furthermore, β_2 that has been cross-linked at one interface is capable of being loaded by γ complex, and therefore only one interface needs to be opened during the clamp-loading operation. Maintaining the integrity of one dimer interface ensures that β is easily reclosed.

Structure of the β_1–δ Complex Biochemical studies have shown that δ binds tightly to a mutant $\beta(\beta_1)$ that is rendered monomeric by mutating two hydrophobic residues at the dimer interface. This stable complex

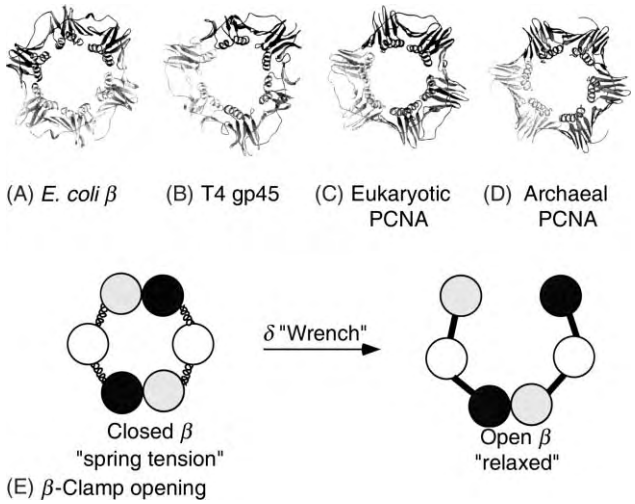

FIGURE 2 Similarity of clamp structures: The structures of (A) *E. coli* β-clamp, (B) T4 bacteriophage gp45, (C) *S. cerevisiae* PCNA, and (D) *P. furiousus* PCNA are shown. Each protomer in the ring is a different shade. Shown in (E) is a schematic of how β opens once it is cracked open by δ. Closed β is under spring tension, which is relieved when β is cracked, driving further opening of the ring.

enables the formation of a $\beta_1-\delta$ co-crystal. The crystal structure of $\beta_1-\delta$ suggests how δ may open β. δ contacts β in two different places. One contact is within a hydrophobic pocket between the middle and C-terminal domains of β and is thought to provide most of the binding energy. A second site of contact is between an α-helix in δ and a loop in β. This loop in β is near the dimer interface and is connected to an α-helix that contains hydrophobic core residues involved in formation of the β-dimer. In the $\beta_1-\delta$ structure the hydrophobic core residues are rotated out of the dimer interface. Perhaps, δ-binding to β forcibly disrupts the hydrophobic core of the dimer interface. Alternatively, there is a rapid exchange between open and closed forms of β, and δ simply stabilizes β in the open conformation. The stability of β on circular DNA suggests that the former case is more likely; however, the exact mechanism remains to be determined.

The β-Dimer is Under Spring Tension The distortion of the β_2-interface by δ may crack the ring, but does not explain how the edges of the crack open wide enough for passage of DNA. A striking difference in the shape of β_1 (with δ) and β_2 provides a strong clue as to how the ring opens up. The β-protomers within the β_2-structure have a higher degree of curvature than β_1. The change in curvature seems to result from rigid body motions between the three domains of the β-monomer. The largest of these changes occurs farthest away from the area of δ contact, suggesting that these rigid body motions are not a direct result of δ-binding β but are instead powered intrinsically within β itself. The increased curvature of β within β_2 suggests that β_2 is strained. Presumably, the two protomers come together and inward to form a ring due to the strength of the interaction. In other words, the free energy of forming the dimer interface is greater than the energy needed to bend the domains and form a closed ring. When the interface is disrupted by δ, the tension between the domains is allowed to relax and the ring opens (Figure 2E). This idea of a "spring-loaded" β-dimer is supported by molecular dynamics simulations that demonstrate that a protomer of β in the dimeric, strained conformation rapidly assumes the relaxed, monomeric conformation. When β_1 is modeled as a dimer, a gap at one interface is produced (as illustrated in Figure 2E).

Clamp Opening by γ Complex

Although δ is able to open the β-clamp in the absence of ATP, γ-complex requires ATP to open the β-clamp. γ is the only subunit that utilizes ATP and thus may be thought of as the motor that drives clamp loading. In the absence of ATP, γ-complex can no longer bind β, suggesting that other subunits occlude δ from binding β. In the presence of ATP, γ re-establishes a tight interaction between δ and β, suggesting that ATP binding (ATP hydrolysis is not necessary) powers a conformational change that exposes δ for interaction with β. Study of γ and δ' suggests that they interfere with $\delta-\beta$ interaction, implying that within the γ complex, δ' and γ may prevent $\delta-\beta$ contact in the absence of ATP.

$\gamma_3\delta\delta'$ Form a Heteropentameric Ring

The structure of the minimal $\gamma_3\delta\delta'$-clamp loader reveals that the subunits are arranged in a circle in which δ and δ' bracket three γ-subunits (Figure 3B). Each of the subunits shares a similar three-domain structure (Figure 3A). In fact, they share the exact same-chain-folding topology from head to tail. This similar structure was expected for γ and δ' since they are homologous to one another. However, this observation is somewhat surprising for δ since it shares no sequence similarity with δ' and γ. Most of the subunit contacts within $\gamma_3\delta\delta'$ are within the carboxy-terminal domains, which form a closed pentameric circle. However, when viewed from the amino-terminal face of the assembly, there is a gap between the amino-terminal domains of δ and δ'.

One of the striking features of this structure is the position of nucleotide-binding sites; they are located at the interfaces between subunits. There are three ATP-binding sites, one in each γ subunit, at the $\delta'-\gamma_1$, $\gamma_1-\gamma_2$, and $\gamma_2-\gamma_3$ interfaces. Each nucleotide-binding site seems to rely on residues from two different subunits for function. For example, the $\delta'-\gamma_1$ site is comprised of a canonical nucleotide-binding site in γ_1 and an arginine residue from δ'. The arginine residue is encoded by an SRC motif that is conserved in clamp loader residues from bacteria, phage, archaea, and eukaryotes.

Active and Inactive States of γ Complex The β-binding element in δ is located on the amino-terminal domain of δ, and is positioned in the gap between δ and δ'. This was somewhat surprising since the crystal structure was determined in the absence of ATP and thus should not be able to bind β. However, when β is modeled onto the $\gamma_3\delta\delta'$ assembly, using the $\beta_1-\delta$ structure as a guide, there is a severe clash between β and the clamp loader subunits. Thus, the complex would appear to be in an inactive state, unable to bind β.

What changes in the γ-complex structure occur, dependent on ATP binding, to accommodate interaction between δ and β? To dock β onto δ without clashing with other subunits, the N-terminal domain (domain I) of δ must be rotated outwards by at least 20–30° with respect to the C-terminal domain (domain III). Presumably, the binding of ATP to the γ subunits powers this change.

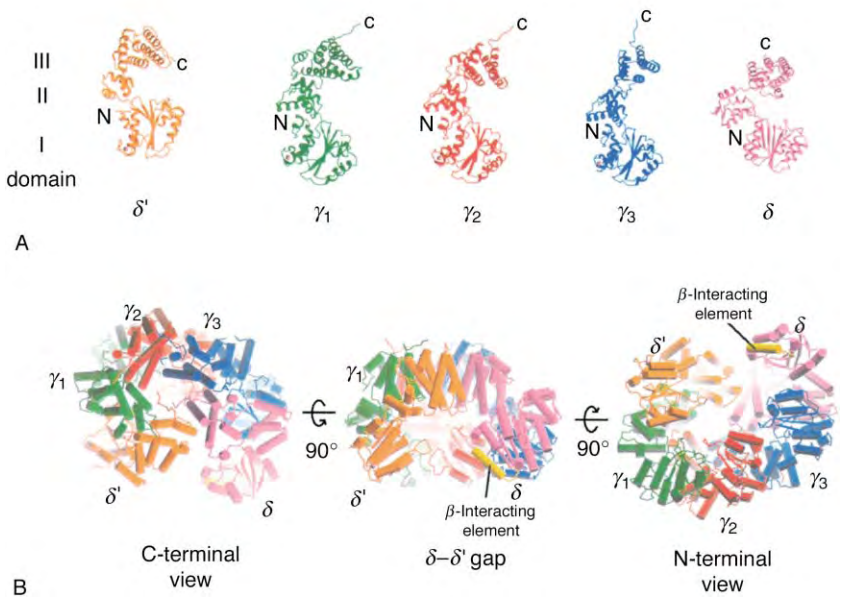

FIGURE 3 The structure of $\gamma_3\delta\delta'$ and individual subunits. Each of the clamp loader subunits is shown in (A). The three domains are indicated as well as the amino (N) and carboxy (C) terminal of each protein. In (B), the $\gamma_3\delta\delta'$-assembly is shown from three different views.

δ′ as a Stator All three subunits are present in different conformations, mainly due to the rigid body motion between domain III and domains I/II. Likewise, δ has a similar conformational difference upon comparing δ in $\beta_1-\delta$ and $\gamma_3\delta\delta'$-complexes. These observations suggest a flexibility between domain III and domains I/II in these protomers. However, the crystal structure of δ' alone is very similar to the structure of δ' in the $\gamma_3\delta\delta'$-assembly, implying that δ' is a more rigid protein than γ or δ. Examination of the structure of δ' reveals extra packing interactions between domains II and III, which may account for the apparent rigidity. Because of this seeming rigidity, δ' has been termed the stator (the stationary part of a motor against which other parts move). δ' can also be thought of as a backboard against which the ATP-dependent motions of the other subunits are braced.

Release of β and Closing of the Clamp

Once the γ-complex has bound to β and opened the clamp, it brings β to the primed site. The clamp loader-clamp complex binds tightly to primed DNA, which is, in fact, the best effector of ATP hydrolysis by γ-complex. When the clamp loader–clamp complex interacts with the primed site, the clamp loader hydrolyzes ATP and dissociates from β, leaving it on the primed site (Figure 4). It is proposed that the clamp loader is brought back to the inactive state upon hydrolysis of ATP (Figure 4). This presumably brings δ back into close proximity to γ and δ', pushing β off the δ wrench thereby releasing and allowing it to close around DNA.

The Role of χ and ψ

Neither χ nor ψ are required for clamp loading *in vitro*. However, when χ and ψ are missing from the clamp loader, both clamp loading and elongation become

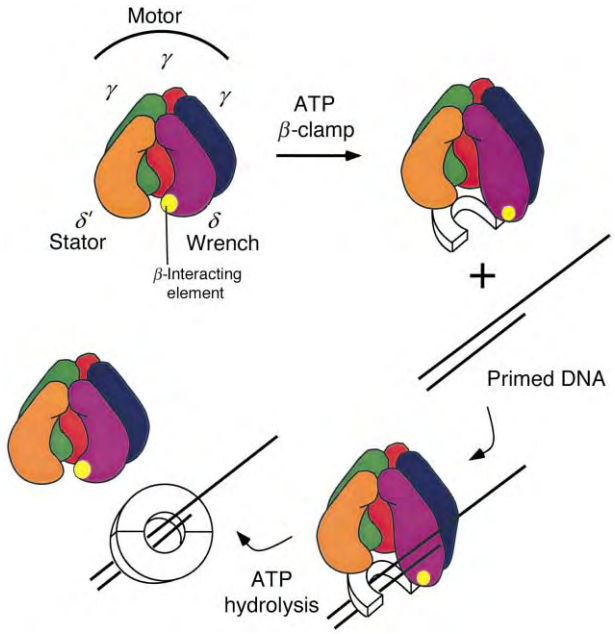

FIGURE 4 Clamp loading cycle by γ-complex. First, γ-complex binds ATP, which renders it capable of binding to and opening β. The clamp loader–clamp complex interacts with primed DNA which triggers ATP hydrolysis by γ-complex. ATP hydrolysis may cause γ-complex to release the clamp, allowing it to close around DNA.

sensitive to increased salt concentrations. This sensitivity is thought to arise from an interaction between χ and single strand DNA-binding protein, SSB. The contact between χ and SSB is important for the exchange of primase for both clamp loader and polymerase at the primed site. The role of ψ is somewhat less clear. It interacts with χ in a 1:1 complex. ψ also binds γ and forms a link between χ and the γ complex.

τ-Subunit and Interaction with DNA Polymerase III

The *dnaX* gene that encodes γ (47 kDa) also produces another protein, τ (71 kDa). A translational frameshift results in a stop codon to produce γ, whereas τ is the full-length protein. Therefore, τ is composed of γ plus 24 kDa of extra carboxy-terminal sequence. τ can fully substitute for γ in the clamp loader. Furthermore, while cells can survive in the absence of γ, they lack viability in the absence of τ. Thus, the carboxy-terminal residues unique to τ are essential. The carboxy-terminal sequences of τ interact with the DNA polymerase III core and with the replicative helicase, DnaB, providing a link between the clamp loader and the replisome. In the replicase, the clamp loader is thought to contain two τ subunits and one γ subunit, enabling this single clamp loader to cross-link two core polymerases for simultaneous synthesis of leading and lagging strands of the chromosome.

T4 Bacteriophage Clamp Loader

Although most viruses and bacteriophage do not employ a clamp and clamp loader machinery, T4 phage produces a clamp (gp45) and clamp loader for its chromosomal replicase (gp43). The clamp loader is composed of two different subunits, gp44 and gp62. Each clamp loader contains four copies of gp44 and one copy of gp62. Thus, the T4 phage clamp loader is a heteropentamer, like γ-complex. The gp44 subunit is homologous to γ and δ', and thus probably provides the motor function of the clamp loader. Gp62 has no known homologues.

In T4 bacteriophage, as in several eukaryotic DNA viruses, replication is tightly coordinated with late gene transcription (i.e., the early to late gene switch). Several elegant studies have revealed that the gp45 clamp slides along DNA and binds directly to RNA polymerase, specifically activating it at late gene promoters.

Archaeal RFC

Like the T4 bacteriophage clamp loader, archaeal cells contain only two different clamp loader subunits. These subunits are referred to as RFCL (L for large subunit) and RFCS (S for small subunit). Together these proteins form a complex that is capable of loading its cognate clamp onto DNA and stimulating the replicative DNA polymerase in several species of archaea. Initial characterization of the composition of these RFC complexes suggests a pentamer, with one or two copies of RFCL and three or four copies of RFCS, depending on the species. A structure of the small subunit from *Pyrococcus furiousus* has been solved. RFCS forms a dimer of trimers, and the trimer unit shares similar structure to the γ-trimer in γ-complex. In fact, RFCS has the same chain-fold and three-domain structure as γ, δ, and δ'.

Eukaryotic Clamp Loader

The eukaryotic clamp loader, termed replication factor C (RFC), is composed of five different subunits known as Rfc1-5 in *S. cerevisiae* and p140, p37, p36, p40, and p38 in human cells. All five subunits share sequence homology to each other and to the γ and δ' subunits of γ complex. Analogous to γ complex, the C termini of the RFC subunits are needed to form the pentamer. There is no crystal structure information on eukaryotic RFC; however, atomic force and electron microscope studies of RFC indicate a similarity to *E. coli* γ-complex. Atomic force microscope images of RFC indicate that the subunits are arranged in a circle similar to the C-terminal view of γ-complex. Electron microscope images of RFC in the presence of ATP show a gap in the circle similar to the amino-terminal face of γ-complex.

The results of biochemical experiments suggest that RFC may also function similarly to γ-complex. However, there are some important differences between γ-complex and RFC. For example, RFC has four rather than three ATP sites. This observation and the observation of five different subunits in RFC may reflect the greater complexity of eukaryotic cells compared to bacteria. It has been shown that PCNA interacts with numerous other proteins besides DNA polymerases. In addition, there are modified RFC assemblies in which one of the subunits has been substituted with a different protein. Hence, RFC (and modified RFCs) are thought to be involved in many different cellular processes such as DNA repair, cell cycle control/checkpoint, and chromosome segregation. PCNA can therefore be thought of as a "bull's eye," targeting proteins to DNA for specific events.

Biography

Megan J. Davey is a Research Associate with Mike O'Donnell at The Rockefeller University, where she has pursued her interest in the assembly of replication–initiation complexes in bacterial and eukaryotic systems. Previously, Megan earned her Ph.D. studying plasmid segregation with Barbara Funnell at the University of Toronto.

Mike O'Donnell works in the area of DNA-replication mechanisms in several systems. He initially discovered the circular sliding clamp and the clamp–loader complex in the *E. coli* DNA-replication system in 1991. He obtained his Ph.D. from the Biological Chemistry Department at the University of Michigan, and then did postdoctoral training with Arthur Kornberg and Robert Lehman at Stanford University. He is now an Investigator at Howard Hughes Medical Institute (HHMI) and Professor at Rockefeller University in Manhattan, New York.

Propionyl CoA–Succinyl CoA Pathway

Wayne A. Fenton
Howard Hughes Medical Institute and Yale School of Medicine, New Haven, Connecticut, USA

The importance of the short metabolic pathway from propionyl CoA to succinyl CoA in humans was recognized in the 1960s with the description of newborns with severe, often fatal, metabolic acidosis accompanied by massive excretion of propionic or methylmalonic acid. It was established that these conditions resulted from deficiencies in the activity of propionyl CoA carboxylase or methylmalonyl CoA mutase, respectively, two of the enzymes in the pathway. These enzymes themselves were found to be defective in many cases. Because each requires a vitamin-derived coenzyme for activity, however, other cases resulted from defects in the transport or metabolism of the vitamins (biotin and vitamin B_{12}, respectively). Many of the proteins and enzymes involved in these steps have subsequently been described.

The Propionyl CoA–Succinyl CoA Pathway

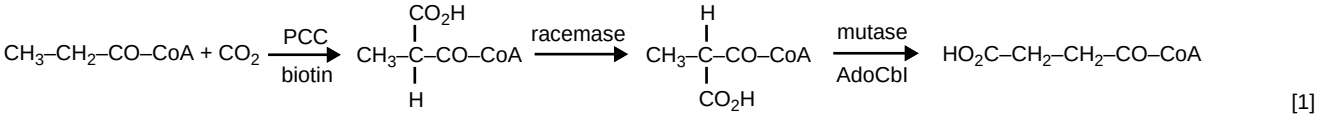
The pathway involved is shown in eqn. [1]. Propionyl CoA is carboxylated by propionyl CoA carboxylase (EC 6.4.1.3), a biotin-containing enzyme, to form D-methylmalonyl CoA. This product is racemized by methylmalonyl CoA racemase (epimerase) (EC 5.1.99.1) to D,L-methylmalonyl CoA. The L-isomer is the substrate for methylmalonyl CoA mutase (EC 5.4.99.2), which carries out an adenosylcobalamin (coenzyme B_{12})-dependent rearrangement of the carbon backbone to form succinyl CoA. This product then enters the tricarboxylic acid cycle.

Propionyl CoA arises from a number of metabolic pathways, predominantly the catabolism of certain amino acids (isoleucine, methionine, threonine, and valine) and the β-oxidation of odd-chain fatty acids, with minor contributions from the degradation of thymine, uracil, and the side chain of cholesterol. Methylmalonyl CoA is produced essentially only from propionyl CoA. Gut bacteria produce a significant amount of propionic acid (and lesser amounts of methylmalonic acid); thus, propionyl CoA can also arise from this source by the action of cellular acyl CoA synthases.

The Enzymes

Propionyl CoA Carboxylase

Propionyl CoA carboxylase (PCC) is a large enzyme (~770 kDa) composed of two dissimilar subunits, α (72 kDa) and β (56 kDa), arranged in an $(\alpha\beta)_6$ quaternary structure. It is ubiquitously expressed and is localized to the mitochondrial matrix. The individual subunits are synthesized in the cytosol as larger precursors, which are proteolytically processed to their mature sizes and assembled after translocation into the mitochondrion. The α-subunit bears the lysine to which biotin is covalently bound via an isopeptide linkage to the ε-amino group and carries out the half-reaction in which carbon dioxide is activated to react with biotin, forming an enzyme-bound carboxyl-biotin intermediate. The β-subunit completes the reaction by transferring the carboxyl moiety to propionyl CoA to form methylmalonyl CoA.



[1]

propionyl CoA | D-methylmalonyl CoA | L-methylmalonyl CoA | succinyl CoA

Methylmalonyl CoA Racemase

It is a dimer of identical subunits (~16 kDa) and is likely to be mitochondrially localized, but its expression pattern has not been established. The reaction mechanism appears to involve a simple abstraction/replacement of the labile proton on the α-carbon. In fact, racemization of methylmalonyl CoA occurs spontaneously in solution at a significant rate under physiologic conditions by exchange of this proton.

Methylmalonyl CoA Mutase

It is a dimer of identical subunits (78.5 kDa) and is expressed in all tissues examined. Its subunits are synthesized as larger precursors in the cytosol, translocated into mitochondria, and processed and assembled in the mitochondrial matrix. The coenzyme, adenosylcobalamin (AdoCbl), is very tightly bound to mutase; X-ray crystallography of the homologous enzyme from *P. shermanii* indicates that AdoCbl is buried in the interior of the enzyme. The reaction mechanism, while typical of AdoCbl-dependent enzymes, is unique in mammalian metabolism. In the presence of substrate, the carbon–cobalt bond of AdoCbl cleaves homolytically to form a free radical pair, Cbl^{II} and a deoxyadenosyl radical. The deoxyadenosyl radical abstracts hydrogen from the substrate to form a substrate radical that undergoes a rearrangement to form the product radical. This species recovers the hydrogen from deoxyadenosine to generate the final product and the original radical pair, which reverts to AdoCbl as the product leaves. Because these radical species are very labile to quenching by solvent, they appear to be highly protected in a buried active site. Crystal structures of the *P. shermanii* enzyme complexed with substrate analogues have been interpreted to suggest that the active site cleft opens to permit substrate entry, then closes until the reaction is completed, at which time it opens again to release the product.

The Cofactors

Biotin

Biotin is an abundant vitamin, available from a variety of plant and animal sources. It is used directly as a cofactor by four carboxylases in humans: acetyl CoA carboxylase, pyruvate carboxylase, β-methylcrotonyl CoA carboxylase, and PCC. Its metabolism is relatively uncomplicated, involving only two enzymes of note. One is biotinidase, a serum enzyme in man and other mammals, which specifically cleaves the isopeptide bond in biocytin (-biotinyl-lysine), the end product of proteolysis of biotin-containing enzymes, to release biotin for reuse. The other is holo-carboxylase synthase, the enzyme that forms the isopeptide bond between cellular biotin and the ε-amino group of the active site lysine in the apocarboxylases. Genetically determined defects in each of these have been described in humans, leading to a general deficiency of all of the carboxylases (multiple carboxylase deficiency) and pleiotropic metabolic effects, including propionic acidemia/aciduria (PA).

Vitamin B_{12} (Cobalamin)

In contrast to biotin, cobalamin is a rare vitamin that is available only from animal sources, which largely derive it in turn from gut bacteria. Plants, including yeast, do not synthesize the vitamin or use its cofactor forms. Although the daily requirement for vitamin B_{12} in humans is low (the current recommended dietary allowance, RDA, is 2.4 μg), an elaborate system of digestive enzymes and specific, high-affinity binding and transport proteins exists to ensure its efficient capture from dietary sources and delivery to cells throughout the body. Two distinct cofactor forms of the vitamin, methylcobalamin (MeCbl) and AdoCbl, are produced by a series of intracellular metabolic steps (eight have been recognized genetically) and are used by only two enzymes, methionine synthase and methylmalonyl CoA mutase, respectively. Deficiencies of many of these enzymes and proteins have been described. The most common are acquired defects in the activities of the digestive and gut transport proteins resulting from diseases of the digestive tract or surgical resection of these organs. These lead to a general vitamin B_{12} deficiency and the condition known as pernicious anemia. Genetic defects in these same proteins have been described, but are much rarer; they also lead to a form of pernicious anemia, generally at a much earlier age. Pernicious anemia is usually accompanied by methylmalonic acidemia/aciduria, although the hematologic defects are clinically more significant. Defects in cellular cobalamin metabolism lead to a variety of conditions, including methylmalonic acidemia/aciduria.

The Diseases

Propionic Acidemia/Aciduria (PA)

PA occurs in the setting of reduced activity of PCC (Figure 1). This can be due to biotin deficiency (very rare), biotin transport and activation defects (biotinidase or holocarboxylase synthase deficiency; sites 3 and 2, respectively), or defects in PCC itself (site 1). The first two of these lead to multiple carboxylase deficiency, in which all four biotin-dependent carboxylases are affected. This condition is characterized by neurologic symptoms, hypotonia, and failure to thrive, sometimes accompanied by skin rashes and allopecia. In genetically

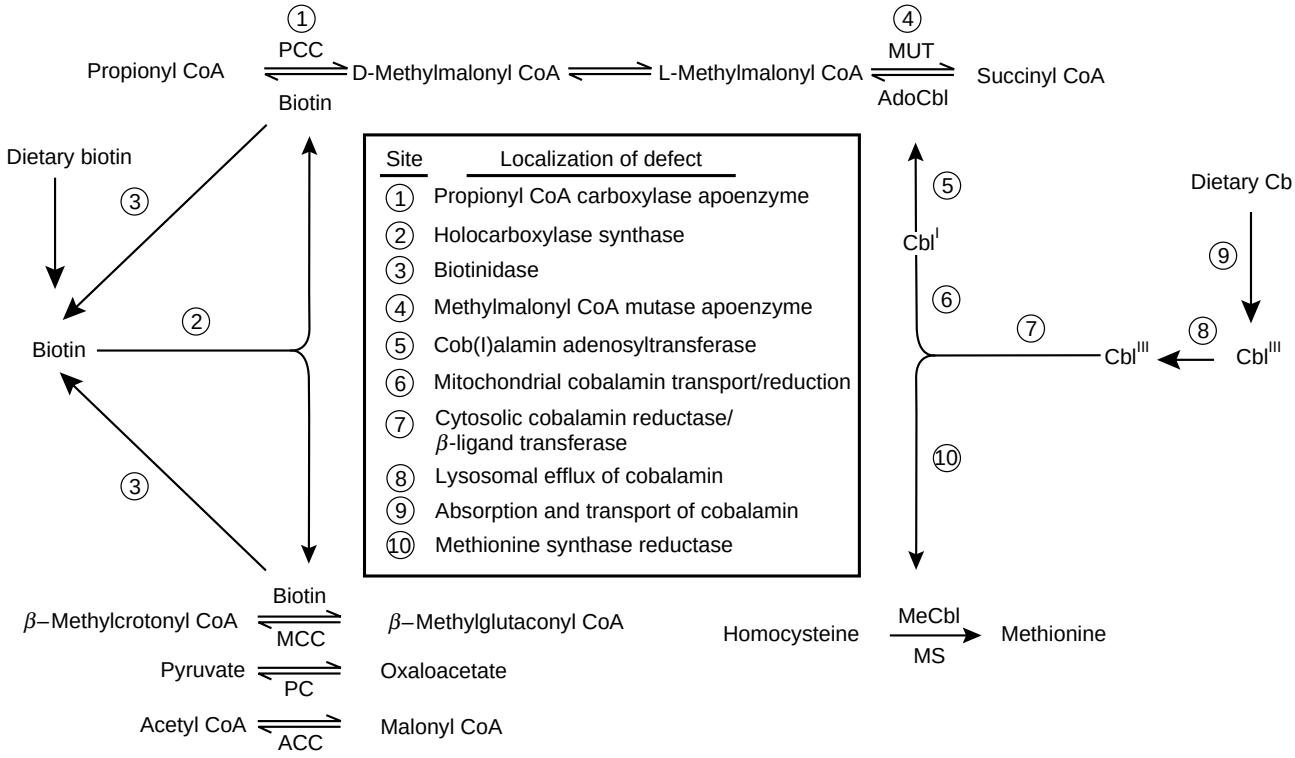


FIGURE 1 Sites of defects affecting the propionyl CoA–succinyl CoA pathway. A schematic of the biotin and cobalamin metabolism pathways is shown, along with their intersections with the propionyl CoA pathway. In several instances, the indicated sites encompass more than one enzyme or gene product. Genetic analysis suggests two gene products are involved at site 6; only one, of undefined activity, has been identified. Likewise, two gene products affect site 7 and the indicated metabolic activity. Defects in multiple gene products can contribute at site 9, including those in intrinsic factor, intrinsic factor receptor (megalin), and transcobalamin II, the serum cobalamin-carrying protein. Note that defects at site 10 and in methionine synthase (MS) affect a separate branch of cobalamin metabolism that has no impact on the propionyl CoA pathway. ACC, MCC, PCC, PC, acetyl CoA, β-methylcrotonyl CoA, propionyl CoA, and pyruvate carboxylase, respectively; MS, methionine synthase; MUT, methylmalonyl CoA mutase; Cbl, Cbl^{I}, Cbl^{III}, cobalamin and its 1+ and 3+ oxidation states, respectively; AdoCbl, MeCbl, adenosylcobalamin and methylcobalamin, respectively.

determined cases, onset of symptoms is often neonatal (synthase deficiency) or infantile (biotinidase deficiency), but may be delayed beyond the second decade. Biochemically, multiple carboxylase deficiency is marked by specific excretion of both propionic acid and methylcrotonic acid, their secondary metabolites (such as β-hydroxy propionic acid and tiglic acid), and glycine conjugates of these acids. Activities of the affected enzymes are low in serum (biotinidase) or cultured cells from patients, as are the activities of the carboxylases. At the genetic level, multiple carboxylase deficiency is an autosomal recessive trait, and mutations have been found in the genes for each of these enzymes. Treatment with high doses of biotin is usually effective in ameliorating these conditions.

PA arising from genetic defects in PCC itself is both more specific and often more severe. Neonatal onset is common, with vomiting, hypotonia, and neurologic symptoms resulting from an overwhelming metabolic acidosis. Massive excretion of propionic acid and its metabolites and conjugates is often accompanied by severe hyperammonemia. PCC activity is low or absent in cultured cells, but the other carboxylases are unaffected. PCC deficiency is inherited as an autosomal recessive trait, and causative mutations have been found in the genes for both the α- and β-subunits. Initially, treatment is supportive, seeking to reverse the profound metabolic acidemia and equally life-threatening hyperammonemia. Long-term therapy includes protein restriction using synthetic diets formulated to have reduced amounts of the metabolic precursors of propionate, such as branched-chain amino acids and odd-chain fatty acids, and antibiotic treatment to reduce the contribution of gut bacteria to the total metabolic load of propionate. Only a few patients with isolated PCC deficiency have responded to biotin supplementation. The long-term outcome for most patients has been poor, with many succumbing to acute metabolic decompensation triggered by infectious illnesses. However, a few have survived to adulthood and there are also a number of patients who have not been diagnosed until late into their second or even third decade. Although it has been suggested that genetic factors, such as the severity of the effects of a mutation on PCC activity, may

play a role in determining long-term survival, no clear genotype/phenotype correlation has been uncovered.

Methylmalonic Acidemia/Aciduria (MMA)

MMA arises from deficiencies in the activity of mutase. Although racemase deficiency would also be expected to produce MMA, no patients with this defect have been described. Environmental cobalamin deficiency, acquired and genetically determined cobalamin transport deficiencies, and cellular cobalamin activation defects, as well as defects in mutase itself, all of these contribute to the occurrence of this condition. Although environmental cobalamin deficiency is rare, it does occur in strict vegans and particularly in their breast-fed children. Much more common is acquired cobalamin deficiency resulting from disease processes affecting the stomach, including ulcers, alcoholism-induced destruction of the gastric mucosa, and surgical intervention including gastric bypass. All of these reduce the ability of the gastric parietal cells to produce intrinsic factor, a cobalamin transport protein that is essential for delivering ingested cobalamin to cells of the intestinal mucosa, where it is taken up and transported into the blood stream. The multi-step intestinal transport system for cobalamin (site 9) is also subject to genetic defects, although these are relatively rare. Clinically, the resulting cobalamin deficiency in all of these cases produces pernicious anemia, a characteristic megalobastic anemia. Biochemically, MMA can be demonstrated in these patients, although it is often mild, depending on the degree of cobalamin deficiency, and cellular mutase activity may be reduced. Therapeutically, the pernicious anemia and MMA resulting from cobalamin deficiency, whatever the underlying cause, can be treated effectively by injections of vitamin B_{12}.

Much more profound MMA occurs in patients with genetically determined defects in cellular cobalamin metabolism or in mutase itself. In these cases, severe neonatal metabolic acidosis is accompanied by massive excretion of methylmalonic acid, as well as lesser amounts of propionic acid and their metabolites. Because at least three of the eight cellular metabolic steps are common to AdoCbl and MeCbl production (sites 7 and 8), patients with defects in these steps also excrete homocystine, the oxidized form of homocysteine, the substrate of methionine synthase. Mutase activity is reduced or absent in cultured cells from patients with these disorders and from those with defects in the three metabolic steps that affect only AdoCbl metabolism (sites 5 and 6), although it can be restored in extracts of cells from patients by the addition of exogenous AdoCbl. Extracts from cells of patients with defects in mutase itself (site 4) generally do not show activity even with AdoCbl supplementation, except in rare cases where massive amounts of the coenzyme produce activity from a defective mutase enzyme with an abnormally high binding constant for AdoCbl. Genetically, all of these conditions appear to be inherited as autosomal recessive traits. In most cases, causative mutations in the individual genes for the affected enzymes have been found. Treatment of patients with defects in cellular cobalamin metabolism and in mutase has included symptomatic treatment of the severe metabolic acidosis, followed by protein restriction, synthetic diet, and antibiotic therapy, as with PA. Similarly, the long-term prognosis of these patients is poor, with one group of exceptions. In contrast to the lack of biotin-responsiveness in isolated PA, the clinical state of some MMA patients respond dramatically to supplementation with massive amounts of coenzyme in the form of injected hydroxocobalamin, with almost complete resolution of their clinical condition. Most of these patients have defects in one particular cobalamin metabolic enzyme (at site 6). The long-term prognosis of patients in this group seems very promising, although the effect of chronic MMA, which these patients still exhibit, remains unclear.

Glossary

coenzyme/cofactor A small bio-organic compound, usually derived from a vitamin, that plays an essential role in assisting a specific enzyme to carry out its reaction.

hyperammonemia The condition of a high concentration of ammonium ion (ammonia) in the blood; ammonium ion is a common metabolic product and is normally found in significant amounts in the blood, but moderate elevations can damage the central nervous system if untreated.

metabolic acidosis A condition of reduced blood pH and bicarbonate ion concentration in response to the overproduction or decreased excretion of acidic metabolites.

pernicious anemia A distinctive blood disorder characterized by macrocytes in circulation and megaloblasts in bone marrow, generally due to a deficiency of either vitamin B_{12} (cobalamin) or folic acid.

propionic/methylmalonic acidemia The condition of excessive amounts of these metabolites in blood, where they are normally present in very small amounts.

propionic/methylmalonic aciduria The condition of excretion of very large amounts of these metabolites in the urine.

Biography

Wayne A. Fenton is a Research Scientist in Genetics at Yale University School of Medicine. His general interests are in cobalamin metabolism and the mechanisms of protein folding and unfolding. He received a Ph.D. from Brandeis University and carried out postdoctoral work at Yale University.

Prostaglandins and Leukotrienes

William L. Smith
University of Michigan Medical School, Anna Arbor Michigan, USA

Robert C. Murphy
University of Colorado Medical School, Colorado, Denver, USA

Prostaglandins and leukotrienes are different types of eicosanoids – oxygenated, 20 carbon fatty acids synthesized from arachidonic acid (AA) (all *cis* 5,8,11,14-eicosatetraenoic acid). AA is a member of the n-6 family of fatty acids that are essential for mammals. There are three major groups of eicosanoids formed via three distinct pathways – the cyclooxygenase, lipoxygenase, and epoxygenase pathways. These pathways occur in higher eukaryotes that contain highly unsaturated fatty acids. Prostanoids, which include the prostaglandins (PGs) and thromboxanes (TXs), are formed through the cyclooxygenase pathway, leukotrienes and related hydroxy fatty acids come from the lipoxygenase pathway, and epoxy and dihydroxy acids are formed via epoxygenase (P450) pathways. Prostanoids and leukotrienes function through G protein-linked receptors, and there are one or more receptors for each prostanoid and leukotriene. These compounds act locally near their sites of synthesis without entering the circulation. They coordinate intercellular communication between the same (autocrine) and different (paracrine) cell types. Prostanoids promote inflammation and thrombosis and leukotrienes are involved in asthma. Nonsteroidal anti-inflammatory drugs such as aspirin, ibuprofen, and COX-2 inhibitors function by attenuating prostanoid synthesis while inhibitors of leukotriene synthesis and action such as zileuton and montelukast, respectively, are used to treat asthma.

Prostanoid Structures

Figure 1 shows the biosynthetic relationships among the prostanoids formed from arachidonic acid (AA). The letters following the abbreviation prostaglandins (PGs) indicate the nature and location of the oxygen-containing substituents present in the cyclopentane ring; the subscript indicates the number of carbon–carbon double bonds in the side chains. Greek subscripts denote the orientation of ring hydroxyl groups (e.g., $PGF_{2\alpha}$). Prostanoids known as isoprostanes are formed from AA by nonenzymatic autooxidation and consequently contain many stereoisomers. Interestingly, the amounts of isoprostane metabolites in urine are greater than prostanoids formed enzymatically.

Prostanoid Biosynthesis

Eicosanoids are not stored in cells but are formed on demand in response to extracellular hormonal stimuli (e.g., bradykinin, angiotensin, thrombin) that increase cell Ca^{2+} concentrations. Prostanoid formation requires three enzymatic steps: (1) mobilization of AA (or 2-arachidonylglycerol (2-AG)) from membrane phospholipids, (2) conversion of arachidonate (or 2-AG) to PGH_2 (or 2-PGH_2-glycerol), and (3) isomerization of PGH_2 (or 2-PGH_2-glycerol) to one of the major prostanoids by a terminal synthase. Mobilization of AA involves cytosolic phospholipase A_2 ($cPLA_2$) which translocates to the endoplasmic reticulum (ER) and nuclear membrane (NM) when intracellular Ca^{2+} concentrations rise and cleaves AA from a phospholipid on the cytosolic surface of the membrane. Newly released AA moves, methyl end first, to the luminal half of the bilayer where it enters the active site of a prostaglandin endoperoxide H synthase (PGHS) and is oxygenated to PGG_2 and its 15-hydroperoxyl group is then reduced to form PGH_2; PGHSs are also called cyclooxygenases (COX) and there are two isoforms (PGHS-1 and -2; COX-1 and -2). Once formed, PGH_2 is isomerized by a synthase located in the ER (e.g., TXA synthase, PGE synthase). Recently, 2-AG has been found to be converted to 2-PGH_2-glycerol by PGHS-2. This latter intermediate can be converted to the 2-prostanyl-glycerol derivatives but not 2-thromboxane-glycerol. 2-AG itself is probably formed from phosphatidylcholine by phospholipase C and monoacylglycerol lipase.

PGHS Catalysis and Inhibition

Figure 2 is a model of the cyclooxygenase and peroxidase active sites of ovine PGHS-1. To initiate oxygenation of AA at the cyclooxygenase site, the heme group at the peroxidase site must first be oxidized by a hydroperoxide. This causes formation of an oxidized

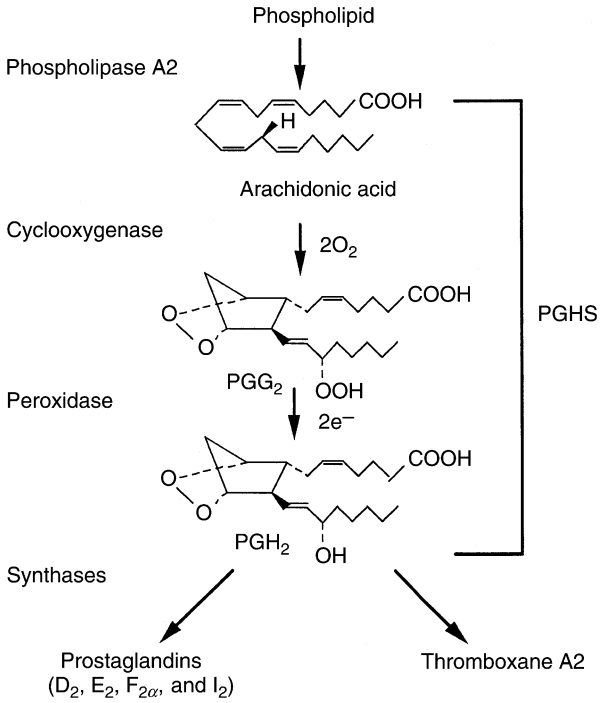

FIGURE 1 Biosynthesis of common prostanoids from AA.

heme intermediate that is reduced by an electron from Tyr385 thereby generating a Tyr385 radical. This radical abstracts a hydrogen from AA so that it can react with oxygen (Figure 1). The guanidino group of Arg120 binds to the carboxylate group of AA.

PGHS-1 is a constitutive enzyme purified in 1975 and its cDNA cloning has been reported in 1988. PGHS-2 is an inducible enzyme discovered in 1991 as an immediate early gene product in phorbol ester-activated murine 3T3 cells and in *v-src*-transformed chicken fibroblasts. PGHS-2 contains a unique 18 amino acid insert of as yet unknown function near its carboxyl terminus. The reason for the existence of the two PGHS isoforms is not known. Each protein functions as a homodimer with a monomer mass of 72 kDa. PGHSs are integral membrane proteins which instead of having transmembrane helices have a cluster of four amphipathic helices that interact with only one face of the lipid bilayer.

PGHSs are inhibited by nonsteroidal anti-inflammatory drugs (e.g., aspirin, ibuprofen, naproxen), which compete with AA for binding to the cyclooxygenase site of PGHSs. Prostaglandin synthesis mediated by PGHS-2 can be inhibited by anti-inflammatory steroids, which block the synthesis of PGHS-2 protein. Drugs called COX-2 inhibitors (e.g., rofecoxib and celecoxib) target PGHS-2 specifically and are used as anti-inflammatory and analgesic agents. Aspirin, acetylsalicylic acid, binds the cyclooxygenase site of PGHSs and acetylates Ser530 causing irreversible inhibition of PGHSs (Figure 2). Low doses of aspirin are used prophylactically to reduce coronary thrombosis; at low doses, aspirin inhibits PGHS-1 in platelets blocking thromboxane formation. PGHS inhibitors appear to reduce mortality from colon cancer.

PGHS-1 and PGHS-2 Gene Expression

There are separate genes for PGHS-1 and PGHS-2 located on different chromosomes. They have similar intron/exon structures but the PGHS-2 gene is 8 kb and the PGHS-1 gene is 22 kb. Little is known about the regulation of PGHS-1 gene expression. PGHS-2 gene transcription can be induced by cytokines and growth factors that function through multiple response elements in the PGHS-2 gene promoter. There is much interest in

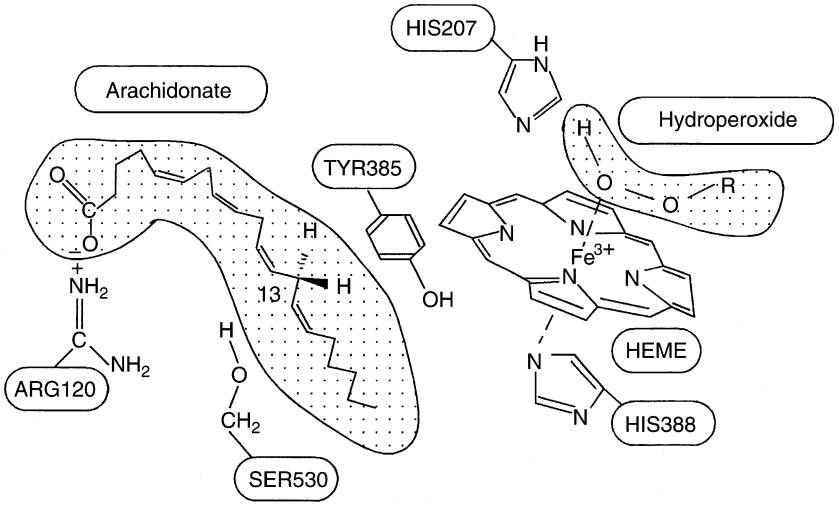

FIGURE 2 Model of the cyclooxygenase and peroxidase active sites of the ovine PGHS-1.

this because of the potential role of altered PGHS-2 expression in carcinogenesis.

PGH_2 Metabolism

Different cells form different prostanoids. PGE_2, PGD_2, PGF_2, PGI_2, and TXA_2 synthesis from PGH_2 is catalyzed by PGE synthase, PGD synthase, PGF synthase, PGI synthase, and TXA synthase, respectively; all of these enzymes catalyze isomerization reactions. PGF_2 formation involves a two-electron reduction of PGH_2. PGI synthase and TXA synthase are cytochrome P-450s. PGE synthase is a member of the MAPEG family of transmembrane ER proteins and requires reduced glutathione for activity. There are two PGD synthases; one is glutathione dependent and has been isolated from spleen and another is glutathione independent and occurs in brain.

Prostanoid Catabolism

The initial step in the inactivation of PGE_2 is oxidation of the 15-hydroxyl group to a 15-keto group catalyzed by 15-hydroxyprostaglandin dehydrogenase. Further catabolism involves reduction of the double bond between C-13 and C-14, β-oxidation, and ω-oxidation.

Prostanoid Actions

There are pharmacologically distinct receptors for each of the known prostanoids. In the case of PGE_2, four different prostaglandin E (EP) receptors have been identified and designated as EP1, EP2, EP3, and EP4 receptors. EP1 is coupled through G_q to the activation of phospholipase C, EP2 and EP4 are coupled via G_s to the stimulation of adenylate cyclase and EP3 receptors are coupled via G_i to inhibition of adenylate cyclase (16).

EP3 receptors are involved in the development of fever, EP2 and EP4 function in bone resorption and EP1 receptors are involved in chemically induced colon cancer. Prostanoids can activate some isoforms of peroxisomal proliferator activated receptors (PPARs). PGI_2 can be involved in PPARδ-mediated responses such as decidualization and apoptosis.

Leukotrienes and Lipoxygenase Products

Leukotrienes were discovered in 1979 during the search for the chemical structure of the "slow reacting substance of anaphylaxis." Leukotrienes are produced by the action of 5-lipoxygenase (5-LO) (Figure 3) which catalyzes both an oxygen insertion to form 5-HpETE and a dehydration reaction to form leukotriene A_4 (LTA_4). LTA_4 is converted to the biologically active leukotrienes LTB_4 and LTC_4 by LTA_4 hydrolase and LTC_4 synthase, respectively. LTB_4 is a potent chemotactic and chemokinetic agent for human polymorphonuclear leukocytes whereas LTC_4 constricts specific smooth muscle (e.g., bronchial smooth muscle) and mediates leakage of vascular fluid in the process of edema. The formation of LTC_4 versus LTB_4 is controlled by the expression of LTA_4 hydrolase or LTC_4 synthase by specific cell types. For example, the human neutrophil expresses LTA_4 hydrolase and produces LTB_4 while mast cells and eosinophils express LTC_4 synthase and produce LTC_4.

5-Lipoxygenase

Human 5-lipoxygenase (5-LO) (E.C.1.13.11.34) is a nonheme iron containing protein of 673 amino acids. It catalyzes the abstraction of a hydrogen atom from C-7 of AA and insertion of O_2 at C-5 to generate 5(S)-HpETE (Figure 3). The LTA_4 synthase activity of 5-LO then catalyzes removal of 10 pro-R hydrogen atoms from 5(S)-HpETE through a second redox cycle and an internal rearrangement of double bonds to form LTA_4. LTA_4, has a half-life of less than 10s at pH 7.4. Purified 5-LO requires Ca^{2+}, ATP, fatty acid hydroperoxide, and phosphatidylcholine in addition to the AA and O_2 substrates. Ca^{2+} facilitates the association of 5-LO with internal membranes. The need for an increase in intracellular Ca^{2+} concentrations differentiates 5-LO from other lipoxygenases. 5-LO oxygenates AA at the interface between membrane and cytosol. When Ca^{2+} concentrations increase in neutrophils and mast cells, 5-LO and cytosolic PLA_2 become associated with the nuclear membrane (NM) where another protein required for LTA_4 synthesis – 5-lipoxygenase activating protein (FLAP) – is found. In other cells 5-LO is constitutively associated with the NM while in alveolar macrophages 5-LO is present in the nucleus. The drug zileuton inhibits 5-LO.

The 5-LO gene is large (ca. 80 kb) and has 14 exons. It is on human chromosome 10. The human 5-LO gene promoter contains Sp1 and EGR-1 binding sites at -88 to -212 bp upstream of the translation start site. Genetic polymorphisms in humans are found in Sp1 binding sites.

5-Lipoxygenase Activating Protein (FLAP)

FLAP was discovered as a novel protein essential for leukotriene synthesis which was the target of an

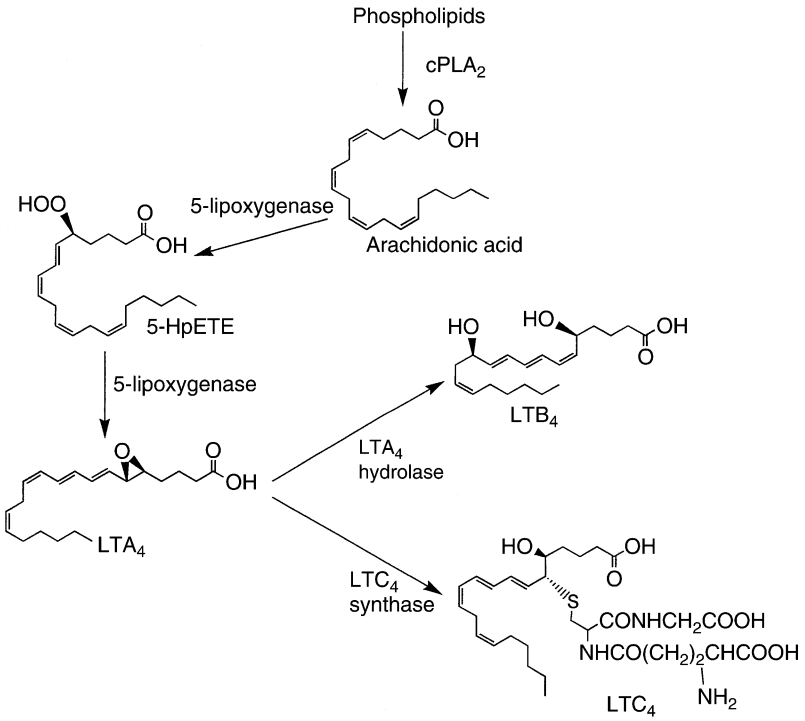

FIGURE 3 Biochemical pathway of the conversion of AA into the biologically active leukotrienes. AA released from phospholipid by $cPLA_2$ is metabolized by 5-LO to 5-hydroperoxyeicosatetraenoic acid (5-HpETE) and leukotriene A_4 (LTA_4) which is then converted to LTB_4 by LTB_4 hydrolase or conjugated to glutathione to form LTC_4 by LTC_4 synthase.

investigational drug from Merck (MK886). FLAP is an integral membrane protein of the NM containing 161-amino acids. The function of FLAP is unclear but it does bind AA analogues suggesting that it may transfer AA to 5-LO. LTC_4 synthase has 31% amino acid identity to FLAP with a highly conserved region putatively involved in AA binding.

LTA_4 Hydrolase and LTC_4 Synthase

LTA_4 hydrolase catalyzes the stereochemical addition of water to C-12 of LTA_4 to form the neutrophil chemotactic factor LTB_4. LTA_4 hydrolase contains 610 amino acids and one essential zinc atom. The enzyme is structurally related to zinc metalloproteases and exhibits protease activity; bestatin and captopril inhibit the enzyme. LTA_4 hydrolase is found in many cells including those which do not contain 5-LO, and it is felt that such cells function in transcellular LTB_4 synthesis. LTA_4 hydrolase is localized in the cytosol. To metabolize the unstable LTA_4, LTA_4 hydrolase must either come in contact with the NM during LTA_4 formation or a carrier protein must transfer LTA_4 to LTA_4 hydrolase. The crystal structure of LTA_4 hydrolase has been determined.

LTC_4 synthase (E.C.2.5.1.37) conjugates reduced glutathione (γ-glutamyl-cysteinyl glycine) to LTA_4. LTC_4 synthase is located on the NM. The enzyme has significant sequence homology to microsomal glutathione-S-transferases and FLAP. LTC_4 synthase is found predominantly in mast cells, macrophages, eosinophils, and monocytes. MK-886, which interacts with FLAP, also inhibits LTC_4 synthase. The gene for LTC_4 synthase is located on human chromosome 5.

Leukotriene Metabolism

LTB_4 can be oxygenated to 20-hydroxy-LTB_4 by specific cytochrome P-450s of the CYP4F family. 20-hydroxy-LTB_4 can be further metabolized to 20-carboxy-LTB_4 by CYP4F3 or to 20-oxo-LTB_4 by alcohol dehydrogenase then to 20-carboxy-LTB_4 by fatty aldehyde dehydrogenase. An alternative pathway involves an initial oxidation of the 12-hydroxy group to a 12-oxo moiety followed by reduction of the conjugated dienone and the 10,11 double bond. A secondary catabolic pathway, β-oxidation can occur from the C-1 carboxyl moiety of LTB_4 resulting in the loss of the C-5 hydroxyl group and from the 20-carboxy terminus of 20-carboxy-LTB_4. Individuals with genetic deficiencies in peroxisomal metabolism (Zellweger disease) that reduce β-oxidation or in aldehyde dehydrogenase (Sjogren–Larsson

syndrome) excrete intact LTB_4 and 20-hydroxy-LTB_4. LTC_4 catabolism involves peptide cleavage reactions involving glutamyl transpeptidase and various dipeptidases to yield LTD_4 and LTE_4, both of which have biological activity. The sulfur atom of sulfidopeptide leukotrienes can be oxidized by reactive oxygen species. More specific metabolic processing of the sulfidopeptide leukotrienes includes ω-oxidation by cytochrome P-450 followed by β-oxidation from the I terminus.

Leukotriene Biology and Leukotriene Receptors

LTB_4 functions in inflammatory processes through its chemotactic and chemokinetic affects human polymorphonuclear leukocytes. LTB_4 induces the adherence of neutrophils to vascular endothelial cells and enhances the migration of neutrophils (diapedesis) into extravascular tissues. The biological activity of LTB_4 is mediated through two specific G-protein coupled receptors termed BLT_1 and BLT_2. LTC_4 and its peptide cleavage products LTD_4 and LTE_4 mediate bronchial smooth muscle contraction in asthma and cause edema. There are two G protein-linked receptors for cysteinyl leukotrienes called $CysLT_1$ and $CysLT_2$. $CysLT_1$ is found in bronchial and intestinal smooth muscle; LTD_4 and LTC_4 activate $CysLT_1$. Montelukast, pranlukast, and zafirlukast inhibit the $CysLT_1$ receptor in humans. $CysLT_2$ receptors are abundant in the heart and in vascular endothelial cells.

Glossary

aspirin A nonsteroidal anti-inflammatory drug that inhibits cyclooxygenase by acetylating an active site serine residue and blocking productive binding of arachidonic acid.

cyclooxygenase Common name of the oxygenase enzyme that converts arachidonic acid and related 20 carbon essential fatty acids to prostanoids.

FLAP 5-lipoxygenase activating protein, an accessory protein that is required for 5-lipoxygenase functioning in intact cells.

leukotriene Those oxygenated derivatives of 20 carbon essential fatty acids formed through the action of 5-lipoxygenase and containing a conjugated triene system of double bonds.

5-lipoxygenase The oxygenase that converts arachidonic acid and related 20 carbon essential fatty acids to leukotrienes.

montelukast A drug used in the treatment of asthma that inhibits the binding of peptidoleukotrienes to the $CysLT_1$ receptor.

prostanoid Those oxygenated derivatives of 20 carbon essential fatty acids formed through the action of prostaglandin endoperoxide H synthase.

Biography

William L. Smith is a Professor of Biological Chemistry at the University of Michigan Medical School. His research interests are in the area of lipid mediators, particularly the enzymes involved in the biosynthesis of prostanoids. He has contributed to understanding the molecular basis for the actions of nonsteroidal anti-inflammatory drugs such as aspirin.

Robert C. Murphy is a Professor of Pharmacology at the University of Colorado Health Sciences Center in Denver. His research interests are in the area of lipids and lipid mediators particularly the metabolism of leukotrienes and related lipoxygenase products. Dr. Murphy determined the structures of the peptidoleukotrienes and has developed tools (mass spectrometry) for characterizing and quantifying lipids and lipid mediators.

Proteases in Blood Clotting

John D. Kulman and Earl W. Davie
University of Washington, Seattle, Washington, USA

Proteases are enzymes that hydrolyze peptide bonds within protein substrates. In vertebrates, proteases play an essential role in preventing the loss of blood by promoting hemostasis, a process that culminates in the formation of a platelet plug and the deposition of a polymerized fibrin network at sites of vascular injury. The mechanism of this process was first studied in the mid-1800s by a Scottish surgeon Andrew Buchanan, who proposed the existence of a clot-promoting factor that he called thrombin. This article discusses the coagulation cascade, and the structure and function of the blood clotting proteases.

The biochemical pathways leading to thrombin formation are now well understood, as are the mechanisms by which thrombin promotes and modulates hemostasis. In response to vascular damage, thrombin is generated from an inactive precursor by a series of biochemical reactions collectively known as the coagulation cascade (Figure 1). Thrombin subsequently catalyzes a series of reactions that lead to platelet aggregation, fibrin polymerization, and ultimately, feedback down-regulation of the coagulation cascade itself (Figure 2). The enzymes involved in these pathways are structurally and functionally related to trypsin, the prototypical serine protease of the digestive system. However, in contrast to trypsin, the coagulation proteases are characterized by a complex modular architecture that facilitates interactions with one another, with other protein substrates, as well as with protein cofactors. These interactions serve to restrict the proteolytic reactions of the blood coagulation cascade to coagulation-promoting surfaces at sites of vessel injury.

The Coagulation Cascade

The Extrinsic Pathway

Almost since the 1960s, the coagulation cascade has been envisaged as a series of stepwise reactions in which inactive forms of serine proteases are converted to active forms by limited proteolysis in a process known as zymogen activation. The coagulation cascade is initiated when tissue factor, an integral membrane protein located in the tissue adventitia, is exposed to circulating blood following a vascular injury (Figure 1). The binding of tissue factor to factor VII or to the active serine protease factor VIIa (trace amounts of which circulate in the blood) initiates the extrinsic pathway of coagulation. The tissue factor–factor VIIa complex converts factors IX and X to their active forms (IXa and Xa). Feedback amplification is achieved when inactive factor VII bound to tissue factor is converted to its active form (VIIa) by factors VIIa, IXa, and Xa, resulting in enhanced generation of factor Xa. The factor Xa thus produced generates thrombin from its inactive form (prothrombin) in the presence of calcium, the nonenzymatic cofactor factor Va, and anionic phospholipid (primarily phosphatidylserine (PS)) exposed on the surface of activated platelets or other cells. Thrombin generated in the extrinsic pathway initiates an additional feedback amplification loop by generating factors Va and VIIIa by limited proteolysis. These surface-bound protein cofactors serve as scaffolds for the assembly of complexes that facilitate the production of factors Xa and thrombin (the Xase and prothrombinase complexes, respectively).

The Intrinsic Pathway

Thrombin enhances flux through the coagulation cascade by activating the intrinsic pathway of coagulation. In this arm of the cascade, thrombin generates factor XIa from its zymogen form (XI) by limited proteolysis. Factor XIa then generates factor IXa by a similar mechanism. The precise physiological role of the intrinsic pathway has been the subject of considerable debate, particularly since defects or deficiencies of factor XI are mild, and are associated with a form of hemophilia that is quite distinct from classical hemophilia. Bleeding due to factor XI deficiency is typically associated only with major surgery or trauma, whereas deficiencies of factor VIII (hemophilia A) or factor IX (hemophilia B) give rise to spontaneous soft tissue and joint bleeding. Thus, whereas the extrinsic pathway is required in most cases of vessel injury, the intrinsic pathway appears to be necessary for sustained thrombin generation in response to severe hemostatic challenges.

The Role of Thrombin

Thrombin is a multifunctional enzyme that employs limited proteolysis to effect a variety of biochemical

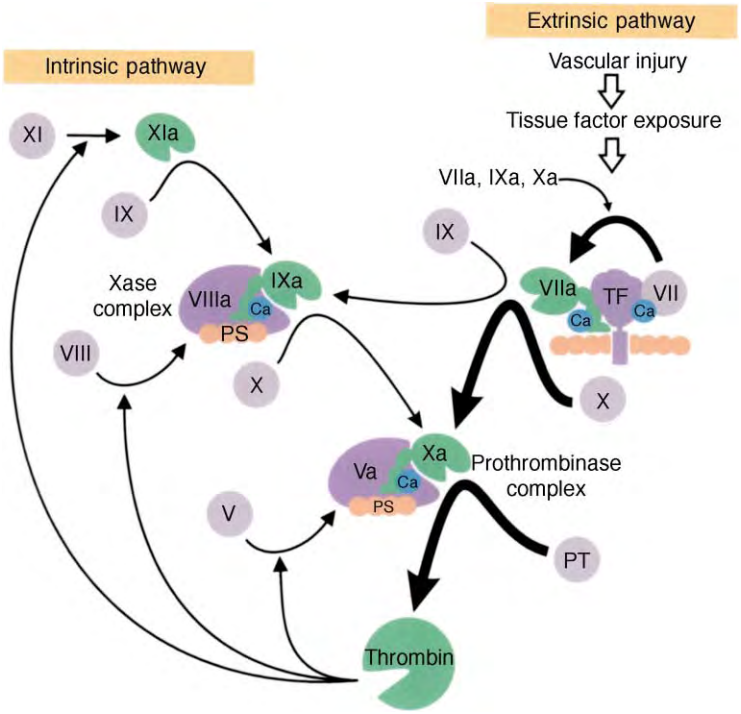

FIGURE 1 The blood coagulation cascade. Inactive cofactors and inactive (zymogen) forms of serine proteases are represented by gray circles. Active proteases are shown in green. Active protein cofactors are shown in purple. Phospholipid membranes are shown in orange. Proteolytic reactions are indicated by solid arrows. Ca, divalent calcium ions; PS, membrane surface-exposed phosphatidylserine; TF, tissue factor; PT, prothrombin.

reactions at the site of vascular injury (Figure 2). Thrombin has many physiological roles, such as promoting the formation of a cross-linked fibrin clot, the activation and aggregation of platelets, and ultimately, the attenuation of the clotting cascade.

Fibrin Polymerization

Fibrinogen is one of the more abundant proteins in the blood, circulating at a concentration of ~ 3 mg ml^{-1}. The fibrinogen molecule consists of six individual polypeptide chains arranged roughly in a dumbbell shape, with the amino termini localized to a central core and the carboxy termini located at each of the two ends. The carboxy terminal end comprises binding pockets that are unoccupied in the circulating fibrinogen molecule. Thrombin converts fibrinogen to fibrin by selectively cleaving short peptides (fibrinopeptides) from the central core region, thereby exposing new amino termini that interact with the carboxy terminal binding pockets on adjacent fibrin molecules (Figure 2, arrow A). In this way, fibrin monomers associate to form thin fibrils that thicken to form an insoluble fibrin clot.

Fibrin Cross-Linking by Factor XIIIa

When fibrin is formed, it accelerates the conversion of factor XIII to XIIIa in a reaction catalyzed by thrombin in the presence of calcium ions (Figure 2, arrow B). Factor XIIIa is unique among the coagulation enzymes in that it is not a serine protease. Rather, it is a transglutaminase that covalently links the side chains of lysine and glutamine residues present in the carboxy terminal regions of adjacent fibrin molecules. This cross-linking imparts structural integrity and rigidity to the clot.

Platelet Activation

Thrombin activates platelets by limited proteolysis of proteins called protease-activated receptors (PARs). PARs constitute a small subset of a much larger family of G protein-coupled receptors (GPCRs). GPCRs are seven-pass transmembrane proteins that transduce extracellular signals via intracellular activation of heterotrimeric G protein signaling pathways. The PARs are unique among the GPCRs in that they utilize a "tethered ligand" mechanism in which limited proteolysis within the extracellular region of the receptor unmasks a protein sequence that auto-activates the receptor itself (Figure 2, arrow C). In platelets, the proteolysis of PARs 1 and 4 by thrombin results in the expression of the hallmarks of platelet activation, namely, morphological change, degranulation, the expression of surface proteins required for aggregation, and the translocation of PS from the inner to the outer leaflet of the platelet membrane.

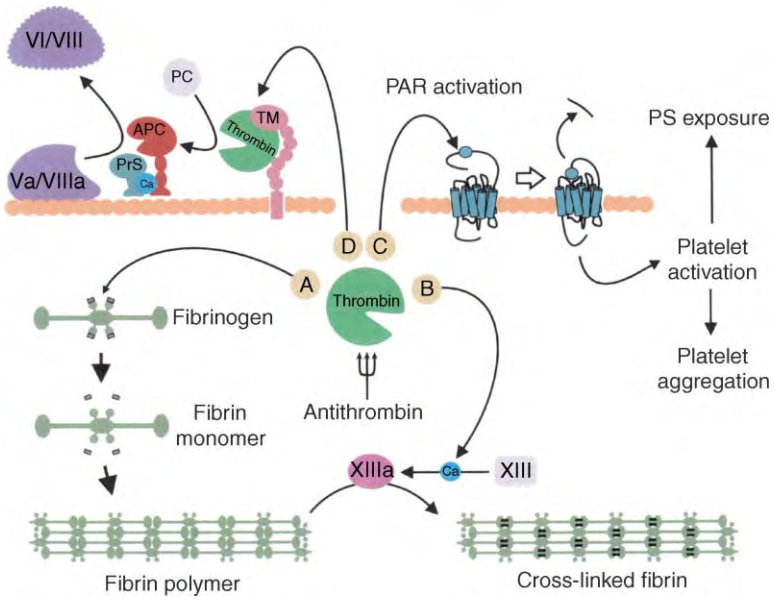

FIGURE 2 Effects of thrombin. Arrow A: Thrombin cleaves short fibrinopeptides from the central region of fibrinogen. The newly exposed termini spontaneously associate with the terminal domains of adjacent molecules allowing formation of polymeric fibrin. Arrow B: Proteolytic cleavage of factor XIII converts it into an active transglutaminase (XIIIa) that chemically cross-links adjacent fibrin molecules, providing structural integrity to the clot. Arrow C: Thrombin cleaves the extracellular region of protease-activated receptors (PARs) on the platelet surface. This modification exposes a tethered ligand that auto-activates the PAR, leading to platelet activation. Activated platelets aggregate to form a hemostatic plug and expose phosphatidylserine (PS), providing a pro-coagulant surface for the coagulation cascade. Arrow D: Feedback down-regulation of the coagulation cascade. Thrombin binds to thrombomodulin on the surface of endothelial cells. This association alters the substrate specificity of thrombin such that it cleaves protein C (PC) to form activated protein C (APC). In the presence of calcium and the cofactor protein S (PrS), APC promotes anticoagulation by proteolytically converting factors Va and VIIIa to their inactive forms (Vi and VIIIi).

The exposure of PS has dramatic consequences for amplification of the coagulation cascade. Under normal cellular homeostasis, PS is tightly restricted to the inner leaflet of the plasma membrane and, as such, is not exposed to the general circulation. However, the exposure of PS (whether through translocation on the platelet surface or by mechanical disruption of cells lining the vasculature) provides a surface for the recruitment of the components of the coagulation cascade, including the serine proteases and factors V and VIII. Viewed in this light, platelet activation and subsequent PS exposure provide yet another positive feedback loop for the generation of thrombin.

Attenuation of the Coagulation Cascade

The unregulated activation of the coagulation cascade would have serious consequences for an organism, including the occlusion of blood vessels and the formation of clots at locations other than the site of injury. Numerous serine protease inhibitors are present in the blood, and serve to restrict coagulation to sites of vessel injury. The most abundant among these is antithrombin, which is present at a concentration ~3 times that of prothrombin. Antithrombin rapidly and irreversibly inactivates thrombin, particularly in the presence of heparan sulfate, a proteoglycan present in the blood vessel wall. Antithrombin has also been shown to inhibit factors IXa, Xa, and XIa.

In an alternative mechanism for attenuating the coagulation cascade, thrombin initiates a pathway that leads to the destruction of factors Va and VIIIa. In this pathway, thrombin binds to thrombomodulin, an integral membrane protein located on the vascular endothelium (Figure 2, arrow D). As the name implies, thrombomodulin modulates the specificity of thrombin such that it generates activated protein C (APC), by limited proteolysis of protein C. APC then inactivates both factors Va and VIIIa by minor proteolysis in a reaction that requires calcium ions, anionic phospholipid, and the protein cofactor, protein S.

Structure and Function of the Blood-Clotting Proteases

Similarity to Trypsin

The proteases involved in blood coagulation are functionally and structurally related to trypsin, the

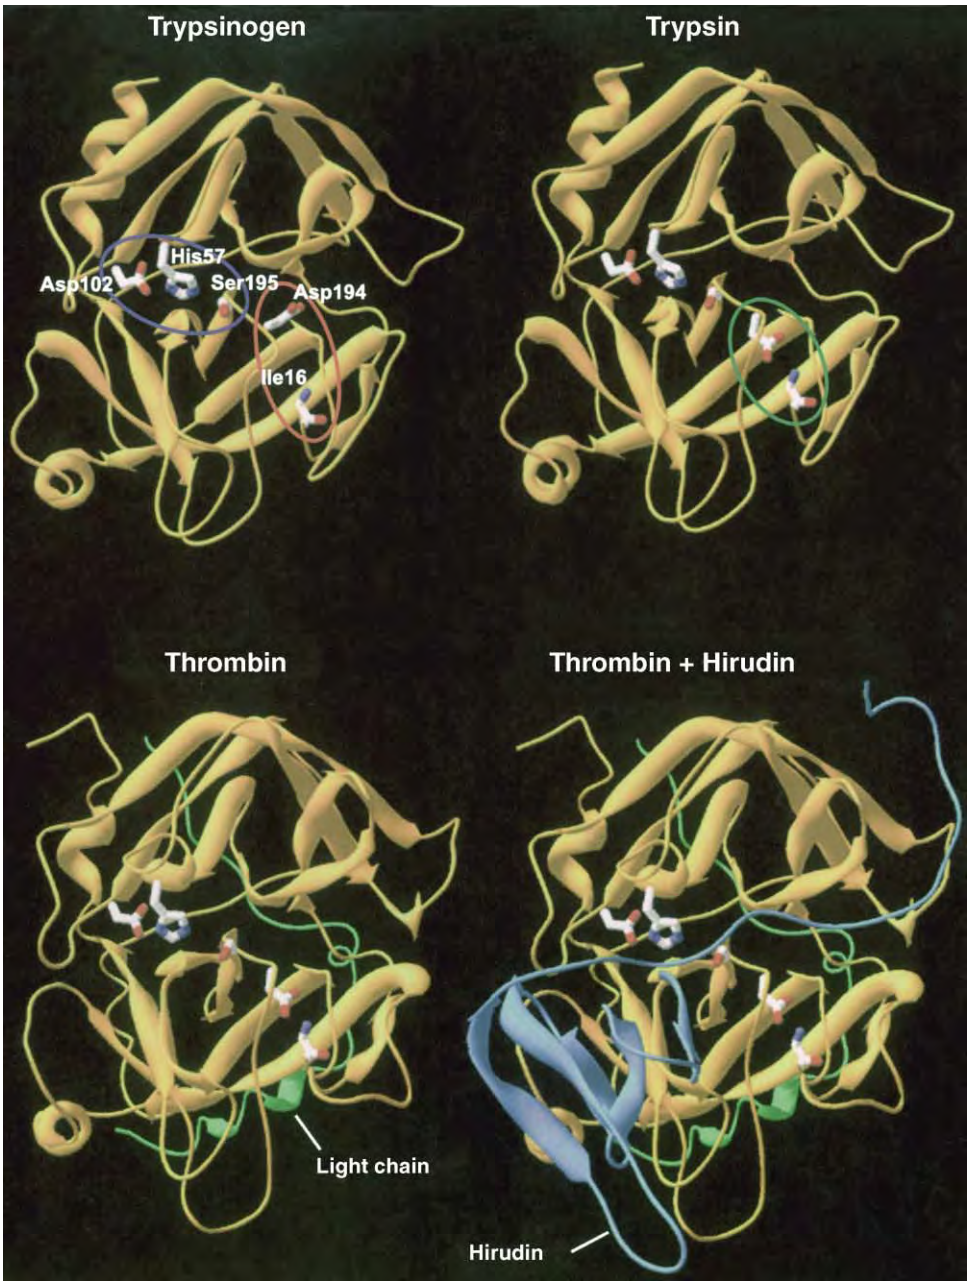

FIGURE 3 Related structures of trypsinogen, trypsin and thrombin. The structure of trypsinogen (upper left panel) reveals clamshell topology with a cleft harboring the active site. Residues His57, Asp102, and Ser195 constitute the catalytic triad (blue oval). In the inactive (zymogen) form of the enzyme the sidechain of Asp 194 does not contact the amide nitrogen (blue atom) of Ile16 (bounded by red oval). The preceding 15 residues have been omitted from the structure to provide ease of interpretation. The structure of trypsin (upper right panel) illustrates the structural change upon zymogen activation. Here the newly formed amino terminus at Ile16 forms a salt bridge with the side chain of Asp194. The structure of thrombin (lower left panel) illustrates its overall topological similarity with that of trypsin. The light chain of thrombin is shown in green. The structure of thrombin bound to the leech anticoagulant protein hirudin (lower right panel) demonstrates the molecular basis for hirudin's anticoagulant effect. Hirudin (depicted as a blue ribbon) blocks the active site of thrombin and extends an arm around thrombin to block its fibrinogen-binding exosite.

prototypical serine protease of the digestive system. Like trypsin, the proteases involved in blood coagulation (thrombin, APC and factors VIIa, IXa, Xa, and XIa) constitute a class of serine proteases that cleave their target proteins after basic (arginine and lysine) amino acid residues. However, trypsin cleaves nonspecifically after basic residues, whereas proteases of the coagulation cascade recognize and cleave only after basic residues surrounded by specific sequences within their targets. As is the case with the clotting proteases,

trypsin exists in a zymogen form (trypsinogen) that is activated by limited proteolysis. Thus, while trypsin does not possess the high degree of substrate specificity of the coagulation proteases, it shares the same general mode of zymogen activation and mechanism of catalysis.

The three-dimensional representation of trypsinogen solved by X-ray crystallography reveals a two-lobed structure resembling a clamshell with a cleft running between the two individual halves (Figure 3). The primary catalytic machinery of trypsin, the so-called "catalytic triad" consisting of histidine, aspartic acid, and serine residues, resides within this cleft. (It is the catalytic serine residue from which the serine proteases derive their name.) Trypsinogen is catalytically inactive until it is cleaved just prior to an isoleucine residue located near the amino terminus of the molecule. This proteolytic event triggers a subtle rearrangement of the molecule, driven by the generation of an electrostatic interaction between the positively charged amino group at the new amino terminus and a negatively charged aspartic acid residue adjacent to the catalytic serine residue. The formation of this salt bridge alters the structure of trypsin and renders it catalytically active.

The structure of thrombin is remarkably similar to that of trypsin (Figure 3), as are those of the other coagulation proteases. Thrombin shares with trypsin its overall clamshell structure, its catalytic triad, and its mode of zymogen activation upon limited proteolysis. However, in addition to the trypsin-like catalytic domain (heavy chain), thrombin possesses an additional polypeptide (the light chain)—a property shared by the other clotting proteases. In addition, thrombin possesses a secondary binding site on its surface that confers specificity for both fibrinogen and PAR1. The position of this so-called "fibrinogen-binding exosite" is illustrated in the structure of thrombin complexed with the leech

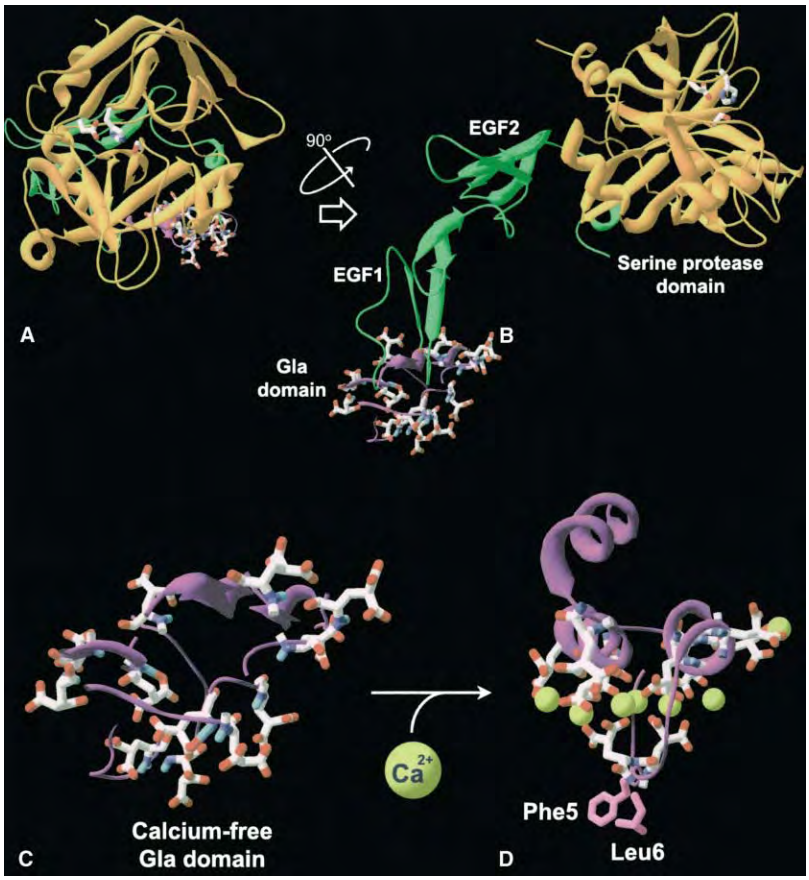

FIGURE 4 The role of Gla domains in the blood-clotting proteases. Panel A: Structure of factor IXa showing the serine protease domain with amino acid residues of the catalytic triad highlighted. In this view the light chain, consisting of a Gla domain and two tandem EGF domains is obscured. The factor IXa structure depicted was determined in the absence of calcium ions. Panel B: Rotation of the structure reveals the amino terminal Gla domain as well as the EGF domains. Panel C: Close-up of the Gla domain of calcium-free factor IXa. In the absence of calcium, the Gla domain is relatively disordered with the Gla residues projecting outward into solution. Panel D: The calcium-bound form of a Gla domain. The coordination of calcium ions by Gla residues within the core of the domain drives the exposure of a hydrophobic "thumb" consisting of a phenylalanine and a leucine residue. This region of the domain contacts the hydrophobic region of membranes. The nearly planar arrangement of positively charged calcium ions may provide specificity for negatively charged phospholipids such as PS.

salivary protein hirudin, which exerts its anticoagulant effect by simultaneously blocking access to the active site and occupying the fibrinogen-binding exosite with a long "arm" (Figure 3).

Gla Domains

The presence of both a catalytic heavy chain and a light chain is a common feature of the activated coagulation proteases. However, in contrast to thrombin, which has a relatively short light chain, the light chains of factors VIIa, IXa, Xa, and APC are longer and are characterized by the presence of multiple modular protein domains. (The crystal structure of factor IXa illustrates this arrangement—Figure 4, panel A.) When viewed in the same orientation as previously depicted structures of trypsinogen, trypsin and thrombin, the serine protease domain with its characteristic catalytic triad is clearly visible. However, this orientation obscures the light chain, which consists of an amino terminal Gla domain followed by two tandem modules that bear structural and sequence similarity to epidermal growth factor (EGF1 and EGF2). The modular structure of the factor IXa light chain is visible when the protein is rotated (Figure 4, panel B).

The Gla domain derives its name from a modification of glutamate residues that occur during the biosynthesis of factors VII, IX, and X, prothrombin, and protein C. The amino terminal 45 residues of these proteins contain between 9 and 13 glutamate (Glu) residues that are converted to γ-carboxyglutamate (Gla) residues in a reaction that requires vitamin K as a cofactor. Gla residues are capable of binding divalent ions, particularly calcium. The three-dimensional structure of factor IXa, determined in the absence of calcium, reveals an amino terminal Gla domain that is relatively disordered, with Gla residues projecting into solution. However, at physiological calcium levels found in the blood, the Gla residues coordinate with calcium and drive the Gla domain into its native conformation (Figure 4, panel C). In this form, the Gla domain is organized around a nearly planar array of calcium ions and projects a hydrophobic 'thumb' into solution. It is believed that the hydrophobic thumb associates with the hydrophobic regions of membranes, while the positively charged calcium ions associate electrostatically with the negatively charged head groups of PS exposed on coagulation-promoting surfaces such as the surface of activated platelets.

Gla domains are essential for localizing factors VIIa, IXa, and Xa, and APC, as well as their zymogen forms, to PS on the surface of activated platelets located at sites of vascular injury. (Thrombin is unique in that its Gla domain is removed from the light chain during the proteolytic activation of prothrombin.) The essential role of Gla domains and the Gla residues that they bear in directing the components of the coagulation cascade to PS-containing surfaces is underscored by the anticoagulant effect of warfarin, a potent vitamin K antagonist. Warfarin inhibits the conversion of Glu residues to Gla residues, rendering the clotting factors incapable of binding to the platelet surface. Originally employed at high doses as a rodent poison, warfarin is currently one of the most widely prescribed drugs for depressing the coagulation cascade in patients who are at risk of heart attack or stroke.

Glossary

Gla The amino acid gamma-carboxyglutamic acid.

hemophilia Any of several hereditary blood coagulation disorders in which the blood fails to clot normally.

hemostasis The stoppage of blood flow characterized by vasoconstriction and the formation of a platelet plug and polymerized fibrin.

platelet A small, non-nucleated, cell body found in the blood that functions to promote blood clotting.

protease Any of various enzymes that catalyze the hydrolytic breakdown of proteins into peptides or amino acids.

proteolysis The hydrolytic breakdown of proteins into smaller proteins, peptides, or individual amino acids.

transglutaminase Any of various enzymes that catalyze the covalent linkage of protein-bound glutamine and lysine amino acid side-chains.

vitamin K A fat-soluble vitamin that promotes blood coagulation and prevents hemorrhage.

warfarin A synthetic organic compound, derived from the natural product "coumarin," that antagonizes the effect of vitamin K.

zymogen The inactive precursor of an enzyme, converted into an active enzyme by proteolysis.

Biography

John Kulman is a postdoctoral fellow in the Department of Biochemistry at the University of Washington. He earned an M.Phil. from the University of Cambridge where he studied biotin-dependent enzymes while in residence at Churchill College. He holds a Ph.D. from the University of Washington where he completed his doctoral research in the laboratory of Professor Earl W. Davie in the Department of Biochemistry. His principal research interests are in elucidating novel physiological roles of vitamin K and investigating the interplay between vitamin K-dependent proteins and cellular ubiquitination pathways.

Earl W. Davie received his Ph.D. from the Department of Biochemistry at the University of Washington, and then did postdoctoral studies with Professor Fritz Lipmann at Harvard University. After six years on the faculty at Case Western Reserve University, he joined the Department of Biochemistry at the University of Washington where he is a Professor. His research interests have focused mainly on the coagulation cascade and the proteins involved in fibrin formation.

26S Proteasome, Structure and Function

Peter Zwickl and Wolfgang Baumeister
Max Planck Institute of Biochemistry, Martinsried, Germany

The ubiquitin–proteasome pathway is the major route used by eukaryotic cells for disposing of misfolded or damaged proteins and for controlling the lifespan of regulatory proteins. The 26S proteasome is a huge molecular machine of ~2.5 MDa, which degrades protein substrates by an energy-dependent mechanism. It comprises two subcomplexes, the 20S-core particle and one or two regulatory complexes, the 19S caps. The 20S complex allows confining the proteolytic action to a nanocompartment, in which sequestered from the cellular environment substrates undergo degradation. The 19S regulatory complex recruits substrates targeted for degradation and prepares them for translocation into the 20S-core complex. The sequence of events encountered by a substrate until it is finally degraded is reflected by a linear arrangement of functional modules within the 45 nm long supramolecular assembly (Figure 1).

The 20S Proteasome

20S proteasomes are found in all domains of extant organisms in archaea, bacteria, and eukaryotes and share a highly conserved quaternary structure. Although their complexity in terms of subunit composition is surprisingly different, 20S proteasomes are generally built from two types of subunits, α and β, which segregate into seven-membered rings and collectively form a barrel-shaped complex with a network of internal cavities. These cavities or "nanocompartments" harbor the active sites and thus allow segregating the proteolytic action from the surrounding cytoplasm. This regulatory principle, referred to as "self-compartmentalization," is for prokaryotes, which lack membrane-bordered compartments, the only means of spatial confinement.

In addition to self-compartmentalization, proteasomes rely on another mechanism to prevent the uncontrolled breakdown of proteins that is not uncommon amongst proteases. The β-type subunits of 20S proteasomes, which bear the active site residues, are synthesized in an inactive precursor form; for the formation of the active sites, the propeptides must be removed posttranslationally. This process is tied in with the assembly of the 20S proteasome in such a manner that activation is delayed until assembly is complete and the active sites are sequestered from the cellular environment. In mature 20S proteasomes access to the inner proteolytic compartment is through narrow gates at the polar ends of the complex and thus restricted to small peptides and unfolded proteins. Therefore, the proteasome behaves, with respect to folded proteins, as a "latent" protease, which is dependent on regulatory complexes to assume its function. At the heart of the regulatory complexes, or "activators," are members of the AAA family of ATPases. In prokaryotes, members of this family form homohexameric complexes; in eukaryotes, six paralogs form heterohexameric complexes, which are integrated into the larger and multifunctional 19S regulatory complexes.

Subunit Composition

20S proteasomes from all three domains of life have a common overall architecture. They are built of 28 subunits arranged in a stack of four seven-membered rings. All subunits are members of the same superfamily of proteins, which group into two families, designated α and β. The two polar rings of the proteasome are formed by α-type subunits; the two equatorial rings are formed by β-type subunits (Figure 2A). Both families comprise a number of subfamilies. The sequence similarity between members of a subfamily, even from evolutionary distant species, is considerably higher than similarity between the members of different subfamilies from one species. While human and yeast proteins of the same subfamily have at least 50% similarity, there is only ~30% similarity between the seven subfamilies, and even less among the two families, α and β.

The main difference between eukaryotic and prokaryotic 20S proteasomes is one of complexity. Prokaryotic proteasomes are mostly composed of identical copies of 14 α-subunits and 14 β-subunits, eukaryotic proteasomes recruit α- and β-subunits out of 14 different subfamilies. Thus, the multiple axes of

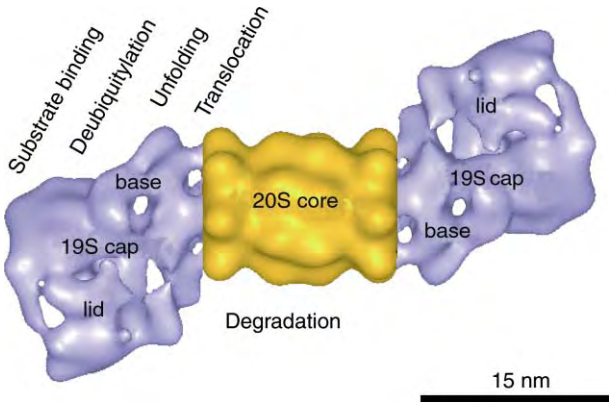

FIGURE 1 Composite model of the three-dimensional (3D) structure of the 26S proteasome combining a 3D reconstitution from electron micrographs of *Drosophila* 26S complexes and the crystal structure of the *Thermoplasma* 20S proteasome.

symmetry of the *Thermoplasma* proteasome are reduced to C2 symmetry in the eukaryotic proteasome; each of the 14 different subunits is found twice within the complex and occupies well-defined positions. According to their location within the α and β rings, yeast subunits are sequentially numbered $\alpha 1/\beta 1$ through $\alpha 7/\beta 7$, and those related by C2 symmetry are distinguished by the prime symbol ($\alpha 1'/\beta 1'$ through $\alpha 7'/\beta 7'$). The subunit topology in higher eukaryotes corresponds to that in yeast, i.e., members of the same subfamily occupy the same positions. Hence, that systematic nomenclature is generally applicable. While lower eukaryotes assume a stoichiometry of $(\alpha_1-\alpha_7)$ $(\beta_1-\beta_7)$ $(\beta_1-\beta_7)$ $(\alpha_1-\alpha_7)$, vertebrates have achieved an even higher degree of complexity. In addition to the 14 constitutive subunits, they contain 3 γ-interferon-inducible β-type subunits, which can replace their constitutive counterparts ($\beta 1$, $\beta 2$, and $\beta 5$) to form "immunoproteasomes."

Structure

On electron micrographs, 20S proteasomes from prokaryotes and eukaryotes are virtually indistinguishable, and also the crystal structures of *Thermoplasma* and yeast proteasomes are very similar. Proteasomes are barrel-shaped particles, with overall dimensions of 15 nm in length and 11 nm in diameter. A channel traverses the particle from end to end and widens into three internal cavities, each ~5 nm in diameter (Figure 2B). The two outer cavities are formed jointly by one α- and one β-ring; the central cavity is formed by the two adjacent β-rings. At a glance there appears to be one major difference between the crystal structures of the *Thermoplasma* and the yeast proteasome: In the archaeal proteasome 1.3 nm wide openings are visible at the center of the α rings, while in the yeast proteasome this channel appears to be closed. However, one has to keep in mind that in the crystal structure of the *Thermoplasma* proteasome the 12 N-terminal residues of the α-subunits remained invisible because of disorder; in yeast the corresponding residues plug the channel and act as a gate.

As expected from their sequence similarity, proteasome α- and β-subunits have the same fold (Figure 2C): a four-layer structure with two five-stranded antiparallel β-sheets (S1–S10) flanked on either side by α-helices, two on the one (H1 and H2), three on the other side (H3, H4, and H5). The β-sheet package is unusual in that one sheet is rotated relative to the other through a positive dihedral angle of +30°, in contrast to the value of the typical β-sheet twist, which is −30°. In the β-type subunits, the β-sheet sandwich is open at one end to form the active site cleft, and closed at the other end by four hairpin loops. In α-type subunits, however, an additional helix (H0) crosses the top of the β-sheet sandwich and fills the cleft. The fold of proteasome subunits was initially considered to be unique, but as it turned out, it is prototypical of a new family of proteins referred to as Ntn (N-terminal nucleophile) hydrolases.

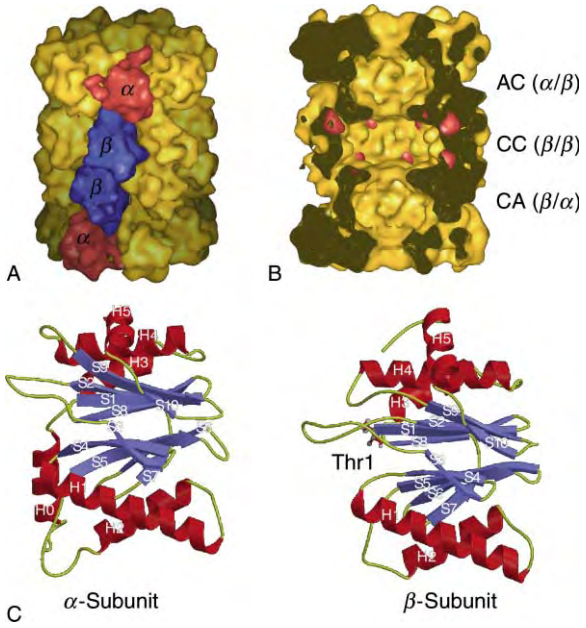

FIGURE 2 Structure of the 20S proteasome. (A) Low-resolution model (1 nm) of the 20S proteasome from the crystal structure of the *Thermoplasma* 20S proteasome. (B) The same structure as in (A) cut open along the sevenfold axis to display the two antechambers (AC and CA) and the central chamber (CC) with the 14 active sites (marked in red). The channel openings at the two ends of the cylinder are 1.3 nm in diameter. (C) Folds of the α and β-subunit from *Thermoplasma* 20S proteasomes. Helices are numbered H0 to H5 in the α-subunit, and H1 to H5 in the β-subunit; strands are numbered S to S10. H0 in the α-subunit occupies the cleft leading to the active site in the β-subunit. The active site threonine (Thr1) in the β-subunit is shown in ball-and-stick representation.

Currently known members of this family, whose primary structures have diverged beyond recognizable similarity, are aspartylglucosaminidase (AGA), glutamine phosphoribosyl pyrophosphate amidotransferase (GAT), penicillin acylase (PA), and L-aminopeptidase D-Ala-esterase/amidase (DmpA). Beyond the common fold, these enzymes share the mechanism of the nucleophilic attack and autocatalytic processing, but none of them has a quaternary structure similar to the proteasome.

The Active Site

A characteristic feature of Ntn hydrolases is a "single-residue" active site; both the nucleophile and the primary proton acceptor are provided by the same N-terminal residue of the proteins. The nucleophilic attack is initiated when the free N terminus, the primary proton acceptor, strips the proton off the catalytic side chain, the nucleophile; for steric reasons, a water molecule is supposed to mediate the proton shuttle, at least in the proteasome and in penicillin acylase. Different N-terminal residues are used as nucleophiles in Ntn hydrolases; serine in PA and DmpA, cysteine in GAT, and threonine in AGA and in the proteasome. In agreement with a catalytic mechanism that relies on a single residue, there is no consensus of residues in the vicinity of the active site. Nevertheless, several other residues are critical for activity of proteasomes, as consistently shown by site directed mutagenesis with archaeal, bacterial, yeast, and mammalian proteasomes. The exact roles of these residues, all highly conserved and in close proximity to Thr1, remain to be clarified. Lys33, which forms a salt bridge to Glu17, may lower the pK_a of the N terminus by electrostatic effects or may be part of the charge relay system in delocalization of the proton from the Thr1 hydroxyl group. Asp166 may be required for the structural integrity of the active site or directly be involved in catalysis.

Although all proteasome subunits have the Ntn-hydrolase fold, not all are actively involved in substrate cleavage. As mentioned above, in α-subunits, the active site cleft is occupied by an additional N-terminal α-helix, H0 (Figure 2C). Of the different eukaryotic β-type subunits, only three (β1, β2, and β5 and their interferon inducible counterparts) display proteolytic activity, whereas subunits β3, β4, β6, and β7 lack one or more of the critical residues and are inactive. This assignment, initially derived from the conservation pattern of the active site residues, has been confirmed by the crystal structure of yeast 20S proteasomes soaked in N-acetyl-Leu-Leu-norleucinal; only three subunits, β1/Pre3, β2/Pup1, and β5/Doa3, contain the inhibitor bound to Thr1. Since the backbone geometry is well conserved between all subunits, active or inactive, one would expect that introducing all residues regarded as critical would render inactive subunits active. However, this is not the case; the yeast subunits β3/Pup3, β6/Pre7, and β7/Pre4 remained unprocessed and consequently inactive, when the respective mutations were made.

The 26S Proteasome

Cellular Functions

In eukaryotic cells, the 20S proteasome assembles with one or two 19S regulatory complexes (RC) in an ATP-dependent manner to form the 26S proteasome. The 26S holoenzyme is the most downstream element of the ubiquitin–proteasome pathway. It is an abundant complex, both in the nucleus and in the cytoplasm, and studies with proteasome inhibitors indicate that the bulk of cellular proteins, 80–90%, are degraded via this pathway. It is not only used as a disposal machinery for misfolded proteins (termed DRiPs, for defective ribosomal products) and for proteins damaged by stress or aging, but also the lifespan of many short-lived regulatory proteins is controlled via this pathway. Interestingly, the 26S proteasome does not only degrade proteins completely, but also activates certain transcription factors by limited proteolytic processing of precursors, e.g., human NFκB and NFκB2, *Drosophila* Ci or yeast Spt23 and Mga2. In addition to its function in ubiquitin-dependent proteolysis, the 26S proteasome was also found to mediate ubiquitin-independent degradation of several proteins, e.g., ODC, c-Jun, IκBα, and $p21^{Cip1}$. Moreover, not yet fully understood nonproteolytic roles of proteasomes in nucleotide excision repair and transcriptional regulation have been described.

The 19S Regulator and its Subcomplexes

Slightly differing sets of RC subunits have been reported for different organisms and the abundance of factors that have been described to associate to the RC in a tissue- and development-specific manner and with variable affinities, makes it difficult to draw the line between interacting factors, transiently bound subunits or integral components of the RC. However, as the mass of the *Drosophila* RC, ~890 kDa, determined by scanning-transmission electron microscopy (STEM) measurements is in good agreement with the summed masses of the 18 individual subunits (932 kDa) identified on 2D gels, it seems likely that the catalogue of integral subunits is now complete. The catalogues of the *Drosophila* and yeast 19S subunits are identical, except for a single subunit (p37A), which seems to be absent from yeast 26S proteasomes.

The 19S regulator of the yeast proteasome can be dissociated into two subcomplexes, the "base" and the "lid," which are located proximally and distally with respect to the 20S core (Figure 1). The complex formed by the base and the 20S proteasome is sufficient for the ATP-dependent degradation of nonubiquitylated protein substrates, but does not mediate degradation of ubiquitylated substrate proteins. From the location of the base in the 26S complex, it had been inferred to have a role in substrate unfolding, acting as a "reverse chaperone," and in controlling the gate in the coaxial opposed α-rings of the 20S particle. A chaperone-like activity was demonstrated for the base, and likewise for the ancestral PAN complex. Both have the ability to recognize proteins destined for degradation, to unfold and to translocate them into the proteolytic-core complex in an ATP-dependent manner. The degradation signals remain to be defined, possibly some local unfolding and an exposure of hydrophobic segments is sufficient for targeting substrates. In one case, specific recognition of an ubiquitylated substrate by the Rpt5 ATPase subunit of the base was shown.

As only the 26S holoenzyme, but not the 20S-base complex degrades ubiquitylated proteins, it is likely that recognition, and binding of ubiquitin-tagged substrates is mainly mediated by the eight subunits of the lid subcomplex. Very little is known about the molecular mechanisms of substrate shuttling from the E3 ubiquitin–ligase complexes, where the final step of ubiquitylation takes place, to the lid subcomplex of the 26S proteasome. Free diffusion of ubiquitylated substrates to the 26S proteasomes would be consistent with the rather high-binding constants observed *in vitro*. On the other hand, subcomplexes or subunits of the RC, such as the lid or S5a/Rpn10, could serve as substrate carriers. Indeed, free-lid complexes exist and can be isolated from human erythrocytes as stable particles. Recently, it has been reported that E2 ubiquitin-conjugating enzymes, E3 ubiquitin-ligases, such as Ubr1 and Ufd4, and E3 ubiquitin-ligase complexes, such as SCF and APC, interact directly with subunits of the RC. In addition, adapter proteins such as Rad23 and Dsk2 proteins were shown to bind ubiquitylated proteins via their UBA (ubiquitin-pathway-associated) domain and to the S1 or S2 subunit of the base via their ubiquitin-like (UBL) domain. The latter findings imply that certain substrates may be first recognized and bound by uncomplexed adapter proteins, before the latter bind to the 19S regulator and transfer the substrate for degradation. Moreover, there is evidence that molecular chaperones were also involved in protein degradation by the 26S proteasome. It was found recently that the Hsp70 cochaperone CHIP has E3 ubiquitin-ligase activity and mediates degradation of certain substrate proteins by the 26S proteasome. Bag-1, another Hsp70-interacting protein, was also shown to stimulate substrate ubiquitylation and to bind directly to the 26S proteasome via its UBL domain. Thus, two distinct molecular machineries, the molecular chaperones and the 26S proteasome, seem to interact physically and cooperate in cellular protein quality control.

The molecular understanding of the steps involved in transferring ubiquitylated substrates from the lid to the base and eventually into the 20S core is crucial. One prerequisite for substrates to enter the proteolytic center is the removal of the multi-ubiquitin chain. In yeast, the deubiquitylating enzyme Doa4 was shown to interact physically and functionally with the proteasome supporting the model that Doa4 removes ubiquitin from proteolytic substrates en route to the 20S complex. Mammalian and *Drosophila* RCs were shown to contain a deubiquitylating subunit with a molecular mass of ~37 kDa. However, so far, this activity has only been reported to decrease substrate degradation rates, suggesting that it may have an editing function, rescuing incompletely ubiquitylated substrates. Very recently, Rpn11, a constituent subunit of the lid, was found to be essential for deubiquitylation and subsequent degradation of substrates. This suggests that coupling between deubiquitylation and degradation exists, which assures that a recognized substrate is irreversibly committed to destruction.

Biography

Peter Zwickl is a Research Group Leader in the Department of Structural Biology at the Max Planck Institute of Biochemistry. His principal research interest is the functional and structural characterization of ATP-dependent proteases. He holds a doctorate from the Technical University of Munich and received his postdoctoral training at Harvard Medical School, Boston.

Wolfgang Baumeister is Director at the Max Planck Institute of Biochemistry and Head of the Department of Structural Biology. His principal research interests are in the field of intracellular protein degradation and in the development of new techniques for structural studies, in particular electron tomography. He is an Honorary Professor of physics at the Technical University, Munich, and a member of several academies, including the German Academy of Sciences, Leopoldina and the American Academy of Arts and Sciences (Foreign Honorary Fellow). He has received several awards, most recently the Louis-Jeantet Prize for Medicine (2003).

Proteasomes, Overview

Martin Rechsteiner
University of Utah, Salt Lake City, Utah, USA

Proteasomes are cylindrical, multisubunit proteases found in eukaryotes, eubacteria, and archaebacteria. Eukaryotic proteasomes come in two sizes, the 20S proteasome and the considerably larger, ATP-dependent 26S proteasome formed when the 20S proteasome binds a regulatory complex. The 26S proteasome is the central protease in the ubiquitin (Ub)-mediated proteolytic pathway and is essential for a vast array of cellular processes including cell cycle traverse, transcription control, regulation of enzyme levels, and antigen presentation. Both 20S and 26S proteasomes can associate with protein complexes that activate peptide hydrolysis and may serve to localize the enzymes within cells.

The 20S Proteasome

Structure

The 20S proteasome is a cylindrical particle consisting of 28 subunits arranged as four rings of heptamers stacked upon one another (see Figure 1). The simpler archaebacterial enzyme is composed of just one kind of α-subunit and one β-subunit which form the end rings and the two central rings, respectively. Proteolysis is the province of the β-subunits, and their active sites face a central chamber within the cylinder. The α-subunit rings seal off the proteolytic chamber from the external solvent making the 20S proteasome a perfect protease to have among the critical proteins that comprise nucleus and cytoplasm. Unless a native protein is forced into the proteasome interior, it will be impervious to the enzyme. Moreover, proteasome β-subunits are not catalytically active unless they are present in the holoenzyme.

Eukaryotic proteasomes maintain the overall structure of the archaebacterial enzyme, but they exhibit a more complicated subunit composition. There are seven different α-subunits and at least seven distinct β-subunits. Although current evidence indicates that only three of its seven β-subunits are catalytically active, the eukaryotic proteasome cleaves a wider range of peptide bonds. The archaebacterial enzyme, with its 14 identical β-subunits, preferentially hydrolyzes peptide bonds following hydrophobic amino acids and is therefore said to have chymotrypsin-like activity. By contrast, the eukaryotic proteasome contains two copies each of trypsin-like, chymotrypsin-like, and post-glutamyl-hydrolyzing subunits. For this reason it is capable of cleaving almost any peptide bond having difficulty only with Pro-X, Gly-X, and to a lesser extent with Gln-X bonds. There is a further complication in higher eukaryotes. In immune tissues or after exposure to interferon γ, the three catalytically active β-subunits found in the proteasomes of most organs are replaced by β-subunits with differing substrate specificities. Thus, in higher vertebrates there are constitutive and immunoproteasomes. The latter are thought to play an important role in class I antigen presentation.

Enzyme Mechanism and Proteasome Inhibitors

Whereas most proteases use serine, cysteine, or metals to cleave peptide bonds, the proteasome employs N-terminal threonines in an unusual catalytic mechanism. The N-terminal threonines, generated by self-removal of short peptide extensions from the active β-subunits during assembly of the 20S particle, act as nucleophiles during peptide hydrolysis. There are highly specific inhibitors of the proteasome. The fungal metabolite lactacystin and the bacterial product epoxomicin covalently modify the active site threonines and inhibit the enzyme. Both compounds are commercially available; other inhibitors include vinylsulfones and various peptide aldehydes that are generally less specific.

The 26S Proteasome

Whereas bacteria may possess as many as five ATP-dependent proteases, the 26S proteasome is the only ATP-dependent protease discovered so far in the nuclear and cytosolic compartments of eukaryotic cells. As the 20S proteasome's internal cavities are inaccessible to intact proteins, openings must be generated in the enzyme's outer surface for proteins to be degraded. A number of protein complexes have been found to bind the proteasome and stimulate peptide hydrolysis. The most important of the proteasome-associated

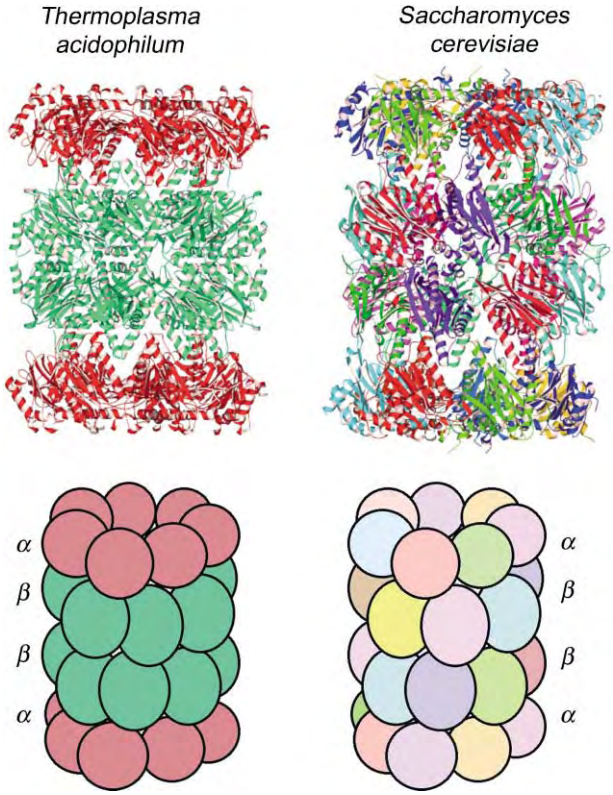

FIGURE 1 20S Proteasomes. At the top are ribbon diagrams of an archaebacterial proteasome (left) and a eukaryotic proteasome (right) as revealed by X-ray crystallography. Schematic representation of their subunit arrangements are shown below each crystal structure. Note that the archaebacterial proteasome is assembled from 14 copies of a single α-subunit and 14 copies of the same β-subunit. By contrast, the yeast 20S proteasome consists of two copies each of seven different α- and seven different β-subunits.

components is the 19S regulatory complex (RC) for it is a major part of the 26S ATP-dependent enzyme that degrades ubiquitylated proteins in eukaryotic cells (see Figure 2). As its name suggests, this 19S particle is roughly the same size as the 20S proteasome except that it is a more complex protein assemblage containing 18 different subunits. Among the RC subunits are six ATPases, an isopeptidase, a subunit that recognizes polyubiquitin chains, and a number of subunits whose functions are yet to be determined. RC subunits are arranged in two large subcomplexes, called the base and the lid. The ATPases and two other subunits comprise the base that sits directly on the end rings of the 20S proteasome; the lid is separated from the base by what appears to be a cavity. Overall the regulatory complex looks much like a Chinese dragon-head in negatively stained EM images.

Presumed Mechanism

The six ATPases in the 19S RC are members of the large family of AAA nucleotidases, whose members share the common property of altering the conformation or association state of proteins. In the case of the 19S RC ATPases, they are thought to act as "unfoldases" and translocases. Presumably ubiquitylated proteins are captured by the RC after which the ATPases unfold the bound substrate protein and thread it through the α ring of the 20S proteasome for its subsequent degradation in the central proteolytic chamber (see Figure 3). Most of the resulting peptide fragments are 5–10 residues in length, but fragments as long as 35 amino acids can be present. Furthermore, in some cases the 26S proteasome only partially degrades the substrate protein, releasing instead functionally processed domains.

How the 26S proteasome recognizes ubiquitylated proteins has not been firmly established. Ub chains containing four or more monomers are preferred substrates, and one RC subunit, called S5a, has been shown to bind polyUb. However, deletion of the gene encoding this subunit in budding yeast has only minor impact on intracellular proteolysis. Hence there must be other subunits or additional mechanisms by which the 26S enzyme recognizes polyUb-substrates. In this regard, there are recent reports that the 26S proteasome interacts directly with ubiquitin ligases or ligase-associated proteins that are ubiquitylated but not degraded. It should be noted that some non-ubiquitylated proteins are also degraded by the 26S proteasome.

Tissue and Subcellular Distribution of Proteasomes

Proteasomes are found in all organs of higher eukaryotes, but the degree to which the composition of proteasomes and its activators varies among tissues is largely unexplored territory. At the subcellular level 26S proteasomes are present in cytosol and nucleus where they appear to be freely diffusible. They are not found in the nucleolus or within membrane-bound organelles other than the nucleus. When large amounts of misfolded proteins are synthesized by a cell, they often accumulate around the centrosome in what are called "aggresomes". Under these conditions 26S proteasomes, chaperones, and proteasome activators also redistribute to the aggresomes presumably to refold and/or degrade the misfolded polypeptides.

Physiological Importance

Deletion of yeast genes encoding 20S proteasome and 19S RC subunits is usually lethal indicating that the 26S proteasome is required for eukaryotic cell viability. Known substrates of the 26S proteasome include transcription factors, cell cycle regulators, protein

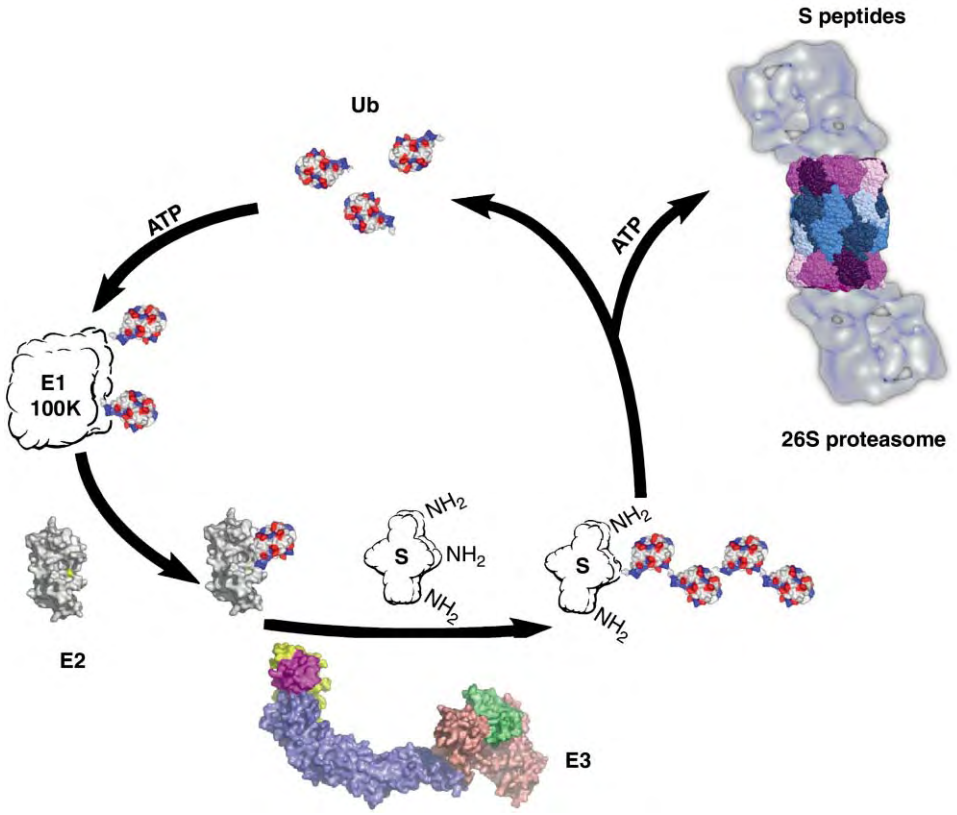

FIGURE 2 Schematic representation of ubiquitin activation and ATP-dependent proteolysis of conjugated substrates. Ubiquitin molecules are activated by an E1 enzyme in an ATP-dependent reaction, transferred to a cysteine residue (yellow) on an E2 or Ub carrier protein and subsequently attached to a substrate protein (S) by an E3 or ubiquitin ligase. Note that chains of Ub are generated on the substrate and these are recognized by the 26S proteasome depicted in the upper right at 1/20th scale.

kinases, etc., – essentially most of the cell's important regulatory proteins. Surprisingly even proteins secreted into the endoplasmic reticulum are returned to the cytosol for degradation by the 26S proteasome. Given the scope of its substrates, it is hardly surprising that in higher eukaryotes the ubiquitin-proteasome system affects a vast array of physiological processes ranging from cell cycle traverse to circadian rhythms to learning. The ubiquitin-proteasome system impacts a number of human neurological diseases that include Parkinson's, Huntington's, and Alzheimer's. Mutations in components of the ubiquitin-proteasome pathway also cause various other diseases.

Proteasome Activators

In addition to the RC there are two protein complexes, REG$\alpha\beta$ and REGγ, and a single polypeptide chain, PA200, that bind and stimulate peptide but not protein degradation by the proteasome (see Figure 4). A fourth protein, called ecm29 in yeast, associates with the proteasome. Like the RC, proteasome activators bind the ends of the 20S proteasome, and importantly, they can form mixed or hybrid 26S proteasomes in which one end of the 20S proteasome is associated with a 19S RC, and the other is bound to a proteasome activator. This latter property raises the possibility that proteasome activators serve to localize the 26S proteasome within eukaryotic cells. At present, we do not know whether activation, or targeting or something else is the primary function of proteasome activators.

REGs or PA28s

There are three distinct subunits of the 11S regulator (REG) called α, β, and γ. REGsα and β form hetero-heptamers found principally in the cytoplasm, whereas REGγ forms a homo-heptamer located in the nucleus. REGα and β are abundantly expressed in immune tissues while REGγ is highest in brain. In addition to their different locations the REGs differ in their activation properties. REG$\alpha\beta$ activates all three proteasome active sites; REGγ only activates the trypsin-like subunit. There is reasonably solid evidence that REG$\alpha\beta$ plays a role in class I antigen presentation, but we have no idea what REGγ does especially since REGγ knockout mice have almost no phenotype.

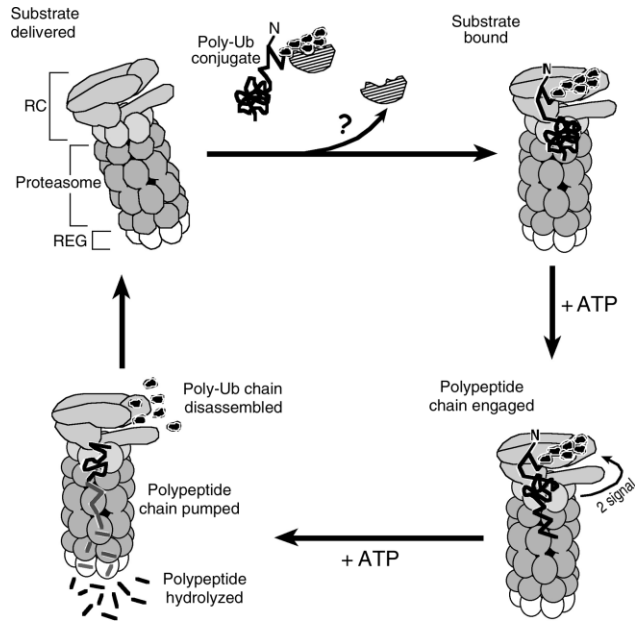

FIGURE 3 Hypothetical Reaction Cycle for the 26S Proteasome A polyubiquitylated substrate is delivered to the 26S proteasome possibly by chaperones (step 1). Substrate is bound by polyubiquitin recognition components of the regulatory complex (RC) until the end of the polypeptide chain is engaged by the ATPases (step 2). As the polypeptide chain is unfolded and pumped down the central pore of the proteasome, a signal is conveyed to the metallo-isopeptidase to remove the polyUb chain (step 3). The unfolded polypeptide is eventually degraded within the inner chamber of the proteasome (step 4) and peptide fragments exit the enzyme.

The crystal structure of REGα reveals seven subunits that form a donut-shaped structure with a central aqueous channel, and the structure of an REG–proteasome complex provides important insight into the mechanism by which REGα activates the proteasome. The carboxyl tail on each REG subunit fits into a corresponding cavity on the α-ring of the proteasome and loops on the REG subunits cause N-terminal strands on several proteasome α-subunits to reorient upward into the aqueous channel of the REG heptamer. These movements open a continuous channel from the exterior solvent to the proteasome central chamber.

PA200

A new proteasome activator, called PA200, was recently purified from bovine testis. Human PA200 is a nuclear protein of 1843 amino acids that activates all three catalytic subunits with some preference for the PGPH active site. Homologues of PA200 are present in budding yeast, worms, and plants. A single chain of PA200 can bind each end of the proteasome, and when bound, PA200 molecules look like volcanoes in negatively stained EM images. Mutation of yeast PA200 results in sensitivity to the DNA-damaging agent bleomycin, and evidence from both yeast and mammals indicates that PA200 is involved in DNA repair.

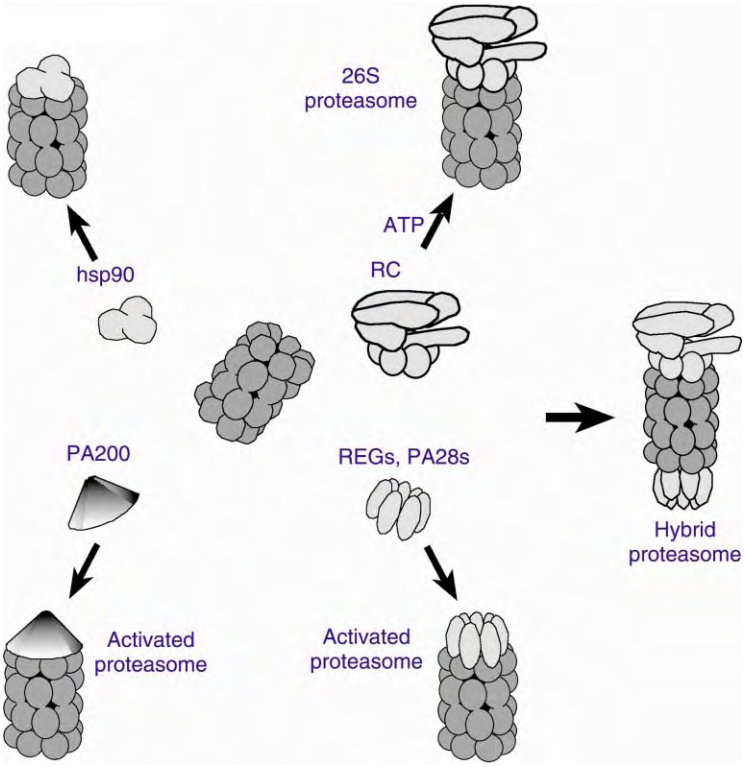

FIGURE 4 Schematic representation of the 20S proteasome assembling with various activator proteins (RC, REGs, PA200) and with the chaperone hsp90, a protein that inhibits the enzyme.

Ecm29

Another proteasome-associated protein, called ecm29p, has been identified in several recent proteomic screens. It has been reported that ecm29p serves to stabilize the yeast 26S proteasome, but the human homologue of ecm29p is found predominately associated with secretory and endocytic membranes, as per an unpublished observation by Gorbea and his associates, a location suggesting a role in secretion rather than 26S proteasome stability. Ecm29p clearly associates with the 26S proteasomes; whether it activates proteasomal peptide hydrolysis is unknown.

Protein Inhibitors of the Proteasome

Two proteins have been found to suppress proteolysis by the proteasome. One of these is PI31; the other is the abundant cytosolic chaperone, Hsp90. Both may affect how the proteasome functions in Class I antigen presentation. PI31 is a 30 kDa proline-rich protein that inhibits peptide hydrolysis by the 20S proteasome and can block activation by both RC and REG$\alpha\beta$. Although surveys of various cell lines show PI31 to be considerably less abundant than RC or REG$\alpha\beta$, when overexpressed, PI31 is reported to inhibit Class I antigen presentation by interfering with the assembly of immuno-proteasomes. A number of studies have shown that Hsp90 can bind the 20S proteasome and inhibit its chymotrypsin-like and PGPH activities. Interestingly inhibition by Hsp90 is observed with constitutive but not with immuno-proteasomes, a finding consistent with proposals that Hsp90 shuttles immuno-proteasome-generated peptides to the endoplasmic reticulum for Class I presentation.

Summary

The 20S proteasome was discovered in 1980 and its 26S version six years later. Since the 1980s, a great deal of knowledge has been gained about these two enzymes and their central importance in eukaryotic cell physiology. Still, there is much more to discover, e.g., the crystal structure of the 19S RC and the mechanism by which the 26S proteasome degrades its substrates; how the 26S proteasome is itself regulated; and the extent to which proteasomal components vary among tissues in higher eukaryotes.

Glossary

hybrid proteasome A 20S proteasome with an RC at one end and a proteasome activator at the other, essentially a 26S proteasome bound to a proteasome activator.

immuno-proteasome A 20S proteasome in which each of the three active β-subunits are replaced by interferon-γ inducible catalytic subunits.

proteasome activators Single polypeptide chains or small protein complexes that bind 20S proteasomes and stimulate peptide hydrolysis.

regulatory complex A particle containing 6 ATPases and 12 other subunits that binds the 20S proteasome to form the 26S proteasome, the eukaryotic cell's major ATP-dependent protease.

ubiquitin A small highly conserved protein that can be covalently attached to other proteins and to itself. Chains of ubiquitin target proteins for destruction by the 26S proteasome.

Biography

Martin Rechsteiner is a Professor of Biochemistry at the University of Utah. Intracellular proteolysis has been his principal scientific interest since the 1980s. During this period, the laboratory discovered and functionally characterized the 26S proteasome as well as several proteasome activators, and also proposed that PEST sequences, regions rich in proline (P), glutamic acid (E), serine (S), and threonine (T), target proteins for rapid degradation.

Protein Carboxyl Esterification

Shilpa G. Lalchandani and Jeffry B. Stock
Princeton University, Princeton, New Jersey, USA

Carboxyl methylation is a reversible protein modification that regulates cellular responses to environmental stimuli. The present article describes this process in bacterial chemotaxis and eukaryotic signal transduction proteins.

Introduction

The methylation and demethylation reactions are catalyzed by two types of enzymes; methyltransferase (Mtase) and methylesterase (MEase). The Mtase transfers methyl groups from the universal methyl donor S-adenosylmethionine (SAM), to a carboxyl group in a target protein. This converts a negatively-charged carboxylate anion on the protein surface into a neutral methyl ester with concomitant formation of S-adenosylhomocysteine (SAH). The methyl group is subsequently removed by a MEase, that catalyzes the hydrolysis of the methyl ester to restore the carboxylate anion on the target protein with the concomitant production of methanol.

$$\text{MTase}: \text{SAM} + \text{Protein} \rightarrow \text{SAH} + \text{Methylated Protein}$$

$$\text{MEase}: \text{Methylated Protein} + H_2O \rightarrow \text{Methanol} + \text{Protein}$$

The central role of carboxyl methylation in sensory receptor function was first evidenced by the discovery, that membrane receptors proteins are methylated and demethylated during bacterial chemotaxis. The involvement of methylation in sensory regulation was extended to vertebrate systems by the finding that RAS related and heterotrimeric G proteins were subject to carboxyl methylation and demethylation. Finally, an exhaustive search for additional systems of carboxyl methylation revealed a second major regulatory locus in eukaryotic cells that involves methylation and demethylation of phosphoprotein phosphatase 2A (PP2A), the major phosphoprotein phosphatase in brain.

To understand how carboxyl methylation works to regulate cellular responses to extracellular signals, it is informative to consider the role of another type of protein modification chemistry, the phosphorylation, and dephosphorylation of protein side chains. As with carboxyl methylation, protein phosphorylation is controlled by two types of converter enzymes. A kinase catalyzes the transfer of a phosphoryl group from the universal phosphodonor, ATP, to an acceptor residue at the surface of a target protein with concomitant formation of ADP, and a phosphoprotein phosphatase catalyzes the hydrolysis of the protein phosphoester with concomitant production of inorganic phosphate. Phosphorylation generally acts as a switch to control the activity of a target protein. The first example of this regulatory mechanism was obtained through studies of the regulation of hormonal control of glucose metabolism in muscle and liver. There it is shown that the release of glucose from glycogen in response to epinephrine involves the activation of a specific kinase that turns on glycogen phosphorylase by transferring a phosphoryl group from ATP to a serine hydroxyl side chain in the enzyme. This modification is later reversed by a phosphoprotein phosphatase to turn off glycogen phosphorylase under resting conditions when glucose needs to be stored. Subsequent research has shown that regulation by phosphorylation and dephosphorylation is a ubiquitous mechanism. A typical vertebrate genome encodes upward of a thousand different protein kinases whose activities are controlled by different regulatory signals, and it has been estimated that a quarter of the proteins in a typical vertebrate cell are subject to regulation by phosphorylation and dephosphorylation.

One might suppose that carboxyl methylation and demethylation would provide the same type of switching mechanism as phosphorylation and dephosphorylation, however this is not the case. Whereas phosphorylation is quite common, carboxyl methylation is rare and present at only 2% of the level of phosphorylation. There appear to be only three MTase enzymes in living systems: one in prokaryotes that methylates chemotaxis receptors, and two in eukaryotes, the G protein and PP2A MTases. Moreover, in these instances carboxyl methylation does not function as an on/off switch, but serves instead to modulate the output of a regulatory network of kinase/phosphatase switches to optimize the response to a given stimulatory input. The global regulatory role of carboxyl methylation is best understood within the context of bacterial chemotaxis.

Carboxyl Methylation in Bacterial Chemotaxis

Virtually all motile prokaryotes use the same basic mechanism to control their motor activities in response to attractant and repellent stimuli. Generally, each cell has a signal transduction apparatus composed of a cluster of thousands of α-helical hair-like fibers that traverse the cytoplasmic membrane (Figure 1). The portion of each fiber located at the outside surface of the membrane acts as a sensory receptor, interacting with specific-attractant and -repellent stimuli in the extracellular medium. The portion of the fibrous array inside the cell controls the activity of an associated protein kinase that catalyzes the transfer of a phosphoryl group from ATP to a small protein in the cytoplasm, that subsequently interacts with the motor apparatus affecting a chemotaxis response. While the cytoplasmic domains of receptor fibers and their associated kinase/phosphatase signaling enzymes are highly conserved, the extracellular sensing domains are variable depending on the particular stimuli with which they interact. The number of different sensory receptor fibers encoded in a given genome ranges from just a few, e.g., five in the case of *Escherichia coli*, to a several dozen, e.g., 46 in *Vibrio cholera*.

Stimulus-response coupling through this phosphorelay signaling apparatus is modulated by carboxyl methylation. Sequences within the cytoplasmic portions of each fiber between the membrane spanning domain and the kinase regulatory domain contain a series of at least four glutamate residues that are subject to methylation and demethylation by specific MTase and MEase enzymes. The degree of methylation of the glutamyl carboxylate side chains control the link between stimulus binding to the extracellular sensory portions of the fibrous array and the intracellular kinase. In most bacteria lower levels of methylation act to increase the cell's sensitivity to attractant stimulation. The level of methylation is controlled by several parameters including the availability of SAM and feedback from the kinase, as well as by conformational changes in the fibers induced by stimulus interactions with the extracellular sensory receptor domains. Since changes in methylation occur at a much slower rate than changes in kinase activity, methylation provides an adaptive mechanism, whereby the sensory apparatus adjusts the phosphorylation response, to fit a given background stimulus intensity. The result is analogous to light–dark adaptation in vertebrate visual systems where sensitivity is shifted in response to background light intensity.

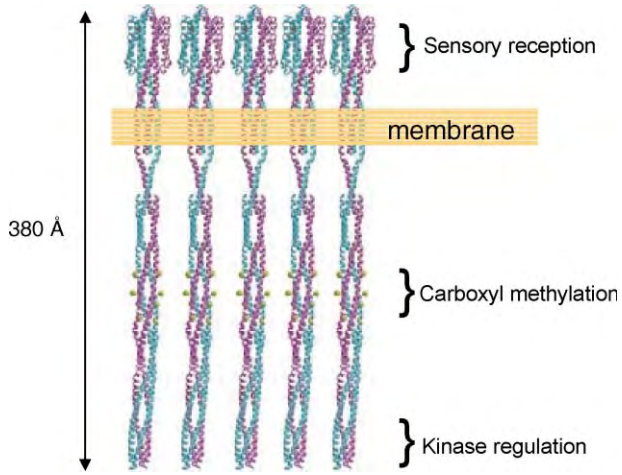

FIGURE 1 Model of the chemotaxis receptor fibers. Transmembrane methylatable receptors are employed as sensors in bacterial chemotaxis.

Carboxyl Methylation of Eukaryotic Signal Transduction Proteins

Responses of eukaryotic cells to extracellular signals is generally mediated by sensory receptor proteins that traverse the cytoplasmic membrane. Portions of these proteins at the cell surface interact with hormones and other stimuli. These interactions cause structural changes in portions of the proteins that extend into the cytoplasm, and these changes act in turn to cause associated G proteins to exchange bound GDP for GTP. The G proteins in their GTP-bound state are activated to produce second messengers such as cAMP that activate protein kinases that regulate key enzymatic activities by phosphorylating serine and threonine side chains. The phosphoryl groups are subsequently removed through the action of phosphoprotein phosphatases such as PP2A. These types of signal transduction pathways are modulated by carboxyl methylation and demethylation of alpha carboxyl groups at the C terminus of the G proteins and PP2A. Thus, although the chemistry is somewhat different, carboxyl methylation modulates receptor-mediated responses in eukaryotes just as it does in bacterial cells.

Ras-Related and Heterotrimeric G Protein

The majority of carboxyl methylated proteins in eukaryotic cells are Ras-related and heterotrimeric G proteins. These signal transduction proteins are targeted to membranes where they relay information from sensory receptors. Membrane targeting depends on a series of posttranslational modifications at the C terminus that includes prenylation, proteolytic cleavage and carboxyl methylation (Figure 2). The initial event, prenylation,

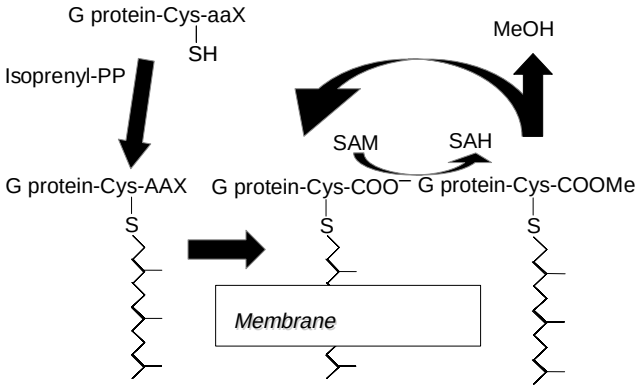

FIGURE 2 Sequence of processing events involved in isoprenylcysteine carboxyl methylation. The methylated molecules are soluble GTPases in the cytosol which are targeted to the membranes by a series of posttranslational modifications at the C-terminal that includes a prenylation, C-terminal proteolytic cleavage, and carboxyl methylation reactions.

depends on a characteristic C-terminal tetrapeptide, termed a CaaX motif, consisting of a cysteine, C, followed by two aliphatic amino acids, aa; and a final amino acid that is variable, X. The prenyl group is either a C-15, farnesyl, or C-20, geranylgeranyl, polyisoprenoid depending primarily on the nature of the C-terminal, X, residue. In either case, prenylation causes the G protein to become associated with Endoplasmic Reticulum (ER) membranes where a membrane-associated protease catalyzes the cleavage of the aaX sequence leaving a prenylcysteine alpha carboxyl group at the C terminus. This is the site of methylation by a specific MTase and demethylation by one or more MEase activities.

G protein methylation is catalyzed by an integral membrane protein that is localized in the ER. This MTase appears to have a broad specificity for prenylcysteine alpha carboxyl groups. It even catalyzes the methylation of amino acids such as N-acetyl-S-farnesylcysteine or N-acetyl-S-geranylgeranylcysteine. The rate of methylation is controlled at several levels. Whereas G protein activation leads to increases in methylation, elevated levels of SAH, feed back to inhibit MTase activity. Methylation is not required for receptor-mediated G protein signaling per se, but rather acts to modulate the stimulus response coupling. Mutant mice with MTase deletions die during early development.

Protein Phosphatase 2A

Protein phosphotase 2A (PP2A) is generally isolated as a trimeric complex consisting of three nonidentical subunits A, B, and C. The 65 kDa, A-subunit serves as a scaffold for the association of the 36 kDa catalytic C-subunit, and of regulatory B subunits. Although, AC dimers are abundant in tissue, ABC trimers of PP2A enzyme are prevalent *in vivo* and account for the main biological activities of the phosphatase. While only two isoforms of the A and C subunits have been reported so far in humans, there is a wide array of B-subunits and these B-subunits are reported to be in part responsible for the specificity of PP2A toward its numerous phosphoprotein substrates. It has been estimated that PP2A is responsible for roughly half of the total phosphoprotein phosphatase activity in vertebrate tissues. It is one of the most abundant enzymes in brain where it plays a critical role in the regulation of axonal microtubule assembly.

The PP2A catalytic subunit has a highly conserved C-terminal extension. The last six residues, TPDYFL being identical in all PP2As. The alpha carboxyl group of the C-terminal leucine residue is the site of methylation and demethylation (Figure 3). Methylation is essential for the assembly of PP2A holoenzymes. The discovery of the PP2A methylation system led to the purification and characterization of specific enzymes responsible for PP2A methylation and PP2A demethylation.

The PP2A MTase was initially purified from bovine brain as a soluble 38 kDa monomer. The enzyme appears to be completely specific for the methylation of PP2A AC dimers. PP2A methyl esters are hydrolyzed by the action of a specific MEase with similar specificity. The PP2A MEase has been purified from bovine brain as a soluble 46 kDa monomer. The MTase and MEase are highly conserved in species ranging from yeast to human.

Methylation has been demonstrated to function as a molecular switch that controls the assembly of the PP2A subunits. PP2A holoenzyme assembly could alter dephosphorylation of proteins due to changes in substrate targeting. Differential methylation of PP2A has been observed during cell cycle progression, suggesting that methylation might be altering the subcellular localization

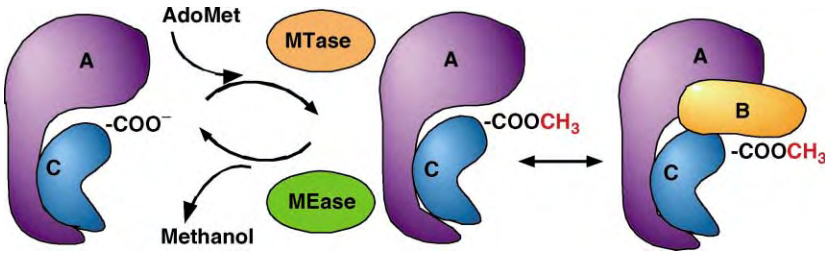

FIGURE 3 Carboxyl methylation regulates PP2A by controlling the association of regulatory B-subunits.

of PP2A. Selective microtubule-associated PP2A is differentially regulated during the cell cycle, implying that PP2A is regulated by methylation. The level of PP2A methylation is stimulated by cAMP and inhibited by SAH.

PP2A methylation seems to play an important role in growth control. Mutant yeasts that completely lack PP2A MTase activity are resistant to rapamycin and sensitive to antibiotics such as nacotazol that inhibit microtubule function. It has recently been proposed that in humans, inhibition of PP2A by SAH in brain may help explain why elevated homocysteine levels are a risk factor for Alzheimer's disease since homocysteine can condense with adenosine to generate SAH.

Protein Data Resources

Philip E. Bourne
University of California, San Diego, California, USA

Protein resources are defined here as Internet accessible data sources containing both primary data and interpretations of these data. Asking a bioinformatician to write about such resources is like asking a molecular biologist to write about cell signaling. Both are very broad and dynamic topics to which data and knowledge are constantly being added. To avoid providing a superficial view of protein resources, or a view that is going to be outdated before it is published, this article provides a description that will likely not change regardless of what new knowledge is acquired. Hence, this overview will focus on well-established resources of interest to the molecular and possibly cellular biologist. In short, the article addresses content associated with the sequence–structure–function triad, but does not address the significant amount of informatics and computational science research that goes into such resources. The number of protein resources addressing this triad is large and volatile – resources come and go. Emerging are resources that address proteins in the larger biological context through their role in biochemical pathways and in the functioning of a complete model organism. Examples of such resources are introduced to illustrate what can be expected in the future.

Primary and Secondary Resources

What are well-established resources? Well established implies the resource will likely be accessible in five years. That is, they are valuable enough to a broad community to warrant continuous financial support. Broadly speaking, established resources are of two types, primary and secondary. Primary resources are those which directly receive scientific input from the community in the form of protein sequences (usually translated from the DNA sequence), protein structures, expression data, NMR data, mass spectrometry data, measured binding constants, and so on. These data are usually annotated and curated either by humans, by machine, or by a combination of both. They form a backbone from which the study of the life sciences can proceed in an orderly way. Examples of primary resources are Genbank (primary sequences) and the protein data bank (PDB; macromolecular structure).

Secondary resources are derived using data from the primary resources and add value to this primary information either through expert opinion, computation or both. Examples of secondary resources include Swiss-Prot annotated protein sequences taken from TrEMBL and SCOP (Structure Classification of Proteins), which classifies structures from the PDB according to fold, family, and superfamily. Consider the process by which data enters and is processed by a primary and secondary resource so that the quality of these resources can be evaluated. Quality can be broadly judged by four criteria: amount, accuracy, completeness, and usability. This brief discussion does not consider usability.

The Process of Data Acquisition and Processing

We consider the PDB as an example of a primary data resource and Swiss-Prot as an example of a secondary data source.

Primary Data Acquisition – the PDB

The PDB is the single worldwide repository for data on the structure of biological macromolecules derived primarily by X-ray crystallography and NMR spectroscopy. Structural biologists submit depositions to the PDB almost exclusively through a web interface to one of three sites worldwide (Rutgers University, USA; the European Bioinformatics Institute, UK; and Osaka University, Japan). This submission comprises the final output of a program describing the atomic coordinates and any annotation provided by the depositor. The depositor immediately receives a PDB identifier which is the unique and immutable reference to that structure. The incentive to deposit comes from most journals not accepting a structure-based paper unless it includes a PDB identifier. Once received an annotator takes responsibility for processing this entry. A series of checks are performed to validate the integrity of this entry, these include the use of correct atom, residue and ligand naming, stereochemical correctness, and association of the structure with the nearest protein sequence derived

from the sequence databases. A completely annotated and validated entry is returned to the depositor usually within 1–2 working days for their approval. Either the depositor approves or a further round of refinement of the entry will ensue. Once finalized, the entry is released immediately, held until the primary paper associated with the structure is published and then released (the most common situation) or held for a maximum of 1 year. Every effort is made to make entries as complete, consistent, and accurate as possible based on the knowledge of the field at the time. The PDB in no way polices the data – the depositor always has the final say about what is released.

Secondary Data Acquisition – Swiss-Prot and TrEMBL

Swiss-Prot connects amino acid sequences with an annotated description of that protein. Each protein entry provides an interdisciplinary overview of relevant information, bringing together experimental results, computed features and sometimes even contradictory conclusions. Swiss-Prot provides annotated entries for all species, but concentrates on the annotation of entries from human and other model organisms. As a complement, TrEMBL strives to comprise all protein sequences that are not yet represented in Swiss-Prot, by incorporating a perpetually increasing level of mostly automated annotation. Consider the annotation steps associated with a Swiss-Prot entry, the source of which is TrEMBL. Much of this description is available from the Swiss-Prot web site.

The annotation steps are different depending on the source of the sequence. Sometimes scientists' isolate and then biochemically characterize the protein encoded by the gene they have sequenced. Other times they infer this information through similarity to other proteins within the same, conserved family. If it does not belong to a particular family they infer through purely sequence similarity. Finally there are the genome sequence data that often does not have an accompanying citation reporting any such classification. As a first step the sequence is aligned, using FastA or Blast, against all existing Swiss-Prot and TrEMBL entries. This determines whether the sequence can be related to existing families in Swiss-Prot. The next step is to read the article(s), assess the information given, and add relevant comments and features to the entry.

Often from reading the abstract of the paper and analyzing the FastA results the protein can be seen to belong to a particular family. In these cases, care is taken to look at other members of the family and to become familiar with the annotation that already exists. Any standard annotation that is common to the family, for example, the description line(s) and the keywords, can be added to the new entry. Other comments and features, specific to the family, can be added in conjunction with reading the paper. Any additional information from the paper, for example posttranslational modifications, is then added to the entry.

In the majority of articles reporting gene sequencing, the gene is translated to give the protein sequence but the *in vivo* protein is rarely isolated and characterized. Often a probe from a similar organism is used to pinpoint the gene and then the authors infer biochemical characteristics. In these cases, curators assess what the authors imply with the results of the alignments against Swiss-Prot and TrEMBL. When the sequence "hits" against a particular family the description line(s), the similarity comments, and keywords specific to the family, can be added to the new entry. More care is taken when looking at function, subunit, and sequence features. The annotation is then characterized as "probable," "potential," and "by similarity."

Genome sequencing has caused a massive influx of data into the nucleotide sequence databases and this has led to the same influx into TrEMBL giving thousands of entries waiting to go into Swiss-Prot. This sequence data is submitted to the nucleotide sequence databases and is reported in publications that show the entire genome sequence as well as genes that are predicted by a number of methods. Apart from these gene designations the papers rarely include experimental information about any of the predicted proteins from these analyses. By making use of what is reported coupled to the assessment of results from sequence alignments, that hit against both characterized and part-characterized protein sequences, Swiss-Prot makes an effort to add relevant biochemical information to these translated protein sequences.

In summary, established protein resources are generally staffed by knowledgeable scientists dedicated to the task of providing a worldwide community with accurate and timely information.

Data Dissemination

Currently the majority of access to protein resources is via the web, and the following sections provide details of access to a variety of resources. However, access via a web browser is by no means the only forms of access. Some resources provide bulk downloads either via ftp sites or through distribution of hard media, notably CDROM. For example, see http://www.rcsb.org/pdb/cdrom.html for receiving CDROMs of the PDB or contact datalib@ebi.ac.uk by email to receive copies of Swiss-Prot on CDROM. Users can also link to different resources from their own web pages and download data on demand, see for example, http://www.rcsb.org/pdb/

linking.html for linking to the PDB. The National Center for Biotechnology Information (NCBI) has an interesting service called Cubby to use with their Entrez integrated service. Cubby allows you to customize and store searches for future use. It is likely that in the future more protein resources will become more journal-like in that updates to the contents of the database will be provided by email in the same way the table or contents are provided by journals today. The sheer volume of data will require some prefiltering. One can imagine subscribing to a service that returns results of a user request such as "once per month send me a list of all serine/threonine kinase structures solved by X-ray crystallography to better than 2.5Å."

A Roadmap to Protein Data Resources

To anyone who has searched for protein data using a web browser it is immediately apparent there is an endless source of information, some good, some bad. Peer review is clearly needed and fortunately has been undertaken by the journal *Nucleic Acids Research* (NAR; http://nar.oupjournals.org/). NAR publishes both an annual database issue in January each year and a web server issue in July of each year. Resource developers strive to be included in these issues and reviewers carefully check the capabilities of the resource in the same way a scientific paper is considered for publication. The ever expanding list of quality resources are catalogued on-line at http://nar.oupjournals.org/cgi/content/full/31/1/1/DC1. This article considers a subset of those resources, which are considered most widely useful.

Primary Resources

As stated above, primary resources (Table I) are defined here as those that accept primary biological data through direct deposition from the author(s). These data may be supplemented by annotators adding data from the published literature and with some form of validation and cross checking. The vast majority of protein sequence data are derived from translation of DNA sequences. Sequence data ranges from data submitted on complete genomes via high throughput sequencing technologies to individual sequences submitted as part of a biochemical study to expressed sequence tags. A more complete list of resources can be found at the National Center for Biotechnological Information (NCBI; http://www.ncbi.nlm.nih.gov/Sitemap/index.html), perhaps the major keeper of biological information worldwide.

Structure data found in the PDB are derived both from high throughput structural genomics projects and more functionally driven conventional structural biology. The sequences of structures under consideration by the structural genomics projects can be found at http://targetdb.rcsb.org. The sequences of some structures awaiting release by the PDB can be found at http://www.rcsb.org/pdb/status.html.

TABLE I

Major Sources of Primary Data

Name	Description
Genbank	Primary source of DNA sequence information and coordinated with EMBL and DDBJ – http://www.ncbi.nlm.nih.gov/Genbank/index.html
PDB	Primary source of the 3D structures of biological macromolecules determined by X-ray crystallography and NMR – http://www.pdb.org
Entrez-Genome	Over 1000 genomes from bacteria, archea, and eukaryota – http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db = Genome
dbEST	Sequence data and other information on "single-pass" cDNA sequences, or Expressed Sequence Tags, from a number of organisms – http://www.ncbi.nlm.nih.gov/dbEST/

Secondary Sources

Secondary resources (Table II) in some way add value to data available through the primary resources. This occurs through processes such as provision of additional experimental data and/or additional annotation, validation, and checking, reductionism, computation of derived features, and provision of alternative views on the data. For example, for protein sequences, Swiss-Prot specializes in annotation, Pfam, SMART, and ProDOM are examples of resources that provide annotation at the level of the domain, whereas Prosite, Blocks and Prints use different methodologies to provide details at the level of short (usually functional) motifs.

For structure, PDBSum, MSD, and PDBj provide alternative views and mode of access to PDB primary data. A variety of structure classification tools exist as shown in Table II. SCOP is the most popular and classifies protein structures by fold, family (close sequence-structure-function relationship), and superfamily (structural and suggested evolutionary relationship).

Since proteins sequences outnumber structures by several orders of magnitude, yet structure provides an important linkage between sequence and function, there is a very significant effort to predict three-dimensional structure from sequence. Progress in this field is

TABLE II

Major Sources of Secondary Data

Sequence	
Swiss-Prot	Annotated protein sequence database – http://us.expasy.org/sprot/
TrEMBL	A computer-annotated supplement of Swiss-Prot that contains all the translations of EMBL nucleotide sequence entries not yet integrated in Swiss-Prot http://us.expasy.org/sprot/
Uniprot	The Universal Protein Knowledgebase is a central database of protein sequence and function by joining the forces of the Swiss-Prot, TrEMBL and PIR protein database activities – http://www.pir.uniprot.org/
Sequence – domains	
Pfam	Multiple sequence alignments and hidden Markov models covering many common protein domains and families – http://www.sanger.ac.uk/Software/Pfam/
SMART	A Simple Modular Architecture Research Tool which allows the identification and annotation of genetically mobile domains and the analysis of domain architectures – http://smart.embl-heidelberg.de/
ProDOM	A comprehensive set of protein domain families automatically generated from the SWISS-PROT and TrEMBL sequence databases – http://prodes.toulouse.inra.fr/prodom/current/html/home.php
Sequence – short sequence motifs	
Prosite	Protein families and domains with assigned functional motifs – http://us/expasy.org/prosite/
Blocks+	Blocks are multiply aligned ungapped segments corresponding to the most highly conserved regions of proteins – http://www.blocks.fhcrc.org/
Prints	A compendium of protein fingerprints – http://bioinf.man.ac.uk/dbbrowser/PRINTS/
Genomic sequence	
Ensembl	Genome browser for a number of model organisms – http://www.ensembl.org/
Structure	
PDBSum	Summaries for all protein structures including validation checks – http://www.biochem.ucl.ac.uk/bsm/pdbsum/
MSD	Database and tools for access and manipulation of PDB data – http://www.ebi.ac.uk/msd/
PDBj	Database and tools for access and manipulation of PDB data – http://pdbj.protein.osaka-u.ac.jp
Structure classification	
SCOP	The Structure Classification of Proteins – http://scop.mrc-lmb.cam.ac.uk/scop/
CATH	Class (C), Architecture (A), Topology(T), and Homologous superfamily (H) – http://www.biochem.ucl.ac.uk/bsm/cath_new/index.html
DALI	DALI Domain Dictionary – http://www.embl-ebi.ac.uk/dali/domain/
VAST	Vector Alignment Search Tool – http://www.ncbi.nlm.nih.gov/Structure/VAST/vast.shtml
CE	Polypeptide chain comparison – http://cl.sdsc.edu/ce.html
3Dee	Protein Domain Definitions – http://jura.ebi.ac.uk:8080/3Dee/help/help_intro.html
Structure prediction	
Eva	Evaluate of protein prediction servers – http://cubic.bioc.columbia.edu/eva/
LiveBench	Benchmarking of structure prediction servers – http://bioinfo.pl/LiveBench/
Protein–protein interactions	
DIP	Database of Interacting Proteins – http://dip.doe-mbi.ucla.edu/
BIND	The Biomolecular Interaction Network Database – http://www.bind.ca/

measured by the bi-annual Critical Assessment of Structure Prediction (CASP) meeting. CASP provides a blind test of how researchers worldwide are improving the ability to predict structure using comparative (homology) modeling, fold recognition (threading), and other more *ab initio* techniques. Progress in CASP is documented in a special issue of *Proteins, Structure, Function and Genetics*. A promising approach to the problem is the use of metaservers that provide a consensus view of prediction over a number of individual resources and approaches. Livebench and Eva are the most popular in this regard (Table II).

Data Reduction

The current wealth of proteomic data is both a blessing and a curse. It depends on what a user is trying to determine. If the results of a sequence search for

TABLE III
Reduced Data Subsets

Resource	Description
RefSeq	Curated, nonredundant set including genomic DNA contigs, mRNAs and proteins for known genes, mRNAs and proteins for gene models, and entire chromosomes – http://www.ncbi.nlm.nih.gov/RefSeq/
Astral	Nonredundant structure subsets at different levels of sequence identity – http://astral.stanford.edu/

homology returns hundreds of near identical sequences it may confuse the result rather than lead to a meaningful solution. Nonredundancy can assist in this regard by providing a filtered set of data. The issues then become the level of redundancy retained, the type of redundancy and the choice of a representative. Table III outlines the two common sources of reduced sequence and structure data. It should be noted that protein sequence redundancy is different than protein structure redundancy. Two protein sequences sharing a sequence identity of over 30% will likely share the same fold. However, structures with the same fold could have a sequence identity of less than 10% – the evolutionary drift of sequences is greater than that of structure. A key issue is then redundancy with respect to what. Table III describes two resources dealing with sequence redundancy, RefSeq provides a set of reference sequences and Astral a set of reference structures filtered by sequence identity and with an effort to select the most accurate structure as a representative. Some of the resources under structure classification in Table II provide a nonredundant set of structures with respect to the three-dimensional structure, not the sequence.

Consistent Annotation

Comparison of data, either within a given resource or certainly across resources, requires consistent annotation. This presents a very significant problem across molecular biology and thus with protein data. For example, there are issues of multiple common versus systematic names for proteins, lack of a singular systematic description at the time the protein was discovered and lack of the use of systematic nomenclature even when it exists. The use of International Union of Pure and Applied Chemistry (IUPAC; http://www.iupac.org) descriptors for chemical descriptions helps, as does the use of Enzyme Commission (EC; http://us.expasy.org/enzyme/) numbers for describing enzymes. Most recently, thanks to the work of database developers in recognizing the need for standardization, the Genome Ontology (GO) has been developed by the GO Consortium (http://www.geneontology.org/). GO provides consistent descriptions for biochemical process, molecular function, and cellular location in the form of a directed acyclic graph. That is, a node can have multiple parents, for example, a given protein can have multiple functions. Many of the resources described in Table I and II now assign GO annotation to their entries.

TABLE IV
Integrated Resources

Resource	Description
InterPro	InterPro is a database of protein families, domains and functional sites – http://www.ebi.ac.uk/interpro/
Entrez	Integrated scientific data and literature – http://www3.ncbi.nlm.nih.gov/Entrez/
Kegg	Kyoto Encyclopedia of Genes and Genomes – http://www.genome.ad.jp/kegg/kegg2.html
AfCS	The Alliance for Cell Signaling – http://www.afcs.org/
SRS	Sequence Retrieval System – http://srs.ebi.ac.uk
EcoCyc	Integrated description of *E. coli* – http://www.ecocyc.org

Integrated Resources

A number of cross-referenced resources which include primary and secondary protein data have been developed. Table IV provides a flavor of the wide variety of resources available. Usually this integration is achieved by sequence comparison between resources and subsequent cross checking of information like GO terms. Such cross checking also reveals errors in these databases. InterPro combines data from PROSITE, PRINTS, Pfam, SMART, TIGRFAMs, PIR SuperFamily, and SUPERFAMILY (sequence-motif methods) and ProDom (a sequence cluster method). Entrez combines a variety of sequence and structure data with the literature described mostly as abstracts in PubMed. SRS links a large variety of biological databases (over 200) and is a good place to start to explore resources in general, since the majority of major resources are cross referenced here.

The Future

A compendium of protein sequences or structures is not how a biologist thinks about a problem. Rather they often see a protein as part of a network of interactions with one or more roles that can be measured by a biochemical or phenotypic response, where the data associated with that response can be downloaded and further analyzed. Resources that place proteins as part of a pathway or more specifically in the correct biological

context are likely to be more common in the future. Several exist today (Table IV) and offer a window into what will become commonplace in the next five years. Ecocyc provides literature-based curation of the entire genome of *Escherichia coli* K12 MG1655 including transcriptional regulation, transporters, and metabolic pathways. The Alliance for Cell Signaling is modeling signaling pathways in several organisms and Kegg offers an integrated view of pathways and genomic data.

Clearly the challenge of the future is not having appropriate data, rather how to make the best use of the wealth of data in a way that it can be interpreted by those scientists who can gain most from it. At the same time traditional publishing models are changing through the use of the Internet and Open Access models. One can imagine a future in which the traditional journal article is merely one type of user interface to the data. Interesting times indeed!

Biography

Philip E. Bourne is a Professor in the Department of Pharmacology, University of California, San Diego and Co-Director of the Protein Data Bank. He is a former President of the International Society for Computational Biology and a Fellow of the American Medical Informatics Association. He received his Ph.D. from the Flinders University of South Australia. His research interests are broadly in the area of structural bioinformatics and the application of high performance computing technology to problems in the life sciences.

Protein Degradation

Tomo Šarić
Institute of Neurophysiology, University of Cologne, Cologne, Germany

Alfred L. Goldberg
Harvard Medical School, Boston, Massachusetts, USA

Nearly all proteins within cells and most in the extracellular space are in a state of continuous turnover, being synthesized from amino acids and, after varying life spans, broken down back to amino acids. The term "protein degradation" refers to several intracellular processes by which proteins are broken down to their basic constituents. Protein degradation occurs in all living species, from bacteria to humans, and is mediated by the sequential action of several endo- and exopeptidases.

Essential Biological Functions of Protein Degradation

Because cells use significant amount of energy for new protein synthesis, the continual destruction of proteins might appear highly wasteful. However, this process serves multiple important biological functions that are essential for life. The degradation of intracellular proteins is a highly selective and tightly regulated process that is required for removal of many regulatory proteins (transcription factors and signal transducers) and many key rate-limiting enzymes, whose rapid degradation is essential for maintaining cellular homeostasis.

Unlike most regulatory mechanisms (e.g., phosphorylation, ubiquitylation), peptide bond cleavage is an irreversible process, and proteases therefore act as unidirectional biological switches. The only way that cells can reduce the steady-state level of a particular protein is by proteolytic degradation, and removal of certain proteins permits cells to adapt to changes in cellular environment and new physiologic conditions. This kind of adaptation occurs in mammals, for example, in the liver during fasting when enzymes for glycogen production are removed and enzymes required for gluconeogenesis are up-regulated.

Under fasting conditions, protein breakdown also serves as a source of essential amino acids, especially in skeletal muscle, where it provides essential precursors for gluconeogenesis, protein biosynthesis, or energy production. Protein breakdown functions also as a quality control mechanism that selectively removes abnormal proteins resulting from mutation, chemical damage (e.g., oxidation), biosynthetic errors (e.g., premature termination of translation), or failure of normal folding or assembly (which may be a common event in cytosol and endoplasmic reticulum).

Most extracellular proteins (such as plasma proteins) also continuously turn over, mainly by uptake and degradation inside the cells. In higher vertebrates, protein degradation is critical for the function of the immune system. Proper defense against intracellular pathogens (e.g., viruses) or pathogens in the extracellular space (e.g., bacteria) is dependent on continual production of peptide antigens by intracellular proteolytic pathways. In eukaryotic cells, there are two principal pathways for complete degradation of proteins: endocytic–lysosomal and the ATP-dependent ubiquitin–proteasome pathway. The former occurs within the membrane-enclosed vesicles and the latter operates in the cytosol and nucleus. These pathways involve very different enzymes and serve different functions in the cell. Proteolytic systems are also present in some organelles (e.g., mitochondria). Bacteria and archaea do not have lysosomes or ubiquitin but, nevertheless, possess soluble or membrane-bound proteases, many of which are evolutionary precursors of more sophisticated eukaryotic enzymes. One critical feature of all these intracellular degradative systems is that they require metabolic energy, unlike the typical proteases functioning in the extracellular space. As explained in this article, energy-dependent processes help insure exquisite selectivity and allow regulation of the proteolytic enzymes.

Endocytic–Lysosomal Pathway

This pathway is responsible for degradation of extracellular proteins, most membrane proteins, some organelles, and some intracellular proteins. It is composed of heterogeneous groups of vesicles that differ in

morphology, function, and biochemical and biophysical properties. The principal component of this pathway where most protein degradation takes place is the lysosome (or the vacuole in yeast).

Lysosomes

Lysosomes are single membrane-bound spherical organelles in the cytoplasm. They were discovered by Christian de Duve and co-workers in the mid 1950s and are found in all mammalian cells except red blood cells. Lysosomes are not found in higher plants, but the plant cell vacuole performs some of their degradative functions. Lysosomes play an important role in innate immunity, adaptation to stress or starvation, recycling of cytoplasmic organelles, development, cell differentiation, and some forms of programmed cell death.

Uptake of Substrates

Lysosomes receive substrates for degradation by fusing with other intracellular vesicles that are formed by endocytosis (endosomes, pinosomes, phagosomes) or autophagy (autophagosomes). Endocytosis refers to the process of uptake of extracellular material or membrane proteins by invagination of the cell membrane, followed by formation of vesicles inside the cell. Before these vesicles reach the lysosomes (pH 4.5–5.0), ingested material moves from the less acidic early endosomes (pH 6.0–6.5) to the more acidic late endosomes (pH 5.0–6.0). There are three major forms of endocytosis: (1) receptor-mediated endocytosis (uptake of membrane proteins, such as cell surface receptors and their ligands), (2) pinocytosis (ingestion of extracellular liquid with its solute molecules), and (3) phagocytosis (engulfing of large particles such as bacteria or apoptotic bodies by specialized cells such as neutrophils, macrophages, or amoeba) (Figure 1). Pinocytosis and phagocytosis are nonselective bulk processes, but receptor-mediated endocytosis is a specific, regulated cellular process that is used, for example, by most cells to take up extracellular products (e.g., lipoproteins, transferin) or to reduce the levels of surface receptors (down-regulation) after receptors are occupied by ligands, or by some cells, such as B lymphocytes, to internalize antigens using antibodies on the cell surface as receptors. Autophagy is regulated, but nonselective, digestion of intracellular material (Figure 1). It serves an adaptive role in response to nutritional deprivation and stress and is responsible for digestion of some cytosolic proteins and redundant or damaged intracellular organelles, such as mitochondria and peroxisomes. In addition, some cytosolic proteins that contain specific amino acid motifs (e.g., KFERQ) are transported into lysosomes selectively through a specific energy-, chaperone-, and receptor-mediated process that is activated by nutrient deprivation (Figure 1).

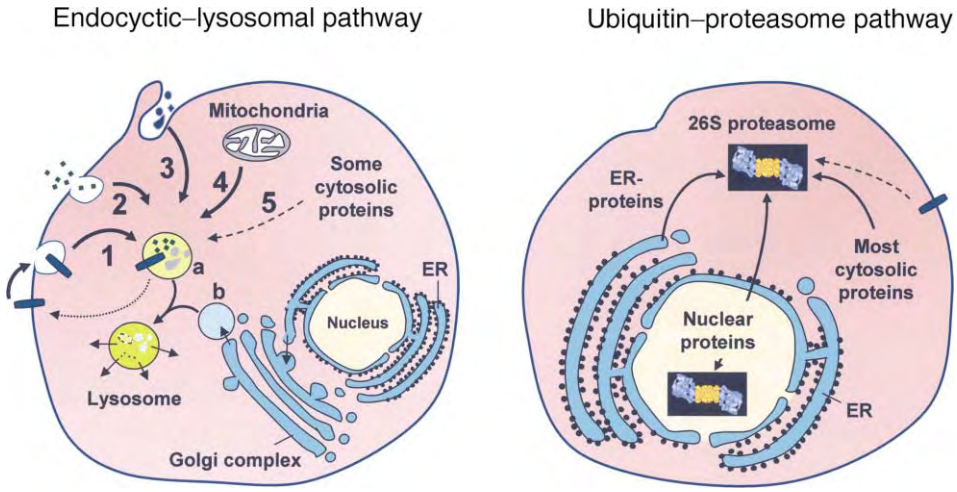

FIGURE 1 Pathways of protein breakdown in mammalian cells. Most intracellular proteins in the cytosol, nucleus, and endoplasmic reticulum (ER) are degraded by the ubiquitin–proteasome pathway (right panel). Extracellular and autophagocytized proteins and most membrane proteins are broken down within the endocytic–lysosomal compartment (left panel). Substrates are delivered to this pathway by receptor-mediated endocytosis (1), pinocytosis (2), phagocytosis (3), autophagy (4), and a selective process for some cytosolic proteins containing specific amino acid motifs (5). Some internalized membrane proteins are recycled back to the plasma membrane (dotted arrows). After the internalized material is enclosed in vesicles (a), the vesicle fuses with primary lysosomes (b), derived from the Golgi complex and ER, to form secondary lysosomes where final degradation takes place. Degradation products are transported across the lysosomal membrane into the cytosol. Some plasma membrane proteins are broken down by the ubiquitin–proteasome pathway, and some cytosolic proteins are degraded in lysosomes (dashed arrows). Although worn out mitochondria are cleared by autophagy, mitochondrial proteins are selectively broken down by their own ATP-dependent proteases.

Lysosomal Enzymes

Lysosomes contain at least 50 different hydrolytic enzymes, which catalyze the breakdown of proteins, nucleic acids, carbohydrates, and lipids into their components. Lysosomal hydrolases normally cannot escape into the cytoplasm and their isolation in this vesicular compartment is essential for protecting from nonspecific degradation of key cell constituents. However, during necrotic cell death, lysosomes release their content, which helps destroy the cell. Release of lysosomal enzymes outside of cells causes severe inflammation and contributes to the symptoms of some diseases (e.g., gout). Most lysosomal enzymes are optimally active at an acidic pH of 4–6, which is maintained by a cell membrane hydrogen ion ATPase. Many lysosomal proteases are traditionally called cathepsins, and most belong to the mechanistic family of cystein proteases. The most abundant proteases are cathepsins D and L (endopeptidases) and cathepsins B and H (exopeptidases). The acidic milieu in lysosomes not only keeps lysosomal enzymes at their most active state, but it also helps denature protein substrates, which enhances their susceptibility to proteolytic digestion. Once the protein substrates are degraded, the products of their digestion are transported across the membrane into the cytosol, where they are further metabolized.

Additional Roles of the Endocytic Pathway

The endocytic–lysosomal pathway plays an important role in maintaining the structural integrity of plasma membrane by continuously recycling internalized membranes and some membrane receptors back to the cell surface. In addition, in specialized antigen-presenting cells (macrophages, dendritic cells, and B cells), some peptides derived from breakdown of extracellular proteins escape complete destruction and are bound in late endosomes by specialized membrane receptors, called major histocompatibility (MHC) class II molecules. These complexes are transported to the cell surface for presentation to a subpopulation of T lymphocytes responsible for generation of humoral immune responses against non-native proteins, e.g., ones from pathogens.

Ubiquitin–Proteasome Pathway

Most cytosolic and nuclear proteins are degraded by the ubiquitin–proteasome pathway (Figure 2). This system catalyzes the breakdown of most normal long-lived proteins, which comprise the bulk of proteins in cells, and many short-lived proteins that regulate a wide variety of essential cellular processes, ranging from cell cycle progression to signal transduction and gene transcription. In addition, it catalyzes the selective and rapid elimination of damaged, misfolded, or mutated proteins, which are continuously produced due to imperfections of biosynthetic and folding machineries in the cell. The discovery of the ubiquitin–proteasome pathway resulted from the finding that the breakdown of intracellular proteins was ATP-dependent, which was surprising because the peptide bond cleavage *per se* does not require energy. Biochemical dissection of this pathway in the early 1980s revealed that it consists of two ATP-dependent processes: the conjugation of a small protein ubiquitin to proteins that marks them for degradation, and the hydrolysis of ubiquitylated proteins by the very large proteolytic machine, the 26S proteasome (Figure 2), (S refers to Svedberg – the unit of time used to measure velocity at which the protein sediments in a centrifuge).

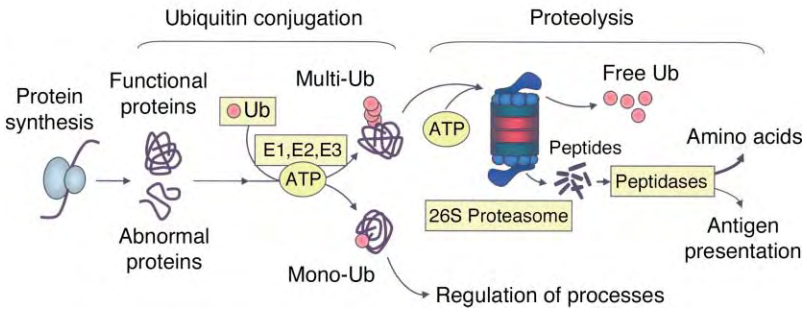

FIGURE 2 Ubiquitin–proteasome pathway for degradation of intracellular proteins. In eukaryotic cells, the site for degradation of most intracellular proteins is a large proteolytic particle, termed the 26S proteasome. Protein substrates destined for degradation by the 26S proteasome are first polyubiquitylated in ATP-dependent manner in a series of reactions involving at least three groups of enzymes (see text for details). Polyubiquitylated substrates are rapidly hydrolyzed by the 26S proteasome and monomeric ubiquitin is recycled by the action of deubiquitinating enzymes. The energy of ATP is required for ubiquitin conjugation, binding, and unfolding of a substrate and its translocation into the inner cavities of the proteasome. Most peptides produced by proteasomes are further degraded to amino acids by endo- and exopeptidases in the cytosol and nucleus, but a small fraction of peptides escapes complete hydrolysis and are utilized for MHC class I antigen presentation. Some proteins are conjugated to only a single ubiquitin molecule. This modification does not mark proteins for degradation by proteasomes but is utilized for regulation of cellular processes, such as endocytosis and transcription.

Ubiquitin Conjugation

Formation of Polyubiquitin Chains

In order to be degraded by 26S proteasomes, most intracellular proteins must be first conjugated to a chain of ubiquitin molecules. This process ensures that only selected substrates are degraded in a regulated manner and prevents the uncontrolled degradation of other cellular proteins. Ubiquitin is a 76-residue globular protein, which is present only in eukaryotic cells, and not in bacteria and archaea, where highly selective protein degradation is achieved through ATP-dependent proteolysis independent of ubiquitin. Ubiquitin conjugation to other proteins and the formation of polyubiquitin chains is mediated by the sequential action of three types of enzymes, called E1 (ubiquitin-activating enzyme), E2s (ubiquitin-conjugating enzymes or ubiquitin-carrier proteins) and E3s (ubiquitin-protein ligases). In this process, the single E1 enzyme activates ubiquitin in an ATP-dependent reaction by forming a highly reactive thiolester linkage between the C terminus of ubiquitin and the thiol group in the active site of the E1. The activated ubiquitin is then passed from the E1 to a sulfhydryl group on one of the cell's $\sim$30 E2s. Next, the activated ubiquitin molecules are linked to a lysine side chain or, in some cases, to the N-terminal amino group in the substrate protein, directly from the E2 (or in some cases after transfer of ubiquitin from the E2 to the E3). A single E2 may function with multiple E3s to provide specificity in a combinatorial fashion. Cells contain hundreds of distinct E3s. These enzymes are the main determinants of substrate specificity and are capable of recognizing a few or multiple substrates through specific degradation signals. E3s are soluble or membrane-bound proteins; some are monomeric enzymes containing distinct domains for binding a substrate and a specific E2 enzyme, while others are very complex oligomeric structures in which different subunits subserve different functions required for highly specific and efficient substrate recognition and ubiquitylation. A polyubiquitin chain is synthesized by linking new ubiquitin molecules to previously conjugated ubiquitin through its lysine residues. In most cases, proteasomal degradation requires formation of ubiquitin chain where ubiquitin molecules are linked to lysine 48, but other types of ubiquitin chains exist in cells and serve other regulatory roles distinct from proteolysis. Once conjugated to chains of four or more ubiquitins, proteins are degraded by 26S proteasomes. Ubiquitylation of certain cell surface receptors (e.g., growth factor receptors) results in their internalization and degradation in lysosomes, but not in proteasomes.

Mechanisms of Substrate Recognition

Ubiquitylation of proteins is triggered by various features of the substrates that act as signals (the so-called "degrons") that are recognized by the E3 and thus decrease the stability of the protein in the cell. These structural features can be constitutive elements in the substrate itself (e.g., a specific N-terminal amino acid residue or a short internal sequence of amino acids in a target protein) or can be acquired covalent modifications. Phosphorylation of substrates is one of the frequently employed acquired signals that regulate protein ubiquitylation. In many instances, this modification leads to direct recognition of a substrate by the specific E3, but, in some cases, phosphorylation of a substrate can inhibit ubiquitylation. Phosphorylation-dependent ubiquitylation is responsible for degradation of IκB during inflammatory response and of the various cyclins that control progression through the cell cycle. Other types of posttranslational protein modifications can either prevent or stimulate ubiquitylation, including acetylation, glycosylation, or attachment of small ubiquitin-like proteins, SUMO-1 or Nedd8. An interesting posttranslational modification that induces ubiquitylation of a substrate is hydroxylation of proline residues in the transcription factor HIF1-α, which plays an important role in transcriptional adaptation to hypoxia. Under normoxic conditions, two prolines in HIF1-α are readily hydroxylated, leading to its recognition and ubiquitylation by the specific E3. In yet another scenario for substrate recognition, association of the substrate with an adapter protein is required for its recognition and ubiquitylation by the specific E3 enzyme. This strategy is particularly exploited by some viruses. The best example is the E6/E6-AP-mediated ubiquitylation of p53. The selective degradation of unfolded proteins involves their initial recognition and binding by specific molecular chaperones and a chaperone-dependent E3, termed CHIP. For most substrates, degradation signals have not yet been defined. For example, it is unclear how cells recognize and selectively degrade abnormal proteins or normal myofibrilar proteins in skeletal muscle during muscle atrophy.

Deubiquitination

Ubiquitin conjugation to cellular proteins is a reversible process and is mediated by deubiquitinating enzymes, which are all cystein proteases. They catalyze the continuous disassembly of ubiquitin conjugates during degradation of ubiquitin-conjugated proteins by the 26S proteasome. They must play important roles in recycling monomeric ubiquitin for use in new conjugation reactions, and in preventing the accumulation of free polyubiquitin chains that could act as competitive inhibitors of the binding of ubiquitylated substrates to

the proteasome. These enzymes also probably serve as a proofreading system, which insures that no erroneous ubiquitylation of substrates takes place. Mutations in deubiquitinating enzymes can cause neuronal degeneration and may contribute to the occurrence of cancer.

Protein Degradation

The 26S Proteasome

Proteasomes are abundant evolutionarily highly conserved multimeric structures localized in the cytosol and nucleus of all eukaryotic cells. The proteasome complex responsible for degradation of ubiquitylated proteins is termed the 26S proteasome, which consists of the 20S core particle and one or two regulatory 19S particles (Figure 3).

The 20S Core Particle In eukaryotes, the 20S proteasome is a hollow cylinder and consists of four stacked rings, each containing seven homologous subunits. There are two identical outer α-rings and two identical inner β-rings (Figure 3). Three of the subunits in each inner β-ring contain the proteolytic active sites. The outer α-rings surround the narrow openings into the 20S particle at either end, through which substrates can enter into the inner proteolytic chamber. These openings are tightly regulated and protein access is enabled through the association of α-rings with different regulatory particles. This closed architecture with isolated active centers evolved to prevent the uncontrolled destruction of needed cell proteins. The proteasomal active sites in β-rings are confined to the interior of the cylinder where proteins are degraded. Each of the three active subunits has a different catalytic activity: one cleaves preferentially after basic amino acids in a protein substrate, one after large hydrophobic residues, and one after acidic residues. The active site nucleophile of the proteasome is the hydroxyl group of the threonine at the amino terminus of the β-subunit, and proteasomes thus belong to a novel mechanistic class of threonine proteases. The existence of this new type of proteolytic mechanism, not utilized by other known proteases, has enabled the synthesis of highly specific proteasome inhibitors. They are now an irreplaceable research tool and are very promising in clinical trials to treat myeloma and other cancers, and in animals have dramatic effect against diseases such as arthritis and stroke.

19S Regulatory Particle The 19S particle consists of at least 18 different subunits and associates with α-rings on one or both ends of the 20S proteasome. Two functionally different substructures of this complex have been distinguished: the base and the lid (Figure 3). The base, which touches the α-rings of the 20S core

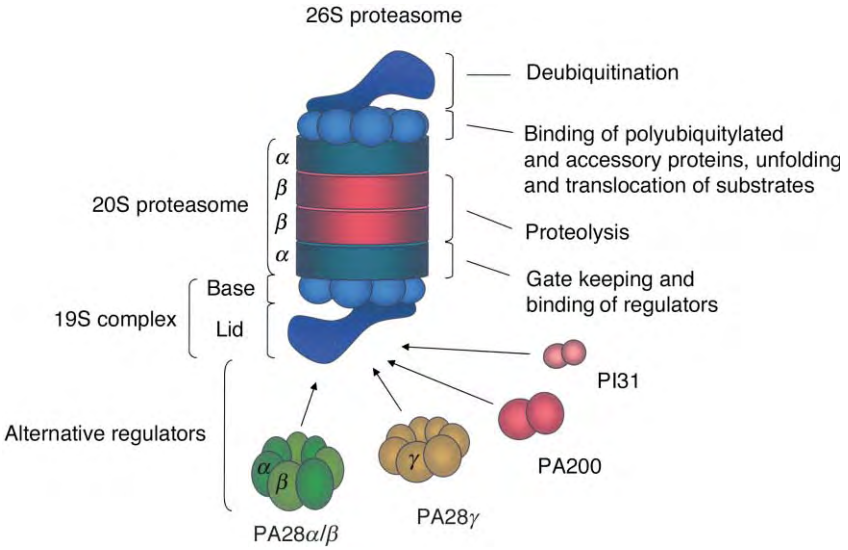

FIGURE 3 The 26S proteasome and its regulatory components. The 26S proteasome consists of the 20S core particle and one or two regulatory 19S particles. Different structures comprising the 26S proteasome carry out distinct functions (as detailed in the illustration). In addition to 19S regulators, eukaryotic 20S proteasomes can also associate with other ring-forming complexes, such as PA28α/β or PA28γ, or simpler proteins (PA200 or PI31). PA28α/β is a heptameric ring composed of α- and β-subunits. It promotes opening the channel enclosed by α-rings of 20S proteasomes. PA28γ is related to α- and β-subunits of PA28α/β and forms a homoheptameric complex that binds to 20S proteasomes and activates mainly the cleavages after charged residues in peptide substrates. It is predominantly found in the nucleus and, in some cells, is down-regulated by interferon γ. Its biological function is still not well understood. PA200 is a recently discovered 20S proteasome-interacting protein of 200 kDa that is localized in the nucleus. The mechanism of its association with proteasomes is not well understood, but like PA28, it activates only peptide hydrolysis by proteasomes. It appears to play a role in DNA repair by recruiting proteasomes to damaged DNA. PI31 is a homodimeric protein that was discovered by its ability to inhibit peptide hydrolysis by 20S proteasomes *in vitro*. Recent *in vivo* data suggest that this protein does not affect proteasome-mediated proteolysis but rather interferes with MHC class I antigen presentation by slowing maturation of immunoproteasomes.

particle, contains eight polypeptides including six ATPases that form a ring. These ATPases bind substrates and use the energy of the ATP to unfold protein substrates, open the gate in α-rings, and promote rapid translocation of substrates into the 20S core particle for degradation. The base of the 19S particle also contains surfaces responsible for transient binding of: (1) polyubiquitin chains, (2) deubiquitinating enzymes, and (3) ubiquitin-like domains of various adaptor proteins that may function in bringing ubiquitylated substrates to close proximity of proteasomes. The lid contains eight non-ATPase subunits of unknown function. This structure is required for proteolysis of ubiquitylated proteins, probably through interaction with the polyubiquitin chain.

Immunoproteasome and Hybrid Proteasome

In higher vertebrates that have an immune system, a small fraction of peptides generated by proteasomes is not completely degraded to free amino acids but instead transported into the ER, where they associate with specific membrane-bound MHC class I molecules and are subsequently transported to the cell surface. The immune system is continually surveying the surface of all cells for non-native peptides originating from viral or mutated proteins. If cells carrying such non-native peptides are encountered, they are rapidly destroyed by cytotoxic T-lymphocytes. Proteasomes found in most of the tissues (the so-called constitutive proteasomes) contribute to the generation of basal levels of antigenic peptides in the absence of infection. However, during inflammation, two additional types of proteasomes appear to play a major role in enhancing MHC class I antigen presentation and are termed immunoproteasomes and hybrid proteasomes. They are normally found in lymphoid tissues (e.g., spleen and thymus), but are induced in other tissues during infection in response to the cytokine interferon γ. Immunoproteasomes are formed by replacement of all three catalytic β-type subunits in constitutive proteasomes with alternative proteolytically active β-subunits. The alternative immunosubunits possess qualitatively different cleavage specificities than constitutive β-subunits and appear to play a major role in increasing the supply of appropriate peptides for MHC class I antigen presentation. Hybrid proteasomes are formed when 20S immunoproteasomes are capped on one side with the 19S particle and on the other side with an alternative protein complex, called PA28α/β (Figure 3). Most probably, in these hybrid particles, ubiquitylated substrates initially bind to the 19S regulator and peptide products are released at the opposite side through the PA28α/β that apparently promotes opening the channel enclosed by α-rings and allows generation of peptide fragments particularly suitable for MHC class I antigen presentation during inflammation.

Mechanism of Protein Degradation

Although the exact sequence of events in which proteins are degraded by 26S proteasomes is not fully understood, a rough outline of steps can be provided. Upon binding of the polyubiquitylated substrate by the proteasome, the substrate is first unfolded in an energy-dependent manner by the action of ATPases localized in the base of the 19S particle. Recent data suggest that proteins are unfolded prior to their translocation into the proteasome's inner cavity. Conformational changes induced by hydrolysis of ATP promote opening the gate in α-rings followed by translocation of the unfolded substrate into the inner chambers of the proteasome. Successful translocation of the substrate must follow disassembly of polyubiquitin chain by deubiquitinating enzymes attached to the 19S particle. Translocation can occur from its free amino or carboxyl terminus, depending on the substrate, or even internally by the process in which a polypeptide loop enters the axial channel to permit initial endoproteolytic cleavage. In some cases, proteasomes degrade substrates only partially, yielding biologically active protein fragments, like in the generation of the p50 subunit of the transcription factor NFκB from the larger precursor and in the processing and activation of some membrane-bound transcription factors. Once in the central chamber of the 20S particle, the substrate is cleaved by six catalytic subunits into small peptides ranging from 3 to 25 residues in length. Unlike traditional proteases, the proteasome does not simply cleave a protein and release the partially digested fragments; on the contrary, a protein substrate, once bound by the proteasome, is cut until small peptides are generated. This behavior ensures that partially digested proteins do not accumulate within cells. The product release may be facilitated in some cells by PA28α/β, as well as by hydrophobic products themselves which can trigger gate opening in α-rings. In eukaryotic cells, the products generated by proteasomes appear to be hydrolyzed into amino acids by the sequential actions of endopeptidases and aminopeptidases. The whole process of degradation of one molecule of the protein substrate requires several hundred molecules of ATP and is completed in a matter of seconds or minutes, depending on the size of a substrate. Generally, subtrates must be first ubiquitylated in order to be degraded by proteasomes. However, 26S proteasomes can degrade certain substrates *in vivo* (e.g., ornithin decarboxylase associated with cofactor antizyme) and many polypeptides *in vitro* (e.g., denatured casein, aged calmodulin) in ubiquitin-independent manner. It still remains uncertain whether *in vivo*

TABLE I

Disturbances of Ubiquitin-Dependent Proteolysis in Human Disease

Protein substrate	Disease	Mechanism
Increased proteolysis		
p53	Cervical carcinoma	E6/E6-AP-mediated degradation of p53
$p27^{Kip1}$	Colorectal/breast Ca.	Enhanced degradation of a cell cycle inhibitor
IκB	Inflammation	Activation of NFκB transcription factor
CFTR	Cystic fibrosis	Point mutation in CFTR, misfolding and degradation through ERAD
MHC class I heavy chain	Cytomegalovirus infection	Down-regulation of MHC class I by viral proteins
Most muscle proteins	Muscle atrophy, cachexia	Up-regulation of an SCF E3, Atrogin-1, and the RING finger E3, MurF-1
Decreased proteolysis		
HIF1-α	von Hippel–Lindau disease	Mutation in SCF E3, VHL
ENaC	Liddle syndrome	Mutation in HECT E3, NEDD4
Receptor tyrosine kinases	Cancer	Mutation in RING finger E3, c-Cbl
α-synuclein, unknown	Parkinson disease	Mutation in RING finger E3, Parkin
Unknown	Angelman syndrome	Mutation in HECT E3, E6-AP
α1-antitrypsin	Liver disease in some α1-antitrypsin deficient patients	Decreased degradation of mutated α1-antitrypsin by ERAD pathway
Epstein–Barr virus nuclear antigen 1 (EBNA1)	Epstein–Barr virus-associated malignancies	Immune evasion due to lack of EBNA1 degradation

there are more proteins that are degraded in ubiquitin-independent manner.

Endoplasmic Reticulum-Associated Degradation (ERAD)

Many newly synthesized proteins are translocated into the lumen of the ER or are inserted into the ER-membrane. They may remain in the ER or be exported into other organelles, or the cell surface membrane or be secreted into the extracellular space. The ER contains an abundant set of chaperones and enzymes that assist newly synthesized proteins in attaining their correct conformation and activity, but sometimes, this maturation process fails and misfolded proteins are generated. Such abnormal proteins are effectively removed so as not to aggregate and form potentially toxic inclusions and the process of their disposal is often called ER-associated degradation (ERAD). In this process, misfolded proteins are retrotranslocated from the ER back into the cytosol, where they are ubiquitylated and degraded by 26S proteasomes. This export is necessary because the ER does not contain proteolytic enzymes necessary for protein degradation. ERAD is used by some viruses to down-regulate MHC class I molecules in the ER (e.g., cytomegalovirus) as a means of viral evasion of the immune system. In addition, disturbances in ERAD pathway can cause serious human disease, such as cystic fibrosis or a form of α1-antitrypsin deficiency (Table I).

Proteolysis in Mitochondria

As in the cytosol and nucleus, proteins in mitochondria also have different half-lives and mitochondria can selectively degrade abnormal proteins. Although mitochondria as a whole can be degraded in lysosomes by autophagy, this process is nonselective and cannot account for different turnover rates of regulatory mitochondrial proteins. Since the matrix and the inner membrane of mitochondria are not accessible to cytosolic proteases, these sites harbor their own autonomous proteolytic system, which consists of several evolutionarily conserved ATP-dependent proteases. This system has dual functions; it mediates complete degradation of nonassembled or misfolded proteins, and it enables selective proteolysis of specific normal regulatory proteins that are important for the maintenance of mitochondrial functions. The matrix of mammalian mitochondria contains two kinds of soluble proteases that are homologous to eubacterial Lon and ClpXP proteases and responsible for degradation of matrix proteins. The mitochondrial inner membrane of all eukaryotic cells has two proteases that belong to the AAA superfamily of ATPases, termed *i*-AAA

(*i*, intermembrane) and *m*-AAA (*m*, matrix). These enzymes are complex structures with a native molecular mass of ~1 MDa composed of smaller subunits of 70–80 kDa. They expose their catalytic sites toward either the matrix or intermembrane space and have chaperone-like activity that is required for protein unfolding and subsequent degradation at proteolytic sites. Substrates of these proteases are proteins located in the inner membrane, and their degradation is essential for the maintenance of oxidative phosphorylation. Impaired function of these proteases causes neurodegeneration in humans and severe growth defects in yeast.

Proteolysis in Bacteria and Archaea

Roles of Proteolysis in Bacteria

Although bacteria and archaea do not have lysosomes, ubiquitin, or 26S proteasomes, they carry out very selective and highly regulated degradation of intracellular proteins. These prokaryotes contain several distinct ATP-dependent proteases that mediate initial steps in degradation of proteins in their cytoplasm. These enzymes serve functions similar to those in eukaryotic cells. Bacteria selectively destroy abnormal proteins, including those arising from mutations, gene fusions, misfolding, chemical damage, or genetic engineering. In fact, successful expression of many recombinant proteins in *Escherichia coli* (*E. coli*) has been hampered by the action of these enzymes, and several bacterial strains defective in some of these proteases have been developed to increase the stability of cloned foreign proteins. Exposure to harsh environmental conditions, such as high temperature (heat shock), induces the genes which encode several molecular chaperones and ATP-dependent proteases to refold or degrade unfolded proteins that may be generated and protect against the buildup of these potentially toxic polypeptides. During normal exponential growth, most normal bacterial proteins are quite stable entities. However, even during normal growth, certain polypeptides with major regulatory functions are degraded very rapidly. For example, the specific component of bacterial RNA polymerase, so-called sigma factor σ^{32}, has a half-life of 1–2 min in *E. coli* under normal conditions, but it becomes transiently stabilized during heat shock, when it mediates the heat shock response. A general enhancement of protein breakdown occurs in nongrowing cells deprived of nutrients in order to provide the starving organism with a source of amino acids for new protein synthesis or energy production. In many gram-positive bacteria, prolonged starvation triggers sporulation, which is also accompanied by the marked degradation of most normal cellular proteins to provide amino acids for the expression of spore-specific genes.

Bacterial ATP-Dependent Proteases

Many eubacterial and archaeal ATP-dependent proteases are ancestors of more complex eukaryotic enzymes. Archaea, for example, contain proteasomes that have similar architecture as eukaryotic 20S proteasomes, but are built only from single α- and β-subunits and function in protein breakdown in association with the ATPase PAN. This hexameric-ring structure is homologous to the six ATPases found in the 19S base of the eukaryotic proteasome and has the capacity to unfold globular proteins and promote their entry into the 20S particle. The major ATP-dependent proteases in eubacteria are the cytoplasmic serine proteases La/Lon, "caseinolytic serine proteases" ClpAP and ClpXP, the cytoplasmic threonine protease HslUV, and the inner membrane zinc-metalloprotease FtsH. The proteases La/Lon and caseinolytic proteases have their homologues in eukaryotic mitochondria. Bacterial ATP-dependent proteases are multimeric enzymes (400–700 kDa) that have distinct substrate specificities and subunit composition. They are composed of proteolytic domains and regulatory ATPase domains, which actually determine substrate specificities. The simpler proteases, La/Lon and FtsH, contain these two domains in a single polypeptide chain. Lon consists of four or eight identical 87 kDa protein subunits and was the first ATP-dependent protease described. Other proteases that are structurally related to the eukaryotic 20S proteasomes (such as HslUV and ClpAP) contain these domains in two separate structures. For example, the HslUV contains a central proteolytic chamber (HslV) composed of two hexameric rings with the active sites facing inward. Two ring-forming HslU complexes have ATPase activity and associate with proteolytic HslV cylinders on both ends to form a four-ring 20S proteasome-like particle capable of binding, unfolding, and degrading bacterial proteins. Besides proteases, the degradation of many proteins *in vivo* also requires chaperones of the Hsp70 and chaperonin (GroEL) families as cofactors that act in the recognition of unfolded substrates. ATP-dependent proteases generate short peptides of 10–40 amino acids, and they are degraded to amino acids by energy-independent peptidases.

Selection of Substrates

Bacteria lack ubiquitin and any homologous mechanism for covalent modification of substrates destined for proteolysis. The ATPase-ring components (e.g., HslU, ClpA or ClpX) of bacterial proteases determine the substrate specificity. With some exceptions, the exact recognition motifs on bacterial proteins are not well defined. However, special sequences on the N and C

termini of cell proteins have been identified that lead to recognition by ClpXP and may become particularly important in conditions when overall protein degradation is accelerated. All bacteria selectively degrade prematurely terminated proteins. A specific tRNA incorporates the tagging peptide SsrA (11-residue stretch of amino acids) into nascent polypeptide chain if ribosomes are stalled. The presence of an SsrA tag at the C terminus of a protein leads to its rapid hydrolysis by ClpXP and FtsH proteases. In addition to this recognition motif, in the case of multiprotein complexes, some proteins become substrates if present in cells without their natural binding partners because the motifs that are recognized may be more accessible. Finally, chaperones may also provide some assistance in increasing susceptibility of substrates to bacterial proteases.

Targeting Proteolysis for Drug Development

Although a number of lysosomal diseases are known, the major ones are not due to defects in lysosomal proteases but rather to failure to degrade polysaccharides or lipids due to lack of a specific lysosomal hydrolase. Commonly, these diseases are called lysosomal storage diseases because undegraded material progressively accumulates in lysosomes. One component of the endocytic–lysosomal pathway, the autophagy, has been reported to be disturbed in some malignancies, neurodegenerative, and cardiovascular disease; however, it is unknown if the impaired breakdown of a specific protein(s) is part of the underlying pathophysiological mechanism, or a secondary consequence. However, a number of major malignant, neurological, metabolic, and viral diseases are caused by the gain or loss of function of the ubiquitin–proteasome proteolytic system (Table I). Since the disturbances in the ubiquitin–proteasome system underlie the pathogenesis of many human diseases, drugs that target this system are being developed. The proteasome inhibitors are the first so far to be tested in animal models and are now in clinical trials for treatment of neoplastic disease. However, proteasome inhibition is not a very specific strategy to modulate stability of a specific protein and more selective approaches should prove to be more effective and have fewer side effects. A typical approach would be to develop small molecule inhibitors to target events upstream of proteasomes (e.g., ubiquitin ligation and substrate recognition).

Glossary

AAA ATPase (ATPases Associated with diverse cellular Activities) A distinct family of ATPases characterized by the presence of highly conserved domains in their primary sequence, hexameric structure, and protein unfolding activity.

ATPase Type of enzyme that hydrolyzes ATP and uses the energy released to drive biological processes such as pumping ions, unfolding proteins, and moving molecules.

folding A process in which newly synthesized polypeptides attain their native three-dimensional structures.

molecular chaperones Specialized proteins, many being ATPases, that prevent protein aggregation and may function to facilitate proteins attaining their native conformations; some can promote protein unfolding and solubilization of aggregated proteins.

Biography

Tomo Šarić is currently a Senior Scientist at the Institute for Neurophysiology, University of Cologne, Germany. His principal research interest is in intracellular proteolysis, especially in proteases acting downstream of proteasomes and their role in regulating immune responses. He holds an M.D. and a Ph.D. from the University of Zagreb in Croatia and received his postdoctoral training at the University of Texas and Harvard Medical School.

Alfred L. Goldberg is Professor of Cell Biology at Harvard Medical School in Boston. His principal research interests are in the field of protein degradation. His laboratory has contributed to many major discoveries in this field, such as the discovery of the ATP requirement for degradation of most intracellular proteins, discovery of the first ATP-dependent proteases in bacteria and proteasomes in eukaryotic cells, introduction of proteasome inhibitors and the role of the proteasome in antigen presentation, and muscle atrophy.

Protein Folding and Assembly

David P. Goldenberg
University of Utah, Salt Lake City, Utah, USA

In order to carry out their biological functions, most polypeptide chains must fold into stable three-dimensional (3D) structures, for it is the precise spatial distribution of chemical groups within a protein that gives the molecule its ability to interact specifically with other molecules and, in the case of an enzyme, catalyze a chemical reaction. In many cases, individual polypeptide chains must also assemble into larger structures containing additional proteins or nucleic acids. The folding of many proteins is reversible, so that the native structure can be disrupted by a change in temperature or addition of a chemical denaturant, and the unfolded protein can then be induced to refold and assemble by returning it to physiological conditions. Experiments of this type demonstrate that the information specifying the native structure of a protein resides in its amino acid sequence, and *in vitro* studies have provided important insights about the energetic factors that drive folding and assembly and the kinetic mechanisms of these processes. Folding *in vivo* is often facilitated by transient interactions with other proteins, molecular chaperones. Folding may also compete with the formation of aberrant aggregates *in vivo*, sometimes leading to pathological conditions such as amyloid diseases.

Thermodynamics of Protein Folding

The thermodynamic stability of a protein is defined by the equilibrium between the native folded form and the highly disordered unfolded state that is induced by elevated temperatures or chemical denaturants, such as urea or guanidinium chloride (GuHCl). Relatively small monomeric proteins, composed of 50–150 amino acid residues, typically unfold and refold efficiently and cooperatively, so that the process can be described as a simple equilibrium:

$$N \rightleftharpoons U$$

where N and U represent the native and unfolded states (Figure 1). While the native state usually has a well-defined 3D structure, the unfolded state is best thought of as a broad distribution of rapidly interconverting conformations.

Under physiological conditions, the change in free energy for unfolding (ΔG_u) for a small monomeric protein typically lies in the range of 5–15 kcal mol^{-1}. This relatively small preference for the native protein reflects a delicate balance between three major factors: (1) A large loss of entropy as the chain is converted from a highly disordered state to an ordered state, (2) the transfer of nonpolar groups from an aqueous environment to a nonpolar environment in the protein interior, and (3) the formation of stabilizing interactions within the protein, including hydrogen bonds, salt bridges, and van der Waals interactions.

During the 1980s and 1990s, a great deal of effort was devoted to measuring the stabilities of genetically modified proteins in which single amino acid residues were replaced so as to delete one or a few stabilizing interactions. Taken together, these studies revealed that proteins are surprisingly tolerant of amino acid replacements, so that most mutations destabilize the native state by only a few kcal mol^{-1}, and substitutions that completely prevent folding are quite rare. Substitutions that remove hydrogen bonds or nonpolar interactions cause, on an average, roughly similar degrees of destabilization (usually of the order of 1–3 kcal mol^{-1}), implying that both types of interactions play important roles in stabilizing native proteins.

Folding Kinetics and Mechanisms

Levinthal's Paradox

Much of the work on folding mechanisms, both experimental and theoretical, has been motivated by the realization that the number of possible conformations accessible to a polypeptide chain is so immense that random sampling to find the structure with minimum free energy would take a ridiculously long time. For instance, if a chain is composed of 100 residues, and each residue can take on ten possible conformations, then the total number of conformations is 10^{100}. If the various conformations are randomly sampled at a rate of 10^{13} s^{-1} (approximately the rate of rotation for a covalent bond), then the total time

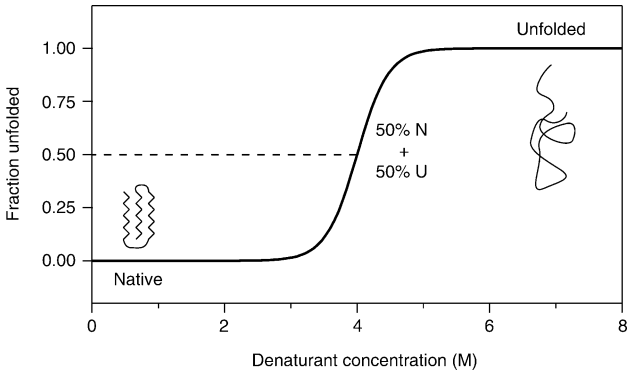

FIGURE 1 A cooperative protein unfolding–refolding transition. In a typical experiment, the native protein is incubated in solutions with increasing concentrations of denaturant such as urea or guanidinium chloride, and the fraction of unfolded molecules is determined by monitoring a spectroscopic signal, such as UV absorbance, fluorescence, or circular dichroism. For small monomeric proteins, the transition is usually highly cooperative, so that only the fully folded and unfolded forms are significantly populated and the fraction unfolded represents the relative concentrations of the two forms.

required to sample all of the conformations would be $\sim 10^{80}$ years!

The calculation outlined above is frequently identified as the "Levinthal Paradox," in recognition of an insightful 1969 paper by Cyrus Levinthal. Although this argument undoubtedly represents a great oversimplification, since many of the conformations assumed to be accessible to the chain will, in fact, be excluded by steric clashes among atoms in different residues, the calculation suggests that there must be some mechanism by which the search for the native conformation is limited.

Folding and Unfolding Rates

The rates at which different proteins fold and unfold vary tremendously. Even considering only relatively small proteins composed of a single domain, experimentally determined folding rate constants cover at least the range from 0.1 to $10^5\ s^{-1}$. While it might be expected that smaller and thermodynamically more stable proteins would fold the fastest, folding rates for unrelated proteins are poorly correlated with size or stability. Instead, a major determinant of folding rate appears to be the topological complexity of the native structure. While true topological knots are rarely found in folded proteins, different structures vary with respect to the relative prevalence of interactions formed between closely and distantly spaced residues, and faster folding in often associated with topologies in which short-range interactions are more prominent. The physical basis for this correlation is not yet fully understood, but it strongly suggests that the rate-determining step in folding is associated with formation of the correct topology, as opposed, for instance, to formation of a local structure that then nucleates rapid folding of the rest of the chain.

Unfolding rates also vary greatly among different proteins and under different solution conditions. For some proteins, unfolding may be a surprisingly common event, even under physiological conditions. For instance, if the stability of a protein, ΔG_u, is 5 kcal mol^{-1} at 25°C, and the folding rate is $10^3\ s^{-1}$, the unfolding rate is predicted to be about $0.5\ s^{-1}$, so that 99% of the molecules in a population will undergo an unfolding event over a period of 10 s. Since unfolded proteins are typically much more sensitive to proteolysis than folded proteins, spontaneous unfolding may be an important factor in determining the rate of protein turnover *in vivo*. Transient unfolding may also contribute to formation of aberrant structures, such as the amyloid fibers described below.

Folding Intermediates

Following the tradition of biochemists who have successfully dissected other processes by identifying and characterizing discrete intermediates, many investigators have studied kinetic intermediates that accumulate transiently before protein-folding reactions reach equilibrium. While there is considerable diversity in the intermediates observed in the folding of different proteins, there appear to be common features among many of them.

Generally, the most easily detected intermediates form very rapidly (on the ms timescale or faster) after the unfolded protein is transferred to conditions that favor the native state. Often, the intermediate appears to contain ordered secondary structure, especially α-helices, but there is little evidence of well-defined interactions between the side chains from different segments of the chain. The average dimensions of the chain in these intermediates typically lie between those of the native protein and the fully unfolded state in denaturants. Kinetic intermediates of this type also resemble partially unfolded states that can sometimes be generated under special solution conditions, including low pH for some proteins, or when a ligand (such as a metal ion or heme group) is removed from a native protein. These states, typically characterized by the presence of regular secondary structure but the absence of stable tertiary interactions, are described as "molten globules."

Because the most frequently observed partially folded states often interconvert rapidly with the fully unfolded protein, establishing whether or not these species are actually productive intermediates in folding, as opposed to products of side reactions, is quite difficult. As a consequence, there is presently a great deal of uncertainty and disagreement about the significance of these states for understanding folding mechanisms. Some authors believe that the formation of intermediates

is important for limiting the search for the native conformation, while others argue that they are simply compact forms of the denatured state and do not play any special role in directing the chain towards the native state.

Transition States

It might seem surprising that the concept of a transition state, derived from studies of simple chemical reactions, could be usefully applied to a process as complex as protein folding. However, the folding kinetics of many proteins can be well-described by a simple model in which the rate is determined by an equilibrium between the unfolded state and a higher energy state that is rapidly converted to the native conformation (Figure 2). The transition state can be envisioned as an ensemble of partially ordered conformations that collectively have an equal probability of being converted to either the native or fully unfolded states.

By their very nature, transition states cannot be characterized directly by spectroscopic or other physical methods. Instead, their properties must be inferred from the results of experiments in which the kinetics of folding and unfolding are compared after perturbing either the structure of the protein or its environment. For instance, replacing an amino acid residue that contributes to the stability of the transition state is expected to increase the free energy barrier for folding and, thereby, decrease the folding rate. On the other hand, a substitution that weakens an interaction that is present in the native protein but not the transition state is expected to increase the unfolding rate, without affecting the folding kinetics.

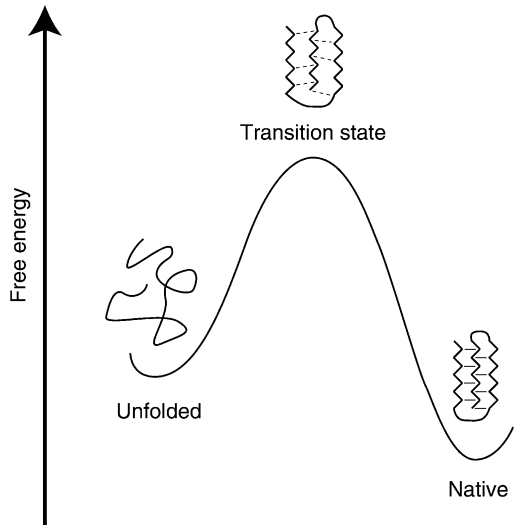

FIGURE 2 Hypothetical energy profile for a protein folding reaction. Currently available data, especially from mutational analyses of folding kinetics, suggest that the transition state for folding and unfolding is an ensemble of conformations that possess much of the topology of the native protein, but in which many of the native interactions are missing or weakened. The transition state ensemble is poised to fold completely or unfold rapidly.

Detailed mutational analyses of transition states have now been carried out for several proteins. In general, it has been found that substitutions that destabilize the native protein most often increase the unfolding rate more than they decrease the folding rate, suggesting that most interactions that are present in the native protein are significantly weakened in the transition state. Also, the relatively few residues that appear to play specific roles in stabilizing the transition state are often separated in the amino acid sequence but lie relatively close together in the native protein. These patterns suggest that the transition state ensemble may have a topology similar to that of the native protein, but not the network of cooperative interactions found in the fully folded structure (Figure 2). Poised with the correct topology, the molecules in the transition state can rapidly form these interactions, but can also unfold rapidly.

Collectively, studies of folding intermediates and transition states over the past decade generally support a view of folding in which there is considerable breadth in the distribution of conformations representing different stages of the process, a view that has also emerged from computational simulations of folding. The conformational heterogeneity of these states makes detailed structural analysis very difficult, and there is much about folding mechanisms that still remains hidden from experimental view. More detailed descriptions of folding can in principle be derived from computational simulations, and the rapidly increasing power of computers and the development of new algorithms is now making it possible to carry out detailed molecular dynamics simulations of folding reactions. The past several years have seen much more extensive collaborations between experimentalists and computational scientists working on protein folding, and this development is already leading to important new insights into both the details of specific folding reactions and the general principles of the process.

More Complex Folding Reactions

Although the great majority of protein-folding experiments and simulations have been carried out with small monomeric proteins, most proteins found in nature are larger and more complex structures. Most polypeptides form multiple domains when they fold, and many assemble into structures composed of multiple subunits. In addition, some proteins are stabilized by disulfide bonds, which are formed during the folding process, and others contain tightly bound ligands such as metal ions, heme groups, or cofactors required for enzyme activity.

Proteins with Multiple Domains

Early in the study of protein structure, it was recognized that most proteins composed of more than 100–200 amino acid residues are typically organized into domains in which segments of 50–150 residues are folded into compact structures that are relatively independent of one another. Although a precise definition of a domain is somewhat elusive, the organization of a protein into substructures is often quite apparent from inspection of the 3D structure or by computer analysis (Figure 3). Experimentally, domains can often be defined by limited treatment with a protease, since the polypeptide segments separating domains are usually much more sensitive to digestion than the regions within domains. The functions of larger proteins are often divided among their substituent domains, with different domains typically interacting with different molecules. It is clear from comparisons of protein structures and sequences that the same domains have frequently been exchanged among different proteins by genetic recombination, and the domain architecture of a protein can often be deduced by comparison of its sequence with those of known domains.

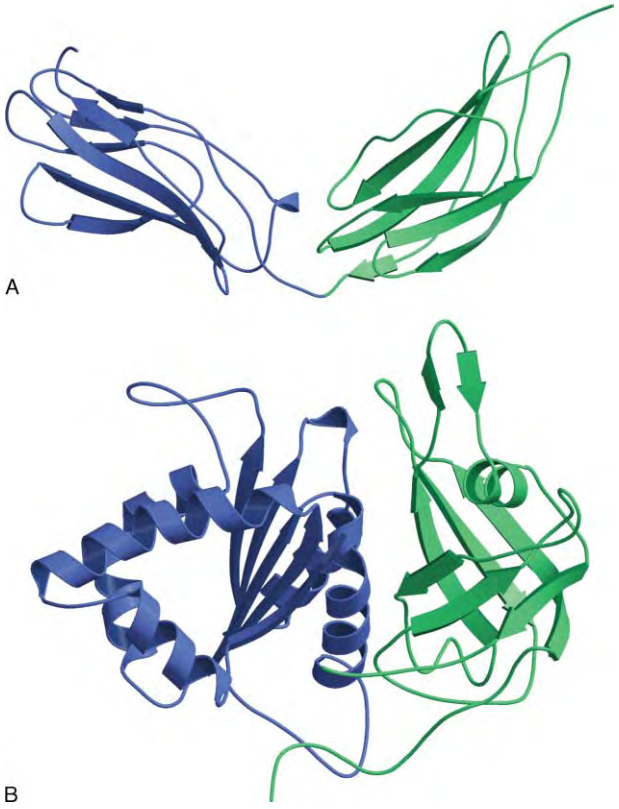

FIGURE 3 Domain structures of two proteins. In each drawing, the domains are distinguished by color. (A) Two domains of a cellular adhesion molecule, neuroglian from *Drosophila melanogaster*. The intact protein contains nine other domains, three of which are similar to the two shown here, which are members of the fibronectin III domain family. Drawn from the atomic coordinates of entry 1CFB in the Protein Data Bank (Huber, A. H., Wang, Y. M., Bieber, A. J., and Bjorkman, P. J. (1994). Crystal structure of tandem type III fibronectin domains from *Drosophila* neuroglian at 2.0Å. *Neuron* **12**, 717–731). (B) Ferrodoxin reductase from spinach chloroplasts. In this structure, the two domains do not resemble one another and interact much more extensively than the two fibronectin domains shown in (A). Drawn from the atomic coordinates of entry 1FNB in the Protein Data Bank (Bruns, C. M., and Karplus, P. A. (1995). Refined crystal structure of spinach ferredoxin reductase at 1.7Å resolution: Oxidized, reduced and 2′-phospho-5′-AMP bound states. *J. Mol. Biol.* 247, 125–145). The drawings in Figures 3 and 4 were made with the computer programs MOLSCRIPT and Raster3d.

When isolated from the rest of the protein, individual domains typically retain their native conformations and undergo cooperative unfolding transitions similar to those observed with smaller proteins. Furthermore, when the intact protein unfolds, the resulting spectroscopic signals often resemble a simple superposition of those for the isolated domains. In these cases, the domains appear to be truly independent, and studying their folding individually probably provides a good description of the folding mechanism for the intact protein. In other cases, however, the domains may interact more intimately, so that the entire structure unfolds cooperatively. The folding mechanism may also involve interactions among the domains before their individual structures are fully defined.

Disulfide-Coupled Folding

Many proteins, especially among those that function extracellularly, are stabilized by disulfide bonds, covalent bonds between the sulfur atoms of cysteine (Cys) residues that are formed by oxidation of the Cys thiol groups. *In vivo*, disulfide bonds are formed after the polypeptide is synthesized and translocated to either the endoplasmic reticulum in eukaryotes, or the periplasmic space in bacteria. In both types of cells, disulfides in the newly synthesized proteins are formed by exchange with disulfides present in special proteins that act as catalysts of the process.

In a landmark series of experiments in the early 1960s, C. B. Anfinsen and his colleagues demonstrated that the four disulfide bonds of bovine ribonuclease A could be induced to reform spontaneously *in vitro* after the protein had been fully reduced and unfolded in urea. The regeneration of active enzyme, even after the covalent constraints on the polypeptide chain had been broken, provided a vivid demonstration that the 3D structure was encoded by the amino acid sequence.

When refolding of a reduced protein is initiated, disulfides typically form quite randomly, leading to a distribution of molecules with different disulfide bonds that can rapidly interconvert. The formation of an initial disulfide, however, can often favor conformations that then bring other Cys residues together to form a second disulfide. These conformations can also be stabilized by

noncovalent interactions, leading to a high degree of cooperativity among the various interactions.

As more of the 3D structure forms and is stabilized by additional disulfides, the ability of the molecule to undergo additional disulfide formation and rearrangement steps can become severely constrained, leading to the accumulation of species that contain most or all of the native structure but lack one or more disulfides. *In vivo*, disulfide isomerase enzymes can catalyze the slow rearrangements necessary to convert the trapped molecules to the native form, or may promote alternative pathways that avoid the kinetic traps.

Ligand Binding

Yet another way in which folding can be influenced is through the binding of ligands such as metal ions or prosthetic groups. In most cases, ligands have little tendency to interact with unfolded proteins, so that the molecule must be at least partially folded before the interaction takes place. A thermodynamic consequence of this is that the stability of the folded protein is enhanced by the presence of ligand and depends on both the affinity of the interaction and the concentration of free ligand in solution. If the binding site is formed only when the protein is fully folded, binding may not greatly alter the folding process either *in vitro* or *in vivo*. On the other hand, interactions of ligands with partially folded species could favor some pathways over others and might prevent aberrant interactions with other molecules.

Proteins that require the binding of reactive metal ions such as those of iron, copper, or nickel present a particularly interesting problem during folding *in vivo*. Because these ions are highly toxic, their free concentrations are maintained at very low levels by transport and storage proteins that bind tightly to them. The ions must then be transferred to other proteins for which they are required for activity, such as catalysis. Although the details are not yet well-understood, it appears that quite elaborate systems involving multiple transfer proteins have evolved to facilitate the safe transfer of ions to their proper sites.

Some prosthetic groups, such as the heme group of cytochrome *c*, are covalently bonded to the polypeptide chain. For these proteins, the covalent modifications, and the enzymes that catalyze them, are likely to be intimately involved in the folding process.

Molecular Chaperones

While many proteins refold spontaneously and efficiently *in vitro*, it is now known that folding *in vivo* is often facilitated by molecular chaperones, proteins that interact transiently with the polypeptide chain and either promote folding or decrease the likelihood of nonproductive interactions. The best-characterized molecular chaperones include members of the GroEL/-GroES and HSP70 families. Members of both groups utilize the energy of ATP hydrolysis to couple conformational changes in the chaperone to a cycle of substrate protein binding and release, during which the substrate folds to its native conformation. Other examples of molecular chaperones include the catalysts of disulfide formation and exchange and the metal chaperones mentioned above. Although the chaperones can increase the efficiency of folding, it does not appear that they influence the final structure. Their discovery, therefore, has not required a revision of the fundamental idea that the folded structure of a protein is determined by the amino acid sequence. But, we now have a much greater appreciation of protein folding as a biological process that is intimately coupled to numerous other intracellular events.

Assembly of Oligomeric Proteins

Only a minority, perhaps 20%, of proteins contain a single polypeptide chain, the remainder being assemblies of multiple subunits. Dimeric and tetrameric complexes are the most common, but assemblies of 20–50 subunits are also known. The assembly of subunits into larger complexes can offer a variety of functional advantages, including mechanisms for regulating the activities of enzymes, the creation of novel binding sites at subunit interfaces and the coordination of multiple related functions in a single complex.

Multimeric proteins can be assembled from a single type of subunit, resulting in a homo-oligomer, or they can be hetero-oligomers composed of two or more different kinds of chains. Quite often, these structures are highly symmetrical. Dimers of identical polypeptide chains are especially common, and dimers are often the basic units of higher order structures, such as tetramers, hexamers, etc.

The types of interactions that hold the subunits of oligomers together are essentially the same as those found within monomeric proteins or the individual subunits themselves, including hydrogen bonds, ionic and van der Waals interactions. However, surveys of the distribution of different interaction types in various protein environments have revealed some differences between those found between and within subunits, with ionic interactions being more common in the interfaces between subunits.

Many oligomeric proteins have been successfully refolded and assembled *in vitro* after being unfolded in denaturants, though the reactions are often slower and less efficient than the folding of small monomeric proteins. In some cases, the rate of refolding is dependent on protein concentration, indicating that the rate is determined by intermolecular association

reactions. In other cases, the reaction kinetics are limited by intramolecular rearrangements that occur either before or after subunit association.

These differences in kinetic behavior suggest that oligomeric structures may form by a variety of mechanisms. In order to assure specificity, the initial interactions between two subunits presumably requires that one or both of them first takes on at least a partially folded conformation. In some cases, the interaction may only occur after the subunits are fully folded, so that folding and assembly are distinct processes. This mechanism requires that the individual subunits have compact self-contained structures similar to those of monomeric proteins, as epitomized by the four subunits of hemoglobin (Figure 4A). For some oligomers, however, the subunits form extensive interactions with one another along extensive interfaces that make it unlikely that the individual subunits could fold completely before assembling. In extreme cases, the subunits are actually wrapped around one another, as observed in the structure of the tailspike protein of bacteriophage P22 (Figure 4B). These more complex arrangements of subunits likely lend the structures a great deal of kinetic stability, but possibly at the cost of more complex folding mechanisms involving unstable intermediates that may be prone to aberrant misfolding or aggregation reactions.

Protein subunits can also form complexes with either RNA or DNA, as in ribosomes or the nucleosomes of eukaryotic chromatin. These interactions are often mediated by electrostatic interactions between Arg or Lys residues of the proteins and the negatively charged phosphate groups of the nucleic acids, but nonpolar interactions can also play a role. Just as protein subunits can associate with one another either before or after being fully folded, the formation of protein–nucleic acid complexes may involve folding processes that take place after association as well as before.

Protein Folding Pathologies

Over the past decade, defects in protein folding or assembly have become recognized as important factors leading to a variety of diseases. These include cystic fibrosis, some forms of emphysema and a large number of conditions associated with the formation of long fibrillar protein structures, the amyloid diseases. Mutations that destabilize the native protein may lead to premature degradation or the formation of aberrant assemblies, which, in turn, may lead to a deficiency for an important activity or the formation of structures that are actually toxic. At present, the amyloid diseases appear to be the most important category of folding pathologies. Diseases associated with amyloid formation include neurodegenerative conditions such as Alzheimer's and Parkinson's diseases and amyotrophic lateral sclerosis, as well as several systemic amyloid diseases. In an intriguing minority of diseases, particles of amyloid fibers from one individual can promote fibril

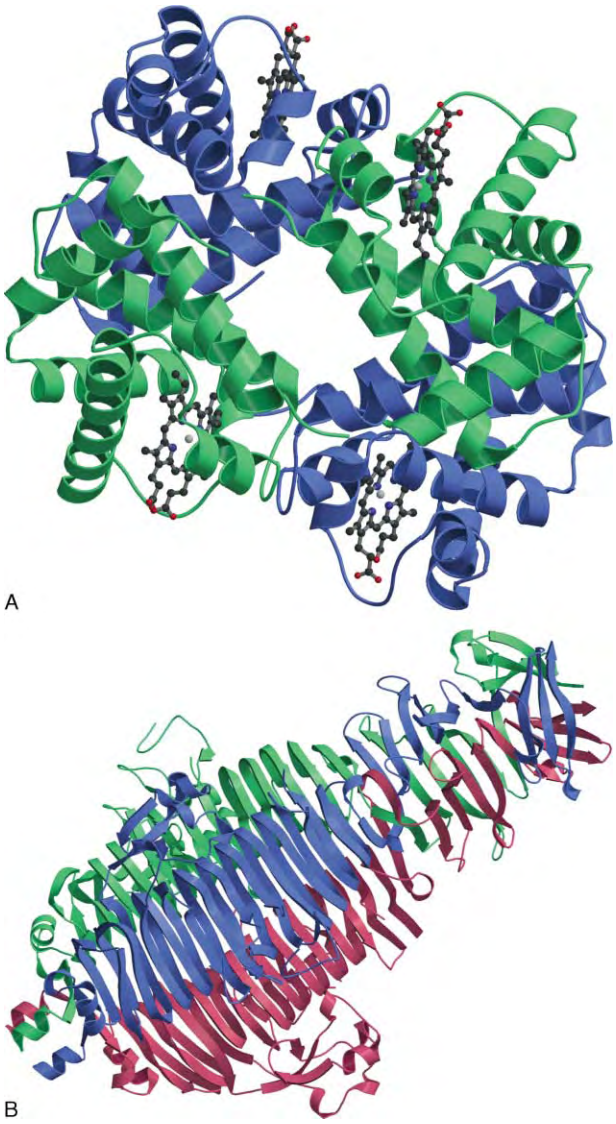

FIGURE 4 Subunit structures of two proteins. (A) Human hemoglobin, a tetramer formed of two types of subunits, colored green and blue in the drawing. Each of the subunits is a compact and self-contained structure. The heme groups associated with each of the four chains are also shown in a ball-and-stick representation. Drawn from entry 2HHB in the Protein Data Bank (Fermi, G., Perutz, M. F., Shaanan, B., and Fourme, R. (1984). The crystal structure of human deoxyhaemoglobin at 1.74Å resolution. *J. Mol. Biol.* 175, 159–174). (B) A fragment of the trimeric tailspike protein of bacteriophage P22. The intact protein includes an additional domain at the amino-terminus of the chain (at the lower left corner of the drawing), by which the tailspike binds the rest of the virus particle. In this structure, the individual subunits interact extensively with one another and are intertwined, requiring an assembly mechanism in which the chains do not fold completely until after they have associated. Drawn from entry 1TSP of the Protein Data Bank (Steinbacher, S., Seckler, R., Miller, S., Steipe, B., Huber, R., and Reinemer, P. (1994). Crystal structure of P22 tailspike protein: Interdigitated subnits in a thermostable trimer. *Science* **265**, 383–386).

formation in another, providing a mechanism of infectivity that does not involve either bacteria or viruses. These infectious agents have been named "prions" and the diseases they are associated with include scrapie (in sheep) and bovine spongiform encephalopathy (BSE or "mad cow disease"), as well as the human disease Kuru and a variant of Creutzfeld–Jacob disease that is believed to be derived from BSE. The transmission of an altered physiological state by a protein amyloid is not at all restricted to mammals, however, as a very similar process has been found in the unicellular yeast, *Saccharomyces cerevisiae*, and this discovery has provided an important experimental system for analyzing the prion phenomenon. A surprisingly large number of proteins are now known to form amyloid-like fibers under at least some *in vitro* conditions, and it may be that the ability to form these structures is a nearly universal property of polypeptide chains. Remarkably, there is a great deal of similarity among the structures of fibers formed from proteins with quite different native structures. The fibers are generally about 50–100Å in diameter and a fraction at least of the polypeptide chain has a β-strand conformation, with the strands oriented so that their backbones are approximately perpendicular to the fiber axis.

Fibril formation *in vitro* is typically favored by conditions that destabilize the normal folded conformation but do not fully unfold and solubilize the polypeptide. *In vivo*, conversion to the amyloid state may be promoted by inherited mutations, environmental stress or, as noted above, "seeding" by an existing fibril fragment. At present, it is difficult to establish a clear mechanistic link between fibril formation and the physiological changes associated with amyloid diseases. In some cases, the amounts of protein deposited in fibrils are so large, as much as several kg in some patients, that these structures are clearly able to interfere with normal organ function. Smaller fibrils may similarly be toxic at the cellular level. In other cases, it may be that diversion of essential proteins into fibrils leads to functional deficiencies.

Because amyloid fibril formation usually competes with normal folding, investigators are actively pursuing the possibility that these diseases might be prevented or treated by agents that favor productive folding or disfavor unfolding, for instance by binding to the native structure. These developments provide a vivid link between the basic science of protein folding and important medical problems.

Glossary

amyloid A polymeric and fibrous form of a protein, usually formed by polypeptides that have undergone unfolding or misfolding.

domain A compact structure composed of 50–150 amino acid residues that can fold independently of other parts of a protein.

folding intermediate A partially folded conformational state that may form transiently during the conversion of an unfolded protein to the native state.

molten globule A partially folded state that is characterized by the presence of regular secondary structure (usually α-helices), but lacking well-defined interactions between side-chains distant in the sequence.

native state The well-defined folded structure of a protein usually associated with biological activity.

unfolded state An ensemble of rapidly interconverting conformations with little or no stable structure, usually generated by incubating a native protein with a denaturant or at elevated temperature. *In vivo*, polypeptides that have not yet folded into their native conformations may resemble artificially unfolded proteins.

Biography

Dr. David Goldenberg is a Professor of biology at the University of Utah. He received his Ph.D. at the Massachusetts Institute of Technology and carried out postdoctoral research at the Medical Research Council Laboratory of Molecular Biology in Cambridge, UK. His research interests are in the areas of protein folding and dynamics, and he has worked extensively on the folding of disulfide-bonded proteins and the effects of mutations on folding energetics.

Protein Glycosylation Inhibitors

Alan D. Elbein
University of Arkansas for Medical Sciences, Little Rock, Arkansas, USA

Many proteins that are synthesized in eukaryotic cells undergo chemical modifications other than addition of amino acids, either while the protein is being synthesized, or after protein synthesis is finished. One of the major types of modifications that occur on many proteins is glycosylation, i.e., the covalent attachment of sugars to these proteins, to form glycoproteins. Proteins may be glycosylated either with O-linked sugars (sugars attached via hydroxyl groups of serine or threonine), or with N-linked-sugars (oligosaccharides attached to protein via the amide nitrogen of asparagine), or some proteins have both types of oligosaccharides. This article discusses the use of glycosylation inhibitors that either prevent the formation of N-linked oligosaccharides, or that modify the structure of the N-linked oligosaccharide chain after it is transferred to protein. The specific N-linked sugar structure on a particular protein may play an important role in protein folding, protein targeting, chemical recognition, and/or various disease processes. For this reason, inhibitors that alter the structure of the oligosaccharide can be valuable as tools to help decipher how specific carbohydrate structures are recognized by proteins that mediate these processes. In addition, this information can be utilized to prevent some of these processes, or to enhance those that are useful, and such a situation may be important in various therapies.

Mechanism of Action of Glycosylation Inhibitors

There are a number of glycosylation inhibitors that work on enzymes in the first series of reactions, i.e., the lipid-linked saccharide pathway that involves the participation of dolichyl-phosphate (see Figure 1). One of the most widely used and useful of these inhibitors is the antibiotic tunicamycin (Tun), a reversible tight-binding inhibitor of the GlcNAc-1-P transferase. This glycosyltransferase catalyzes the initial reaction in the assembly of N-linked oligosaccharides, i.e., the transfer of GlcNAc-1-P to dolichol-P to form GlcNAc-PP-dolichol. Since this inhibitor prevents this initial reaction, it essentially blocks the assembly of all N-linked oligosaccharide chains, and those proteins that normally have this type of glycosylation are synthesized in the unglycosylated form. As a result, many of these unglycosylated proteins do not fold properly in the ER, and are therefore degraded by the ubiquitin protein degrading system. In some cases, especially with hydrophobic membrane proteins, absence of the hydrophilic carbohydrate structure renders these proteins insoluble and causes them to aggregate into insoluble complexes. In most systems where N-linked glycoproteins are involved in recognition and binding interactions, Tun has dramatic effects. For example, this drug inhibits cell adhesion and spreading in various animal cell systems, and causes defects in the transport of glucose, uridine, and amino acids in chick fibroblasts. Treatment of mouse 3T13 fibroblasts with Tun inhibits their *in vitro* differentiation into adipose-like cells. This antibiotic also inhibited the fusion of myoblasts to form myotubes during muscle development. The difficulty with using tunicamycin in animal systems, or in chemotherapy against cancer or other diseases, is that it prevents glycosylation of all N-linked glycoproteins and therefore is quite toxic to most cells.

Amphomycin (Ampho) is a lipopeptide antibiotic that inhibits the formation of lipid-linked sugars in membrane fractions, but is not effective in whole cells, probably because it cannot cross the plasma membrane and get into the cells. This inhibitor blocked the formation of dolichyl-P-mannose (also refered to as mannosyl-P-dolichol), the donor of the last four mannose residues of the $Man_9GlcNAc_2$-PP-dolichol, resulting in the accumulation of $Man_5GlcNAc_2$-PP-dolichol in cell-free membrane preparations. Ampho has been a useful tool to demonstrate that the last four mannoses are donated by dolichyl-P-mannose, rather than by GDP-mannose.

Various sugar analogues, such as 2-deoxy-D-glucose (2-DG) and 2-deoxy-2-fluoro-D-glucose, also inhibit N-linked glycosylation and viral replication, as well as other processes that involve N-linked glycoproteins. This inhibition is probably due to the fact that these sugar analogues are incorporated by intact cells into various biosynthetic intermediates in place of the normal mannose residues, but these intermediates cannot be further elongated by addition of other sugars. These various inhibitors and others not reported here have been used in a variety of living systems to prevent

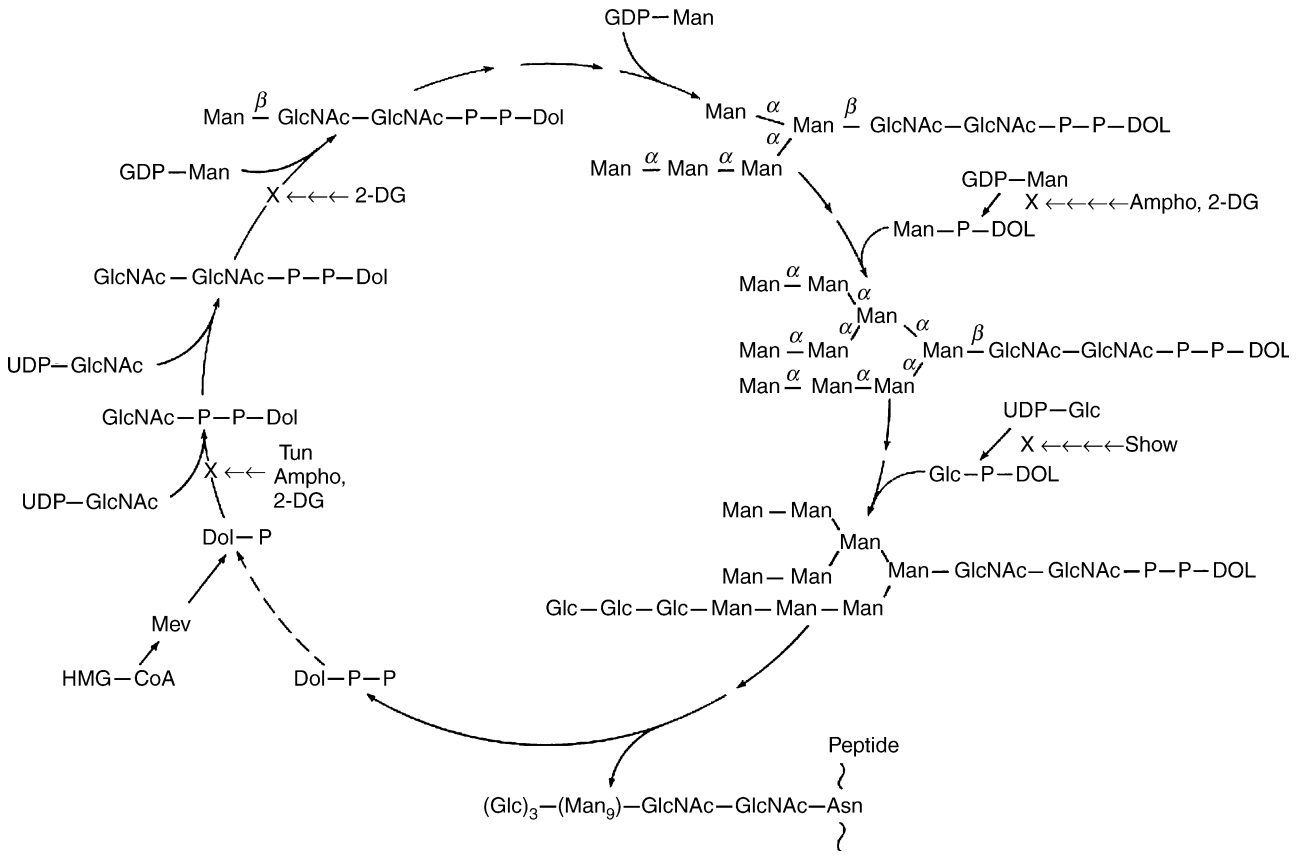

FIGURE 1 Inhibitors of N-linked oligosaccharide assembly. The biosynthesis of the N-linked oligosaccharides occurs on a dolichol carrier lipid in the endoplasmic reticulum. The individual sugars, N-acetylglucosamine (GlcNAc), mannose and glucose are sequentially added to the lipid from their activated form (i.e., UDP-GlcNAc, GDP-mannose or mannosyl-P-dolichol, UDP-glucose or glucosyl-P-dolichol) to form the 14 sugar oligosaccharide attached by a pyrophosphoryl bridge to the dolichol. Various compounds have been found to inhibit at specific sites in the pathway and these inhibitors have been useful tools to decipher and interrupt the biosynthetic pathway. Thus, tunicamycin (Tun), amphomycin (Ampho) and 2-deoxyglucose (2-DG) inhibit the first step in the assembly, i.e., the transfer of GlcNAc-1-P to dolichyl-P. Amphomycin and 2-deoxyglucose also inhibit the addition of the last four mannose residues by inhibiting the formation of mannosyl-P-dolichol (man-P-dol), while showdomycin (Show) inhibits formation of glucosyl-P-dolichol, the glucosyl donor for the three glucose units in the initial N-linked oligosaccharide.

glycosylation, and to show the necessary role of the N-linked oligosaccharides in key biological processes such as growth, cell–cell interactions, differentiation, development, and so on.

Mechanism of Action and Effect of Glycoprotein Processing Inhibitors

A number of plant alkaloids have a structure similar to that of the sugars glucose and mannose, but differ in having a nitrogen rather than an oxygen in the pyranose ring. These types of alkaloids have been found to be potent inhibitors of various glycosidases including those that are involved in the initial processing reactions that lead to the formation of complex N-linked oligosaccharides. The structures of several of these alkaloids and their sites of action in the processing pathway are shown in Figure 2. Castanospermine resembles glucose and inhibits both glucosidase I and glucosidase II, the ER glucosidases that remove all three glucose residues from the initial N-linked oligosaccharide. Castanospermine has been used in many cell culture systems, and in some whole animal studies to block the removal of glucose and prevent the formation of complex types of oligosaccharides. This has provided useful information on the function of specific glycoproteins. For example, in HepG2 cells, blocking the removal of glucoses from the N-linked oligosaccharides greatly reduced the rate of secretion of the serum protein, α_1-antitrypsin. Castanospermine also reduced the number of insulin receptors at the cell surface in IM-9 lymphocytes treated with this drug, and caused a significant decrease in the formation of new HIV viral particles, and in syncytium formation in cell culture. All of these effects were demonstrated to be attributable to the absence of glucose removal, leading to improper

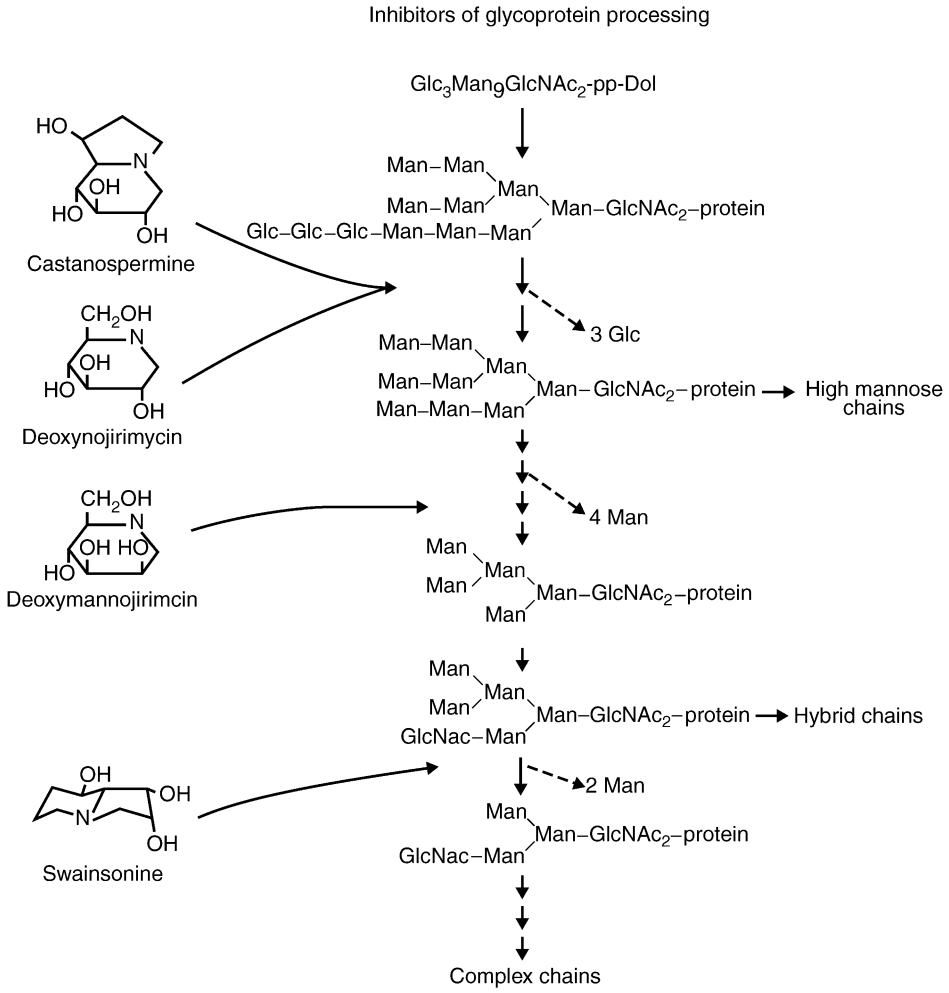

FIGURE 2 Inhibitors of glycoprotein processing. The processing of the oligosaccharide can be blocked at the very first step by the plant alkaloid, castanospermine, which inhibits α-glucosidases such as glucosidase I and glucosidase II. The trimming can also be stopped after the glucoses are removed by the α-mannosidase inhibitors, deoxymannojirimycin or kifunensine to cause accumulation of high mannose oligosaccharides. Finally the plant alkaloid swainsonine inhibits mannosidase II and causes the formation of hybrid structures.

protein folding and degradation of these proteins in the ER. Other glucosidase inhibitors have the same effect.

A second site of processing inhibition is at the stage of removal of the mannose residues. Deoxymannojirimycin (DMJ) is a chemically synthesized compound that resembles the structure of mannose, while kifunensine (KF) is a natural product that also resembles the mannose structure. Both of these compounds inhibit the Golgi α-mannosidase that releases four α1,2-linked-mannoses from the high mannose oligosaccharide. This is an essential step in the formation of complex chains, i.e., the addition of the first N-acetylglucosamine of the complex chains (structure 5 from top) requires a specific $Man_5GlcNAc_2$ structure. As far as formation or secretion of N-linked glycoproteins, these mannosidase inhibitors had essentially no effect on these processes. They also did not affect the formation in tissue culture cells of the influenza viral hemagglutinin, an N-linked glycoprotein coat protein that normally has 3 or 4 complex chains, nor the production of infectious influenza viral particles. These results suggest that the complex chain structures on this viral glycoprotein are not necessary for virus recognition or penetration in tissue culture cells.

DMJ has proven to be a useful tool to demonstrate that the initial removal of mannose residues from the high-mannose oligosaccharides in some cells occurs in the endoplasmic reticulum, and that there is also a mannosidase in the ER that removes a single mannose residue. That ER mannosidase is not susceptible to DMJ or KF. However, the next three mannoses are removed in the cis-Golgi compartment by another mannosidase which is inhibited by these two processing inhibitors. DMJ did inhibit the addition of L-fucose and sulfate into the N-linked oligosaccharides indicating that fucose and sulfate were added after the mannosidase I processing step. It is not clear whether DMJ and KF would affect the function of cell surface glycoproteins that are

involved in specific chemical recognition reactions, but one would expect that they should, since the specific carbohydrate structure should be involved.

A third site of inhibition is another mannosidase called mannosidase II that removes two mannoses from GlcNAc-Man_5-$GlcNAc_2$ to give a GlcNAc-Man_3-$GlcNAc_2$ structure, but this enzyme requires that the GlcNAc be added before it can release the two mannoses. Mannosidase II is not susceptible to DMJ or KF but is inhibited by swainsonine (SW), another plant alkaloid that has a structure related to mannose. Inhibition of mannosidase II by SW gives rise to hybrid structures like those found in humans with HEMPAS disease. In many systems, SW had little effect on functional aspects of the proteins in question, although it did cause the oligosaccharide structures to be of the hybrid type. However, SW did inhibit the attachment of osteoblasts to bone, and it also inhibited the interaction of the parasite *Trypanosoma cruzi* with macrophages when either the parasite or the macrophages were treated with this drug. This alkaloid also caused a dramatic decline in the ability of B16 melanoma cells to colonize the lungs of experimental animals. As a result of these studies, SW has been undergoing various tests to determine whether it will be useful as an anticancer drug.

Glossary

chemical recognition The chemical process by which molecules recognize other molecules and interact with or bind to them; in many cases of chemical recognition in living cells, a protein (called a lectin) on one cell recognizes a specific carbohydrate structure on another cell.

glycosidases Enzymes that cleave glycosidic bonds and release the monosaccharide from the nonreducing end of an oligosaccharide chain; these enzymes are specific for the sugar released and for the anomeric configuration.

glycosylation The process of addition of sugars to another molecule; in the context of this treatise it refers to the addition of sugars to proteins.

glycosylation inhibitors In the broadest context, this terminology refers to compounds that inhibit the formation of glycosidic bonds; in this treatise it refers to compounds that either prevent glycosylation of proteins or cause modifications in the oligosaccharide structure.

glycosyltransferases Enzymes that transfer sugars from their activated state to other sugars or to other molecules with the formation of a glycosidic linkage.

lectins Proteins that recognize specific carbohydrate structures and bind to these carbohydrates; they are frequently involved in recognition.

***N*-linked glycoproteins** Those proteins that have sugars (i.e., oligosaccharides) attached to the protein via an N-glycosidic linkage, which is to the amide nitrogen of asparagines.

Biography

Alan Elbein is Professor and Chairman of the Department of Biochemistry and Molecular Biology at the University of Arkansas for Medical Sciences in Little Rock. He received his Ph.D. in microbial biochemistry from Purdue University and did postdoctoral research at the University of Michigan and the University of California at Berkeley. He joined the faculty as an Assistant Professor of Biology at Rice University and then moved to the Department of Biochemistry at the University of Texas Health Science Center at San Antonio as Professor. His research focuses on the role of complex carbohydrates in glycoprotein function, and on novel carbohydrate target sites in chemotherapy of microbiol diseases.

Protein Glycosylation, Overview

Natasha E. Zachara and Gerald W. Hart
The Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

Protein glycosylation is the enzymatically catalyzed attachment of glycans (carbohydrates) through a covalent bond to the polypeptide backbone of proteins. Protein glycosylation is a common co and/or posttranslational modification of eukaryotic proteins, and has now been found on a subset of proteins in both eubacteria and archaebacteria. Glycosylated proteins, termed glycoproteins, are distributed widely throughout the eukaryotic cell, being found in the extracellular space, on integral and peripheral membrane proteins, in the cytoplasm and nucleus, and in other subcellular organelles. Glycoproteins of prokaryotes (eubacteria and archaebacteria) are predominantly extracellular.

Basic Nomenclature

For small molecules, carbohydrates are complex! Carbohydrates gather their name from early studies which showed they had the chemical composition $(C(H_2O))_x$, or hydrated carbon. The carbons can be arranged in either an open conformation (less common) or one of two ring forms – the furanose (*f*) form (5 membered) or the pyranose (*p*) form (6 membered). Like amino acids, there is a dextrorotatory (D) and a levorotatory (L) enantiomer. The anomeric carbon, the carbon which forms the cyclic hemiacetal, is defined as carbon 1 (See Figure 1) and then the carbons are labeled two through six sequentially around the ring. Moreover, bonds formed by the hydroxyl group of the anomeric carbon can be in either of two conformations, leading to the α-sugar (axial bond), or β-sugar (equatorial bond). A nomenclature has evolved to describe all of these features accurately. For example, glucose or D-Glucopyranose, is abbreviated to D-Glc*p*. When defining the anomericity of the carbohydrate, the abbreviation (α,β) is included preceding the name of the sugar, for example the α-anomer of D-Glc*p* becomes D-αGlc*p*.

Carbohydrates can form covalent linkages through all of their hydroxyl groups to proteins, other carbohydrates or small molecules such as sulfate and phosphate. When sugars are linked together and then to a protein the structure is written from the nonreducing to reducing end (carbohydrate attached to the protein backbone). The position of the linkage is designated by the carbon residue to which the hydroxyl group forming the bond is linked. Thus, when the anomeric carbon of D-βGal*p* (galactose) is linked to the number 3 hydroxyl of D-αGalNAc*p* (*N*-acetylgalactosamine), which is then linked to protein, the resulting disaccharide is written D-βGal*p*1–3 D-αGalNAc*p*1-. Sometimes this is written as D-Gal*p*β1–3 D-GalNAc*p*α1-.

The Protein Carbohydrate Linkage

In the 1930s, Albert Neuberger and co-workers were able to demonstrate the first nonmucin protein carbohydrate linkage. These and subsequent studies showed that there was an amide bond between an asparagine (Asn) residue in chicken egg albumin (ovalbumin) and *N*-acetylglucosamine (GlcNAc). It is now known that of the 20 common amino acids, eight are involved in one of five chemically distinct covalent linkages to one of 13 different classes of carbohydrates. Variations in the covalent linkage, configuration of the linkage (α or β), the amino acid and the carbohydrate result in at least 41 different carbohydrate-protein linkages (Table I).

The five common covalent linkages between carbohydrates and proteins are:

1. *N-linked glycosylation*. This glycosylation typically refers to the amide bond formed between GlcNAc and Asn in the β-conformation. Less common amide bonds have been found between Asn and Glc, GalNAc and Rhamnose (Rham), and more recently between arginine (Arg) and Glc (Table I).
2. *O-linked glycosylation*. This glycosylation describes carbohydrates bound to the protein backbone through hydroxyl residues, such as those in serine (Ser), threonine (Thr), tyrosine (Tyr), hydroxylysine (Hly), and hydroxyproline (Hpr). O-linked sugars involve the greatest number of amino acids, sugars, and anomeric linkages (Table I), although in mammals the best characterized-O-linkage is to αGalNAc. As it was first characterized on mucins, it is often referred to as mucin-like glycosylation.

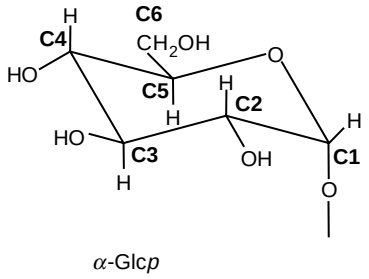

FIGURE 1 The hemiacetyl form of glucopyranose. Carbons are labeled from the anomeric carbon, C1.

3. *Glycosylphosphatidyl inositol (GPI)-anchors*. This is sometimes referred to as glypiation. GPI-anchors link the terminal residue of a protein through phosphoethanolamine to a core structure, which contains mannose (Man), glucosamine (GlcN), and inositol, to a lipid moiety, which anchors the protein in the lipid bilayer.

4. *C-mannosylation*. This is the attachment of an α-Man to carbon-2 of the indole ring of tryptophan (Trp). This form of protein glycosylation has been identified in eukaryotes on proteins such as RNAse2, interleukin-12 and properdin.

5. *Phosphoglycosylation*. This is the linkage of a carbohydrate through a phosphodiester bond to amino acids, such as Thr and Ser.

There are some posttranslational modifications of proteins that contain sugar, such as ADP-ribosylation that will not be discussed in this article. In addition, nonenzymatic glycation, the chemical reaction of reducing sugars with proteins, common in tissues and cells exposed to high levels of reducing saccharides, is not a form of protein glycosylation as (1) this reaction is not catalyzed by glycosyltransfereases; and (2) the Schiff base addition and subsequent Amadori rearrangement of the reducing sugar results in advanced glycation end products which can no longer be classified as carbohydrates.

Glycoprotein Synthesis

The extension of the first carbohydrate linked to the amino acid, sometimes referred to as the reducing terminal sugar, to form longer structures is typically performed in a stepwise manner. The exceptions are N-linked glycosylation and glypiation, where a core structure is added *en bloc* to the polypeptide chain and then remodeled.

Glycosyltransferases

The enzymatic addition of a carbohydrate to the protein backbone and the further modification of this carbohydrate is catalyzed by glycosyltransferases. These enzymes are typically type 2 membrane proteins that are situated in either the membrane of the endoplasmic reticulum (ER) or Golgi apparatus (Golgi), typically orientated toward the lumen of each organelle. Each different carbohydrate linkage is catalyzed by at least one glycosyltransferase.

Activated sugar nucleotide precursors, such as uridine diphosphate (UDP)- and guanosine diphosphate (GDP)-sugars, are necessary for the formation of all enzymatically synthesized glycosidic bonds. However, in some types of glycosylation, the sugar is transferred to a different intermediate donor, such as a lipid carrier, for example polyisoprenol monophosphate:dolichol phosphate (Dol-P), before transfer to the protein.

N-Linked Glycosylation

In eukaryotes, the initiation of N-linked glycosylation involves the synthesis of the core N-linked oligosaccharide, dolichol-diphosphate-$GlcNAc_2Man_9Glc_3$, on the cytosolic side of the ER membrane. After translocation to the lumen of the ER, the core structure is transferred *en bloc* to an Asn residue in the amino acid motif Asn-Xaa-Ser/Thr (Xaa $\neq$ Pro). Recently, it has been shown that when Cys is substituted for Ser/Thr, glycosylation may still occur in some cases. After transfer of the polypeptide to the Golgi, the core structure undergoes remodeling, resulting in three classes of N-linked glycosylation: high-mannose, hybrid, and complex (Figure 2).

High mannose structures contain more than the three mannose residues found in the core structure, and typically no other carbohydrate residues; while in complex structures both the terminal mannose residues in the core structure are typically modified by lactosamine (Gal1-4βGlcNAc) which can subsequently be modified further. Hybrid structures contain more than the three mannose residues in the core structure, as well as one or more lactosamine units.

O-Linked Glycosylation

Mammalian ER /Golgi Glycosylation

Unlike N-linked glycosylation, there is no single glycosylation motif that predicts the addition of O-linked carbohydrates to hydroxyl residues. O-glycosylation of cell-surface and secreted proteins in mammals appears to be initiated in the Golgi with the transfer of a monosaccharide residue from an activated sugar nucleotide to a hydroxyl residue. The reducing terminal sugar is further modified by stepwise addition of sugars from activated sugar nucleotides in the Golgi.

TABLE I

Different Types of Enzymatic Protein Glycosylation

Type	Reducing terminal linkage	Amino acid	Occurrence
N-linked	βGalNAc	Asn	Archaebacteria
	βGlc	Asn	Laminin only (Animals), Archaebacteria
	βGlcNAc	Asn	Common
	Rham	Asn	Eubacteria
	βGlc	Arg	Plants
O-linked	α Ara*f*	Hpr	Plants
	βAra	Hpr	Plants
	α Fuc	Ser, Thr	Animals
	αGal	Hpr	Plants, Eubacteria
	αGal	Ser, Thr	Plants, Eubacteria
	αGal	Hyp	Plants
	βGal	Hly	Collagen only (Animals)
	βGal	Tyr	Eubacteria
	αGalNAc	Ser, Thr	Common
	βGalNAc	Ser, Thr	Eubacteria
	αGlc	Tyr	Glycogen only (Animals)
	βGlc	Tyr	*C. thermohydrosulfuricum*
	βGlc	Ser, Thr	Eubacteria, Animals
	αGlcNAc	Ser, Thr	Protozoan
	βGlcNAc	Ser, Thr	Animals (cytoplasmic/nuclear)
	GlcNAc	Hyp	*D. discoideum*
	αMan	Ser, Thr	Animals, Fungi
	β FucNAc	Ser	*P. aeruginosa*
	β Xyl	Ser	Proteoglycans
	Diactrideoxyhexose	Ser, Thr	*N. meningitidis*
	αpseudaminic acid	Ser, Thr	*C. jejuni*
Phosphoglycosylation	β Fuc	Ser	*D. discoideum*
	αGlcNAc	Ser	*D. discoideum*
	αMan	Ser	*Leishmania mexicana*
	Xy1	Ser, Thr	*Trypanosoma cruzi*
C-mannosylation	αMan	Trp	Mammals
GPI-anchor	Conserved Core	C-terminal	Eukaryotic

Nonmammalian ER /Golgi Glycosylation

O-glycosylation of the protein backbone in fungi appears to be through lipid-P-donors. In yeast, addition of O-linked glycans is restricted to Dol-P-Man, although other fungi are capable of modifying the protein backbone with Glc and Gal. The study of prokaryotic glycosylation is an emerging field, and little information about the biosynthesis of prokaryotic glycosylation is available.

Cytosolic Glycosylation in Eukaryotes

Many nuclear and cytoplasmic proteins are glycoproteins, these proteins are modified with the simplest of the carbohydrate modifications, O-linked β-GlcNAc (*O*-GlcNAc). Unlike other forms of protein glycosylation, this modification is usually not further extended and occurs exclusively on cytoplasmic and nuclear proteins of metazoans. Consequently, the enzyme, which catalyzes the addition of *O*-GlcNAc, UDP-GlcNAc:polypeptide *O*-*N*-acetylglucosaminyl transferase, is not a type 2 membrane protein. Unlike other glycosyltransferases, this protein has tetratricopeptide repeat domains, which are protein–protein interaction domains and which have been shown to play a role in substrate recognition. Another form of intracellular protein glycosylation, involves the addition of GlcNAc to hydroxyproline of the ubiquitin ligase, Skp1, of the slime mold *Dictyostelium discoideum*. The enzyme has

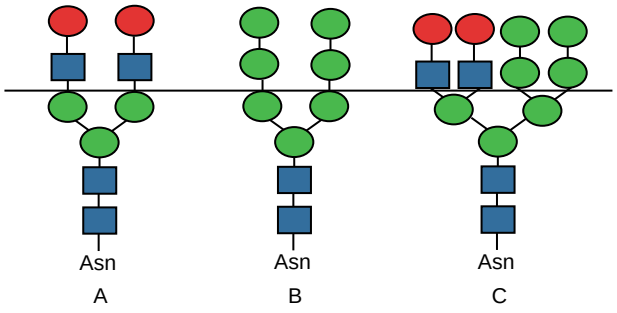

FIGURE 2 Different subgroups of N-linked oligosaccharides. (A) A complex-type oligosaccharide; (B) high-mannose-type oligosaccharide; (C) hybrid-type oligosaccharide. Structures below the solid line are common, while the structures above the line can vary. Further modification of the common structure with GlcNAc and Fuc is known. Different carbohydrates are represented by blue boxes (GlcNAc), green circles (Man), and red circles (Gal).

recently been cloned and appears unrelated to the metazoan GlcNAc transferase.

GPI-Anchors

There are several parallels between the biosynthetic pathways of GPI-anchors and N-linked oligosaccharides. Like the synthesis of N-linked glycosylation, a donor molecule is assembled on the cytosolic side of the ER membrane. Here, UDP-GlcNAc is first added to a phosphatidyl inositol ring, before the acetyl group is removed. Subsequent addition to the GlcN is via Dol-P-Man. Once complete, the structure is translocated through the ER membrane into the lumen, where it is attached to the completed polypeptide after a GPI-anchor consensus motif (C-terminal peptide) is cleaved off. During transit to the cell-surface the lipid component can be remodeled and the carbohydrate core structure can be further processed to give a range of glycoforms. While the core structure of all GPI-anchors appears to be identical, variations in structure appear to involve the nature of the lipid anchor and modification of the core carbohydrate structure with ethanolamine or other carbohydrate chains, the nature of which appear to be species and genera specific.

C-Mannosylation

C-mannosylation represents a linkage in which αMan is attached through a C-glycosidic linkage to the indole ring of Trp. Recently, it has been shown that this modification is added to the first Trp in the motif Trp-Xaa-Xaa-Trp, from a Dol-P-Man donor. This activity has been isolated in crude membrane preparations, suggesting ER/Golgi localization of this enzyme.

Phosphoglycosylation

First identified in *D. discoideum* in 1980 on the endopeptidase proteinase I, this modification, which involves the attachment of carbohydrate through a phosphodiester linkage to the protein backbone, has now been identified on a number of other proteins and in a number of different organisms, although the carbohydrate component differs. Recently, the *N*-acetylglucosamine-α-1-phosphate transferase from *D. discoideum* was partially purified from microsomal preparations and characterized.

Glycoforms of Glycoproteins

The carbohydrate components of proteins are by nature heterogeneous! Variations can occur in terms of the occupancy of potential sites of glycosylation (macroheterogeneity) or in the structures at sites of glycosylation (microheterogeneity), resulting in a variety of protein populations or glycoforms. One example of microheterogeneity is ovalbumin, which has one site of N-linked glycosylation, at which 22 different polysaccharides have been characterized.

Unlike proteins, the sequence of carbohydrates are not directly encoded for by the genome. The modification of proteins is dependent on the expression and regulation of different glycosyltransferases, sugar nucleotide levels, folding and transport of the polypeptide, and a myriad of other factors. Thus, different organisms, tissues and proteins are modified differently depending on the cellular environment, that is, the state of differentiation, development, disease, and cell cycle.

Glycosylation and Function

Deletion or mutation of glycosyltransferases results in predominantly severe to lethal phenotypes, underlying the importance of carbohydrates in the development and maintenance of organisms. While the inherent heterogeneity of carbohydrates has made defining the exact function of carbohydrate structures challenging, several clear roles have emerged from functional studies (Table II). Some examples are discussed below:

Protective

The epithelial surfaces of many organisms are coated with a mucous layer, one component of which are mucins. These high molecular weight glycoproteins are heavily glycosylated, and the carbohydrate component of these proteins are multifunctional. The negatively

TABLE II

Hormonal actions

charged sugars in the oligosaccharides bind water tightly, preventing evaporation from the cell. In addition, the resulting gel protects cells from mechanical damage and bacterial attack, while providing specific binding sites for lectins.

Structural

Heavily glycosylated domains, that are reminiscent of mucins, are sometimes referred to as mucin-like domains. Here, hydration of the sugar residues appears to stiffen the protein backbone projecting different domains of proteins from each other and/or the plasma membrane.

Regulatory

The modification of nuclear and cytoplasmic proteins of metazoans with monosaccharides of O-Linked β-*N*-acetylglucosamine (*O*-GlcNAc) has been implicated in cellular control, playing an analogous role to protein phosphorylation. Like many forms of protein glycosylation, deletion of the *O*-GlcNAc transferase is lethal. While all of the functions of *O*-GlcNAc have not been elucidated, it is now clear that this modification alters protein–protein interactions, turnover rate of proteins and the phosphorylation state of proteins by competing with kinases for hydroxyl residues. Recently, perturbations in the regulation of *O*-GlcNAc have been implicated in the etiology of Type 2 diabetes.

Proteolysis and Stability

Carbohydrate modifications of proteins can affect the stability of proteins by several mechanisms. Carbohydrate modifications can reduce the availability of the protein backbone to proteolytic attack by steric hindrance, one example of this is seen on tissue plasminogen activator. Carbohydrates can stabilize protein structure by forming bonds, such as hydrogen bonds, with the protein backbone. Examples of this have been found in proteins such as CD2 and PMP-c protease inhibitor.

Intermolecular Interactions

Protein–protein interactions can be mediated by proteins through carbohydrate-binding domains. Proteins with such domains and which do not modify the carbohydrate are called lectins. There are several well-characterized families of lectins which are both intracellular and extracellular. Lectins mediate many important interactions within and between cells, possibly the best-characterized example are those of the selectins. Selectins mediate the interactions/movement between leukocytes and the endothelial surfaces of blood vessels.

Another key example of lectin–carbohydrate interactions are those that occur within the endoplasmic reticulum, between N-linked carbohydrates and the lectins, calnexin and calreticulin. If a protein folds properly, processing of N-linked glycosylation progresses, and calnexin and calreticulin fail to bind; improperly folded proteins are not processed, are bound by the lectins and presented to proteins such as Erp57, a protein disulphide isomerase, for refolding. Lectins are also involved in the export and degradation of misfolded proteins, as well and the transport of proteins from the ER to the Golgi.

Glossary

glycoprotein A glycosylated protein.

glycosyltransferase An enzyme which transfers a sugar from a high energy donor to a protein, carbohydrate, or lipid.

reducing terminal sugar The carbohydrate linked directly to the protein backbone is often referred to as the reducing terminal saccharide or carbohydrate. This term is derived from early colorometric assay where the free hemiacetal form of sugars reduced ferric iron to ferrous iron.

saccharides Saccharide is derived from the Latin word for sugar, *saccharum*. A single sugar unit is referred to as a monosaccharide, two units as a disaccharide, three as a trisaccharides and several (2–10) as oligosaccharides and many (>10) as polysaccharides.

Biography

Natasha E. Zachara received Bachelor of Technology (Biotechnology), Honours, from the School of Chemistry at Macquarie University (Sydney, Australia), in 1994. She completed her thesis entitled "Sequencing Proteins, Sequencing Sugars: A Unified Approach" at the Macquarie University Center for Analytical Biotechnology (Sydney, Australia), in 1998. She is currently working in the laboratory of Prof. G. W. Hart (Johns Hopkins University School of Medicine).

Gerald W. Hart is Director and DeLamar Professor of Biological Chemistry at the Johns Hopkins University School of Medicine. He received his Ph.D. in developmental biology at Kansas State University (USA) in 1977 and did his postdoctoral work with William J. Lennarz at Johns Hopkins, before joining the faculty in the Department of Biological Chemistry (1979). He was the founding editor-in-chief of *Glycobiology.*

Protein Import into Mitochondria

Johannes M. Herrmann and Walter Neupert
University of Munich, Munich, Germany

Mitochondria are essential organelles of eukaryotic cells that accommodate some 10–20% of the cellular proteome. They are made up by two membrane systems that divide the organelle into two aqueous subcompartments: the intermembrane space between the outer and the inner membrane, and the matrix which is enclosed by the inner membrane. The vast majority of mitochondrial proteins are encoded by the nuclear genome and synthesized on cytosolic ribosomes as precursors (also called preproteins). These proteins contain targeting information for specific sorting of each polypeptide to its respective mitochondrial subcompartment. Protein import into mitochondria is achieved by the concerted action of translocation complexes located in both membranes of the organelle.

Mitochondrial Targeting Signals

Targeting signals direct mitochondrial precursor proteins to their particular destination in the organelle. In addition, these sequences can prevent folding of precursor proteins in the cytosol and thereby maintain them in a transport-competent conformation. Proteins of the mitochondrial matrix and many inner membrane proteins are made with N-terminal extensions which are proteolytically removed by proteases following translocation into the mitochondrial matrix. These matrix targeting signals (MTSs) are referred to as presequences. Most mitochondrial proteins carry such N-terminal presequences. In addition, less defined internal signals are used for mitochondrial targeting, typically by proteins of the outer membrane, the intermembrane space, and by some inner membrane proteins.

Presequences

Presequences typically comprise 15–80 amino acid residues that have the potential to form amphipathic α-helices with one hydrophobic and one positively charged face. These signals are both necessary and sufficient for mitochondrial targeting. The addition of presequences to unrelated proteins typically leads to a targeting of the fusion proteins to mitochondria. The MTSs direct the extended polypeptide in an N-to-C-direction across both mitochondrial membranes. Examples were reported in which MTSs are located not at the N terminus, but at the C terminus or in the interior of a preprotein. In the latter case, the internal signal forms an amphipathic hairpin loop which precedes import of the N- and C-terminal parts of the preprotein. Typical N-terminal presequences can be detected by computer algorithms which predict the intracellular location of proteins.

Internal Targeting Signals

Many mitochondrial proteins contain less defined targeting signals which are a part of the mature polypeptide. These are referred to as internal signals. For example, proteins of the solute carrier family of the inner membrane are made up by modules of pairs of transmembrane domains which are imported as loop-like structures. The regions flanking these transmembrane domains are critical for the uptake of these proteins by the mitochondria. The nature of these signals and how they are deciphered is, however, not well understood.

Proteins of the outer membrane are often anchored in the lipid bilayer by terminal transmembrane domains. A moderate degree of hydrophobicity and flanking positive charges specify these proteins for mitochondria and differentiate them from other tail-anchored proteins of the cell.

Little is known about the targeting information that directs proteins into the intermembrane space of mitochondria. Many of these proteins are very small and bind cofactors such as metal ions or heme. The best-characterized example of the latter group of proteins is cytochrome *c*. Although many cytochrome *c* mutants were isolated that fail to be imported into mitochondria, a targeting signal of this protein was not identified so far.

Transport to and Across the Outer Membrane

A number of cytosolic factors were identified that bind to mitochondrial preproteins following their synthesis. Among these factors are members of the general chaperone system, such as Hsp70 and Hsp90,

and components that appear to play a more specific role in the targeting of mitochondrial proteins. These factors keep preproteins in an import-competent conformation and accompany them to the surface of mitochondria.

The TOM Translocase

The outer membrane harbors surface receptors that expose binding sites for MTSs to the cytosol (see Table I). These receptors are part of a multimeric protein translocase, called the *t*ranslocase of the *o*uter *m*embrane (TOM) complex. In fungi, the TOM complex comprises the receptor subunits Tom70, Tom22, and Tom20. These surface receptors direct preproteins to the so-called "general insertion pore" of the outer membrane, the main constituent of which is Tom40. Tom40 is thought to be present in a β-barrel structure in the outer membrane, similar to bacterial porin proteins, and

by oligomerization forms protein-conducting channels. Three small additional subunits, Tom5, Tom6, and Tom7, appear to play a role as structural components and might be involved in regulating the interaction of the receptors with Tom40. In mammals, the TOM complex consists essentially of a similar set of homologous components. High-resolution electron microscopy of isolated TOM complexes revealed two membrane-traversing cavities of 2.2 nm, which most likely represent the preprotein-conducting channels in the outer membrane. Following translocation of preproteins through the general insertion pore, preproteins associate with the *trans* site of the TOM complex. This *trans*-binding site is formed by the intermembrane space domains of Tom40 and perhaps Tom22. An increasing binding affinity from *cis* to *trans* sites on the TOM complex was suggested to drive translocation of preproteins across the outer membrane into the intermembrane space.

Insertion into the Outer Membrane

In addition to its translocation function, the TOM complex facilitates the insertion of proteins into the lipid bilayer of the outer membrane (Figure 1, pathway 1). Although the molecular mechanism of this process is poorly understood, a critical role of the TOM complex was shown for membrane integration and assembly of TOM subunits, as well as for the insertion of other outer membrane proteins. The most abundant protein of the outer membrane, porin, and several tail-anchored proteins, like the apoptosis regulator bcl-2, require cytosolic receptor domains of TOM subunits for mitochondrial targeting. But, whereas integration of porin requires the general insertion pore in the TOM complex, bcl-2 was reported not to use the TOM channel.

Translocation into the IMS

The intermembrane space is a compartment of very small volume since the outer and inner membrane are ~ 8 nm apart which is about the diameter of a membrane. Only a rather small number of components of the intermembrane space are known most of which are required for mitochondrial biogenesis or have a function in respiration. A prominent example is cytochrome *c*, which plays a role in apoptosis apart from its function in shuttling electrons between complexes III and IV. Apocytochrome *c* is imported by the TOM complex and associates in the intermembrane space with the protein cytochrome *c* heme lyase (CCHL). CCHL represents a docking site for apocytochrome *c* and converts it to holocytochrome *c* by incorporation of a heme group. Holocytochrome *c* is not able to traverse the TOM channel and, thus, remains in the intermembrane space. Like cytochrome *c*, many intermembrane space proteins bind cofactors and may be imported by a similar mechanism (Figure 1, pathway 2).

A second group of intermembrane space proteins is synthesized with N-terminal presequences followed by sorting signals. These signals are proteolytically removed by the Imp1/Imp2 protease of the inner membrane and the mature parts of the precursors are released into the intermembrane space. These sorting signals can be transplanted to unrelated sequences and direct these into the intermembrane space. Examples for this type of proteins are cytochrome b_2 or cytochrome b_5 reductase.

Translocation into the Matrix

The mitochondrial matrix contains a large number of proteins, many of which fulfill important functions in metabolic processes, energy production or the replication and expression of the mitochondrial genome. These proteins typically contain N-terminal presequences and are imported on a common import route (Figure 1, pathway 4).

The TIM23 Complex

The TIM23 complex consists of the integral membrane proteins Tim50, Tim23, and Tim17, and the peripherally associated matrix protein Tim44. Tim23 and Tim17 are homologous to each other and form the translocation pore in the inner membrane. In yeast, the N terminus of Tim23 protrudes into the outer membrane and thereby may mediate close contact of the TOM and the TIM23 translocase. Tim50 exposes a large domain to the intermembrane space and might play a role in guiding preproteins from the TOM to the TIM23 complex. Binding of the presequence to the TIM23 complex leads to a membrane-potential-dependent gating of the channel, which allows the presequence to traverse the inner membrane. This translocation reaction is driven by the membrane potential which probably supports the movement of the positively charged presequences to the negatively charged matrix face of the inner membrane. In the matrix, the presequences are bound by the chaperone mtHsp70, which prevents backsliding of the translocation intermediate. MtHsp70 is recruited to the TIM23 translocase by the Tim44 subunit of the complex which warrants a high concentration of mtHsp70 at the exit of the TIM23 channel and, thus, the efficient trapping of the incoming polypeptide. The ATP-dependent interaction of mtHsp70 with the preprotein is regulated by a nucleotide exchange factor, mtGrpE/Mge1, and is responsible for the ATP dependence of the mitochondrial import process. Binding of the preprotein to mtHsp70 leads to the

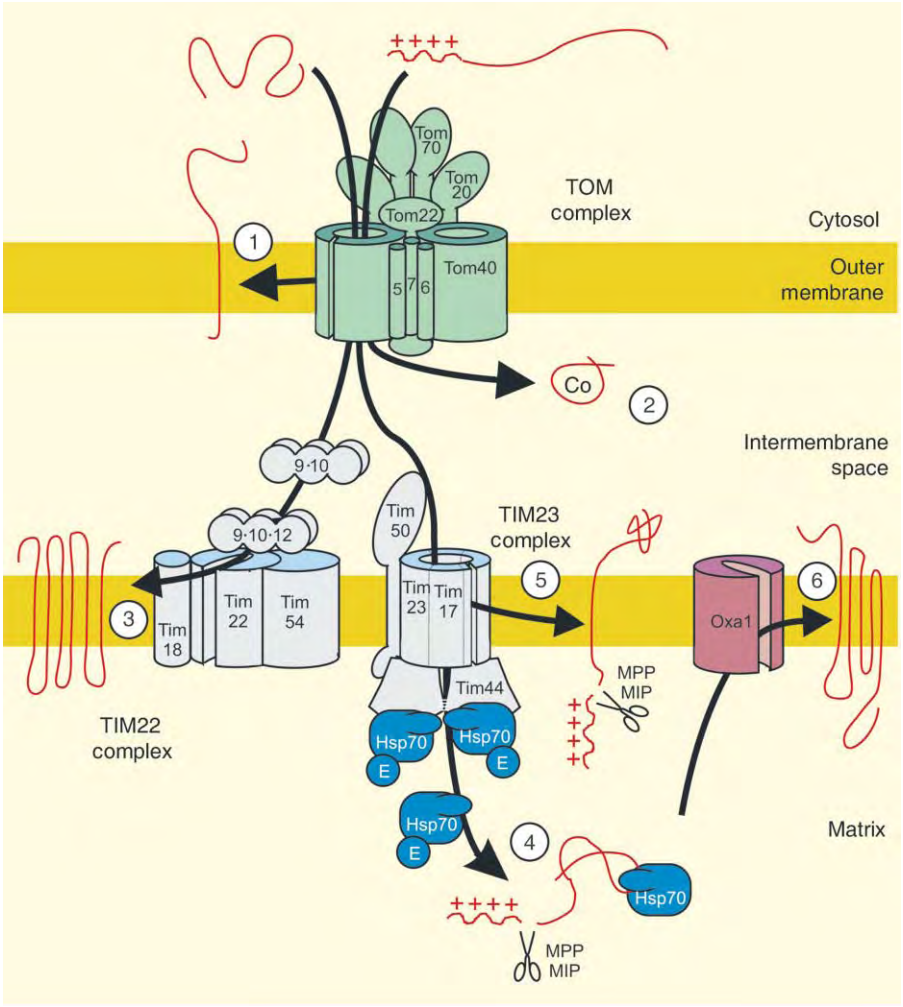

FIGURE 1 Protein import pathways in mitochondria. (1) Most outer membrane proteins bind to the receptor subunits of the TOM complex before they integrate into the membrane. The role of the general insertion pore in this process is not fully understood. (2) Proteins of the intermembrane space are often of small size and bind cofactors. These proteins are translocated through the general insertion pore of the TOM complex formed by Tom40. In the case of cytochrome c, the acquisition of the cofactor heme (Co) is required for efficient translocation of the protein. (3) Members of the solute carrier family and some Tim subunits traverse the outer membrane forming loop-like structures. They are escorted to the TIM22 translocase in the inner membrane by complexes of small Tim proteins in the intermembrane space. (4) Matrix proteins contain presequences that mediate translocation through the TOM channel and interact with the TIM23 complex in the inner membrane. The presequences are transported across the inner membrane in a membrane potential- and ATP-dependent manner, and removed by processing peptidases. After complete translocation across the inner membrane, matrix proteins fold under assistance of molecular chaperones. (5) Monotopic inner membrane proteins can be arrested at the TIM23 translocase and laterally integrated into the lipid bilayer of the inner membrane. (6) Conservatively sorted proteins are first transported into the matrix and form sorting intermediates bound by mtHsp70. Subsequently, these proteins are inserted into the inner membrane in a membrane potential-dependent reaction. The inner membrane protein Oxa1 is required for membrane integration of several of these proteins.

release of mtHsp70 from Tim44, and allows further translocation of the preprotein into the matrix driven by the Brownian movement of the polypeptide. Repeated binding cycles of mtHsp70 then lead to the vectorial import reaction. This mechanism is referred to as Brownian ratchet model as mtHsp70 would prevent backsliding of the preprotein. It was suggested that in addition to its trapping function, mtHsp70 undergoes an intramolecular conformational change and thereby mechanically pulls the bound preprotein into the matrix. The validity and significance of this motor model is still under debate.

Protein Folding and Assembly

In the matrix the presequences are typically removed by processing peptidases. The mitochondrial processing peptidase (MPP) consists of two conserved subunits which convert most matrix proteins into their mature form. In addition, some preproteins are further

processed by the mitochondrial intermediate peptidase, which removes another eight N-terminal amino acid residues. The mature proteins are then allowed to fold into their native structure. This process is facilitated by mtHsp70 which cooperates in this process with the DnaJ homologue Mdj1/hTid. Folding of some matrix proteins depends on the chaperonin complex formed by Hsp60 and Hsp10, which is homologous to the GroEL/GroES complex of the bacterial cytosol.

Protein Insertion into the Inner Membrane

The inner membrane contains a large number and diversity of proteins and belongs to the protein-richest membranes of eukaryotic cells. Inner membrane proteins reach their destination on several different insertion routes.

Insertion via the TIM23 Translocase

A number of monotopic inner membrane proteins are integrated into the inner membrane following translocation arrest at the level of the TIM23 complex (Figure 1, pathway 5). This sorting route was named the "stop-transfer" pathway. Most of these proteins are of $N_{in}-C_{out}$ topology, but some examples were reported which are oriented in a $N_{out}-C_{in}$ topology by internal loop-forming presequences.

Insertion from the Matrix

Alternatively, proteins can be inserted into the inner membrane following complete translocation into the matrix (Figure 1, pathway 6). This transport scheme was called conservative sorting, since the process employs a bacterial-like insertion reaction from the matrix. Examples for this sorting path are both mono- and polytopic inner membrane proteins of prokaryotic origin. Not only the direction of the membrane integration reaction resembles that in prokaryotes, but also the topogenic signals and the components that catalyze the insertion process. Conservatively sorted proteins adhere to the positive-inside rule according to which negative charges flanking the transmembrane segments are preferentially translocated across a membrane. A central player in the insertion process of these proteins is the inner membrane protein Oxa1 which forms the only translocation complex known to be conserved from bacteria to mitochondria. Besides its role in membrane integration of conservatively sorted proteins, the Oxa1 translocase mediates the insertion of mitochondrial translation products into the inner membrane.

Insertion via the TIM22 Translocase

The third group of inner membrane proteins is inserted by an alternative TIM complex, the TIM22 translocase (Figure 1, pathway 3). This pathway is used by members of the solute carrier family and by some TIM subunits. These proteins do not contain presequences but internal signals. Upon translocation through the TOM complex these proteins associate with the hexameric Tim9·Tim10 and Tim8·Tim13 complexes of the intermembrane space which belong to the family of "small Tim proteins." These complexes escort the hydrophobic precursor proteins from the TOM complex through the intermembrane space to the TIM22 complex. The TIM22 complex comprises the membrane-embedded subunits Tim54, Tim22, and Tim18 to which a Tim9·Tim10·Tim12 hexamer is associated. Tim22 is related to Tim17 and Tim23, and forms the translocation pore of the complex. Mutations in the human Tim8 homologue, DDP1, lead to the deafness dystonia (Mohr-Tranebjaerg) syndrome, a progressive, neurodegenerative human disorder.

Glossary

Oxa1 translocase Protein complex of the inner membrane of mitochondria that facilitates membrane insertion of both nuclear and mitochondrially encoded proteins.

preprotein Precursor form of a mitochondrial protein; preproteins often contain presequences that have to be removed by mitochondrial processing peptidases.

presequence Typically N-terminal extension on a protein that serves as mitochondrial targeting signal (MTS).

TIM translocases Oligomeric translocation complexes of the inner membrane of mitochondria.

TOM translocase Multisubunit translocation complex of the outer membrane of mitochondria consisting of receptor subunits and a protein-translocating channel.

Protein Kinase B

Bettina A. Dummler and Brian A. Hemmings
Friedrich Miescher Institute for Biomedical Research, Basel, Switzerland

Protein kinase B (PKB, also known as AKT) is an important mediator in intracellular signaling. Activation of PKB occurs in response to several cellular stimulants that act through receptor tyrosine kinases or G protein-coupled receptors. As a protein kinase, PKB catalyzes phosphorylation of proteins (the covalent linking of a phosphate group) on serine and threonine residues within a specific recognition sequence. Phosphorylation is a common mechanism in signal transduction to reversibly alter protein function, such as intrinsic activity, subcellular localization, half-life, or interaction of proteins with binding partners. Multiple PKB substrates have been identified and regulation of these molecules by phosphorylation plays an important role in the elaboration of physiological changes in a cell in response to extracellular signal molecules. Depending on cell type and stimulus, widely divergent cellular processes are regulated by PKB, including apoptosis, proliferation, differentiation, and metabolism.

Structure of PKB and Activation Mechanism

The AGC Family of Protein Kinases

Protein kinase B (PKB) is a member of a family of protein kinases that originally contained protein kinase *A*, cGMP-dependent protein kinase, and protein kinase *C*, termed the AGC family. Other members of the AGC family include p70 S6 kinase, protein kinase C-related kinase 2 (PRK2), and serum- and glucocorticoid-inducible kinase (SGK). The protein kinases of the AGC family show similarities in many structural and regulatory features. Highly similar in all AGC kinases is a flexible peptide loop (activation loop) proximal to the catalytic pocket of the kinase domain, and phosphorylation of this loop is required for the activation of virtually all AGC kinases.

Isoforms of PKB

There are three mammalian isoforms of PKB, PKBα (AKT1), PKBβ (AKT2), and PKBγ (AKT3). They are products of distinct genes but highly related, exhibiting greater than 80% sequence identity and sharing the same structural organization (see Figure 1A). The three genes are expressed differentially, with PKBα and PKBβ displaying fairly broad and PKBγ more restricted tissue distribution.

Structure of PKB

Each isoform possesses an amino-terminal pleckstrin homology (PH) domain that binds to 3-phosphoinositides, a central catalytic domain, and a carboxy-terminal regulatory domain (Figure 1A). Furthermore, all three isoforms possess two conserved phosphorylation sites, and phosphorylation of both sites is required for full activation of the kinase. The first one (Thr308 in PKBα) lies within the activation loop of the kinase domain and its phosphorylation induces a catalytically active conformation of the kinase. The second one lies within the regulatory domain in a six-amino-acid-long sequence termed the hydrophobic motif (FPQFS^{473}Y). Phosphorylation at Ser473 enables the hydrophobic motif to bind into a pocket within the small lobe (N-lobe) of the kinase domain and thereby it stabilizes the active conformation of PKB (Figure 1B). All PKB isoforms are assumed to have identical or similar substrate specificity. The minimal consensus sequence of preferred PKB *in vitro* phosphorylation sites has been defined as ArgXArgXXSer/Thr-Hyd, where X is any amino acid and Hyd is a bulky hydrophobic residue. Multiple PKB substrates have now been identified (Table 1).

The PI3K/PKB Signaling Pathway

Activation of receptor tyrosine kinases by ligands such as epidermal growth factor (EGF) and platelet-derived growth factor (PDGF) leads to autophosphorylation of specific tyrosine residues on the intracellular portion of the receptor (Figure 2). Recruitment of phosphoinositol 3-kinase (PI3K) then occurs, via binding of the Src homology 2 (SH2) domains of the regulatory subunit (p85) to specified phosphotyrosine residues on the receptor (in the case of insulin receptor this recruitment

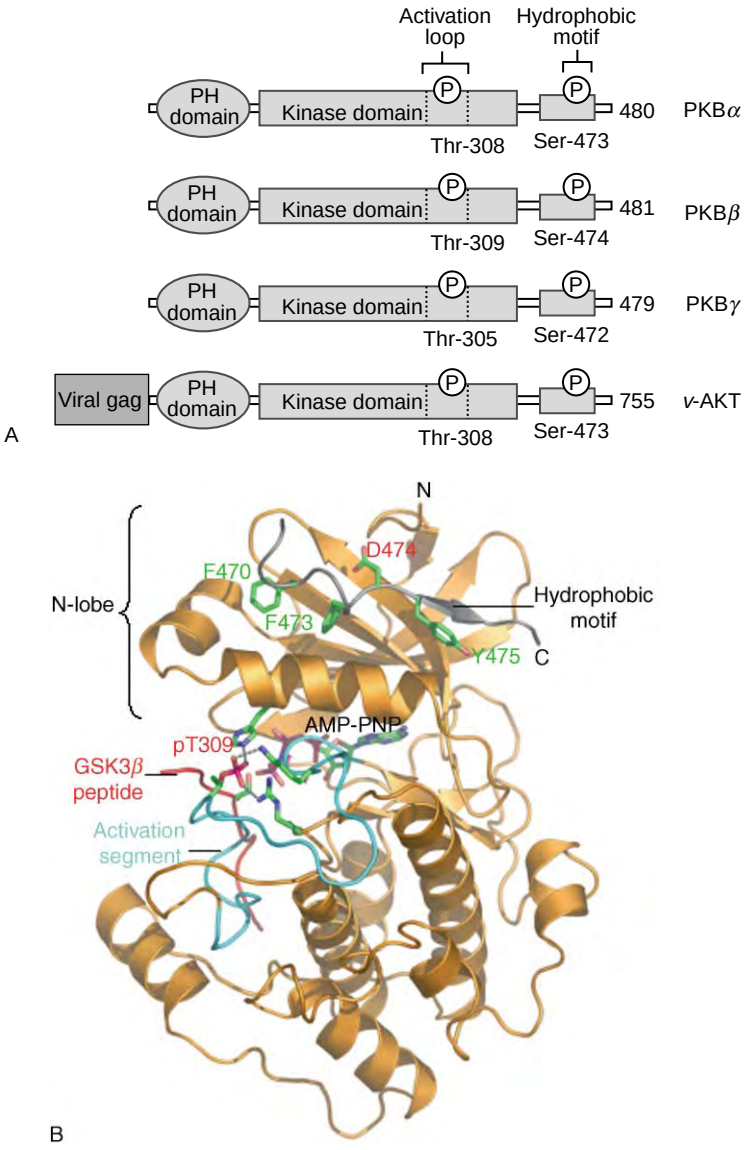

FIGURE 1 (A) Domain structure and regulatory phosphorylation sites of PKB. All isoforms contain a pleckstrin homology (PH) domain, a catalytic domain and a C-terminal regulatory domain. Phosphorylation of the activation loop and the hydrophobic motif (Thr308 and Ser473 in PKBα) are critical for kinase activation. v-Akt is the viral form of PKB and is a fusion between the viral Gag protein and mouse PKBα. (B) Structure of activated PKB. The ribbon diagram shows an activated PKBβ ternary complex with GSK3-peptide (red) bound in the substrate-binding site and AMP-PNP (a hydrolysis-resistant ATP analogue) bound in the ATP-binding site. To obtain an activated conformation, the hydrophobic motif of PKB was replaced with that of another AGC kinase, PRK2, and T309 in the activation segment (blue) was phosphorylated by PDK1. The hydrophobic motif of PRK2 contains an acidic residue (D474) in place of a phosphorylatable serine and binds constitutively to the N-lobe without needing phosphorylation. (Reproduced from Yang, J., Cron, P., Good, V. M., Thompson, V., Hemmings, B. A., and Barford, D. (2002). Crystal structure of an activated Akt/protein kinase B fernary complex with GSK3-peptide and AMP-PNP. *Nat. Struct. Biol.* **9**(12), 940–944, with permission.)

is largely mediated by the insulin receptor substrate (IRS) adapter proteins). This leads to a conformational change in PI3K and consequently to activation of the catalytic subunit (p110). Activated PI3K phosphorylates inositol-containing membrane lipids at the 3′-OH position of the inositol ring, generating phosphatidyl-inositol 3,4,5-trisphosphate (PI(3,4,5)P3). Subsequently, inactive PKB is recruited from the cytosol to the membrane via binding of its PH domain to PI(3,4,5)P3. Membrane recruitment brings PKB in close proximity to 3-phosphoinositide-dependent kinase (PDK1). PDK1 possesses a PH domain in its carboxy terminus, which binds PI(3,4,5)P3 and localizes PDK1 at the membrane. Co-localization of the two proteins and the conformational change induced in PKB upon lipid binding then enable PDK1 to phosphorylate PKB on Thr308 in the activation loop. For full kinase activation, PKB requires phosphorylation of an additional site,

TABLE I

PKB Substrates[a,b]

Protein	Biological effect
BAD	Phosphorylated BAD binds to 14-3-3 and is sequestered in the cytoplasm
BRCA1	Interferes with nuclear localization of BRCA1?
CREB	Increases association with CBP and p130
eNOS	Activates eNOS and leads to NO production
Forkhead family members (FKHR, FKHRL1, AFX)	Inhibits transcriptional activities of Forkhead family members
GSK3α/β	Inactivates GSK3 activity
IKKα	Activates transcriptional activity of NFκB
IRS-1	Positive regulation of IRS-1 function
Mdm2	Nuclear translocation of Mdm2, decreases p53 levels
Nur77	Inhibits transcriptional activity of Nur77
PFK-2	Activates PFK-2
Procaspase-9	Suppression of caspase-9-induced cell death
p21/Cip1	Cell cycle progression
p27/Kip1	Relieves inhibitory effect of p27/Kip1 on Cdk2
Raf1	Inhibition of Raf1 signaling
TSC2	Destabilizes TSC2 and disrupts its interaction with TSC1, leading to p70S6K activation

[a] Abbreviations: BAD, Bcl-2 pro-apoptotic family member; CBP, cAMP binding protein; Cdk2, cyclin-dependent kinase 2; CREB, cAMP responsive element binding protein; eNOS, endothelial nitric oxide synthase; GSK3, glycogen synthase kinase-3; IKKα, I-kB kinase α; IRS-1, insulin receptor substrate-1; NFκB, nuclear factor κB; NO, nitric oxide; PFK-2, phosphofructokinase-2; TSC2, tuberous sclerosis complex 2.

[b] Data supporting the *bona fide* nature of these substrates differs between proteins. Note also that because of space restrictions, not all published PKB substrates are included in the table.

Ser473, by an as yet unidentified Ser473 kinase. Following activation, PKB is detached from the plasma membrane and translocates to the cytosol and the nucleus to phosphorylate its substrates.

Negative Regulation of PKB Activity

Just as important as activation is the negative regulation of PKB activity, to avoid sustained signaling in absence of an appropriate extracellular signal. The key pThr308 and pSer473 residues in PKB have a relatively short half-life and become dephosphorylated by the action of phosphatases, such as PP2A, which returns PKB to its inactive conformation in the cytosol (see Figure 2). Another negative regulator of PKB activity is PTEN, a 3-phosphoinositide-specific phosphatase that dephosphorylates PI(3,4,5)P3, and thus antagonizes PI3K activity and recruitment of PKB to the membrane. Recently, a PKB-binding protein has been identified, carboxy-terminal modulator protein (CTMP), which appears to negatively regulate PKB by inhibiting its phosphorylation at Ser473 and thus maintaining the kinase in an inactive state.

Physiological Functions and Cellular Processes Regulated by PKB

Apoptosis and Cell Survival

The ability of a diverse array of physiological stimuli to promote cell survival can be attributed, at least in part, to the activation of the PI3K/PKB signaling pathway. Direct targets that PKB phosphorylates to protect cells from apoptosis include BAD, the Forkhead family of transcription factors, Mdm2, and the NFκB regulator IκB kinase (IKK) (Figure 3A). Each of these plays a critical role in cell death and by phosphorylation through PKB their pro-apoptotic function is inhibited and anti-apoptotic function promoted, respectively.

PKB Controls Subcellular Localization of BAD

The Bcl-2 protein family is a large family of structurally related proteins, of which some promote cell death and others survival. BAD is a pro-apoptotic member of this family that in its dephosphorylated form directly interacts with pro-survival Bcl-2 family

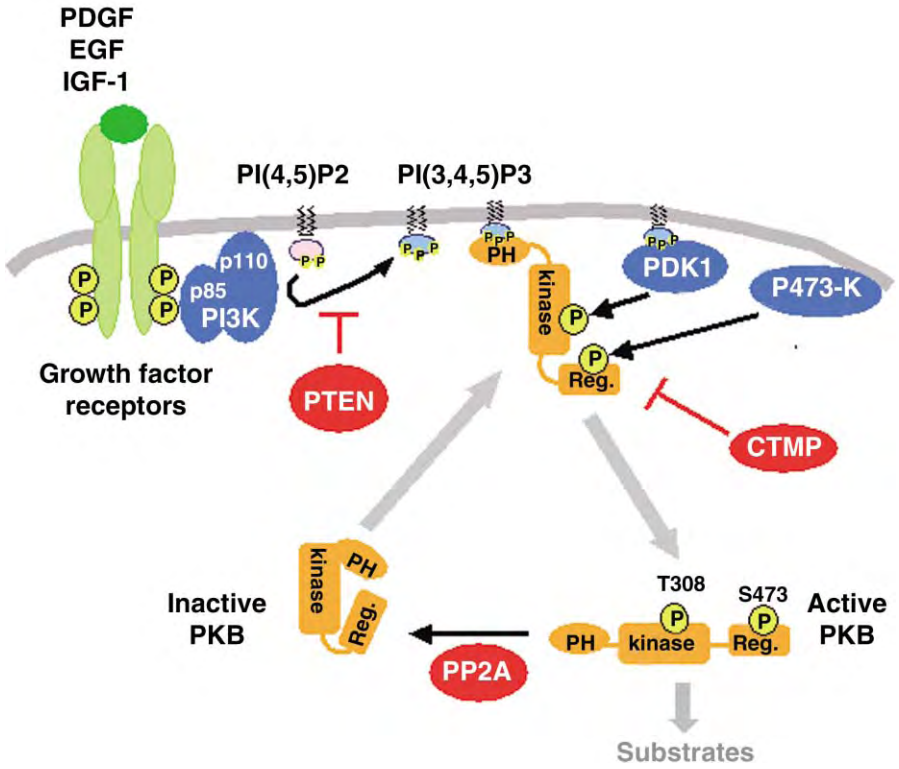

FIGURE 2 Current model for PKB regulation by receptor tyrosine kinases. Growth factor-mediated activation of PI3K leads to generation of PI(3,4,5)P3, which recruits inactive PKB to the plasma membrane. Residues Thr308 in the catalytic site and Ser473 in the hydrophobic motif are subsequently phosphorylated by PDK1 and by an as yet unidentified Ser473 kinase, respectively. Activated PKB can then phosphorylate substrates at the plasma membrane, in the cytosol, and in the nucleus. Activation of PKB is inhibited by the action of PTEN and presumably also by CTMP, which inhibits phosphorylation of PKB at Ser473. The kinase is deactivated by phosphatases such as PP2A.

members, such as Bcl-X_L. This interaction blocks pro-survival function of Bcl-X_L. Phosphorylation of BAD by activated PKB results in dissociation from Bcl-X_L and instead preferential association with cytoplasmic 14-3-3 proteins. The ability of BAD to bind to and inactivate Bcl-X_L is thereby disrupted and cell survival promoted.

PKB Controls Transcriptional Activity of Forkhead Transcription Factors

Many apoptotic stimuli also induce *de novo* gene expression of critical death genes and the Forkhead family of transcription factors mediates transcription of a defined subset of these genes. PKB-mediated phosphorylation of these transcription factors regulates their subcellular localization. In an unphosphorylated state, Forkhead family proteins translocate into the nucleus and activate transcription of their target (death) genes. But under conditions during which PKB is activated, these transcription factors are phosphorylated and are retained in the cytoplasm, potentially by interaction with 14-3-3 proteins, and are thus unable to mediate transcription.

PKB Controls p53 Levels in Cells via Mdm2 Phosphorylation

The p53 tumor suppressor protein is a short-lived protein, which is stabilized in response to cellular stress and promotes apoptosis. The ubiquitination and degradation of p53 are largely controlled by Mdm2, an E3 ubiquitin ligase. PKB can influence degradation of p53 through phosphorylation of Mdm2. Phosphorylation mediates translocation of Mdm2 to the nucleus, where it can bind to and modify nuclear p53, resulting in enhanced p53 degradation.

PKB Controls Transcriptional Activity of NFκB

Cell death is not only prevented by inhibition of apoptosis-promoting proteins on posttranslational and transcriptional level, but also through upregulation of survival-promoting genes. PKB is a signaling intermediate upstream of survival gene expression, which is dependent on the transcription factor NFκB (nuclear factor-κB). This transcription factor is retained in the cytoplasm by proteins of the IκB family. Phosphorylation of IκB by a specific IκB kinase (IKK) targets it for ubiquitination and proteosome-mediated degradation.

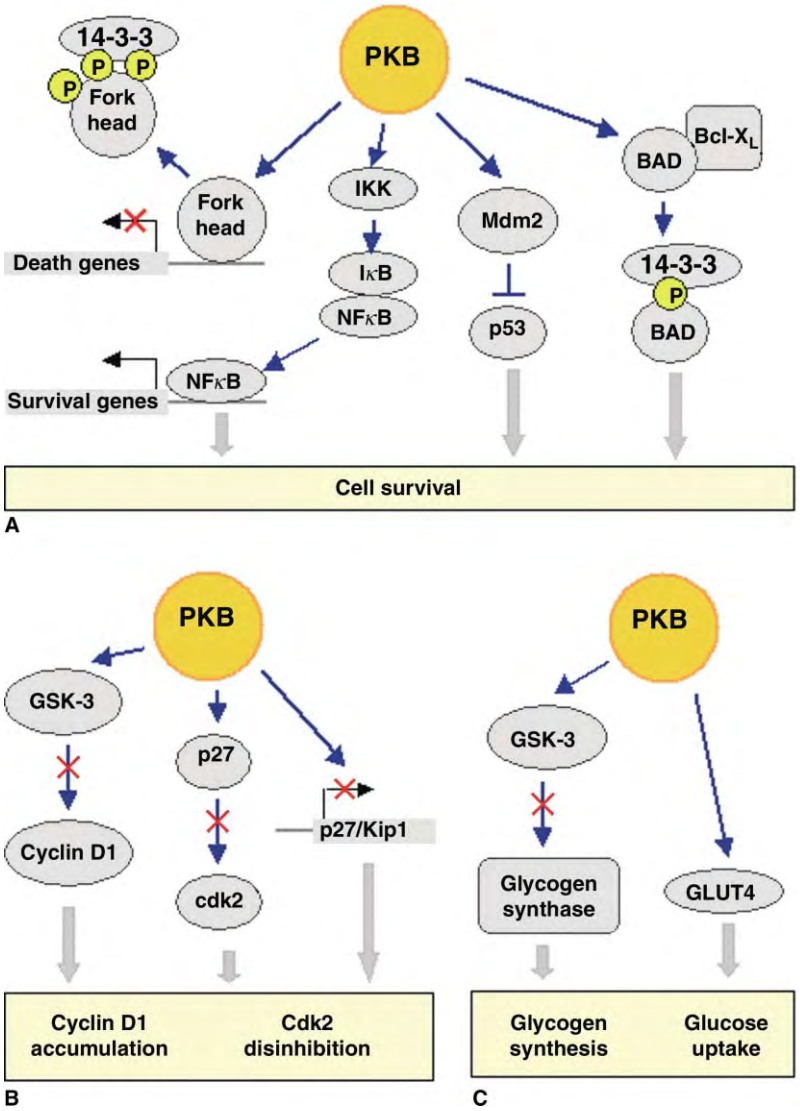

FIGURE 3 Physiological functions of PKB. PKB regulates (A) cell survival and apoptosis, (B) proliferation, and (C) glucose metabolism through phosphorylation of multiple substrates.

PKB regulates NFκB transcriptional activity through regulation of IKK activity. Activation of IKK leads to degradation of IκB and releases NFκB, allowing its nuclear translocation and subsequent activation of target genes.

Regulation of Proliferation

PKB may not be required for cell cycle progression *per se* but several downstream targets of PKB have an impact on the cell cycle machinery (Figure 3B). p27/Kip1 is a protein that blocks cell cycle. Anti-proliferative signals mobilize stored p27 and enable it to bind to and inhibit its nuclear target, cyclin-dependent kinase 2 (Cdk2), an important kinase for the initiation of DNA synthesis in the cell cycle. Phosphorylation of p27 on Thr157 by activated PKB relieves the inhibition on Cdk2. Thr157 lies within a nuclear localization signal and its phosphorylation impairs nuclear import of p27. Thus sequestered in the cytoplasm, p27 can no longer interact with Cdk2 and the kinase is allowed to remain active. In addition, PKB has been reported to downregulate transcription of p27. Another mechanism, by which PKB promotes cell proliferation, is the indirect regulation of cyclin D1 protein stability. The levels of cyclin D1 are important in G1/S phase transition in the cell cycle, and phosphorylation of cyclin D1 by glycogen synthase kinase-3 (GSK3) targets it for degradation by the proteosome. Active PKB can negatively regulate GSK3 activity by phosphorylation and thereby prevent cyclin D1 degradation. Subsequent accumulation of cyclin D1 promotes cell cycle progression.

Regulation of Glucose Metabolism

In skeletal muscle and adipocytes, PKB regulates insulin-stimulated glucose uptake and glycogen synthesis (Figure 3C). In both tissues PKBβ is the predominant isoform and becomes rapidly activated by insulin in a PI3K-dependent fashion. In unstimulated cells, glycogen synthase, the enzyme mediating incorporation of glucose from uridine diphosphoglucose into glycogen, is kept in an inactive state via phosphorylation through GSK3. Activated PKB phosphorylates and thereby inactivates GSK3, thus promoting dephosphorylation of glycogen synthase and increased glycogen synthesis. Another important PKB-dependent metabolic response to insulin is the translocation of GLUT4 from its intracellular storage pool to the plasma membrane. GLUT4 is an insulin-regulated glucose transporter in skeletal muscle and adipocytes, which in resting cells is present in intracellular endosome-like vesicles. Insulin-activated PKB triggers recruitment of these GLUT4-containing vesicles to the plasma membrane, which leads to a marked increase in the rate of glucose uptake.

Kinase-Independent Functions of PKB

In addition to acting as a kinase toward many substrates, PKB forms complexes with other proteins that are not substrates. Such proteins may serve to anchor PKB in different cellular compartments, to protect it from degradation and dephosphorylation, to regulate PKB kinase activity, or to recruit PKB substrates and/or upstream kinases. As an example, heat shock protein 90 (Hsp90) has been found to interact with PKB, possibly indirectly via the co-chaperone Cdc37, and this complex may stabilize active PKB, protecting it from dephosphorylation and degradation. Furthermore, Hsp90 might function as a scaffold protein that recruits the PKB substrate endothelial nitric oxide synthase (eNOS), an enzyme important in cardiovascular homeostasis and angiogenesis.

PKB and Cancer

PKB is the cellular homologue of the transforming oncogene v-Akt, which was found in a retrovirus termed AKT8. This retrovirus was originally isolated from mice with a high incidence of spontaneous lymphoma. v-Akt encodes a fusion protein between the viral protein Gag and full-length cellular PKBα (see Figure 1A). The viral gag domain in v-Akt possesses a myristoylation signal that mediates targeting to the plasma membrane and it thereby confers to v-Akt increased ligand-independent kinase activity as compared to cellular PKB. Deregulation of normal PKB signaling has been documented as a frequent occurrence in several human cancers. In a large number of cancers PTEN, which normally limits PKB activation, is mutated or deleted, resulting in elevated $PI(3,4,5)P_3$ levels and increased PKB activity. Furthermore, PKB gene amplification, mRNA upregulation or protein overexpression have also been reported. Aberrant elevated levels of PKB activity cause transformation of cells predominantly due to the anti-apoptotic function of PKB. Cells that have damaged DNA or are behaving in a discoordinated fashion will survive in this context instead of undergoing apoptosis, and can thus accumulate further mutations. Additionally, implication of PKB in angiogenesis and cell cycle control may contribute to cancer induction.

Glossary

activation loop A short peptide loop present in protein kinases. Its conformation is altered by phosphorylation to increase or decrease catalytic activity.

apoptosis Programmed cell death, induced in cells when they are damaged (e.g., DNA damage), unnecessary, or harmful to the body.

extracellular signaling molecules Specific substances that are synthesized and released by signaling cells and produce a specific response in target cells, which have receptors for these molecules. Extracellular signaling molecules include hormones, growth factors, and neurotransmitters.

oncogene A gene whose product is involved in inducing cancer. Most oncogenes are mutant forms of normal genes involved in the control of cell cycle progression.

pleckstrin homology domain A sequence of about 100 amino acids that is present in many signaling molecules and has affinity for certain phospholipids.

Biography

Brian Hemmings is Senior Group Leader at the Friedrich Miescher Institute. He has devoted a major part of his career to delineating the regulatory mechanisms utilized by protein kinases in signal transduction cascades.

Bettina Dummler is currently working on a Ph.D. thesis in Brian Hemmings' group at the Friedrich Miescher Institute.

Protein Kinase C Family

Alexandra C. Newton
University of California, San Diego, California, USA

Protein kinase C is a family of enzymes that has a central role in transducing information from external stimuli to cellular responses. Members of this family of serine/threonine kinases respond to signals that cause lipid hydrolysis. Protein kinase C isozymes phosphorylate an abundance of substrates, leading to both short-term cellular responses such as regulation of membrane transport and long-term responses such as memory and learning.

Historical Perspective

Protein kinase C was discovered in the late 1970s by Yasutomi Nishizuka and colleagues at Kobe University, Japan. Their initial discovery was of a constitutively active enzyme that required only Mg^{2+} for activity (and hence was named protein kinase M, PKM). Further studies revealed that PKM was a proteolytic product of a full-length enzyme; this enzyme was named protein kinase C because its enzymatic activity could be released by a Ca^{2+}-dependent protease. The subsequent discovery that protein kinase C is activated by the phospholipid hydrolysis product, diacylglycerol, was a major finding in biology: it provided the molecular mechanism for how lipid hydrolysis, discovered 25 years earlier to be triggered by stimuli such as acetylcholine, couples to cellular signaling pathways.

But the discovery that catapulted research on protein kinase C to the forefront of cellular signaling was the finding that it is the receptor for the potent tumor-promoting phorbol esters. Phorbol esters are present in the milky sap exuded from plants of the Euphorbiaceae family; the oil from the seeds of one member of this family, in particular croton tiglium, has particularly strong irritant properties and, as such, has been used over the millennia for purposes as varied as poison for hunting arrows to medicinal purposes. In the 1960s, the active ingredient in the oil was found to be a family of diesters of the tetracyclic diterpene phorbol. Phorbol esters were shown to be extremely potent tumor promoters, and classic studies revealed that painting phorbol esters on the skin of mice allowed otherwise subthreshold amounts of carcinogens to promote tumors. The finding that protein kinase C is the direct molecular target of phorbol esters placed this enzyme at the center of signaling pathways that control normal cell function and carcinogenesis.

Protein Kinase C Family Members

There are ten mammalian isozymes of protein kinase C that share in common a carboxyl-terminal kinase domain linked to an amino-terminal regulatory moiety (Figure 1). The regulatory moiety, in turn, contains a number of functional modules and it is the composition of these functional modules that further defines the three subfamilies of the protein kinase C isozymes. These modules are an autoinhibitory-pseudosubstrate sequence that maintains the enzyme in an inactive conformation, and one or two membrane-targeting modules that direct protein kinase C to the membrane following generation of the appropriate second messengers. Specifically, the C1 domain binds diacylglycerol and phorbol esters and the C2 domain binds Ca^{2+}; each event promotes the binding of the respective domain to membranes.

Conventional protein kinase C isozymes (α, βI, βII, and γ), have a C1 and a C2 domain and respond to both diacylglycerol and Ca^{2+}. Novel protein kinase C isozymes (δ, ε, η, and θ/L) have a C1 domain that binds diacylglycerol, but an impaired C2 domain that does not bind Ca^{2+}. These isozymes respond to cellular increases in diacylglycerol but not Ca^{2+}. Atypical protein kinase C isozymes (ζ and ι/λ) have an impaired C1 domain and no C2 domain and bind neither diacylglycerol nor Ca^{2+}. Thus, stimuli that elevate intracellular diacylglycerol activate conventional and novel protein kinase C family members, with conventional isozymes being additionally regulated by Ca^{2+}.

Protein Kinase C Phosphorylation

Before protein kinase C is competent to signal, it must first be processed by a series of ordered phosphorylations. The first is mediated by an upstream kinase, the phosphoinositide-dependent kinase, PDK-1.

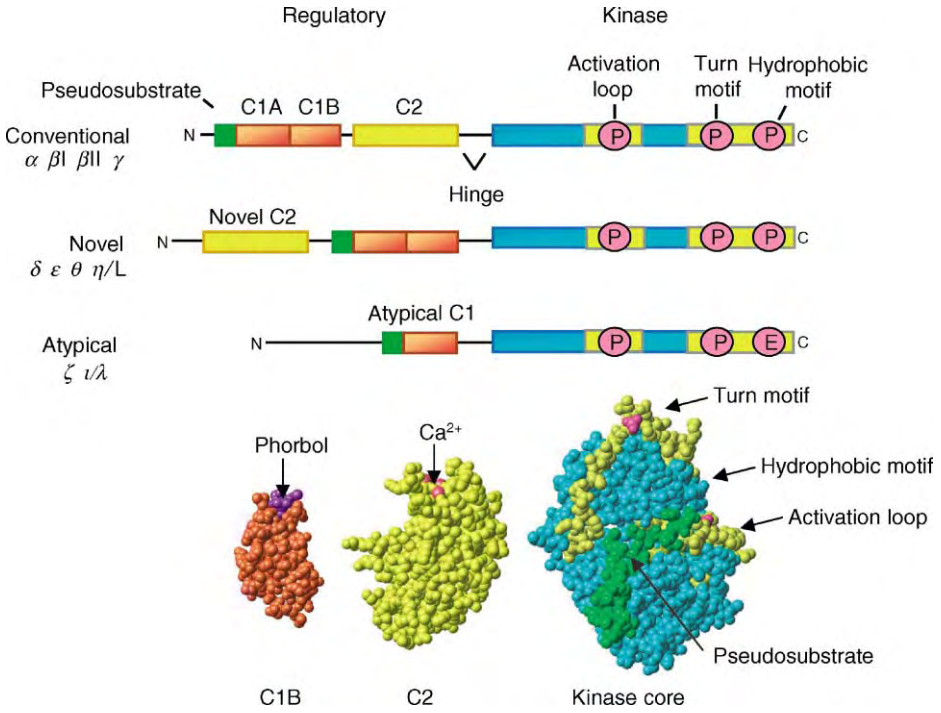

FIGURE 1 Primary structure and domain composition of protein kinase C family members. The amino terminal regulatory moiety contains the autoinhibitory pseudosubstrate sequence (green), the C1 domain, which binds diacylglycerol/phorbol esters (orange; present as a tandem repeat in conventional and novel protein kinase C isozymes), and the C2 domain, which binds Ca^{2+} (yellow). The C2 domain in novel protein kinase Cs and the C1 domain in atypical protein kinases are nonligand-binding variants. The carboxyl terminal catalytic moiety contains the kinase core which has two phosphorylation segments, the activation loop segment and the carboxyl-terminal segment (yellow), with a total of three phosphorylation sites (pink circles; the negatively charged amino acid glutamate (E) occupies the position of the phospho-acceptor position of the hydrophobic motif in atypical protein kinase Cs). The 3D structures of the domains are shown below the primary structure. Reproduced from Newton, A. C. (2003). Regulation of the ABC kinases by phosphorylation: Protein kinase C as a paradigm. *Biochem. J.* **370**, 361–371, by permission of the Biochemical Society.

This kinase has a pivotal position in cell signaling because it provides the activating phosphorylation to many other protein kinases, including the prosurvival kinase, Akt/protein kinase B. PDK-1 phosphorylates a conserved segment near the entrance to the active site referred to as the activation loop (Figure 1), an event that structures the active site for substrate binding and catalysis. The phosphorylation of the activation loop by PDK-1 triggers two intramolecular autophosphorylation reactions at two conserved positions in the carboxyl terminus, the turn motif, and hydrophobic motif (Figure 1). These phosphorylations lock protein kinase C in its mature and catalytically competent conformation. It is this species of protein kinase C that is activated by lipid hydrolysis and transduces signals.

Protein Kinase C Translocation

Mature (i.e., phosphorylated) protein kinase C is typically localized to the cytosol where it bounces on and off the membrane by diffusion-controlled mechanisms. It is maintained in an inactive conformation because the pseudosubstrate sequence occupies the substrate-binding cavity. For conventional protein kinase C isozymes, generation of Ca^{2+} and diacylglycerol target protein kinase C to the membrane by binding the C2 and C1 domains and thus tethering the enzyme to membranes. The membrane-bound species adopts an active conformation by removal of the pseudosubstrate from the substrate-binding cavity, allowing substrate binding, phosphorylation, and downstream signaling. Finding a membrane-embedded ligand (diacylglycerol) by diffusion from the cytosol is a low-probability event, and, in the case of conventional protein kinase Cs, nature has chosen a clever mechanism to increase the efficiency of this. Binding of Ca^{2+} to the C2 domain essentially pretargets protein kinase C to the membrane, where it can now initiate a much more effective search for its membrane-embedded ligand, diacylglycerol. As a consequence, conventional protein kinase Cs translocate to membranes ~1 order of magnitude faster than novel protein kinase C isozymes, which do not have the advantage of pretargeting by a Ca^{2+}-responsive C2 domain.

The advent of fluorescent methodologies has allowed imaging of protein kinase C translocation, and, most recently, activity in real time in living cells (Figure 2).

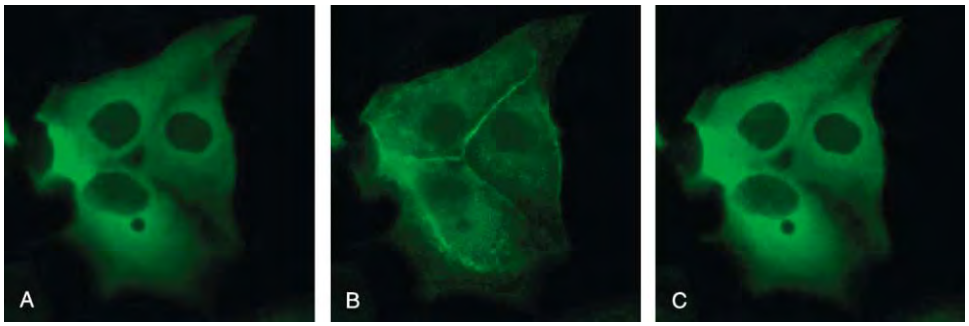

FIGURE 2 Protein kinase C was visualized in cells by expression of a construct of protein kinase C fused to a naturally fluorescent protein from the jellyfish *Aequorea victoria*, the green fluorescent protein (GFP). Panel A shows that protein kinase C is localized to the cytosol in unstimulated MDCK cells (diffuse fluorescence throughout the cell); panel B shows that protein kinase C translocates to the membrane (strong fluorescence intensity at cell peripheri) following 1 min of treatment with the agonist UTP, which induces phospholipid hydrolysis and generation of the two second messengers for protein kinase C:Ca^{2+} and diacyglycerol. Panel C shows that protein kinase C has redistributed back to the cytosol 5 min after UTP treatment; second messenger levels have returned to resting levels. Images courtesy of Jon Violin.

In general, protein kinase C translocation and activity mirrors the generation of its second messengers. For example, histamine stimulation of HeLa cells results in oscillations in protein kinase C substrate phosphorylation that are phase-locked with Ca^{2+} oscillations.

Protein Kinase C Scaffolds

Correct subcellular location is essential for normal signaling by protein kinase C. An abundance of scaffold proteins that tether protein kinase C near its substrates, activators, and regulatory proteins, such as phosphatases, has been described. The importance of correct subcellular location is perhaps best illustrated in the *Drosophila* visual cascade, where mutants lacking the protein kinase C-binding scaffold, InaD, are defective in visual transduction because components of the signaling cascade are mislocalized.

Protein Kinase C Downregulation

Prolonged activation of protein kinase C by treatment of cells with phorbol esters results in degradation of protein kinase C, a phenomenon referred to as down-regulation. In fact, prolonged treatment of cells with phorbol esters is a commonly used approach to deplete cells of all except atypical protein kinase Cs (these are resistant to phorbol ester-dependent down-regulation because they do not bind phorbol esters). The molecular mechanism of this down-regulation involves dephosphorylation of activated protein kinase C, followed most likely by ubiquitination and proteolysis. The molecular chaperone HSP70 has recently been shown to protect protein kinase C from down-regulation by allowing rephosphorylation of the enzyme and sustaining its signaling lifetime.

Protein Kinase C Signaling

Protein kinase C phosphorylates an abundance of substrates, including membrane proteins, cytoskeletal proteins, cytosolic proteins, and nuclear proteins. Yet identifying the precise cellular role and cellular targets of protein kinase C remains elusive. Genetic deletion of specific isozymes results in subtle phenotypic differences, suggesting functional redundancy of the isozymes. Nonetheless, sifting through the abundant studies on protein kinase C function reveals a few defined themes in addition to the general involvement in cell growth and proliferation. Notably, animals deficient in protein kinase C isozymes are deficient in adaptive responses. For example, mice lacking protein kinase C ε have reduced anxiety and have reduced tolerance to alcohol. Mice lacking protein kinase C γ have reduced pain perception, and mice lacking protein kinase C β II have reduced learning abilities and an impaired immune response. This theme carries over to the molecular level where many of the substrates of protein kinase C are receptors which become desensitized following phosphorylation by protein kinase C.

Isozyme-specific functions have been most clearly delineated for novel and atypical protein kinase C isozymes. For example, protein kinase C δ activation has been shown to play a role in apoptosis. Protein kinase C θ plays a key role in immune responses, and mice deficient in this isozyme have impaired T cell signaling and interleukin 2 production. Defined functions have also been established for protein kinase C ζ: this isozyme is required for maintenance of cell polarity and, in addition, regulates cell growth, DNA synthesis, and activation of the transcription factor, NFκB. Much less is known about defined physiological substrates and functions of conventional protein kinase C isozymes. Defining the precise raison d'etre for this

multi-membered class of kinases is one of the pressing issues in biological chemistry.

Glossary

diacylglycerol The membrane-retained lipid backbone released from phospholipids following activation of appropriate phospholipases, enzymes that hydrolyze phospholipids. Diacylglycerol is considered a second messenger because it transfers information from stimuli such as hormones to protein kinase C, which transduces the signal by phosphorylating protein substrates.

kinase The class of enzymes that covalently transfer phosphate from ATP to hydroxyl groups of proteins.

phosphorylation The covalent attachment of phosphate from the cellular energy currency, ATP to hydroxyl residues of proteins, a modification that changes the properties of the protein.

Biography

Alexandra Newton is a Professor in the Department of Pharmacology at the University of California, San Diego, where her research team investigates the biology and chemistry of signaling by protein kinases, with particular focus on the molecular mechanisms of protein kinase C. She holds a Ph.D. in chemistry from Stanford University and received her postdoctoral training with Daniel E. Koshland, Jr., at the University of California, Berkeley.

Protein N-Myristoylation

Erica Dutil Sonnenburg and Jeffrey I. Gordon
Washington University School of Medicine, St. Louis, Missouri, USA

Protein N-myristoylation refers to the covalent attachment of myristic acid, a 14-carbon saturated fatty acid (C14:0), to the N-terminal glycine of proteins. Linkage occurs via an amide bond and takes place as proteins are being synthesized. N-myristoylproteins have varied intracellular destinations, and are involved in myriad cellular functions ranging from signal transduction to protein and vesicular trafficking. N-myristoylproteins are encountered in members of all Kingdoms of the eukaryotic domain (Protist, Fungi, Plant, and Animal) but are not produced by members of Bacteria or Archaea. MyristoylCoA:protein N-myristoyltransferase (Nmt), E.C. 2.3.1.97, a member of the GCN5 acetyltransferase (GNAT) superfamily, is responsible for catalyzing the transfer of myristate from myristoylCoA to proteins. While the acylCoA substrate specificity of Nmt has been highly conserved during evolution, its peptide substrate specificities have diverged among eukaryotes.

Protein N-myristoylation has relevance to a number of diseases. Genetic and pharmacologic studies have shown that Nmt activity is essential for the survival of a number of fungi that cause systemic infections in immunocompromised humans. These organisms include *Candida albicans* and *Cryptococcus neoformans*. Protein N-myristoylation is also critical to the life cycle of viruses, such as human immunodeficiency virus-1. Nmt levels are elevated in human gastrointestinal tract malignancies. Other pathogens, including *Plasmodium falciparum*, the parasite that causes malaria, have Nmts. Therefore, understanding the contributions of myristate to protein function, elucidating the structural basis for the divergent protein substrate specificities of orthologous Nmts, characterizing the myristoyl transfer reaction, and identifying biologically active, species-selective Nmt inhibitors may provide new therapeutic strategies and agents.

N-Myristoylproteins

Function of N-Myristoylation

Myristate exposed on the surface of a protein increases its lipophilicity, allowing transient, low-affinity interactions with cellular membranes or other proteins. This feature makes N-myristoylation an attractive choice for molecules involved in a variety of signaling cascades, such as protein kinases, kinase substrates, and protein phosphatases.

Myristate is not sufficiently hydrophobic to allow stable anchorage to cellular membranes. Therefore, most N-myristoylproteins utilize an additional mode of attachment. One supplementary membrane tether is provided by the reversible posttranslational covalent attachment of palmitate, a 16-carbon saturated fatty acid (C16:0), to cysteine (S-palmitoylation). Alpha subunits of heterotrimeric G proteins provide examples of this type of dual acylation. Other N-myristoylproteins, such as the protein tyrosine kinase Src, uses positively charged exposed residues to interact electrostatically with negatively charged groups in membrane lipids. Some N-myristoylproteins regulate their association with membranes through reversible exposure of their myristoyl moiety. Recoverin, a retinal photoreceptor protein involved in light adaptation, illustrates this "myristoyl-conformational switch": its myristoyl group is unfurled when the protein binds calcium; in the absence of calcium, the acyl chain is encased in a hydrophobic pocket.

Heterogeneous acylation is another device used by N-myristoylproteins to achieve regulated membrane association. Heterogenous acylation refers to Nmt-catalyzed linkage of tetradecanoate (C14:0), tetradecenoate (C14:1$^{\Delta 5}$), tetradecadienoate (C14:2$^{\Delta 5,8}$), or laurate (C12:0) to a substrate protein. At present, this phenomenon has only been described in retinal photoreceptor cells. Augmented production of these acyl-CoAs, and/or increased access of Nmt to these species, are among the mechanisms that have been invoked to account for the observed cell lineage-specificity of heterogenous acylation.

Examples of heterogeneously acylated proteins include recoverin, the α-subunit of the G protein transducin (Gtα), guanylyl cyclase activating protein, and the catalytic subunit of cAMP-dependent protein kinase. Lauric acid, and C14 fatty acids containing a *cis* double bond between C5–C6 (C14:1$^{\Delta 5}$) or C5–C6 and C8–C9 (C14:2$^{\Delta 5,8}$), have reduced hydrophobicity compared to C14:0. A less hydrophobic acyl chain may be required for these proteins to properly operate in photoreceptor cells,

either because of their extraordinarily high concentrations of membranes, and/or because the proteins require short-lived anchorage to membranes to rapidly transduce responses in visual signaling pathways.

Substrate Selection

Most proteins targeted for cotranslational N-myristoylation have an N-terminal consensus sequence of Met-Gly-X-X-X-Ser/Thr. The initiator methionine must first be removed from the nascent protein by another enzyme, methionylaminopeptidase, to expose the acceptor glycine. However, this consensus sequence is too general to allow definitive identification of Nmt substrates. Furthermore, in at least one case involving the pro-apoptotic protein BID, an internal myristoylation site is exposed after posttranslational proteolytic cleavage. Figure 1 provides a more detailed recognition consensus sequence that has been developed from an analysis of known N-myristoylproteins, as well as currently available X-ray crystal structures of Nmt.

There are a number of ways to establish that a protein is N-myristoylated, including metabolic labeling with tritiated or iodinated myristate, mass spectrometric analysis of the purified protein, or *in vitro* Nmt assays that contain the purified acyltransferase, myristoylCoA, and a peptide encompassing the N-terminal 8–15 residues of the candidate protein substrate. A current listing of experimentally confirmed as well as candidate N-myristoylproteins can be found at http://mendel.imp.univie.ac.at/myristate.

Escherichia coli containing a dual plasmid expression system has also been used widely to determine whether a protein is an Nmt substrate, and to study the functional significance of its myristoyl group. The system takes advantage of the fact that this bacterium is able to generate myristoylCoA but does not have any endogenous Nmt activity. The eukaryotic protein modification is recapitulated in this prokaryote by using one plasmid with an inducible promoter to direct expression of an Nmt, and another plasmid, containing a different inducible promoter, to express a candidate Nmt substrate. Production of Nmt is initiated first. Synthesis of the protein substrate is then turned on to allow for its cotranslational acylation. Incorporation of myristate can be verified by metabolic labeling or by mass spectrometry. The properties of the N-myristoylated protein can be compared and contrasted to that of the nonmyristoylated isoform produced in *E. coli* lacking the Nmt expression vector.

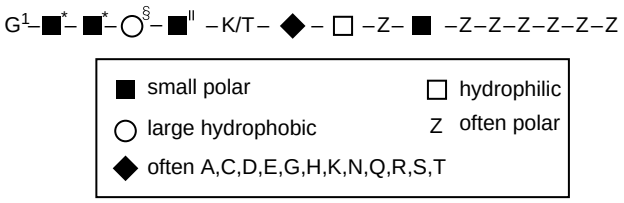

FIGURE 1 Consensus sequence for recognition of protein substrates by Nmt (*side chain volume compensation allowed; fungal Nmts allow hydrophobic residues; § some fungal Nmts prefer small residues; and ‖ often S or T). N-Myristoyltransferase

Thus far, a total of 68 known and postulated Nmts have been identified from 63 species. Four mammalian genomes (*Homo sapiens*, *Mus musculus*, *Rattus norvegicus*, and *Bos Taurus*), plus a plant genome (the mustard weed *Arabidopsis thaliana*), contain two Nmt genes (designated type I and type II). Type I Nmts show a high degree of conservation among one another, as do the type II acyltransferases. Type I and II enzymes diverge most prominently at their N termini. These N-terminal domains are not required for catalytic activity *in vitro* but may help direct the acyltransferase to different intracellular sites. For example, the N terminus of type I human Nmt appears to be involved in its targeting to the ribosome.

Reaction Mechanism

The N-myristoyltransferase reaction mechanism has been characterized using the *Saccharomyces cerevisiae* enzyme as a model. *S. cerevisiae* Nmt contains 455 amino acids, is monomeric, and has no known cofactor requirements. Steady-state kinetics, isothermal titration calorimetrics, and X-ray crystallographic studies indicate that the enzyme has an ordered Bi–Bi reaction mechanism. The apo-Nmt first binds myristoylCoA to form a Nmt:myristoylCoA binary complex. MyristoylCoA binding allows subsequent binding of a nascent protein substrate to generate a Nmt:myristoylCoA:peptide ternary complex. Following the chemical transformation step (conversion of the enzyme:substrate complex to the enzyme:product complex), CoA and then myristoylpeptide are released. Pre-steady-state kinetic studies indicate that the rate determining step occurs after the chemical transformation, most likely involving release of myristoylpeptide.

Catalysis occurs through a classic nucleophilic addition–elimination reaction where the nucleophilic N-terminal Gly amine of the peptide substrate attacks the polarized thioester carbonyl of myristoylCoA. Several elements in the enzyme's active site facilitate this reaction. An oxyanion hole, formed by the backbone amides of two conserved residues, Phe170

and Leu171, polarizes the reactive carbonyl of myristoylCoA. The C-terminal carboxylate (Leu455 in the yeast enzyme) functions as a catalytic base to deprotonate the Gly1 ammonium to a nucleophilic amine. The amine rotates 180Å along Ψ to reduce its distance from the thioester carbonyl of myristoylCoA. H-bonding interactions between the Gly1 amine, Asn169, and Thr205 help direct the reaction trajectory, and facilitate nucleophilic attack of the polarized carbonyl. The oxyanion hole, together with the H-bonding network formed by Asn169 and Thr205, stabilizes the developing tetrahedral intermediate. With subsequent collapse of the intermediate, CoA is extruded. The Gly1 amine is deprotonated, while the thiolate leaving group of CoA is reprotonated (see www.jbc.org/cgi/content/full/276/43/39501/DC1 for an animated schematic of the reaction mechanism).

Three-Dimensional Structure of NMT: Insights about Substrate Recognition/Acquisition and Release

Presently, three X-ray crystal structures of *S. cerevisiae* Nmt have been reported: a binary complex containing bound myristoylCoA (Protein Data Bank (PDF) (www.rcsb.org/pdb/) accession 1IIC), plus two ternary complexes – one with a peptide substrate and S-(2-oxo)pentadecylCoA (a nonhydrolyzable myristoylCoA analogue containing a methylene interposed between the sulfur of CoA and the carbonyl of myristate; PDF 1IID), the other with S-(2-oxo)pentadecylCoA and a dipeptide inhibitor (PDB, 2NMT). In addition, three structures of *C. albicans* Nmt are available: the apo-enzyme (PDB, 1NMT), the enzyme with bound myristoylCoA and peptidic inhibitor (PDB, 1IYK), and the enzyme with a bound benzofuran inhibitor (PDB, 1IYL).

The Nmt fold consists of a large saddle-shaped β-sheet with several α-helices located on either side (Figure 2). There is pseudo-twofold symmetry. The N-terminal half forms the myristoylCoA binding site while the C-terminal half contributes to peptide recognition. The N terminus is disordered.

Binding of myristoylCoA induces two important conformational changes. A 3_{10} helix (A′ in Figure 2) is formed from part of the disordered N terminus, to complete the myristoylCoA binding site. There is also a change in the conformation of a loop connecting helix A and strand b (Ab loop), thereby opening a "lid" overlying the peptide binding site. The pantetheine group of CoA forms a key component of the peptide recognition site. Together, these observations indicate why myristoylCoA binding is a prerequisite for subsequent acquisition of a nascent protein substrate.

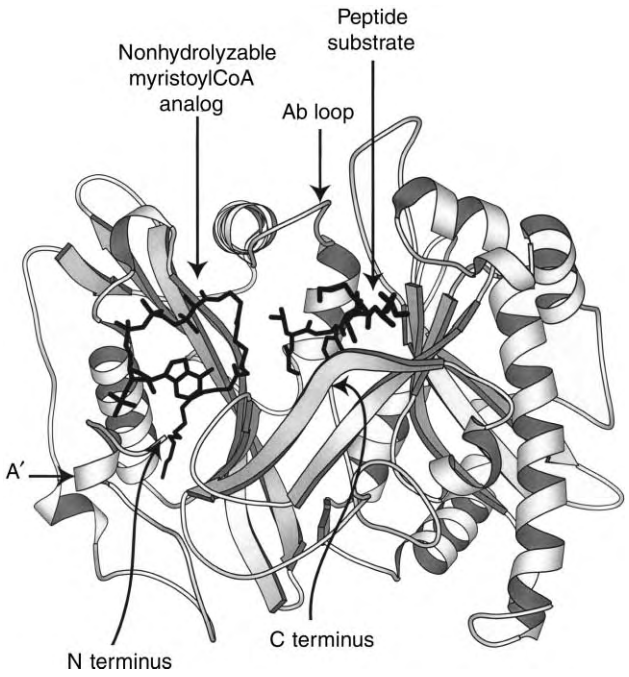

FIGURE 2 Ribbon diagram of *S. cerevisiae* Nmt. The enzyme is shown with a S-(2-oxo)pentadecylCoA, a non-hydrolyzable myristoylCoA analog and competitive inhibitor, and an octapeptide substrate (GlyLeuTyrAlaSerLysLeuAla) derived from the N terminus of ADP ribosylation factor 2 (Arf2). Binding of the myristoylCoA induces ordering of a 3_{10} helix (A′), a change in the conformation of the Ab loop, and completion of the peptide binding site. The C-terminal carboxylate (Leu455) functions as a catalytic base to deprotonate the Gly1 ammonium to a nucleophilic amine.

MyristoylCoA is bound to Nmt in a conformation that resembles a question mark (Figure 2). Nmt uses residues that produce bends at C1 and C6 of the bound myristoyl chain, as well as the floor of its acylCoA binding pocket, to measure and properly position myristoylCoA. Available X-ray structures indicate that the two additional methylenes present in palmitoylCoA cannot be accommodated by the enzyme without adversely affecting positioning of its thioester carbonyl within the oxyanion hole.

The X-ray structures suggest that the extent of ordering of the Ab loop may correlate with the overall catalytic efficiency of different Nmt peptide substrates, and that the rate limiting step in the Nmt reaction is an isomerization involving reversal of the conformational changes that take place when myristoylCoA is bound. In other words, disordering of the 3_{10} A′ helix and opening the lid formed by the Ab loop.

Therapeutics

Alignments of known Nmts disclose that their N-terminal halves are more conserved than

their C-terminal halves. This finding is consistent with their shared specificity for myristoylCoA, and with the divergent nature of their protein substrate specificities. Exploiting the differences in peptide recognition among Nmts may be key to developing species-specific inhibitors. This divergence, and the fact that genetic experiments have established that pathogenic fungi such as *C. albicans* and *C. neoformans* require Nmt for their survival, make N-myristoyltransferase an attractive target for developing new classes of fungicidal agents. The need for such agents is great given the limited number of existing drugs that effectively kill these organisms, and the increasing resistance being encountered to these available compounds.

Several classes of Nmt-targeted anti-fungal agents have been identified to date. Peptidomimetic inhibitors have been produced starting from an octapeptide substrate representing the N terminus of *S. cerevisiae* ADP ribosylation factor 2 (Arf2) (involved in vesicular trafficking). Benzofuran inhibitors have emerged from high throughput screens of chemical libraries. These benzofurans have several advantages over the Arf-derived compounds – smaller size, increased bio-availability, and resistance to degradation. Crystallographic studies of *C. albicans* Nmt revealed that one of the lead benzofurans was positioned in a hydrophobic pocket located within the enzyme's peptide substrate binding site. Using this structural information, a more biologically active derivative, substituted with difluorophenoxy- and pyridyl-terminated side chains, was created that inhibits fungal growth in a rat model of systemic Candidiasis. Further screens for compounds that display specificity for fungal compared to human Nmts are likely to yield additional classes of fungicidal compounds in the future.

of California, San Diego in biomedical sciences and received her postdoctoral training at the Salk Institute for Biological Study in structural biology.

Jeffrey Gordon is the Dr. Robert J. Glaser Distinguished University Professor and Head of the Department of Molecular Biology and Pharmacology. He received his M.D. from the University of Chicago. In addition to characterizing the enzymology and biological significance of protein N-myristoylation, his laboratory uses mouse models to study gut development and the contributions of its indigenous microbial communities to health.

Protein Palmitoylation

Robert J. Deschenes
University of Iowa, Iowa City, Iowa, USA

Palmitoylation is the covalent modification of proteins with 16 carbon acyl chains related to palmitic acid. Protein palmitoylation was first described in the 1970s and is now recognized as a major form of posttranslational modification in all eukaryotes, with a few examples in prokaryotes as well. In many cases palmitoylation is a reversible modification, suggesting that the cell uses it to regulate protein function. This article will focus on the enzymology and functional significance of protein palmitoylation.

Covalent Modification of Proteins with Palmitoyl Groups

Palmitoylation refers to a family of protein modifications involving palmitic acid (Figure 1). The most common forms of palmitoylation are S-palmitoylation and N-palmitoylation. S-palmitoylation occurs on cysteine residues and involves a thioester linkage. In the cases where it has been investigated, S-palmitoylation is a reversible modification. Examples include receptors, signaling proteins, and scaffold proteins. N-palmitoylation reactions occur on the amino terminus or on the epsilon amino group of lysine. Reports of esterification of palmitate with serine and threonine residues (O-palmitoylation) have appeared for myelin proteolipids, however, other studies conclude that myelin proteolipids are S-palmitoylated. Protein palmitoylation is generally detected by labeling cells or cell extracts with [^{3}H]-palmitate. Identification of the covalently linked lipid is done by chemical or enzymatic cleavage followed by HPLC analysis. In most cases, palmitate is found, but in some cases unsaturated forms of palmitate are also detected. An estimate of the total extent of protein palmitoylation in the cell is difficult to obtain because of the rapid reversibility of palmitoylation and the chemical lability of thioesters. Proteomic methods that account for posttranslational modifications have begun, but application to lipid modifications needs further development. However, based on the growing list of palmitoylated proteins reported it is clear that palmitoylation is a significant posttranslational modification.

Palmitoyltransferases

There has been a debate concerning whether palmitoylation is spontaneous or enzyme mediated. The thiol of cysteine is capable of serving as a nucleophile in a spontaneous S-acylation reaction using palmitoyl-CoA as the acyl donor. However, it is difficult to know whether spontaneous palmitoylation occurs *in vivo*. It is more likely that protein acyltransferase(s) (PAT) are responsible for palmitoylation under physiological conditions. In fact, PAT activities have been reported that cofractionate with the plasma membrane and endomembranes suggesting that either there is ubiquitous expression of a single PAT or multiple PATs with distinct subcellular distributions. The recent discovery of protein PATs in model organisms has begun to shed light on this question.

Plasma membrane localization of Ras requires palmitoylation of a conserved cysteine located close to the C terminus. Palmitoylation is associated with the translocation of Ras from the endoplasmic reticulum (ER) to the plasma membrane where it functions in signaling. A genetic screen was carried out in yeast to identify mutants affecting Ras palmitoylation. Mutations in two genes, *ERF2* and *ERF4*, were identified. Lobo and co-workers found Erf2p and Erf4p form a complex that together carries out the enzymatic palmitoylation of Ras. The new enzyme is called Ras PAT. Erf2p has a conserved domain referred to as a DHHC–CRD motif (Pfam designation zfDHHC). Another yeast DHHC–CRD protein, Akr1p, has been shown to be the PAT for yeast casein kinase, Yck2p. Thus, Erf2p/Erf4p and Akr1p are founding members of a new class of S-PATs. The DHHC–CRD motif is found in six other yeast proteins, ~23 human proteins, and all other organisms examined.

Not all palmitoylated proteins are intracellular. The *Drosophila* secretes signaling molecules Hedgehog and Wnt, which are also palmitoylated. Again, genetic screens led to a candidate PAT. The gene goes by the names *skinny hedgehog* (*ski*), *sightless* (*sit*), *or rasp* depending on the group that isolated the mutation. A clue to the function came from a short region of sequence similarity with O-acyltransferases. Members

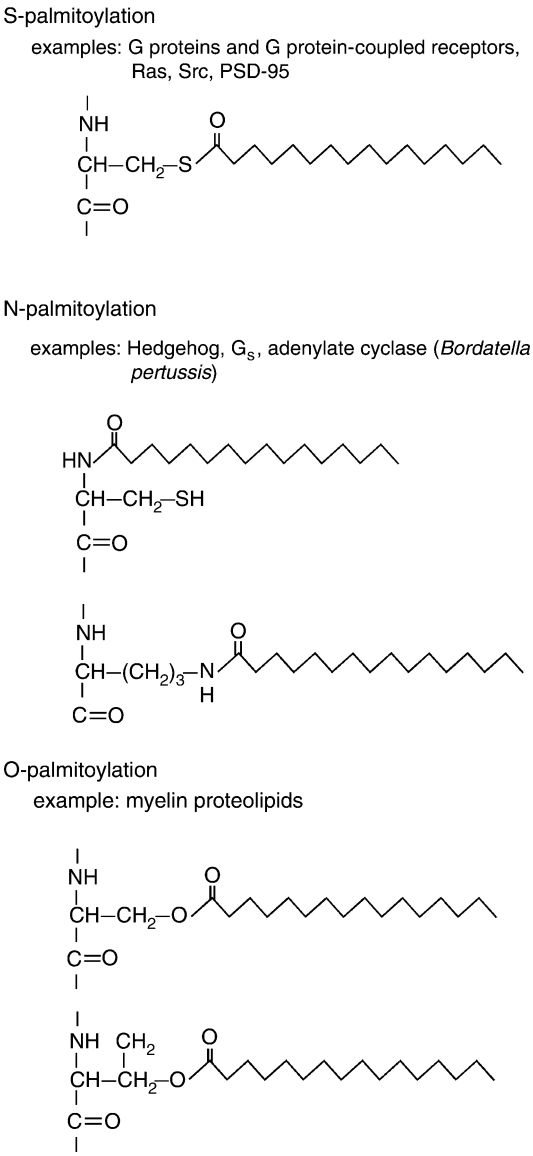

FIGURE 1 The three major classes of covalent attachment of palmitate in proteins. Representative examples of each type are listed.

of this family transfer fatty acids onto hydroxyl groups of nonproteinaceous targets. Mutation of residues in the conserved domain of *ski*/*sit*/*rasp* results in loss of Hedgehog palmitoylation and signaling. Biochemical studies are still needed to confirm that *ski*/*sit*/*rasp* is a PAT and to elucidate the mechanism.

The Wnt proteins are cysteine-rich secreted glycoproteins that have recently been shown to be palmitoylated on conserved cysteine. The modification could be removed by an acylprotein thioesterase (APT1) consistent with it being a thioester. Sequence alignment of Wnt family members reveals that this is the first cysteine residue in the sequence that is conserved in all family members. Thus, palmitoylation is likely to be found on all Wnt signaling proteins. Enzymatic depalmitoylation of purified Wnt3a protein results in the loss of its ability to stabilize β-catenin in mouse L cells, a measure of the Wnt signaling pathway. *porcupine* (*por*) is a segment polarity gene in *Drosophila* that is required for processing and secretion of Wingless (Wg). In *por* mutants, Wg is confined to cells where it is synthesized. Like *skinny hedgehog* (*ski*)/*sightless* (*sit*)/*rasp*, porcupine shares sequence homology with O-acyltransferases making it an excellent candidate for the Wnt PAT.

Palmitoylthioesterases

Given the reversible nature of protein palmitoylation, thioesterases are predicted to play an important regulatory role. However, the first protein thioesterases identified, PPT1 and PPT2, are apparently involved in protein turnover. PPT1 is found in lysosomes and mutations that reduce or eliminate its expression causes a severe neurodegenerative disorder, infantile neuronal ceroid lipofuscinosis (INCL). INCL is formally classified as a lysosomal-storage disorder. The neurological phenotype arising from a deficiency of PPT thioesterases is likely to be caused by the accumulation of palmitoyl peptides or palmitoylcysteine.

A cytosolic palmitoyl protein thioesterase, APT1, was discovered in rat liver extracts. APT1 was originally described as a lysophospholipase, but Duncan and Gilman showed that APT1 cleaves thioesters in acyl-CoAs and acylproteins, as well as oxyesters in lysolipids. In fact, APT1 exhibits a strong substrate preference for acylproteins over lipid substrates consistent with a role for APT1 as a regulator of protein thioacylation and not as a regulator of lipid metabolism. A number of substrates have been proposed for APT1 including G_α-subunits, Ras, and eNOS. APT1 orthologues have been identified in a large number of species, ranging from yeast to humans.

Palmitoylation and Protein Function

The functional significance of reversible palmitoylation depends on the protein under consideration. For peripheral membrane/cytosolic proteins lipid addition can be the primary determinant of membrane recruitment. It can also specify a particular membrane or microdomain of a membrane. A theme that has emerged from many studies is that palmitoylation operates along with other lipid modifications or membrane association sequences. Ras proteins are a case in point. Farnesylation of the C-terminal C*aaX* box targets H-Ras and N-Ras to the cytosolic surface of the ER membrane where it is further processed by a C*aaX* box protease

and methyltransferase. Plasma membrane localization of H-Ras requires palmitoylation by the Erf2p/Erf4p Ras PAT. Once at the plasma membrane, H-Ras reversibly associates with microdomains believed to be involved in signaling. There is intense interest in defining the nature of this microdomain and the role of palmitoylation in Ras signaling.

Reversible palmitoylation also influences the subcellular trafficking of integral membrane proteins. For example, receptor endocytosis and recycling is often controlled by palmitoylation status. In viral infected cells, palmitoylation directs Env proteins to lipid rafts where viral assembly occurs. In addition to surface expression and stability, palmitoylation has been proposed to play a role in signaling of some receptors. Palmitoylation can effect signaling by altering effector binding. For example, mutations in the palmitoylation site on the cytoplasmic tail of the β-adrenergic receptor leads to uncoupling of the receptor, its cognate G protein.

Palmitoylation also plays a role in vesicle trafficking and membrane fusion. Palmitoyl-CoA is required for efficient vesicle fusion in cell free assays. It is generally believed that palmitoylation of a specific protein or proteins accounts for this requirement. A possible candidate has emerged from the study of vacuole inheritance in yeast. Vac8p is a myristoylated and palmitoylated peripheral membrane protein that is required for vacuole inheritance. Palmitoylation, but not myristoylation, is required for Vac8p function. Palmitoylation of Vac8p may be involved in the interaction of Vac8p with vacuole specific SNARE complexes.

Not all palmitoylation is involved with membrane-mediated processes. Mitochondrial methylmalonyl semialdehyde dehydrogenase is covalently modified by palmitate on an active site cysteine residue. Insertion of [^{125}I]-labeled analogue of myristoyl-CoA at this site results in enzyme inhibition. This observation, together with other results that palmitoyl-CoA inhibits the activity of several mitochondrial enzymes suggests a regulatory role of S-acylation in metabolism.

Palmitoylation Inhibitors

The role of palmitoylation in cellular processes has been investigated using inhibitors such as 2-bromo or 2-fluoropalmitate, cerulenin, and tunicamycin. Each inhibits protein palmitoylation, but their mechanisms of action may differ. Cerulenin inhibits fatty acid synthase, but analogues with selectivity toward PATs are being developed and tested. Tunicamycin is a fatty acyl-CoA analogue and has been found to reduce protein palmitoylation without significantly affecting palmitoyl-CoA levels. In some cases 2-flouropalmitate has been shown to decrease uptake of [^{3}H]palmitate and thereby lower the levels of labeled palmitoyl-CoA levels and apparent protein palmitoylation. The recent identification of palmitoyltransferases should allow a more detailed characterization of these inhibitors and the development of new inhibitors with specificity toward the different classes of palmitoylated proteins.

Concluding Remarks

Protein palmitoylation has emerged as an important posttranslational modification used by cells to organize the subcellular distribution of proteins on membranes. The study of protein palmitoylation has entered a new phase with the identification of PATs in yeast and *Drosophila*. As the tools develop, the role of protein palmitoylation, in the cellular physiology, should come into better focus. PATs may be excellent targets for the design of drugs that alter the subcellular distribution of receptors and signaling molecules.

Biography

Robert Deschenes is a Professor in the Department of Biochemistry at the Carver College of Medicine, University of Iowa, Iowa City, Iowa. His research interests focus on signal transduction pathways that regulate eukaryotic cell growth, with an emphasis on the Ras oncogene. He holds a Ph.D. in biochemistry from Purdue University and was an Anna Fuller Cancer Fund Postdoctoral Fellow in the Molecular Biology Department of Princeton University. He is a member of the American Society of Biochemistry and Molecular Biology.

Protein Tyrosine Phosphatases

David J. Pagliarini, Fred L. Robinson and Jack E. Dixon
University of California, San Diego, California, USA

The process of reversible phosphorylation is perhaps the cell's most prevalent means of regulation at the molecular level. It has been estimated that up to 30% of all cellular proteins are phosphorylated, and phosphorylation has been shown to play a crucial regulatory role in such diverse cellular events as metabolism, growth and differentiation, vesicular transport, and gene transcription. Phosphorylation and dephosphorylation are carried out by kinases and phosphatases, respectively. There are currently predicted to be 518 kinases and ~125 phosphatases encoded in the human genome, further underscoring the overall importance of phosphorylation in molecular regulation. Phosphatases are generally divided into two main families based on their catalytic mechanism and substrate specificity: the protein phosphatases (PPs), which exclusively desphosphorylate serine and threonine residues, and the protein tyrosine phosphatases (PTPs), which can dephosphorylate tyrosine residues, and are the focus of this article. PTPs can be further classified into subfamilies based on (1) subcellular location (receptor versus intracellular), (2) substrate preference, and (3) three-dimensional topology. In this article, we describe the different subfamilies of PTPs and their conserved catalytic mechanism. In addition, human diseases that result from disrupted PTP signaling, and the pursuit of PTPs as drug targets are discussed.

Catalytic Mechanism of PTPs

PTPs, regardless of subfamily, are predicted to use similar mechanisms for catalyzing the removal of a phosphate group. All PTPs possess a catalytic domain that contains the active site signature motif cysteine-X_5-arginine (CX_5R; X = any amino acid), which constitutes the phosphate-binding pocket, or "P-loop". The dephosphorylation reaction is initiated when the thiol nucleophile of the active site cysteine attacks the phosphate group on the substrate molecule, forming a cysteinyl-phosphate intermediate (Figure 1). A conserved aspartic acid, usually residing outside of the P-loop, then acts as a general acid to aid in the ejection of the substrate molecule. In the second step of the reaction, the phosphoenzyme intermediate is hydrolyzed by a water molecule that has been activated by the aspartate, thereby releasing free phosphate and regenerating the active enzyme.

Classification of Protein Tyrosine Phosphatases

Intracellular PTPs

PTPs

PTPs can be classified as receptor-like (RPTPs) or intracellular based on their location within a cell. Whereas all RPTPs to date exhibit specificity towards phosphotyrosine substrates (referred to as "classic" PTPs), intracellular PTPs can be classic or dual-specific (DS-PTPs), having the ability to dephosphorylate serine/threonine, RNA, or inositol lipids in addition to pTyr (Figure 2). The major distinguishing factor between classic and dual-specific PTPs appears to be the depth of the substrate-binding pocket, with DS-PTPs having a shallower landscape less conducive to the binding of the long side chain of tyrosine. A series of structural studies over the past decade have revealed that all PTPs possess one of three distinct topologies (Figure 3). This first and largest topological family, referred to simply as PTPs, includes all of the RPTPs, such classic PTPs as PTP1B and the *Yersinia* PTP, and DS-PTPs such as VHR and PTEN, among others (Figure 2).

CDC25 family

The CDC25 family is a set of DS-PTPs involved in the regulation of the cell cycle. Each enzyme of this family is highly specific for a particular serine or threonine residue on a cyclin-dependent kinase/cyclin complex. Although presence of the signature CX_5R motif suggests a common catalytic mechanism, the PTP domains of these enzymes share little sequence homology with other PTPs (Figure 3).

LMW-PTPs

The third family of topologically distinct CX_5R phosphatases is the low-molecular-weight phosphatases

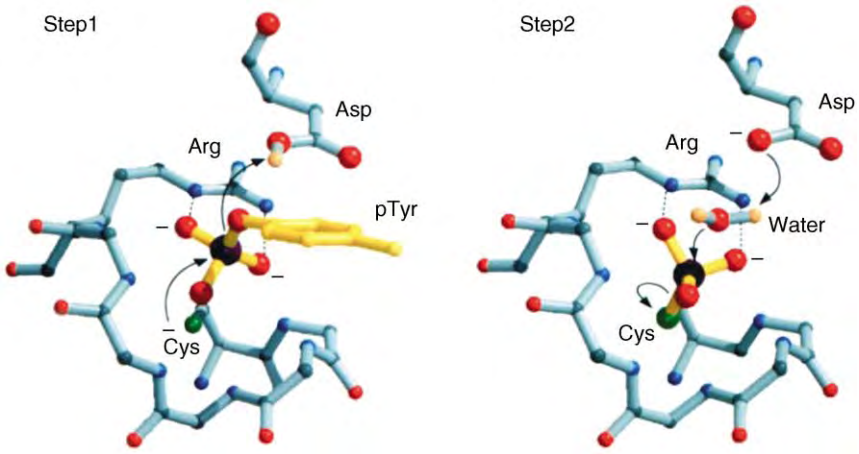

FIGURE 1 Catalytic mechanism of protein tyrosine phosphatases. Step 1: A thiolate anion of the active site cysteine performs a nucleophilic attack on the phosphate of phosphoryl-tyrosyl substrates, resulting in the formation a phospho-enzyme intermediate. An aspartic acid, acting as a general acid, donates a proton to the phosphate group, ejecting the tyrosine side chain. Hydrogen bonds between phosphate oxygen atoms and nitrogen atoms of the arginine guanido group promote phosphate binding and stabilize the transition state. Step 2: Acting as a general base, aspartate activates a water molecule for a nucleophilic attack on the phosphorous atom. The phosphorous–sulfur bond is hydrolyzed, thus regenerating the native enzyme. (Reproduced from Denu, J. M., Stuckey, J. A., Saper, M. A., and Dixon, J. E. (1996). Form and function in protein dephosphorylation. *Cell* **87**, 361–364.)

(LMW-PTPs). Conservation of the catalytic cysteine, arginine, and aspartic acid residues strongly suggests that these enzymes also utilize a similar catalytic mechanism. As with the CDC25 family, however, LMW-PTPs show no homology with other PTPs, and a lack of any other domains outside of their small (~150 amino acids) PTP domain provides few clues to their *in vivo* function. All LMW-PTPs examined to date have been specific for tyrosine-phosphorylated substrates.

Receptor-Like Tyrosine Phosphatases

Receptor-like tyrosine phosphatases (RPTPs) possess an extracellular receptor-like domain, a single transmembrane domain, and one or two intracellular classic tyrosine-specific PTP domains. Where two PTP domains exist, the membrane proximal domain accounts for the majority of catalytic activity. Based on their active site homology and common features of their extracellular domains, RPTPs can be further subdivided into eight subtypes: R1/R6, R2A, R2B, R3, R4, R5, R7, and R8 (Figure 2). The CD45 family (R1/R6) are expressed on nucleated hematopoietic cells and are thought to be involved in the positive regulation of antigen receptor signaling via dephosphorylation of the Src family kinases. RPTPs ρ, μ, κ, and λ (R2A) are marked by an extracellular MAM and an intracellular Cahedrin-like domains. They also possess extracellular fibronectin type III-like repeats and an immunoglobulin-like domain on their extracellular region that are involved in cell adhesion. The LAR-like PTPs (R2B) are primarily expressed in neuronal cells where they are thought to play an important role in neuronal development. They are marked by tandem repeats of immunoglobulin-like and fibronectin type III-like domains resembling neuronal adhesion molecules. Members of the R3 subfamily, e.g., the mammalian OST-PTP, possess multiple fibronectin type III repeats resembling cell adhesion molecules such as collagen type VII, fibronectin, and tenascin. PTP α and PTP ε (members of R4) are marked by their relatively small, highly glycosylated extracellular domains. PTP γ and PTP ζ represent the R5 subfamily, which have a carbonic anhydrase-like domain. RPTPs possessing a meprin domain in addition to immunoglobulin-like and fibronectin type III-like repeats comprise R6. Members of the R7 subfamily possess no additional extra- or intracellular domains, and the more evolutionarily distant R8 family members are predicted to be catalytically inactive.

PTPs and Human Disease

Involvement of PTPs in Mammalian Biology and Disease

At least 18 human protein tyrosine kinases (PTKs) have been shown to behave as oncoproteins when inappropriately activated by mutation. Given this, it was expected that PTPs, which can terminate tyrosine kinase signaling, might be found as genes frequently mutated in cancers. This has generally not proven to be the case. However, links between specific PTPs and human genetic diseases have been, and are continuing to be, established. In addition, numerous studies involving

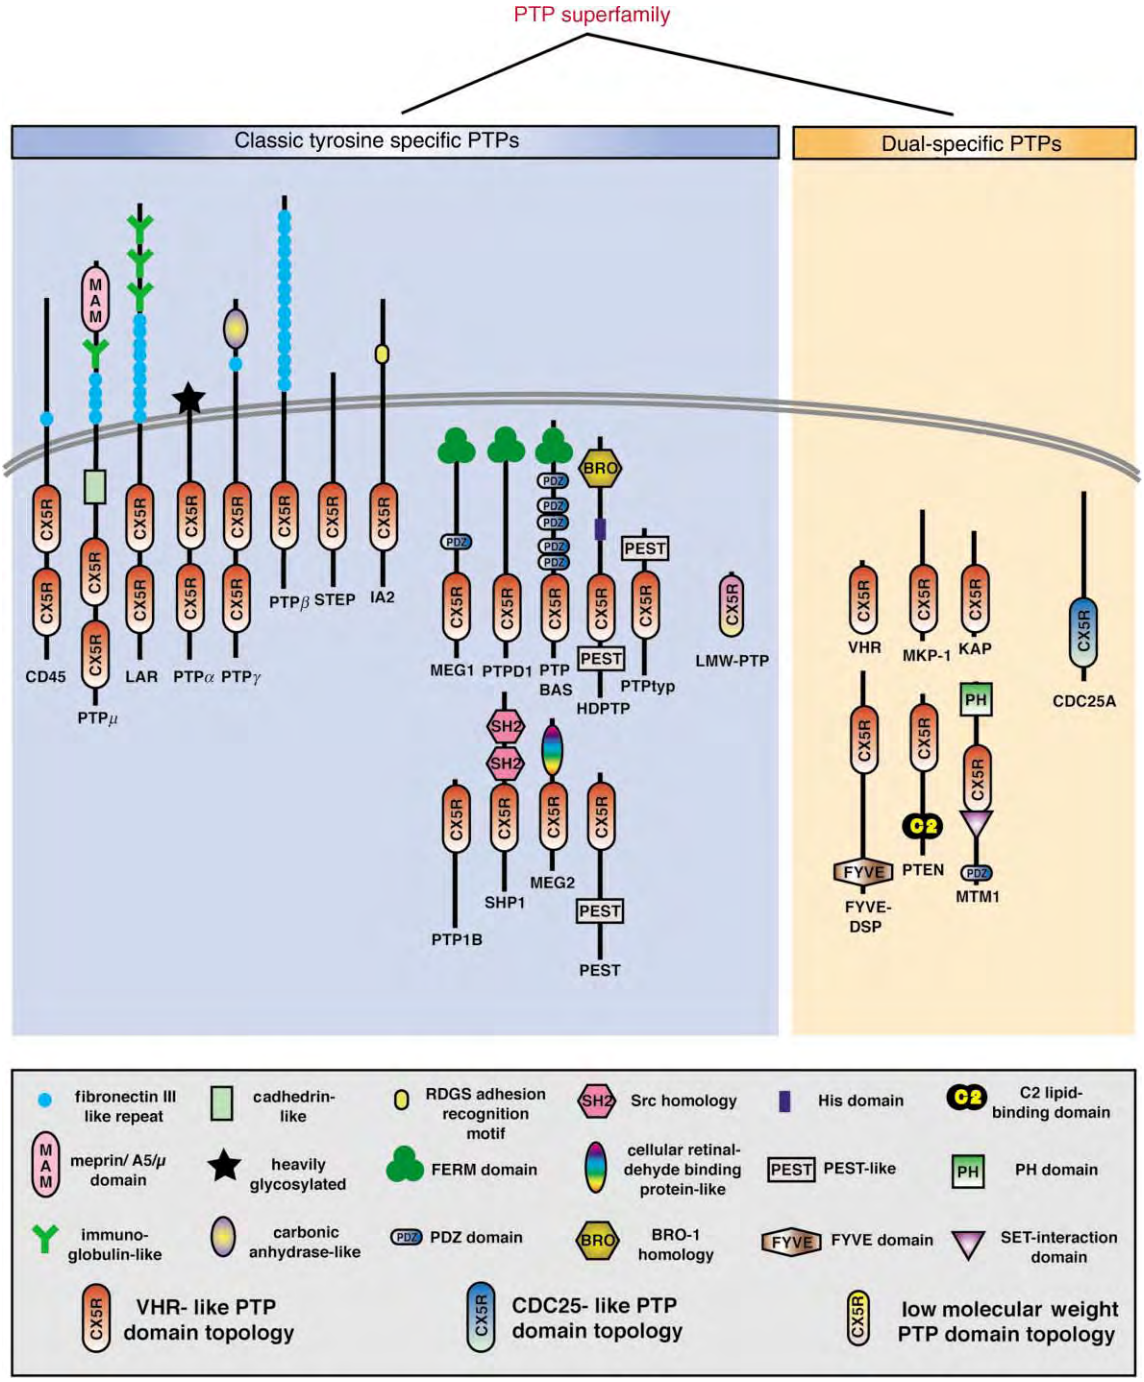

FIGURE 2 Schematic illustration of representative members of the PTP superfamily.

mice with targeted disruptions of individual PTP genes have provided *in vivo* evidence for the involvement of individual PTPs in specific biological processes. Abnormal PTP function has been implicated in a wide array of pathological conditions including diabetes, obesity, cancer, immune disease, neurodegeneration, and vascular disease. In this section, links between PTPs and human disease are briefly discussed. Studies of three PTPs that play essential roles in mammalian physiology are offered in examples. In addition, a summary of the results of PTP gene disruption experiments in mice is provided (Table I). Finally, the development of PTP inhibitors for use as therapeutics and research tools is discussed.

PTP-1B

A number of studies since the late 1990s have indicated that PTP-1B plays a specific role in down-regulating both insulin and leptin receptor signaling in mice.

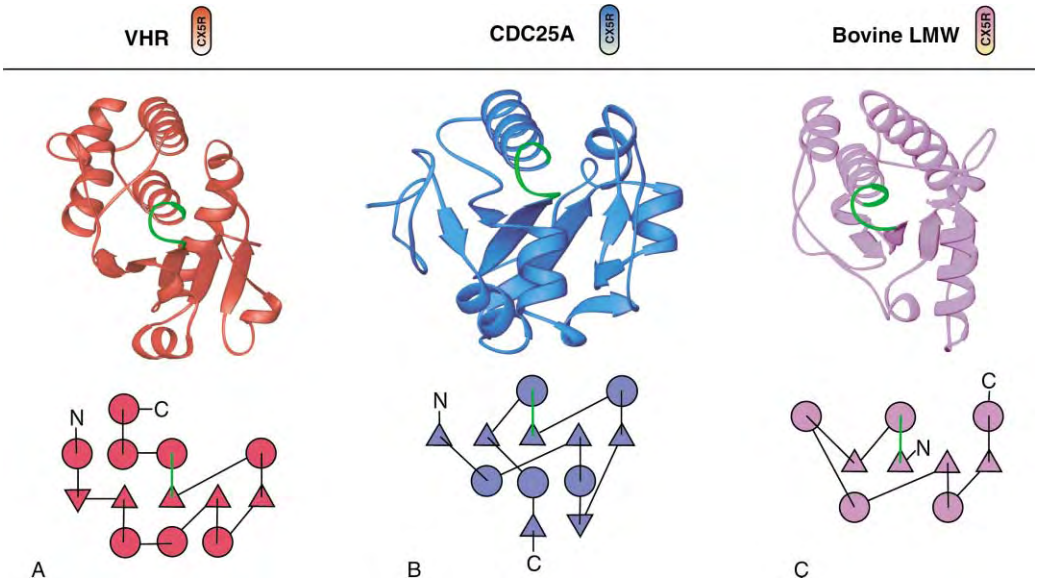

FIGURE 3 Crystal structures and topologies of representative members of each of the three topologically distinct PTP subfamilies. The amino (N) and carboxyl (C) termini of the proteins are indicated. Circles represent α-helixes; triangles represent β-strands. The location of the P-loop possessing the signature CX_5R motif is highlighted in green.

Studies from the laboratories of both Kennedy and Kahn have demonstrated that mice lacking PTP-1B are resistant to diabetes and diet-induced obesity, while displaying no other apparent physiological defects. Enhanced insulin sensitivity in PTP-1B-deficient mice likely results from hyperphosphorylation of the insulin receptor, as these mice display enhanced auto-phosphorylation of this protein in liver and muscle tissues. PTP-1B has been shown to associate with the insulin receptor PTK *in vivo* and both the insulin receptor and insulin receptor substrate 1 (IRS1) have been implicated as substrates for PTP-1B. Taken together, these data indicate a critical role for PTP-1B in turning off insulin signaling in sensitive mammalian tissues. The apparent *in vivo* specificity of PTP-1B function came as a surprise given the many other cellular processes in which this enzyme was thought to be involved. A number of pharmaceutical companies are attempting to generate specific inhibitors of PTP-1B for use as drugs to treat diabetes and obesity.

CD45

CD45 is an RPTP highly expressed in all nucleated hematopoietic cells. The extracellular portion CD45 contains fibronectin-like repeat sequences (Figure 2), is heavily glycosylated and is involved in the homodimerization of the molecule. Ligands for the extracellular domain of CD45 have not been identified, but this segment of the protein is important for the regulation of phosphatase activity. The cytoplasmic portion of CD45 contains two PTP domains; however, only the membrane proximal PTP domain is catalytically active and required for CD45 function. Homodimerization of CD45 is believed to maintain the phosphatase domain in a low activity state. CD45 mutations in either humans or mice result in a severe-combined immune deficient (SCID) phenotype, in which both B and T cells are affected (Table I). Consistent with the SCID phenotype, studies in CD45-deficient mice have indicated a role for this PTP as a critical positive regulator of immuno-receptor signaling in both B and T cells. In T cells, binding of an antigen to the extracellular portion of the T-cell receptor (TCR) results in the assembly of a cytoplasmic complex of TCR-associated signaling proteins. The PTKs Lck and Fyn phosphorylate a number of components of the assembled TCR signaling complex, leading to the recruitment and activation of the ZAP-70 PTK. Activated ZAP-70 participates in the transmission of stimulatory signals to downstream pathway components, ultimately leading to T-cell activation. The kinase activities of Lck and Fyn are negatively regulated by tyrosine phosphorylation on specific residues. By dephosphorylating these key inhibitory tyrosines, CD45 acts to prime Lck and Fyn for full activation, which is achieved through further phosphorylation. In this manner, CD45 is thought to function by setting an important threshold for T-cell activation.

Laforin

Mutations in the human gene for Laforin, a predicted DS-PTP, have been shown to cause Lafora disease, a progressive form of monoclonus epilepsy. The hallmark of Lafora disease is the accumulation of polyglucosan inclusions ("Lafora bodies") in the cytoplasm of cells of

TABLE I

Summary of PTP Gene Disruption Experiments in Mice

PTP	Mouse gene disruption phenotype and references
CD45	Severe-combined immunodeficiency (*1–3*)
CD148	Embryonic lethal (day 11.5); extensive vascular defects (*4*)
Cdc25b	Female sterility due to permanent meiotic arrest of oocytes (*5*)
Cdc25c	No phenotypic defects identified (*6*)
HePTP	Enhanced ERK activation in lymphocytes, but no physiological defects identified (*7*)
Laforin	Neurodegeneration and Lafora body accumulation; ataxia, epilepsy, and impaired behavioral responses (*8*)
LAR	Decreased basal forebrain cholinergic neuron size and hippocampal cholinergic innervation; delayed regenerative neurite outgrowth following nerve injury; impaired mammary gland development; abnormal glucose homeostasis (*9–14*)
PTP-1B	Enhanced sensitivity to insulin, leptin and growth hormone; obesity resistance (*15–19*)
PTPα	No gross phenotypic defects; reduced activation of Src and Fyn kinases; altered integrin signaling and cell migration (*20–23*)
PTPβ	No phenotypic defects identified (*24*)
PTPδ	Impaired learning; altered hippocampal long-term potentiation (*25*)
PTPε	No gross phenotypic defects; abnormal macrophage responsiveness; hypomyelination of sciatic nerve neurons; abnormal voltage-gated potassium channel function (*26*, *27*)
PTPσ	Neonatal or early lethality; developmental defects in neuronal and neuroendocrine cell lineages (*28–33*)
SHP-1	Early lethality ($<$12 weeks); severe hematopoetic dysregulation and autoimmunity (*34–37*)
SHP-2	Embryonic lethality (day 10.5) with gastrulation defects; enhanced MAP kinase activation (*38*, *39*)
TC-PTP	Early lethality ($<$*5* weeks); defective bone marrow function; impaired B and T cell function (*40–43*)

the brain, liver, kidney, skeletal and cardiac muscle, and skin. This human disease phenotype has recently been replicated in Laforin-deficient mice, through the work of Yamakawa and colleagues. In addition to its DS-PTP domain, Laforin possesses a carbohydrate-binding domain, which is required for its association with glycogen particles, and responsible for targeting the phosphatase to the same subcellular location as glycogen synthase. The cellular substrate(s) of Laforin have yet to be identified, but are actively being pursued.

PTPs as Drug Targets

Given the potential involvement of PTPs in many aspects of human biology and disease, there is considerable interest in the development of small molecule inhibitors of PTPs for use as therapeutics. In addition to their potential medical value, highly selective and potent PTP inhibitors would be powerful research tools for determining the functions of individual PTPs in mammalian cells. However, the development of specific PTP inhibitors has proved challenging. Like protein kinases, PTPs comprise a large family of enzymes that utilize a common chemical mechanism for catalysis. Accordingly, structure-based drug design is likely to be critical for the development of highly specific PTP inhibitors.

Structural studies have suggested a strategy by which inhibitor specificity for individual PTPs might be achieved. Investigations with PTPs have indicated that residues adjacent to the pTyr-binding site play essential roles in achieving substrate specificity and catalytic efficiency. Contemporary work has taken advantage of unique properties of the PTP-1B molecule to develop inhibitors with high selectivity. PTP-1B possesses a second phosphate-binding site on the protein surface, adjacent to its active site. Zhang and colleagues have designed small nonpeptide molecules containing two nonhydrolyzable phosphate moieties. Such molecules inhibit PTP-1B at nanomolar concentrations and are highly selective for this enzyme. High affinity and specificity are achieved by the combined action of the two phosphate moieties, with one binding in the active site and the other at the adjacent site. Such "bidentate" inhibitor compounds may serve as a model for the development of additional, highly specific PTP

inhibitors, as they target both the active site, which is highly conserved among PTPs, and adjacent portions of the structure, which are less highly conserved.

BIOGRAPHY

Dave Pagliarini graduated with honors from the University of Notre Dame in 1999 with a B.S. in biochemistry, and is currently a doctoral candidate in Jack Dixon's lab at the University of California, San Diego. His thesis work deals with the novel mitochondrial phosphatase, PLIP.

Fred L. Robinson is a Postdoctoral Research Fellow in the laboratory of Jack E. Dixon at the University of California San Diego. He holds a Ph.D. from the University of Texas Southwestern Medical Center in Dallas. His primary research interests are protein tyrosine and lipid phosphatases.

Jack E. Dixon is a Professor of Pharmacology, Cellular and Molecular Medicine, and Chemistry and Biochemistry, as well as Dean for Scientific Affairs, at the University of California, San Diego. His principal research interests are protein tyrosine phosphatase signaling and molecular mechanisms of bacterial pathogenesis. He holds a Ph.D. from the University of California, Santa Barbara and was a postdoctoral fellow at the University of California, San Diego. He is a member of the American Academy of Arts and Sciences and the National Academy of Science.

Proteinase-Activated Receptors

Kristina K. Hansen and Morley D. Hollenberg
University of Calgary, Calgary, Alberta, Canada

Proteinase-activated receptors (PARs) are members of a recently discovered receptor family, belonging to the seven-transmembrane superfamily of cell-surface G-protein-coupled receptors. They are found in various organs across several species and have a number of physiological roles. To date, four members of this family have been cloned (PAR_1, PAR_2, PAR_3, and PAR_4). Their unique mechanism of activation involves enzymatic cleavage of the N-terminal domain. This cleavage then allows the newly unmasked N-terminal domain of the receptor to bind to another site of the receptor to start the signaling process. This process is an example of a tethered-ligand mechanism. Additionally, synthetic receptor-activating peptides (PAR-APs) of 5–6 amino acids can also bind to the receptor. Once the tethered ligand or PAR-AP binds to the receptor, a conformational change of the receptor leads to G-protein activation, which triggers the signal transduction cascade. This cascade is responsible for transcription, mitogenesis, growth, and differentiation.

Structure

Proteinase-activating receptors are composed of ~400 amino acids (Table I). All four PARs possess a number of potential N-linked glycosylation sequences on their extracellular domains. The sequence homology between all of the PARs is ~30%. The tethered ligand is revealed upon enzymatic cleavage at an arginine or lysine residue present in all of the PARs (Table I). Much evidence has supported the key role for extracellular loop 2 of PAR_1 and PAR_2 in the activation of PARs by PAR-APs. In PAR_1, a sequence of ~10 amino acids in the N-terminal extracellular domain (residues 83-93 in human PAR_1) is also involved in signaling by either the tethered ligand or by the PAR-AP. For activation by proteinases, however, the importance of extracellular loop 2 is less clearly understood. The human genes encoding PAR_1, PAR_2, and PAR_3 are all located on chromosome 5q13, while PAR_4 is located on chromosome 19p12. All of the PAR genes have similar overall structures.

Activating Proteinases

Thrombin was the first proteinase that was shown to activate PARs (Figure 1A). In fact, the original name for PAR_1 was thrombin receptor. It is now known that PAR_1, PAR_3, and PAR_4 are all targeted by thrombin. Thrombin is a key serine proteinase that regulates the blood coagulation cascade. Thrombin, however, does not activate PAR_2. The most common activator of PAR_2 is trypsin. Other serine proteinases that have been shown to target PARs include: cathepsin G, plasmin, granzyme A, factors VIIa/X/Xa/TF, mast cell tryptase, and the dust mite proteinases, Der p3 and Der p9. As already mentioned, the cleavage site that leads to activation for all of the PARs is adjacent to either an arginine or lysine residue ~40 amino acids from the N terminus (see Table I).

Inactivation

Once activated, the individual PAR receptor is no longer capable of producing another signal because it is rapidly desensitized and internalized by phosphorylation-dependent mechanisms, similar to other G-protein-coupled receptors. Another means of inactivation of PAR receptors is by cleavage of the receptor downstream (towards the C terminus) of the activation cleavage site (Figure 1D). For example, the neutrophil enzymes elastase, proteinase 3, and cathepsin G cleave PAR_1 on platelets and endothelial cells downstream of the thrombin cleavage site. The actions of these proteinases effectively inhibit thrombin from activating PAR_1.

Agonist Peptides

Specific agonist peptides (PAR-APs) modeled on the sequence of the tethered ligands can be used in place of proteinases to determine whether or not a certain PAR may be present and responsive in cells or tissues (Figure 1B). These receptor-selective peptide agonists can be used to help understand the physiological role of a particular PAR. Unlike thrombin and trypsin, which can act on various PARs, PAR-APs selective for PAR_1, PAR_2, and PAR_4 have been developed. The sequences of the selective PAR-APs for these three receptors, as designated by the one-letter codes for each amino acid are: TFLLR-NH_2 (PAR_1), SLIGRL-NH_2 (PAR_2), and

TABLE I

Summary of Human Protease-Activated Receptors

	PAR_1	PAR_2	PAR_3	PAR_4
Amino acid composition	425	397	374	385
Cleavage site for receptors	LDPR[41] ↓ SFLLRN	SKGR[36] ↓ SLIGKV	LPIK[38] ↓ TFRGAP	PAPR[47] ↓ GYPGQV
Proteinase activators	Thrombin	Trypsin, tryptase	Thrombin	Thrombin
Selective peptide agonists	TFLLR-NH_2	SLIGRL-NH_2	None known	AYPGKF-NH_2

AYPGKF-NH_2 (PAR_4), respectively (Table I). The peptide SFLLRN-NH_2, which matches exactly the tethered-ligand sequence of human PAR_1, activates both PAR_1 and PAR_2. Although SLIGRL is the tethered-ligand sequence of PAR_2 in both the rat and mouse but not the human, the peptide SLIGRL-NH_2 is a more potent agonist for human PAR_2 than SLIGKV-NH_2. Similarly, AYPGKF-NH_2 is 10 times as potent as a human PAR_4 agonist than the sequences GYPGQV-NH_2 or GYPGKF-NH_2, which represent the tethered ligands of the human and mouse receptors, respectively. The reasons for the improved selectivity and potency of the synthetic sequences versus the naturally occurring sequences have yet to be explained. At present, there is not a selective PAR_3 agonist peptide known.

Activation of PARs by Neighboring PARs

In addition to the ability of proteinases and agonist peptides to activate an individual PAR directly, one PAR can be activated via a neighboring PAR in the cell membrane. For example, it has been demonstrated that the proteolytically revealed tethered ligand of PAR_1 can in turn activate PAR_2 (Figure 1C). Thus, theoretically, PAR_2 can generate a response to thrombin without being directly activated by the enzyme. Further, by acting as a "docking site" for thrombin, PAR_1 and PAR_3 can potentially facilitate thrombin's ability to activate PAR_4. In this manner, the PARs are acting as coreceptors, the one for the other. To date, although able to act as a coreceptor for PAR_4, PAR_3 has not been found to generate an intracellular signal on its own.

Antagonists

To understand the physiological effects of the PARs fully, selective antagonists that inhibit activation of PARs by both activating proteinases and peptides will be of great use. Activation of PAR_1, by either thrombin or a PAR_1-AP, is inhibited by compounds 1 and 2 (Figure 2). Similarly, PAR_4 activation is inhibited by compound 3 (Figure 2). As yet, there are no known synthetic antagonists of PAR_2 or PAR_3.

Distribution

PARs have been detected in a variety of tissues by northern blot analysis. The brain, lung, heart, stomach, colon, kidney, small intestine, liver, pancreas, testes, prostate, uterus, placenta, trachea, thymus, lymph node, skeletal muscle, and adrenal gland have all been shown to have at least one of the PARs. Table II summarizes the tissues and cells in which each PAR is found. It is important to note, however, that cellular expression is not necessarily conserved across species. For example, human platelets express PAR_1 and PAR_4 while mouse platelets express PAR_3 and PAR_4.

Detection Methods

Reverse Transcriptase-Polymerase Chain Reaction (RT-PCR)

To see if known PARs are present in a given cell type or tissue, reverse transcriptase-polymerase chain reaction (RT-PCR) analysis, using the primers specific for each of the individual PARs, may be performed with the total RNA isolated from the cells or tissues. After complementary DNA purification by agarose gel electrophoresis and DNA sequence analysis, it can be concluded whether or not certain PARs are expressed in the sample tested. This method, however, does not guarantee that the PARs are present in their active states.

Northern Blot Analysis

In order to detect if any of the PARs are present in a tissue sample, northern blot analysis can also be performed. The total RNA is isolated from the tissue, separated by agarose gel electrophoresis, and transferred to a blotting membrane (i.e., nitrocellulose paper) via an electric field. The RNA of interest is identified by treatment of the blotting membrane with a complementary RNA or DNA probe that is labeled with ^{32}P or

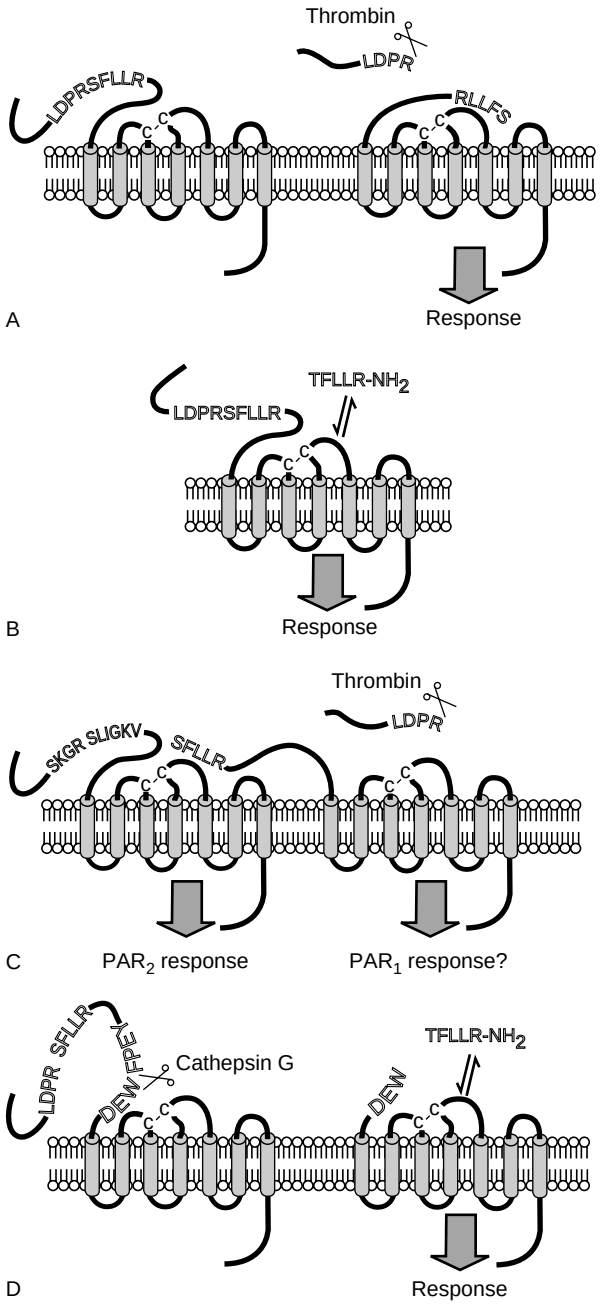

FIGURE 1 Mechanisms of activation and inactivation of PARs. (A) The functional PARs cloned to date contain within their receptor N terminus a serine protease cleavage/activation site that once cleaved by a serine protease, results in the unmasking of a cryptic tethered-ligand sequence. The revealed tethered-ligand sequence is believed to bind to and subsequently activate the receptor. The example provided (A) is for human PAR_1 activation by thrombin. (B) PARs may be activated independently of proteolytic unmasking of the tethered-ligand sequence by small synthetic peptides (PAR-APs) corresponding to the first five or six amino acids of the tethered-ligand sequence. Activation by the receptor-selective PAR_1AP, TFLLR-NH_2, is shown. (C) Intermolecular activation of PAR_1 or PAR_2 may occur following PAR_1 activation, whereby the unmasked tethered ligand of a PAR_1 receptor activates an uncleaved neighboring PAR_2 or PAR_1 receptor. (D) Inactivation of PARs may occur by proteases cleaving the receptor C-terminally of the tethered-ligand sequence, thus amputating the tethered ligand from the receptor body. These amputated receptors can no longer be activated by proteinases but are still responsive to exogenously applied PAR-APs. Note: a putative cysteine palmitoylation site in the C-terminal tail (present in all PARs except human PAR_4) may result in a fourth intracellular loop (not shown) that could play a role in receptor signaling. Reproduced with permission from Hollenberg, M. D., and Compton, S. J. (2002). International Union of Pharmacology XXVIII. Proteinase-activated receptors. *Pharmacol. Rev.* **54**, 203–217.

a fluorescent marker, followed by detection with the appropriate camera. One of the advantages of northern blot analysis is that the sequence of the probe does not need to be an exact match (e.g., from the same species).

Flow Cytometry

Flow cytometry is a technique for identifying and sorting cells that contain a component of interest by staining with a fluorescent dye and detecting the fluorescence by laser beam illumination. Cell-surface expression of PARs in a particular cell line can be identified by treatment of the cells first with anti-PAR antiserum (antibody) followed by the binding of fluorescein isothiocyanate-labeled goat antirabbit IgG that binds to the PAR antibody. Cell-surface expression of the PAR of interest can be quantified by fluorescence-activated cell sorting (FACS) analysis.

Immunocytochemistry/ Immunohistochemistry/ Immunofluorescence

These techniques take advantage of the strong interactions between antigens and their antibodies. The cells are immobilized by centrifugation onto slides using a cytospin machine or are grown directly on the slides, while tissues are embedded in paraffin, cut, and mounted on slides. The cell or tissue preparation is treated with anti-PAR antiserum (antibody) followed by a secondary antibody, which allows for detection. Antirabbit fluorescein isothiocyanate- or rhodamine-conjugated antibodies are examples of secondary antibodies used for fluorescence detection. An example of a visible detection approach is a sandwich streptavidin-conjugated peroxidase method using 3,3′diaminobenzidine as a substrate. These techniques detect the receptor directly.

In Situ Hybridization to Detect Receptor mRNA

In situ hybridization uses a complementary oligonucleotide, DNA, or RNA probe to detect a specific complementary mRNA sequence in intact tissue sections or cell preparations. This technique to locate PARs uses

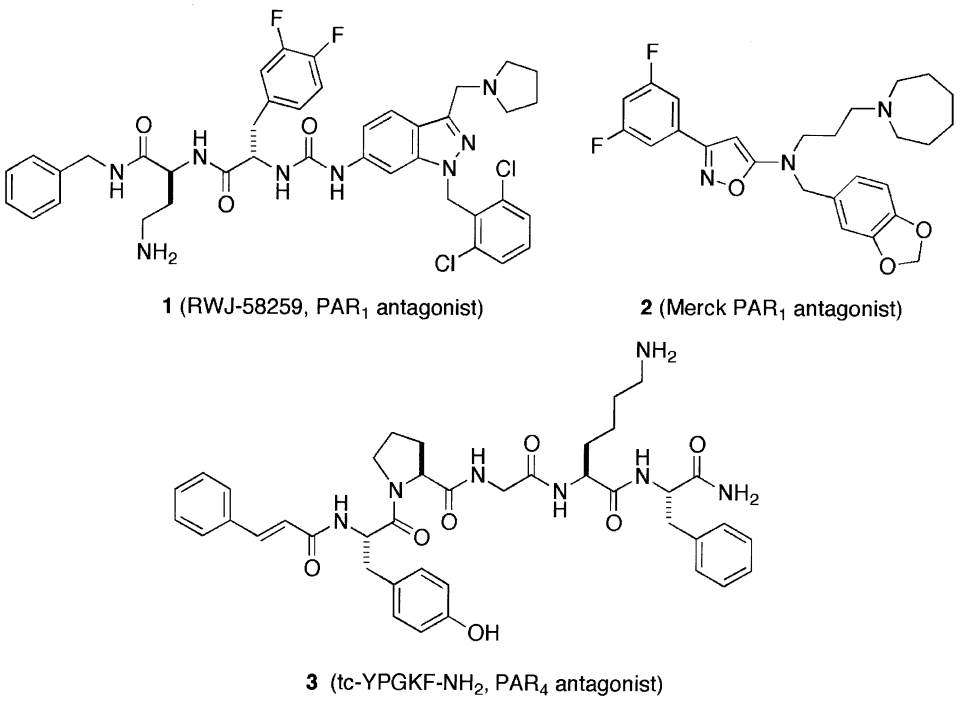

FIGURE 2 PAR antagonists.

the same principles used in northern blot analysis, except that the exact location of the mRNA can be identified. Immunohistochemistry techniques similar to those described above are used to detect the mRNA, instead of the receptor, to show where the receptor is being synthesized.

Bioassays

Measurement of Calcium Signaling Using Fluorescence Emission in Cultured Cells

As PARs are G protein-coupled receptors, once PARs are activated, the G protein undergoes a conformational change that activates phospholipase C (PLC), which then converts phosphatidyl inositol 4,5-bisphosphate (PIP_2) to inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG). The IP_3 causes calcium to be released from the endoplasmic reticulum, thus increasing the intracellular calcium levels. This increase in intracellular calcium concentration can be measured in cells preincubated with a fluorescent calcium-sensitive dye (fluo-3 or fura-2) which is taken up into the cytoplasm. The fluorescence properties of the dye differ whether or not calcium is bound. For a calcium signaling assay, a fluorescence spectrophotometer measures the change in fluorescence at a defined wavelength versus time of a suspension or monolayer of cells preincubated with a fluorescent dye. When a specific PAR agonist is added to PAR expressing cells, a fluorescence peak is observed that reflects increased intracellular calcium. To confirm whether or not an unknown agonist or proteinase activates a certain PAR, cross-desensitization experiments can be performed. For example, PAR_1 and PAR_2 expressing HEK293 cells can be treated first with the PAR_1-specific agonist TFLLR-NH_2 (maximum dose) two times to desensitize PAR_1. This pretreatment is then followed by addition of the unknown agonist. If there is still a response, it can be concluded that the unknown agonist does not activate PAR_1. Likewise, to test for activation of PAR_2 by the same unknown agonist, the experiment can be repeated by exposing the cells first to the PAR_2-specific agonist SLIGRL-NH_2 to desensitize PAR_2. Alternatively, TFLLR-NH_2 may be added after two doses of the unknown agonist (maximum dose). If there is no response to TFLLR-NH_2, it can be concluded that the unknown agonist must have desensitized PAR_1 either by activation or another process.

Tissue Bioassays (Contraction or Relaxation)

To understand better how the activation of PARs leads to a biological response, blood vessels and smooth muscle strips may be treated with PAR-APs. The relaxation of rat aorta via the endothelium-dependent nitric oxide-mediated pathway can be measured. Similarly, contraction of the rat gastric longitudinal muscle can be assessed. For the bioassay experiment, a tissue is

mounted under a resting tension in an organ bath. Changes in tension are detected using a force displacement transducer coupled to an amplifier and a data acquisition system. Known compounds that give a response are added to the organ bath to serve as a control. For example, acetylcholine is known to relax preconstricted aortic rings via an endothelium-dependent process, and potassium chloride is known to cause a large contractile response by acting directly on the smooth muscle present in the gastric or vascular preparation. PAR-APs are then added to the organ bath and the response is compared to the standards. As in the calcium signaling assay, cross-desensitization experiments can be performed to assess the potential contribution of each PAR to the biological response.

Platelet Aggregation

Platelets are known to express PARs. Activation of PARs on platelets causes aggregation. Using a light-transmission aggregometer, platelet aggregation can be monitored by measuring the turbidity of a suspension of platelets. Simply by adding agonists to a suspension of platelets, aggregation can be quantified either as a percentage increase in light transmission relative to that of the initial platelet suspension, or as a percentage of the maximal aggregation, versus time. This assay is commonly used to determine whether or not a compound is an agonist or an antagonist of PAR_1 and PAR_4. For example, if an antagonist is added before a specific PAR-AP, the aggregation of the platelets will be diminished.

Physiological Roles of PARs

PAR_1 plays an aggregatory and secretory role in human platelets and a role as a regulator of endothelial cell function. PAR_1 has also been shown to have an important role in the process of narrowing the arteries after vascular injury. PAR_2 has been suggested to be involved in the cardiovascular, pulmonary, and gastrointestinal systems, as well as having an important role in the settings of inflammation and pain sensation. Since the only role of PAR_3 shown to date is that it functions as a cofactor for thrombin-mediated activation of PAR_4, its physiological role is the same as for PAR_4. PAR_4, like PAR_1, has been shown to be responsible for the activation of platelets. There are many other physiological roles of PARs that have yet to be discovered.

Glossary

agonist Compound that stimulates a cellular receptor to give a biological response.

antagonist Compound that binds to a cellular receptor which prevents a biological response from occurring.

antibody Protein produced by specialized B cells after stimulation by an antigen (foreign substance). Acts specifically against an antigen in an immune response.

glycosylation sequence Three amino acid sequence where the first amino acid is asparagine, the second is any amino acid except proline, and the third is serine or threonine.

proteinase Enzyme which selectively catalyzes the hydrolysis of peptide bonds.

PAR Acronym for proteinase-activated receptor. A G-protein-coupled receptor that is activated upon cleavage of the N-terminal domain by a proteinase.

PAR-AP Synthetic peptide that causes activation of a PAR.

Morley D. Hollenberg is a Professor in the Department of Pharmacology and Therapeutics and the Department of Medicine at the University of Calgary, Faculty of Medicine. His principal research interests focus on membrane receptors and signal transduction. He holds an M.D. from The Johns Hopkins University School of Medicine, Baltimore, Maryland and a D.Phil. From Oxford University, Oxford, UK.

Proteoglycans

Sara K. Olson and Jeffrey D. Esko
University of California, San Diego, La Jolla, California, USA

Proteoglycans (PGs) are glycoconjugates that contain glycosaminoglycans (GAGs) covalently attached to a protein core. They differ from glycoproteins by the unbranched, negatively charged GAG chains, which enables them to interact with numerous ligands, including growth factors, chemokines, cell adhesion proteins, protease inhibitors, and enzymes. This diverse group of molecules turns out to be essential for biological processes ranging from embryonic development to hemostasis and infection.

Proteoglycan Structure

Glycosaminoglycans

Proteoglycans (PGs) consist of two main structural components – the glycosaminoglycan (GAG) chains and the protein cores.

Three classes of GAG chains are covalently attached to PG core proteins: chondroitin sulfate (CS) /dermatan sulfate (DS), heparan sulfate (HS)/heparin, and keratan sulfate (KS) (Figure 1). Their structure, site of assembly, and pattern of sulfation and epimerization distinguish each of these types of GAGs. In addition, vertebrates contain a fourth class of GAGs called hyaluronan (hyaluronic acid, HA), but unlike the other GAGs, HA is not covalently bound to a protein core.

Building Blocks

Sugars used in GAG formation include xylose (Xyl), galactose (Gal), glucuronic acid (GlcA), N-acetylglucosamine (GlcNAc), and N-acetylgalactosamine (GalNAc). All of these sugars are hexoses (6-carbon sugars) except xylose, which contains five carbons. In order to build the chains, individual sugars are added in a stepwise manner. The enzymes that catalyze these reactions use activated sugar nucleotide donors, such as UDP-GlcNAc and UDP-GlcA for HA; UDP-GlcNAc or UDP-GalNAc, UDP-GlcA, UDP-Xyl, UDP-Gal and an activated form of sulfate called phosphoadenosine-5′phosphosulfate (PAPS) for HS/heparin and CS/DS; and UDP-Gal, UDP-GlcNAc, UDP-GalNAc, PAPS, and two additional sugar nucleotides for making keratan sulfate (GDP-Man and CMP-sialic acid). With the exception of UDP-xylose, which is derived from UDP-GlcA in the endoplasmic reticulum, all of the other sugar nucleotides assemble in the cytosol, and sugar nucleotide transporters shuttle them into the Golgi apparatus where they are used. The sugar and sulfate residues add to the growing chain, releasing UDP, PAP, GMP, or CMP for subsequent recycling in the cytoplasm.

Hyaluronan

Hyaluronan or HA is structurally the simplest GAG. It consists of repeating disaccharide units of GlcNAcβ1-4GlcAβ1-3, and does not undergo any further modification. HA is unique among the GAGs in that it does not assemble on a protein core and it is made at the plasma membrane instead of the Golgi apparatus. This orientation facilitates its extrusion from the cell into the surrounding extracellular matrix (ECM). The ECM is the network of polysaccharides and fibrous proteins that give strength, support, and structure to the cells embedded within it. HA chains are especially long, typically reaching 10^4 disaccharides. Due to their length they can intertwine to form a mesh-like material with interesting chemical properties, such as water retention and high viscosity. The turgor properties of the vitreous of the eye, the umbilical cord, and rooster combs reflect the high concentration of HA in these tissues. Several proteins, known as hyalectins, contain motifs that allow specific interactions with HA. HA helps to organize the extracellular matrix, and can bind to signaling and adhesion receptors on the cell surface, affecting growth and migration.

Chondroitin Sulfate/Dermatan Sulfate

Unlike HA, CS/DS (as well as HS/heparin) is synthesized while attached to a core protein. The chains initiate at Serine (Ser) residues of protein cores through the addition of Xyl from UDP-Xyl, followed by addition of two Gal residues, and finally GlcA from their corresponding sugar nucleotides. This linkage tetrasaccharide can undergo additional modifications, including sulfation of the Gal residues and phosphorylation of xylose, which may play a regulatory role in the assembly

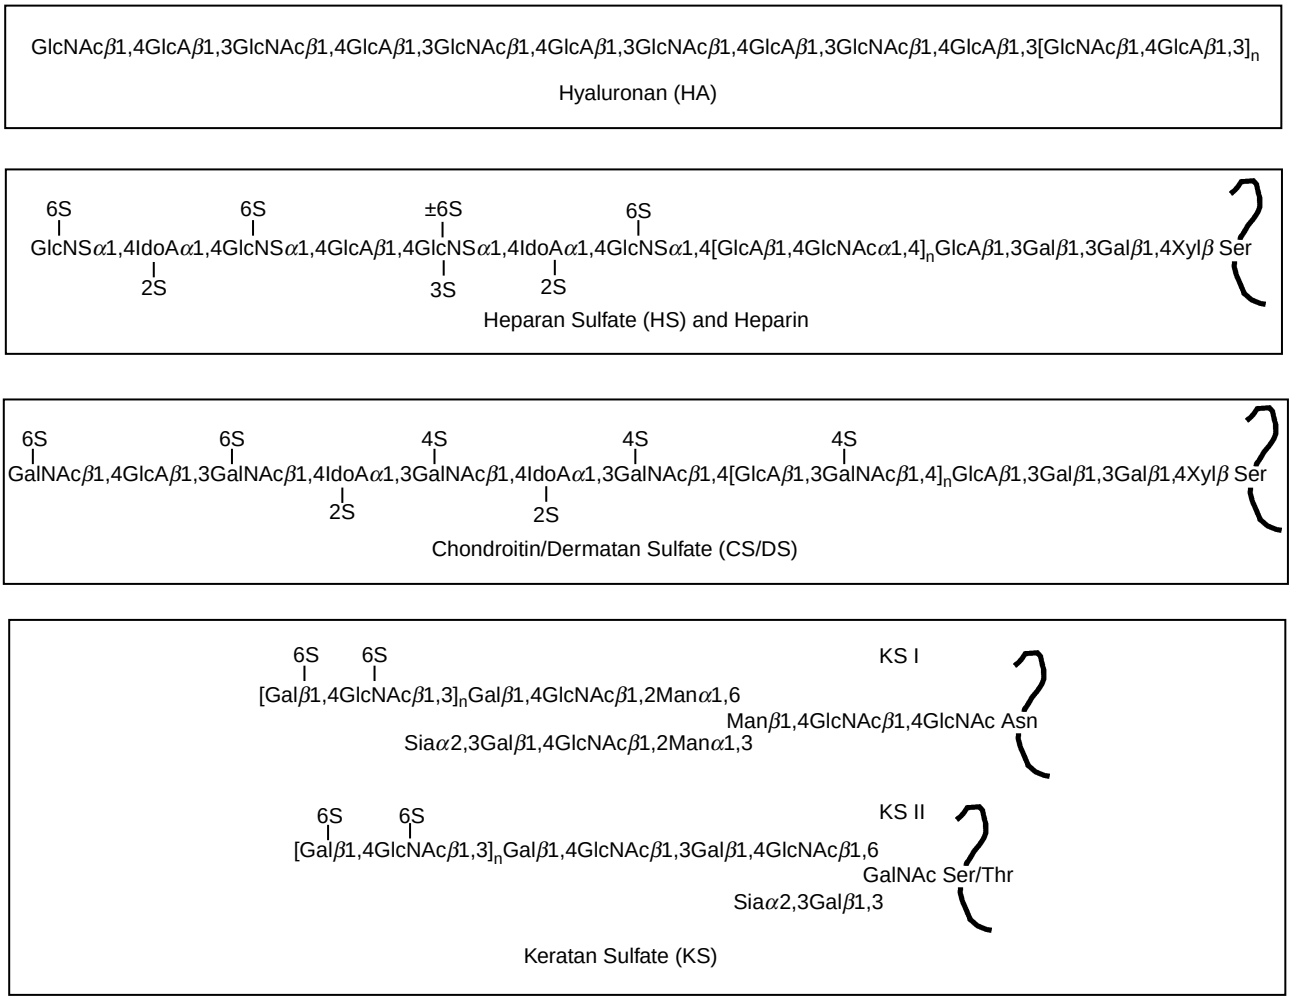

FIGURE 1 Classes of glycosaminoglycans. Hyaluronan (HA) is made up of repeating units of GlcNAc and GlcA. Heparan sulfate (HS) and chondroitin sulfate (CS) arise from a common linkage tetrasaccharide precursor linked to a protein core at serine (Ser) residues. HS consists of repeating GlcNAc and GlcA, while CS is composed of GalNAc and GlcA. Keratan sulfate (KS) is generated by the step-wise addition of GlcNAc and Gal residues. KS I is linked to the protein core via asparagine (Asn), whereas KS II is attached at Ser or threonine (Thr) residues.

process. Separate enzymes catalyze each step of the assembly of the linkage tetrasaccharide.

The growing chain is committed to become chondroitin by the addition of GalNAcβ1-4, and the chain then elongates by the assembly of the repeating units GalNAcβ1-4GlcAβ1-3, by the chondroitin synthase enzyme family. An average chain consists of $\sim$40 disaccharides, but the size varies in different tissues. The chondroitin backbone can be modified by sulfation of GalNAc units at the C-4 and/or C-6 positions, which tends to occur across the entire chain. In DS, a subset of D-GlcA units undergoes epimerization to L-IdoA, which can then be sulfated at C-2. Epimerization of GlcA to IdoA occurs by stereochemical inversion at C-5 (the proton is axial in D-GlcA but planar in L-IdoA).

CS/DS PGs are generally secreted into the extracellular matrix where they perform a variety of structural and developmental roles. The model organism *C. elegans* requires a nonsulfated form of chondroitin for the first embryonic cell division and the process of epithelial cell invagination in the vulva. In vertebrates, chondroitin sulfate plays numerous structural roles in cartilage, tendon, and other organized extracellular matrices. In the nervous system, it appears to affect axonal outgrowth and guidance. Very few binding proteins have been described, suggesting that some of chondroitin's properties may be related to its biophysical properties (hydrostatic and electrostatic effects). DS binds with growth factors and protease inhibitors involved in hemostasis.

Heparan Sulfate/Heparin

HS and heparin synthesis initiates in a manner similar to CS/DS by the assembly of the linkage tetrasaccharide.

The nascent chain becomes heparan upon addition of a GlcNAcα1-4 residue. Polymerization of the chain then ensues by the stepwise addition of GlcAβ1-4 and GlcNAcα1-4. As the chain elongates, it undergoes a number of modifications. Subsets of GlcNAc residues can be N-deacetylated, N-sulfated, and O-sulfated at the C-3 and C-6 positions. As in the case of CS/DS, epimerization of GlcA to IdoA can occur at residues neighboring GlcNS. Additionally, the uronic acids can be sulfated at C-2. HS chains are generally modified in sections, with highly sulfated blocks interspersed between nonmodified regions. Variable deacetylation, epimerization, and sulfation patterns give rise to specific binding sites for a large number of ligands, including growth factors (FGFs, Wnts, BMPs), anticoagulant proteins (antithrombin III, heparin cofactor II, which also binds DS, and thrombin), and matrix components (e.g., laminin, fibronectin, and some collagens). HS plays a vital role in numerous biological processes involved in cell growth, migration, and differentiation. A human disease called hereditary multiple exostosis (HME), characterized by bony outgrowths on the long bones, is caused by mutation of the enzymes responsible for polymerizing the HS chain (EXT-1 and EXT-2).

Heparin is a form of HS that has potent anticoagulant activity due to its ability to bind and activate antithrombin, a protease inhibitor, by way of a unique pentasaccharide sequence. In general, heparin is much more extensively modified compared to HS, containing as much as 85% GlcNS units and 75% IdoA, whereas HS contains 40–50% GlcNS and 25–40% IdoA. However, sections of HS chains can be extensively modified by sulfation and epimerization like heparin. Heparan sulfate is made by virtually all cells, whereas heparin is made selectively by connective tissue-type mast cells and stored in secretory granules. Therapeutic heparin derives from porcine and equine tissue digests. Commercial heparin Sepharose is often used to aid in the purification of proteins.

Keratan Sulfate

KS is classified as a glycoprotein as well as a PG. The chain consists of repeating Galβ1-4GlcNAcβ1-3 units (N-acetyllactosamine), containing sulfate groups in the C-6 positions of Gal and GlcNAc residues. Two forms of KS PGs vary by their linkage to core proteins. In KSI, the linkage of the polylactosamine is identical to conventional Asn-linked glycoproteins, whereas in KSII, the linkage is identical to that found in mucins (Figure 1). Like HS, the disaccharide units of KS can be unsulfated, monosulfated, or disulfated. KS is expressed in cartilage and a number of epithelial and neural tissues, playing a role in events as diverse as collagen fiber assembly, wound healing, and embryogenesis. They are also present in neurosecretory vesicles, suggesting unique roles in vesicle formation and neuronal activity.

Protein Cores

With the exception of HA, all GAGs are synthesized while attached to a protein core. Some PG cores serve functional roles by binding to other matrix molecules and bridging the extracellular matrix to the cytoskeleton. The number of GAG chains carried by individual PGs depends on the number of attachment sites, ranging from a single chain (decorin) up to 100 chains (aggrecan) (Table I). Most PGs contain multiple glycosylation sites, any or all of which may be used. A loose consensus sequence has been identified for HS and CS glycosylation sites on the protein core. Xylose is added to Ser residues that are followed by glycine (Gly), typically flanked by two or more acidic amino acids (Asp or Glu). The factors that regulate the efficiency of initiation are unknown. Evidence also exists that the presence of hydrophobic residues near the attachment sites, the density of attachment sites, as well as inhibitory sequences in the protein cores determine the selection of sites for the assembly of HS/heparin or CS/DS.

Proteoglycan Families

More than 25 PGs have thus far been identified in mammalian systems (Table I), and many fall into gene families based on sequence homologies. Some PGs carry a single type of GAG, whereas others can be hybrid molecules carrying HS and CS or CS and KS. Many PGs also carry other types of O-linked and N-linked glycans. Some PGs are large globular molecules reaching masses of 400 kDa, while others have small masses around 10 kDa. While structurally diverse, they can be classified into the following families based on location and homology.

Secreted and Matrix Proteoglycans

PGs secreted into the ECM can carry CS or DS chains. This group includes the small interstitial PGs, the aggrecan family, the basement membrane PG bamacan, and secretory granule PGs, such as serglycin. Perlecan and agrin are the only known HSPGs specifically secreted into the ECM. However, some membrane HSPGs can be shed from the cell surface and the ectodomains can become part of the ECM or accumulate in extracellular fluids.

TABLE I

Proteoglycan Families

Class	Family	Proteoglycan	Core mass (kDa)	Chain #	Chain type	Tissue
Matrix/secreted	Small interstitial	Decorin	36	1	CS	Connective tissue cells
		Biglycan	38	1–2	CS	Connective tissue cells
		Endocan	20	1	CS	Endothelial cells
		Epiphycan	35	2–3	CS	Cartilage
		Fibromodulin	42	2–3	KS	Broad
		Lumican	38	3–4	KS	Broad
		Keratocan	38	3–5	KS	Broad
		Mimecan/osteoglycin	25–35	2–3	KS	Broad, sulfated in cornea
		Osteoadherin	49	2–3	KS	Bone
	Aggrecan	Aggrecan	208–220	~100	CS/KS	Cartilage
		Versican	265	12–15	CS	Fibroblasts
		Neurocan	145	1–2	CS	Brain
		Brevican	96	0–4	CS	Brain
	Basement membrane	Bamacan	138	1–3	CS	Basement membranes
		Perlecan	400	1–3	HS	Basement membranes
		Agrin	212	2–3	HS	Basement membranes
	Intracellular storage	Serglycin	10–19	10–15	Heparin/CS	Mast cells
		SV2	80	1–3	KS	Synaptic vesicles
	Miscellaneous	Collagen α2 type IX	68	1	CS	Cartilage, vitreous humor
		Collagen type XVIII	150	1–3	HS	Epithelial cells, basement membranes
		Phosphacan	176		CS/KS	Brain
		Testicans 1–3	50	1–3	HS/CS	Testes, brain endothelium
Membrane bound	Syndecans	Syndecans 1–4	31–45	1–3	HS/CS	Epithelial cells, fibroblasts
	Glypicans	Glypicans 1–6	~60	1–3	HS	Epithelial cells, fibroblasts
	Miscellaneous	Betaglycan	110	1–2	HS/CS	Fibroblasts
		Thrombomodulin	58	1	CS	Endothelial cells
		CD44	37	1–4	CS	Lymphocytes
		NG2	251	2–3	CS	Neural cells
		Invariant chain	31	1	CS	Antigen-processing cells

Small Interstitial Proteoglycans (Small Leucine-Rich Proteoglycans)

This class of PGs includes proteins with leucine-rich repeats flanked by cysteines in their central domain. The family has over nine members, and all carry either CS/DS or KS GAG chains. Members include decorin and biglycan, which interact with collagen in the matrix. Much work to date has concentrated on understanding the role of these PGs in stabilizing and organizing collagen fibers. In decorin, this activity appears to be dictated by the PG core since removal of the GAG chains fails to disrupt fibrillogenesis. Mice lacking the decorin PG live to adulthood but show a fragile skin defect. Decorin mutants exhibit great variation in fibril diameter and spacing. In the cornea, KSPGs maintain the register of collagen fibers, which is required for transparency. Decorin is also able to bind TGF-β, serving as a sink to keep the growth factor sequestered.

Aggrecan Family

The Aggrecan family of PGs includes aggrecan, versican, brevican, and neurocan. All four members share these common features: the N-terminal domain is able to bind HA, the central region contains GAG attachment sites, and the C-terminal domain contains a C-type lectin domain (lectins are nonimmunoglobulin, nonenzymatic proteins that bind sugar chains). Aggrecan is the most well-known member of this family, since it is the

major PG present in cartilage. It contains by far the largest number of GAG chains, as many as 100 CS and KS chains per protein. It complexes with HA in the ECM and draws water into cartilage, thereby providing the ability to resist compressive forces. Versican is the largest member of the aggrecan family with a mass of 265 kDa, but it also undergoes alternative splicing events that generate smaller proteins. Roles in neural crest cell and axonal migration have been suggested. Neurocan and brevican are both localized to the brain. Neurocan is expressed in the late embryonic central nervous system (CNS) and acts to inhibit neurite outgrowth. Brevican is expressed in the terminally differentiated CNS, particularly in the perineuronal nets.

Basement Membrane Proteoglycans

The basement membrane is an organized layer of ECM that lies flush against epithelial cells and consists of laminin, collagen, nidogen, and PGs. Basement membranes contain three types of large PGs, each containing 1–3 GAG chains. Bamacan is the most recently cloned member of this family and has not yet been studied in detail. It carries predominantly CS chains. Perlecan and agrin, on the other hand, are HSPGs (though perlecan has been shown to carry CS on occasion). Perlecan is the largest known PG with a mass of 400 kDa and is a modular protein with multiple domains that serve numerous functions. It appears to play a role in embryogenesis and tissue morphogenesis. It is present in the pre-implantation blastocyst and endothelial cells. Agrin is a well-characterized PG that acts in the nervous system by aggregating acetylcholine receptors at the neuromuscular junction, and is additionally expressed in the renal tubules where it plays an important role in determining the filtration properties of the kidney. Homologues of the basement membrane PGs exists in flies and worms.

Secretory Granule Proteoglycans

Serglycin is the main PG localized to intracellular cytoplasmic secretory granules. It is synthesized by endothelial, endocrine, and hematopoietic cells, and it can carry CS, DS or heparin chains. Serglycin is stored in secretory granules until the host cell becomes activated, resulting in secretion of granular contents into the surrounding environment. Serglycin may play a role in packaging granular contents, maintaining proteases in an inactive state, and regulating activities after secretion, such as coagulation, host defense, and wound repair. Heparin, the highly sulfated form of HS, is made exclusively on serglycin present in mucosal mast cells.

Membrane-Bound Proteoglycans

Many PGs reside in cell membranes as type I transmembrane proteins (e.g. syndecan family) or glycosylphosphatidylinositol (GPI)-linked proteins (e.g. glypican family).

Syndecans

In syndecans, a short hydrophobic domain spans the membrane, linking the larger extracellular domain containing the GAG attachment sites to a smaller intracellular cytoplasmic domain. There are four members in mammalian systems, whereas lower organisms such as flies and worms contain only one homologue. They can carry HS and/or CS chains, which bind a wide range of extracellular ligands such as growth factors and matrix molecules. These interactions likely account for the requirement of syndecans at numerous stages of embryonic development and in the adult animal. Syndecans can additionally coordinate signals from the extracellular environment to the intracellular cytoskeleton via their cytoplasmic tails. For example, binding of a ligand to a GAG chain can induce oligomerization of syndecans at the cell surface. This leads to recruitment of factors at the cytoplasmic tail of syndecan, such as kinases (e.g. c-Src), PDZ-domain proteins, or cytoskeletal proteins. The recruitment of cytosolic proteins in turn triggers a signal that leads to actin filament assembly. Proteolytic cleavage of the syndecans occurs, resulting in release of the ectodomains bearing the GAG chains. These ectodomains can have potent biological activity.

Glypicans

The glypican family of cell-surface PGs is involved in numerous aspects of animal development. The C terminus is embedded in the membrane by a hydrophobic GPI-linked anchor, and thus the glypicans do not have a cytoplasmic tail like the syndecans. The N-terminal portion of the protein is globular and has been shown to carry only HS chains *in vivo*. The glypicans bind a wide array of factors that are essential for development and morphogenesis. Their roles in growth factor signaling potentially include both positive and negative regulation. HS chains are able to positively promote signaling by bringing a ligand and its receptor into close proximity. On the other hand, HS chains could negatively regulate signaling by binding a particular ligand and preventing its diffusion or interaction with a receptor.

Six glypican family members exist in mammals, two in flies and one in worms. Glypican-3 (GPC3) is the best-studied member of the family. Human patients lacking functional GPC3 exhibit Simpson–Golabi–Behmel Syndrome, which is characterized as an overgrowth

disorder. The overgrowth phenotype suggests that GPC3 normally functions to inhibit cell proliferation, likely mediated at the level of growth factor signaling at the cell surface.

Miscellaneous Membrane Proteoglycans

A number of membrane PGs do not show homology to syndecans or glypicans, but are expressed on the surface of many different cell types. The CSPG NG2 is a surface marker expressed on stem cell populations that are able to divide throughout an organism's life, including cartilage chondroblasts, myoblasts, endothelial cells of the brain, and glial progenitors. It has been shown to play a role in angiogenesis and inhibits neurite outgrowth. CD44 is a transmembrane cell surface receptor that plays a role in processes as diverse as immune function, axon guidance, and organ development. CD44 is considered a PG since it can carry GAG chains in certain cell types, such as lymphocytes. It is also an HA binding protein. The GAG chains allow CD44 to interact with ECM proteins and growth factors.

Processing

PGs are born in the endoplasmic reticulum (ER) and Golgi, but important steps of the PG life cycle also occur at the cell surface and other intracellular compartments.

Cell Surface Desulfation

The majority of sulfation reactions occur in the Golgi apparatus as the chains assemble prior to secretion. However, a family of cell surface sulfatases has been identified that removes sulfate groups from the C-6 position of glucosamine residues in HS. This sulfatase, called QSulf1 (first identified in quail), can promote Wnt growth factor signaling through HS in a finely tuned manner by desulfating HS at the appropriate time and place.

Turnover and Degradation

PGs are turned over on a continual basis (Figure 2). The syndecans undergo proteolytic cleavage and shedding at the cell surface, mediated by one of the matrix metalloproteases (MMP7). Additionally, some if not all membrane PGs are internalized by endocytosis. Enzymes called heparanases cleave the HS chains into fragments of a defined size, which then become localized to lysosomal compartments. Cells also endocytose HA, CS/DS, and KS proteoglycans, and sulfatases and exoglycosidases degrade the chains completely, while proteases degrade the core proteins. The liberated sugars (GlcNAc, GalNAc, Gal, and Man) and amino acids can then be recycled for the formation of new GAG chains and PGs, whereas the uronic acids and xylose are thought to undergo oxidative catabolism since no salvage pathway has been identified. The function of continuous turnover of the GAG chains and PGs is unclear. However, disruption of this pathway leads to lysosomal storage disorders with devastating health consequences.

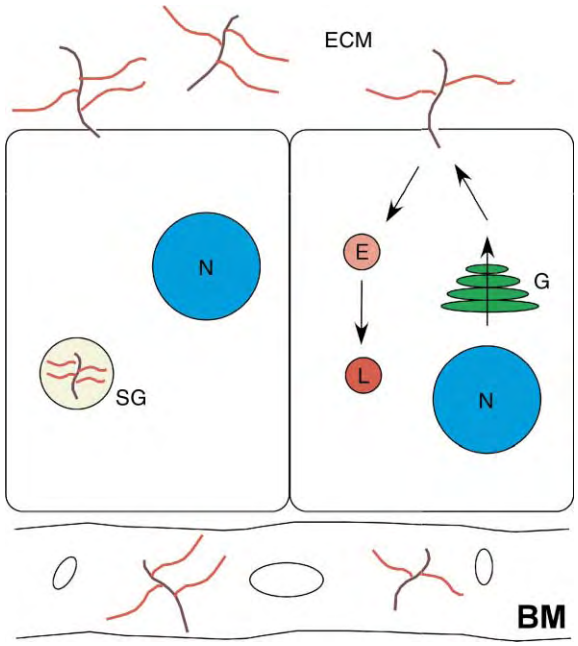

FIGURE 2 Life cycle of a proteoglycan. Proteoglycans are predominantly synthesized in the Golgi apparatus (G). A mature proteoglycan can be embedded in the plasma membrane, stored in secretory granules (SG), or secreted into the extracellular matrix (ECM) or basement membrane (BM). Degradation of proteoglycans begins with endocytic internalization, followed by cleavage of the GAG chains and protein core by glycosidases and proteases, respectively, in endosomes (E) and lysosomes (L). Nucleus (N).

Glossary

chondroitin sulfate A type of glycosaminoglycan defined by the disaccharide unit (GalNAcβ1,4GlcAβ1,3)$_n$, modified with ester-linked sulfate at certain positions and typically found covalently linked to a PG core protein.

dermatan sulfate A modified form of chondroitin sulfate in which a portion of the β-glucuronic acid residues are epimerized to α-iduronic acid.

glycan Generic term for a sugar or assembly of sugars, existing either in free form or attached to another molecule.

glycosaminoglycan Polysaccharide side chains of PGs or free complex polysaccharides composed of linear disaccharide repeating units, each composed of a hexosamine and a hexose or a hexuronic acid.

glycosyltransferase An enzyme that forms a glycosidic linkage between a sugar and an acceptor.

heparan sulfate A glycosaminoglycan defined by the disaccharide unit $(GlcNAc\alpha1,4GlcA\beta1,4/IdoA\alpha1,4)_n$, containing N- and O-sulfate esters at various positions, and typically found covalently linked to a PG core protein.

heparin A type of heparan sulfate made by mast cells that has the highest amount of iduronic acid and of N- and O-sulfate residues.

hyaluronan A glycosaminoglycan defined by the disaccharide unit $(GlcNAc\beta1,4GlcA\beta1,3)_n$ that is neither sulfated nor covalently linked to protein, referred to in older literature as hyaluronic acid.

keratan sulfate A polylactosamine $(Gal\beta1,4GlcNAc\beta1,3)_n$ with sulfate esters at C-6 of GlcNAc and galactose residues found as a side chain of a keratan sulfate PG.

lectin A protein (excluding an antibody) able to bind glycans without causing modification of the glycan structure.

proteoglycan A protein with one or more covalently attached glycosaminoglycan chains.

sugar nucleotide Activated forms of monosaccharides, such as UDP-Xyl, UDP-Gal, UDP-GlcA, and UDP-GlcNAc, UDP-GalNAc, typically used as donor substrates by glycosyltransferases.

Sara Olson is a graduate student in the Biomedical Sciences Graduate Program in the School of Medicine at the University of California, San Diego (UCSD). She received her undergraduate education at Lawrence University where she developed an interest in developmental biology. She helped discover that vulval invagination in *C. elegans* depends on chondroitin biosynthesis.

Jeffrey D. Esko is a Professor of Cellular and Molecular Medicine and Co-director of the Glycobiology Research and Training Center at UCSD. He received his Ph.D. from the University of Wisconsin at Madison and was a Fellow of the Molecular Biology Institute at the University of California, Los Angeles. His principal research interests are in proteoglycan assembly and function using genetically altered cell lines and conditional mouse knockouts.

Pteridines

S. Colette Daubner and Paul F. Fitzpatrick
Texas A&M University, College Station, Texas, USA

The pteridines are a group of heterocyclic compounds containing a wide variety of substitutions on the basic compound pterin. Pterin itself is composed of a pyrazine ring and a pyrimidine ring; the pyrimidine ring has a carbonyl oxygen and an amino group. The biosynthesis of pterins begins with the molecule GTP; the enzyme which controls the conversion of GTP to pterin, GTP cyclohydrolase, is found in both prokaryotes and eukaryotes. Pterins were first discovered in the pigments of butterfly wings and perform many roles in coloration in the biological world. Pterins also function as cofactors in enzymatic catalysis. Folates, "conjugated" pterins which contain p-amino benzoic acid and glutamates in addition to the pterin ring system, are critical compounds in methyl transfer biochemistry. Tetrahydrobiopterin, the major unconjugated pterin in vertebrates, is involved in the hydroxylation of aromatic compounds and synthesis of nitric oxide. Molybdopterin, which contains pterin, a third heterocyclic ring containing an ether oxygen and two thiol substitutes, and molybdenum, is involved in biological hydroxylations, reduction of nitrate, and respiratory oxidation.

The name pteridine refers to the heterocyclic aromatic compound shown in Figure 1, composed of a pyrimidine ring fused to a pyrazine ring. However, the word pteridines has come to stand for an entire group of naturally occurring compounds. Their structures are based upon pteridine, but they have substituents on the pyrimidine ring: an amino group or a carbonyl at position 2 and a carbonyl group at position 4 (position numbers as shown in Figure 1). Pterin contains the amino substituent at position 2; all pterins are derivatives of this molecule. Most naturally occurring pteridines are pterins. The first pterins to be studied, leucopterin and xanthopterin, were pigments isolated from butterfly wings by Sir Frederich Gowland Hopkins at Cambridge University in the late nineteenth century. Their names are derived from the Greek words for wing, *pteron*, white, *leukos*, and yellow, *xanthos*.

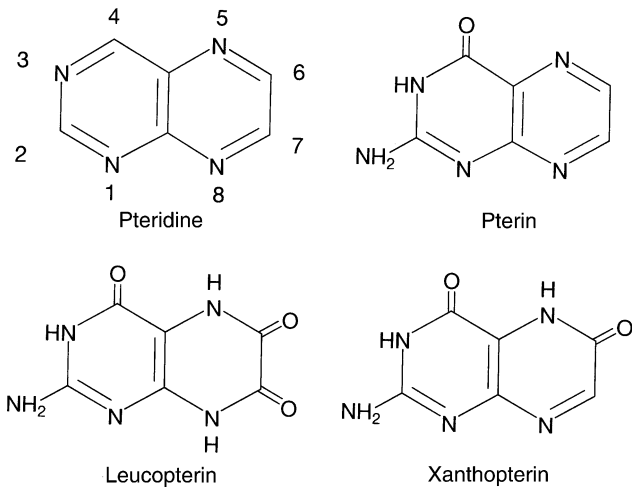

FIGURE 1 Structures of pteridine and three pteridines.

Pterins are referred to as being conjugated or unconjugated. The conjugated pterins are folates, derivatives of folic acid. They contain a *p*-aminobenzoate substituent at the 6-position and one or more glutamate residues. The folates are covered in a separate article in this series. As a general but not fast rule, folates are involved in one-carbon transfers in metabolism and pterins are involved in oxygenation reactions or in pigmentation.

Distribution of Pterins in Nature

Pterins are found in all living organisms, from bacteria, blue-green algae, and trypanosomes, to mammals; they have also been detected in the chloroplasts of spinach leaves and the cotyledons of pea sprouts. A wide variety of pterins exist in bacteria, such as the various pterins with three-carbon side chains of *Escherichia coli*, the glucuronidated pterins of *Bacillus subtilis*, the three ribityl pteridines of the marine bioluminescent bacterium *Photobacterium phosphoreum*, the molybdopterins of photosynthetic bacteria, and the tetrahydromethanopterin of methanogenic bacteria.

As pigments, pterins are not only found in butterfly wings, but also in moth heads, silkworm skin, grasshopper bodies, and honeybee larvae. A list of examples demonstrates the very wide use nature has made of pterins in coloration; diversity is found in species distribution, chemical structures, and hue. Unusual dimeric pterins are found in the eyes of the fruit fly, *Drosophila*. A blue pigment in the roundworm

Ascaris lumbricoides contains biopterin. Pterins are common in the skins of amphibians and fish, and photolabile pterins are found in some amphibians' eyes. The red color of some salmon, the Siamese fighting fish, and the red lizard *Anolis* is due to pterins, as is the green color of some snakes.

Clearly pterins serve widely in coloration, but they are also critical compounds in metabolic pathways. In the vertebrates the major pterin is tetrahydrobiopterin, which serves as a redox cofactor in enzymatic reactions utilizing molecular oxygen.

Biosynthesis of Neopterin and Biopterin

The synthesis of all pterins begins with the ring opening and reclosing of the nucleotide guanosine triphosphate (GTP) by the enzyme GTP cyclohydrolase (GTPCH). GTPCH has been isolated and sequenced from many sources. It is a decamer, each active site containing a zinc atom. As the rate-limiting enzyme of pterin biosynthesis, it is carefully regulated, both by transcriptional and posttranslational mechanisms. The catalytic domains of the *E. coli* and human enzyme are 37% identical in amino acid sequence, testifying to the ancient status of pterins in the living world.

The reaction catalyzed by GTPCH is shown in Figure 2. The purine ring system of guanine supplies all but two of the carbons in the ring system of pterin. The ribose moiety of GTP supplies the two new carbons for the pyrazine ring and the carbons of the erythrose side chain; one carbon from the guanine ring is released as formate. The pterin product is dihydroneopterin triphosphate. In eukaryotes, dihydroneopterin triphosphate is converted to dihydrobiopterin (Figure 3). In contrast, dihydrobiopterin is not formed in most bacteria.

The structures of biopterin and its reduced forms are shown in Figure 3. Reduction of the 7,8 double bond yields 7,8-dihydrobiopterin (a tautomer of 7,8-dihydropterin is quinonoid dihydropterin). Further reduction at the 5,6 double bond gives tetrahydrobiopterin.

Pterins in Metabolism

The Aromatic Amino Acid Hydroxylases (AAHs)

One of the most-studied processes involving biopterin is the hydroxylation of the aromatic amino acids. This is catalyzed by a small family of enzymes containing phenylalanine (PheH), tyrosine (TyrH), and tryptophan (TrpH) hydroxylase. They contain an iron atom and utilize tetrahydrobiopterin and molecular oxygen to hydroxylate a fairly unreactive entity, an aromatic ring. The AAHs are only active in the Fe^{II} state; one role of the tetrahydrobiopterin may be to keep the iron reduced. The major role of tetrahydrobiopterin is to activate the oxygen for eventual transfer to the aromatic amino acid

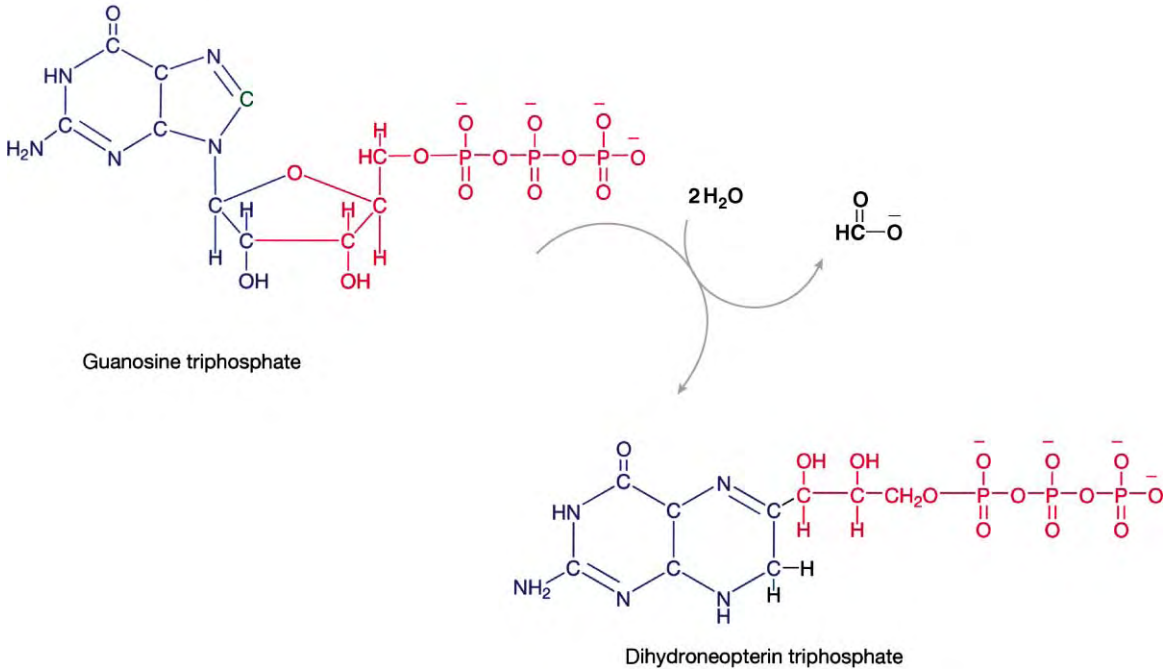

FIGURE 2 The first step in the synthesis of pterins from guanosine triphosphate. The atoms of GTP are color-coded to show their positions in the resulting neopterin molecule. Note that one carbon of GTP, colored green, is lost as formate.

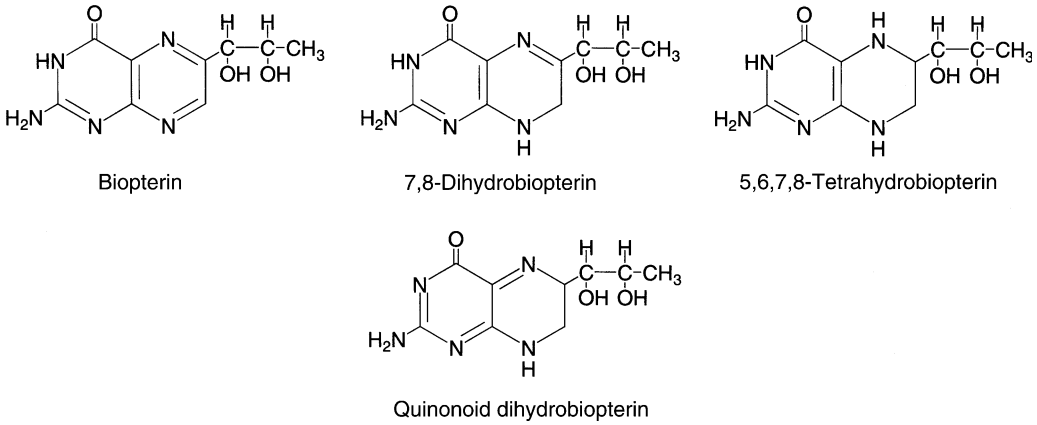

FIGURE 3 Structures of biopterin and its reduced forms.

substrate, probably through formation of a C4a-peroxy pterin intermediate (Figure 4).

Each of the AAHs catalyzes the rate-limiting step in its metabolic pathway: PheH in phenylalanine catabolism, TyrH in synthesis of the catecholamine neurotransmitters, and TrpH in serotonin synthesis. The three enzymes are homologous to a great extent in their catalytic domains (between any two there is 60% identity and 75% similarity). These enzymes as a rule are not found in bacteria, consistent with the general absence of biopterin from prokaryotes. However, PheH has been isolated from several prokaryotes, and from one, *Chromobacterium violaceum*, the sequence is 30% identical to the catalytic domain of human PheH. Two amino acid residues which bind tetrahydrobiopterin (in TyrH, F300 and E332) are conserved in all the aromatic amino acid hydroxylases studied, suggesting a central role for biopterin in the evolution of neurotransmitters and higher nervous systems.

The pterin product of the AAHs is C4a-carbinolamine dihydrobiopterin (Figure 4). It is released from the enzyme and is returned to the state needed for amino acid hydroxylation by the action of two more enzymes, C4a-carbinolamine dehydratase and dihydropterin reductase.

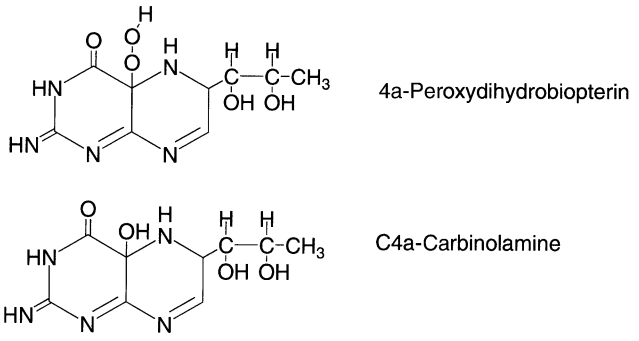

FIGURE 4 Peroxypterin and carbinolamine intermediates in the hydroxylation of aromatic amino acids.

Nitric Oxide Synthase

Nitric oxide synthase (NOS) is responsible for the synthesis of nitric oxide, NO. NOS utilizes tetrahydrobiopterin, NADPH, and molecular oxygen to convert L-arginine to L-citrulline and NO (Figure 5). Nitric oxide is a gas and a highly toxic compound. Because of its toxicity, its short half-life (1–5 s), and its diffusibility, NO serves the mammalian immune system as a killer of foreign intruders and cancer cells. It is also a cellular signal through its stimulation of cGMP synthesis.

NOSs are dimers of identical subunits. NOS contains flavin mononucleotide (FMN), flavin adenine dinucleotide (FAD), heme, and tetrahydrobiopterin. The tetrahydrobiopterin binding site is positioned close to the heme to facilitate electronic interaction between them. The tetrahydrobiopterin binding site is formed by residues in both subunits at the interface where the subunits associate; the pterin ring is sandwiched between a tryptophan residue from one subunit and a phenylalanine from the other. In contrast to the two-electron loss in AAHs, the tetrahydrobiopterin of NOS loses only one electron generating a biopterin radical. Biopterin remains bound to NOS before and after catalysis, another difference between NOS and the AAHs.

Molybdopterin-Containing Enzymes

A very large group of enzymes contain molybdenum (or in a few cases tungsten) in conjunction with a unique pterin, molybdopterin. These enzymes function in general to transfer oxygen to or from a physiological molecule. They can be assigned to two

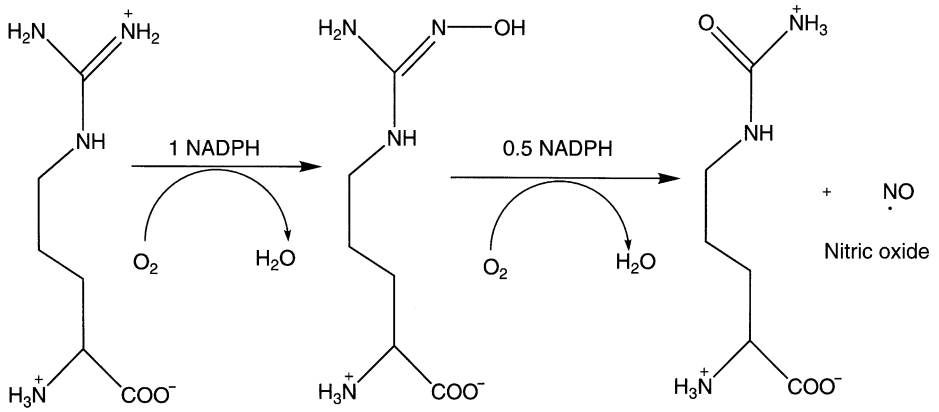

FIGURE 5 Reaction catalyzed by NOS.

categories based on the reaction catalyzed. The first group, the true hydroxylases, performs hydroxylation of aldehydes or aromatic rings; some of the enzymes in this category are milk xanthine oxidase, liver aldehyde oxidase, and bacterial enzymes such as formate dehydrogenase and nicotine dehydrogenase. The second category can be subdivided into: (1) sulfite oxidases and enzymes which reduce nitrate to enable a cell to utilize ammonia and (2) bacterial enzymes which function as terminal respiratory oxidases.

The structures of molybdopterin and the molybdenum cofactor are shown in Figure 6. The R group in prokaryotic systems can be guanine, cytosine, adenine, or hypoxanthine; in eukaryotes it is a hydrogen. The mode of binding the molybdenum cofactor to the protein differs from protein to protein in accord with the classification described above. The enzymes of the xanthine oxidase group contain one single molybdenum center per enzyme subunit, the sulfite oxidase family members are likely to have one molybdenum cofactor bound to a cysteine of the protein, and the final group can contain two molydopterins coordinated to one molybdenum, which can be coordinated to a selenium, sulfur, or cysteine. The biosynthetic pathways of these pterins have not been solved as yet.

The molybdenum enzymes are a vast enough group that a discussion of their properties is inappropriate here. In general, they contain other redox centers in addition to their pterin cofactor, such as heme, iron–sulfur clusters, and flavin. The role of the pterin is postulated to include mediation of electron transfer to the other redox active centers and modulation of the reduction potential of the molybdenum. The pterin is not thought to be itself oxidized and reduced during catalysis, a distinct difference between these enzymes and the NOSs and AHHs.

Tetrahydrobiopterin and Human Disease

Tetrahydrobiopterin deficiency is associated with a rare variant of hyperphenylalaninemia, which cannot be treated by the low phenylalanine diet successful for typical phenylketonuria (PKU) patients. It is characterized by a deficit of catecholamine neurotransmitters and serotonin as well (the products of the AAHs), affecting the nervous system as well as the liver. It can be caused by mutations in GTPCH or in the enzymes which recycle dihydrobiopterin. Decreased levels of tetrahydrobiopterin in cerebrospinal fluid have also

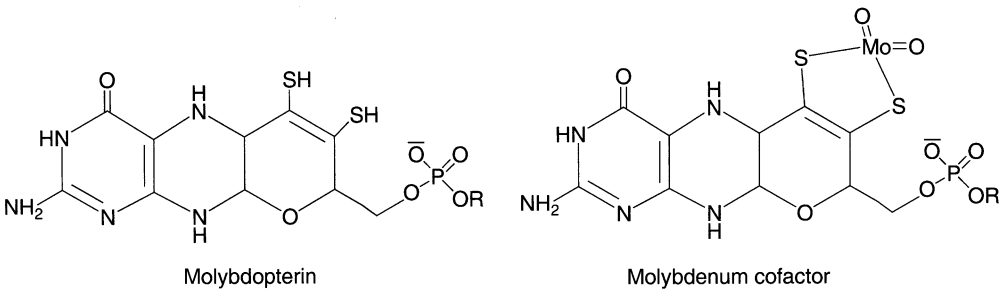

FIGURE 6 The structures of molybdopterin and the molybdenum cofactor.

been noted in such diseases as Parkinson's, autism, depression, and Alzheimer's.

Glossary

aromatic amino acid Aromatic compounds are cyclic compounds containing double bonds so that their three-dimensional structure is planar. Amino acids are small molecules which consist of a central carbon atom, tetrahedrally bonded to a carboxylic acid group, an amino group, a hydrogen, and a fourth group, often called an R group; in the aromatic amino acids it is this R group which is aromatic.

heme A large planar heterocyclic compound consisting of four bridged pyrrole rings which binds Fe in biological systems for the transport or reactivity of oxygen.

heterocycle A ring-shaped compound made up of more than one kind of atom.

pyrimidine and pyrazine Organic heterocyclic compounds consisting of a six-membered ring with two nitrogen atoms separated by one carbon in pyrimidine and two carbons in pyrazine.

radical An atom or group of atoms possessing an odd (unpaired) electron.

Biography

Colette Daubner and Paul Fitzpatrick have been working on the structure and function of the aromatic amino acid hydroxylases in the Department of Biochemistry and Biophysics at Texas A&M University since 1986. Dr. Daubner is a Research Scientist.

Paul Fitzpatrick is a Professor with joint appointment in Departments of Biochemistry and Biophysics and Chemistry. They received their Ph.D. at the University of Michigan and did postdoctoral research at The Pennsylvania State University.

P-Type Pumps: Copper Pump

Ilia Voskoboinik and James Camakaris
The University of Melbourne, Melbourne, Victoria, Australia

Copper pumps are copper-translocating P-type adenosinetriphosphatases (ATPases). Copper P-type ATPases, alongside other heavy-metal pumps, including silver, cadmium, lead, and zinc transporters, constitute group IB of the P-type ATPase family. Copper pumps are indispensable for maintaining copper homeostasis, including the delivery of copper to essential cuproenzymes and efflux of excess copper from the cell. P-type ATPases are the family of enzymes, which translocate a substrate across the lipid bilayer using the energy of ATP hydrolysis and which involve formation of an acyl-phosphate intermediate. P-type ATPases are ubiquitous proteins identified in most organisms, from bacteria to humans. These enzymes have evolved substrate specificity and regulatory mechanisms, which are essential for homeostasis of respective physiological or toxic substrates, amongst which are calcium, magnesium, sodium, potassium, protons, copper, and toxic heavy metals.

P-Type ATPases

Molecular and crystal structures of P-type ATPases have been revealed only in the last few years, despite massive efforts beginning in the early 1970s, to characterize the mechanisms of these enzymes. The best-studied molecules, at this stage, are calcium P-type ATPases, particularly the sarcoplasmic reticulum calcium pump. The catalytic mechanism, based on site-directed mutagenesis studies and the elegant studies by Toyoshima, who recently identified the crystal structure of sarcoplasmic reticulum calcium ATPase, consists of several fundamental steps (Figure 1): (1) Cation binding to high-affinity binding sites in the cation channel, which is formed by several transmembrane domains, leads to (2) conformational changes in the cytosolic ATP-binding domain, which acquire a conformation with high affinity for ATP. Subsequently, the terminal γ-phosphate is transferred to the invariant aspartate residue within the -DKTG- motif and forms a transient acyl-phosphate (aspartyl-phosphate) bond. The residual adenosine diphosphate dissociates from the cytosolic domain. These changes cause such significant conformational alterations within the transmembrane cation channel that its affinity for the cation is reduced and (3) the cation translocates across the membrane in a vectorial fashion. Subsequently, (4) the acyl-phosphate bond is hydrolyzed and (5) the enzyme returns to its original high-affinity cation-binding state. This model is generally accepted as a paradigm for P-type ATPases, including the copper pumps.

Copper

Copper is an essential trace element, whose redox properties (Cu^{2+}/Cu^{+}) are utilized by a number of enzymes catalyzing redox reactions. Cuproenzymes are found in various intracellular compartments, in the cytosol (e.g., Cu,Zn-superoxide dismutase), in the mitochondria (e.g., cytochrome *c* oxidase) and in the Golgi membranes (e.g., lysyl amine oxidase). At the same time, when present in excess, copper may exert its toxicity through the same redox properties. Thus, in the reduced intracellular environment copper undergoes redox cycling, which results in the generation of reactive oxygen species leading to oxidative stress, which, if not counterbalanced by antioxidant systems, may lead to cellular toxicity. In addition, copper, particularly copper(I), binds nonspecifically with high affinity to cellular proteins and can affect their physiological function. Biological systems accommodated both, the beneficial and potentially toxic roles of copper, through the evolution of the finely tuned machinery of copper homeostasis.

General Structure of Group IB P-Type ATPases

The first heavy-metal P-type ATPase was identified in 1989 through studies on cadmium-resistant bacteria. The predicted amino acid sequence analysis revealed little general similarity with other P-type ATPases, apart from some essential catalytic motifs. Since then, dozens of heavy-metal pumps, including copper, zinc, and cadmium transporters, as well as putative heavy-metal ATPases of unknown cation specificity, have either been identified through the predicted open reading frame

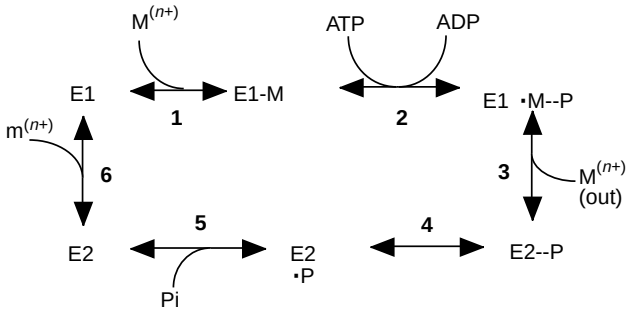

FIGURE 1 General concept of catalytic cycle of P-type ATPases, including copper transporters. $M^{(n+)}$ – cation to be translocated; $m^{(n+)}$ – counterion; P – terminal phosphate group of ATP forming an acyl-phosphate bond with invariant aspartate residue in the -DKTG- motif. (1) High-affinity cation binding; (2) high-affinity ATP binding and the transfer of the terminal γ-phosphate from ATP to the invariant aspartate residue, the formation of acyl-phosphate bond; (3) conformational change from the E1 to E2 state, translocation of the cation to the lumen; (4) transition to the low-energy acyl-phosphate bond; (5) dissociation of inorganic phosphate from the invariant aspartate residue; and (6) potential counterion translocation, transition from the E1 to E2 conformation. Reprinted from Voskoboinik, I., Camakaris, J., and Mercer, J. F. (2002). Understanding the mechanism and function of copper P-type ATPases. *Advances in Protein Chemistry* **60**, 123–150.

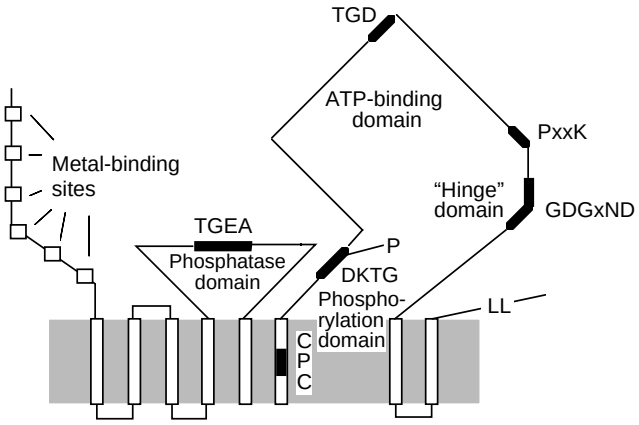

FIGURE 2 General structure of a heavy-metal P-type ATPase. "Metal-binding sites" are putative copper-binding motifs -GMxCxxC-; "phosphatase domain" – a cytosolic loop with conserved region(s), e.g., -TGEA-, essential for de-phosphorylation of the transient acyl-phosphate; P-DKTG is the phosphorylation domain, where P – indicates transient aspartyl-phosphate; "ATP-binding domain" and "hinge domain" – a large cytosolic loop with several conserved regions (e.g., -TGD-, -PxxK-, GDGxND) essential for ATP binding and the transfer of the terminal γ-phosphate of ATP to the invariant aspartate residue of the phosphorylation domain; the -CPC- motif is believed to constitute a part of the cation channel in heavy-metal P-type ATPases; -LL- motif is the internalization signal in ATP7A (position 1487/1488) and ATP7B (position 1454/1455). (ORF) analysis or characterized functionally in prokaryotes and eukaryotes. Heavy-metal transporters have eight predicted transmembrane domains (nonheavy-metal transporters contain ten) with an essentially invariant -CPC- motif in transmembrane domain 6 (Figure 2). The N terminus of these pumps generally contains up to six putative heavy-metal binding sites, with a common sequence GMxCxxC. Heavy metals have been shown to bind within this region with various affinities. The cytosolic ATP-binding loop contains the invariant acyl-phosphorylation motif -DKTG-, putative nucleotide and magnesium binding motifs -TGD- and -MVGDGIND-, yet lacks other conserved, among nonheavy-metal ATPases, regions. Furthermore, the phosphatase domain contains only one, TGE motif, out of three conserved regions (Figure 2). While additional functional motifs ought to be present in heavy-metal ATPases, they are yet to be identified and characterized.

Copper P-Type ATPases

Physiological Roles

Copper P-type ATPases have been identified in a variety of organisms, from bacteria to humans, which indicates their crucial importance for copper homeostasis. This has been proven experimentally in various experimental systems. Thus, the disruption of copper pumps in bacteria decreased their copper resistance, presumably through inability to efflux excess copper from the cell. In yeast, the plasma membrane copper pump, PcaI, also appears to be important for copper efflux. In contrast, the Golgi membrane copper P-type ATPase, Ccc2, has no direct role in copper resistance, but has been shown to be indispensable as a high-affinity copper transporter to the cuproenzyme, Fet3, which is required for high-affinity iron uptake. Similarly, in plants the Golgi membrane copper transporter, RAN1, has a crucial role in ethylene biosynthesis. Interestingly, plants appear to encode far more putative heavy-metal transporters than other organisms. However, their cation specificity and intracellular roles are yet to be identified. The analysis of the *Drosophila melanogaster* genome indicated the presence of a single copper P-type ATPase homologous to its human counterparts. However, the physiological role of this transporter has not been identified. In humans, two copper-translocating P-type ATPases have been identified and characterized: the ubiquitous (except the liver) Menkes protein (ATP7A), and the predominantly hepatic Wilson protein (ATP7B) which has ~65% homology with ATP7A. Unlike in unicellular organisms and in plants, these two transporters evolved a dual role in copper homeostasis, namely, the delivery of copper to cuproenzymes and the efflux of physiological or excess copper from the cell.

The latter function is essential for absorption of alimentary copper from the gastrointestinal tract and the reabsorption of copper in the kidney. The clinical symptoms of inherited genetic diseases, the X-linked recessive Menkes disease, and the autosomal-recessive Wilson disease, which are caused by detrimental mutations in the respective genes, demonstrate the essentiality of both proteins in copper homeostasis. Furthermore, the clinical features of Menkes and Wilson disease represent, respectively, the ultimate effects of systemic copper deficiency due to malabsorption, and toxicity due to copper hyperaccumulation.

Catalysis

Copper P-type ATPases vary in size from ~700 amino acids in bacteria to 1500 amino acids in humans. Nevertheless, they share significant structural similarity within regions, which have been postulated to be important for the catalysis of copper translocation. General elements of the catalytic cycle appear to be similar to those reported for calcium P-type ATPases (Figure 1). Thus, copper binding, presumably within the transmembrane cation channel, precedes the binding of ATP within the high-affinity cytosolic ATP-binding domain. This is followed by acyl-phosphorylation of the invariant, among all P-type ATPases, aspartate residue in the -DKTG- motif and subsequent copper translocation from the cytosolic to the lumenal side of the membrane. To complete the catalytic cycle the acyl-phosphate bond is hydrolyzed and the protein returns to its high-affinity copper-binding state. While copper pumps can be inhibited by orthovanadate, a classical inhibitor of P-type ATPases, the concentration required for such inhibition is considerably higher than the one observed for nonheavy-metal ATPases. Biochemical evidence suggests that copper ATPases can transport only reduced copper (Cu^+), which is the major form of copper in the reduced intracellular environment. The specificity of copper pumps for monovalent copper explains their silver (Ag^+) transporting activity and the lack of cross-specificity with divalent cations of heavy metals, e.g., cadmium, zinc, and lead. Copper ATPases investigated so far appear to be less catalytically active, with respect to cation translocation, than their non-heavy-metal transporting counterparts, as measured by the amount of ATPase-specific cation transported per minute. At the same time, the affinity of copper pumps for ATP is similar to the one determined for other P-type ATPases, consistent with conservation of essential ATP and magnesium-binding motifs in the ATP-binding cytosolic loop. The unique feature of copper P-type ATPases (as well as other heavy-metal pumps) is the presence of cytosolic N-terminal putative copper-binding sites with the sequence -GMxCxxC-. These conserved motifs bind copper(I) with higher affinity compared to copper(II) and other divalent heavy-metal cations. Furthermore, copper binding results in these motifs acquiring a conformation, which protects copper from being removed from these sites by nonspecific ligands, such as glutathione. The exact role of the N-terminal metal-binding sites is yet to be fully clarified, but they do not appear to play an essential role in cation translocation by copper ATPases. Yet these motifs have been shown to regulate the affinity of copper pumps for copper and may be particularly important in allowing its acquisition or delivery to a specific target under basal or copper-limited conditions. Similar findings were reported for the putative metal-binding sites of other heavy-metal P-type ATPases.

Regulation

The mechanisms of regulation of copper pumps vary considerably between prokaryotes and multicellular differentiated eukaryotic systems.

Prokaryotes

In prokaryotes, genes encoding copper ATPases are organized in an operon, which is regulated through a *trans*-acting repressor/activator system. Thus, in *Enterococcus hirae* under physiological or copper deficient conditions copper binds to a copper operon repressor, CopY, whose binding to the promoter region of the operon results in the suppression of copper ATPase synthesis. Conversely, in the presence of elevated copper concentrations, copper binding to a copper activator, CopZ, results in its overcompeting CopY–copper complex at the promoter region. This leads to overexpression of copper pumps, which, through efflux of excess copper, restores copper homeostasis. A member of the MerR family of DNA-binding metal-responsive transcriptional regulators, CueR, has been identified as a regulator of the copper export pump, CopA, in *Escherichia coli*. CueR binds in the promoter region of CopA and responds to elevated copper(I) or silver(I) concentrations by overexpression of CopA. The disruption of CueR causes the loss of CopA expression in bacteria.

Eukaryotes

Copper ATPases in yeast are represented by two pumps, which are localized at the cellular membrane, PcaI, and at the Golgi membrane, Ccc2. These transporters have defined functions: PcaI is presumed to function in copper efflux from the cell, while Ccc2 delivers copper to the multicopper ferroxidase, Fet3, and has no direct copper resistance function. Importantly, Ccc2 is a high-affinity transporter, which, under limited copper concentrations, receives copper from a low-molecular-weight copper chaperone, AtxI. This protein binds copper(I) within the high-affinity copper-binding site, GMxCxxC, and delivers it to the analogous site at the N terminus of Ccc2.

Copper does not appear to directly regulate the expression levels of PcaI or Ccc2. These protein–protein interactions between the copper chaperone Atx1 and the P-type ATPase permit copper transport under conditions where essentially no free ionic copper is available.

Mammals have evolved a novel system for regulating copper homeostasis via the Menkes (MNK; ATP7A) and Wilson (WND; ATP7B) P-type ATPases. These transporters exert a dual role in copper homeostasis by catalyzing efflux of copper from the cell at the plasma membrane and supplying copper to cuproenzymes of the secretory pathway in the Golgi compartment. These functions are achieved through copper-regulated vesicular trafficking of the transporters. Thus, under physiological copper concentrations both pumps are localized at the trans-Golgi network, where they supply copper to cuproenzymes. In the presence of elevated copper concentrations the proteins relocalize to the plasma membrane, they efflux excess copper from the cell. Once copper concentrations subside to physiological levels, the proteins relocate to the trans-Golgi network. Several signaling motifs have been shown to be responsible for regulation of the subcellular localization of ATP7A and ATP7B. These include the N-terminal putative copper-binding sites (important for exocytosis), and the C-terminal dileucine endocytic motifs (important for endocytosis). Importantly, under physiological concentrations copper is delivered to the copper-binding sites of ATP7A and ATP7B by a copper chaperone, ATOX1. The essentiality of such an interaction has been shown by using ATOX1 knock out mice. These transgenic animals have exhibited severe systemic copper deficiency, which has been associated with malabsorption of alimentary copper.

Two inherited diseases associated with mutations in copper P-type ATPases have been identified in humans and analogous disorders are found in other mammals. The systemic copper deficiency disorder, the X-linked Menkes disease, has been associated with detrimental mutations in the *ATP7A* gene, while the copper hepatotoxicity and neurotoxicity disorder, the autosomal-recessive Wilson disease, has been linked to mutations in the *ATP7B* gene. Importantly, the mutations which affect either the catalytic or the trafficking function of the pump can result in the disease phenotype. The nature and severity of the disease phenotype in Menkes and Wilson diseases can be explained for a number of mutations, based on predicted faulty localization/trafficking and magnitude of reduction in catalytic activity.

P-Type Pumps: H^+/K^+ Pump

Jai Moo Shin and George Sachs
University of California at Los Angeles and VA Greater Los Angeles Healthcare System, California, USA

The gastric H^+/K^+ pump is a member of the P_2-type ion-motive ATPase family and is responsible for the elaboration of HCl by the parietal cell of the gastric mucosa. The gastric H^+, K^+-ATPase catalyzes H^+ for K^+ exchange by an electroneutral exchange of cytoplasmic protons for extracytoplasmic potassium, while the protein undergoes phosphorylation and dephosphorylation related to ion binding and release. The gastric H^+, K^+-ATPase is composed of two subunits, the catalytic or α-subunit having ten transmembrane segments and the β-subunit having one transmembrane segment. The gastric H^+, K^+-ATPase α-subunit is a 100 kDa protein consisting of ~1034 amino acids and β-subunit is a glycoprotein with ~290 amino acids.

Structure of the Gastric H^+, K^+-ATPase

The α-Subunit of Gastric H^+, K^+-ATPase

The primary sequences of the α-subunits deduced from cDNA have been identified from pig, rat, and rabbit. The hog gastric H^+, K^+-ATPase α-subunit sequence deduced from its cDNA consists of 1034 amino acids with an M_r of 114 285 Da. The rat gastric H, K ATPase consists of 1033 amino acids with an M_r of 114 012 Da, and the rabbit gastric H, K ATPase consists of 1035 amino acids, showing an M_r of 114 201 Da. The degree of conservation among the α-subunits is extremely high (over 97% identity) among species. The gene sequence for human and the 5′ part of the rat H^+, K^+-ATPase α-subunits have been determined showing that the human gastric H^+, K^+-ATPase gene has 22 exons and encodes a protein of 1035 residues including the initiator methionine residue ($M_r = 114\,047$ Da). These H^+, K^+-ATPase α-subunits show high homology (~60% identity) with the Na^+, K^+-ATPase catalytic α-subunit. The putative distal colon H^+, K^+-ATPase α-subunit has also been sequenced and shares 75% homology with both the H^+, K^+- and Na^+, K^+-ATPases.

The gastric H^+, K^+-ATPase α-subunit has conserved consensus sequences along with the other P type ATPases, the sarcoplamic reticulum Ca^{2+}-ATPase and the Na^+, K^+-ATPase, for the ATP-binding site, the phosphorylation site, the pyridoxal 5′-phosphate-binding site and the fluorescein isothiocyanate-binding site. These sites are thought to be within the ATP-binding domain in the large cytoplasmic loop between transmembrane segments 4 and 5. Structurally, this enzyme can be divided into three domains, viz., cytoplasmic, membrane, and extracytoplasmic domains. The cytoplasmic domain contains four sub-domains, a stalk domain, N-domain, P-domain, and A-domain. The N-domain or nucleotide-binding domain is a large cytoplasmic domain between M4 and M5 where ATP binds. The P-domain or phosphorylation domain is a cytoplasmic domain near M4 where there is phosphorylation and dephosphorylation. The A-domain or activation domain is a cytoplasmic domain between M2 and M3, which moves depending on conformational changes. The stalk domain contains the extension of the transmembrane segments into the cytoplasmic region and forms a link for the passage of ions into the membranes and for transmission of conformational changes from the cytoplasm. The gastric α-subunit structure that is based on the 3D crystal of the SR Ca-ATPase structure is shown in Figure 1. Although this model is probably true in general, it is almost certainly incorrect in its detail.

There is much biochemical evidence showing the applicability of the ten transmembrane segment model to this ATPase. The C terminal amino acids of the α-subunit, tyr–tyr, are present in the cytoplasmic region, which was shown by a method of iodination with peroxidase-H_2O_2–^{125}I followed digestion with carboxypeptidase Y. Four transmembrane pairs connected by their luminal loop were detected in a tryptic digest of the hog gastric H^+, K^+-ATPase. A peptide fragment beginning at gln^{104} represents the H1/loop/H2 sector. The H3/loop/H4 sector was found at a single peptide peak beginning at thr^{291}, and the H5/loop/H6 sector at a peptide beginning at leu^{776}. The H7/loop/H8 region was found in a single peptide fragment of 11 kDa, beginning at leu^{853}. Surprisingly no peptide representing H9 and H10 was found in any enzyme digest procedure.

Antibody 95 inhibits ATP hydrolysis in the intact vesicles, and appears to be K^+ competitive. The sequence

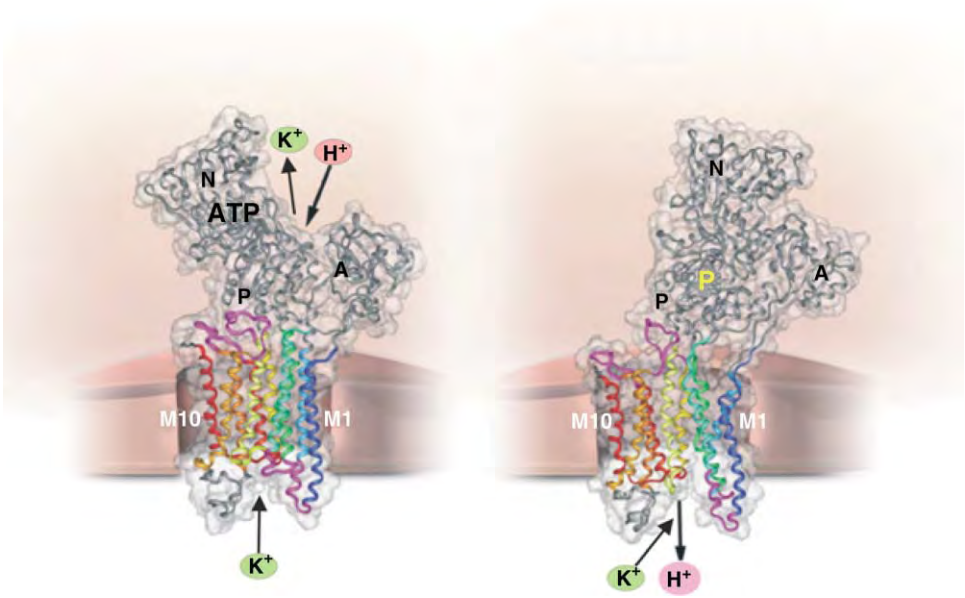

FIGURE 1 Proposed structure of the gastric H^+,K^+-ATPase α-subunit in E_1 (left) and E_2 (right) conformations. There are three lobes in the cytoplasmic domain: N (ATP binding), P (phosphorylation), and A (activation) regions. With binding of H^+ and MgATP to the E_1 form there is transient association of the N and P lobes with phosphorylation of asp386 and a conformational change to E_2P so that the A domain associates with the P domain. This change is transmitted to the membrane domain in the region of TM6 (dark yellow) and H^+ binding to the cation binding domain in the middle of the membrane domain is followed by release of H^+ and binding of K^+ from the luminal surface. There is then dephosphorylation and reformation of the E_1 conformation with release of K^+ to the cytoplasm.

recognized by this antibody was between amino acid positions 529 and 561. Since it inhibits the enzyme in intact cytoplasmic side out vesicles this epitope must be cytoplasmic and it is close to the region known to bind the cytoplasmic reagent, fluorescein isothiocyantate, FITC, a lysine reagent, namely in the loop between H4 and H5. Antibody 1218 was shown to have its major epitope between amino acid positions 665 and 689 in the same N domain. A second epitope for mAb 1218 was also identified to be between amino acid positions 853 and 907. Monoclonal antibody 146 epitope was defined to be between positions 873 and 877 of the hog α-subunit. This is on or close to the extra-cytoplasmic face of H7. The presence of H9 and H10 was shown by *in vitro* transcription/translation of cDNAs encoding these sequences. This technique also showed the presence of H1 through H4 but was unable to detect H5 or H6.

The β-Subunit of Gastric H^+, K^+-ATPase

The primary sequences of the β-subunits have been reported for rabbit, hog, rat, mouse, and human. The β-subunit with ~290 amino acids is a glycoprotein having one transmembrane segment located at the region between amino acid sequence positions 38 and 63 near the N terminus and six or seven N-linked glycosylation sites in the extracytoplasmic region. Using lectin affinity chromatography, the H^+, K^+-ATPase α-subunit was co-purified with the β-subunit, showing that the α-subunit interacts with the β-subunit. By cross-linking with low concentrations of glutaraldehyde, the β-subunit was shown to be closely associated with the α-subunit. In the extracytoplasmic domain, there are six cysteines which are linked through disulfide bonds. Reduction of the disulfides of the β-subunit inhibits the activity of the H^+, K^+-ATPase. In the case of the Na^+, K^+-ATPase, the effect of reducing agents on the ability of the enzyme to hydrolyze ATP and bind ouabain was quantitatively correlated with the reduction of disulfide bonds in the β-subunit. Seven putative N-glycosylated sites (AsnXaaSer and AsnXaaThr) are shown in rabbit H^+, K^+-ATPase β-subunit, which are conserved in rats and humans. Six putative N-glycosylation sites are found in the hog gastric β-subunit. The N-linked oligosaccharides of the β-subunit of rabbit gastric H^+, K^+-ATPase was identified. All N-linked AsnX(Ser/Thr) sequences at positions 99, 103, 130, 146, 193, and 222 were fully glycosylated. Asn 99 was modified exclusively with oligomannosidic-type structures, $Man_6GlcNAc_2$–$Man_8GlcNAc_2$, and Asn193 has $Man_5GlcNAc_2$–$Man_8GlcNAc_2$ and lactosamine-type structures. Asn 103, 146, 161, and 222 contain lactosamine-type structures. All the branches of the lactosamine-type structure

were terminated with Galα-Galβ-GlcNAc extensions. The role of the carbohydrate chains was studied using HEK-293 cells. The enzyme activity was not affected by removal of any one of seven carbohydrates of the β-subunit; however, removal of all carbohydrate chains resulted in the complete loss of activity. Except for the second glycosylation site, each site was essential for trafficking from Golgi to plasma membrane, but not for ER to Golgi movement.

The function of the β-subunit is not clearly known, but this subunit appears to be required for proper assembly and targeting of the catalytic subunit. Perhaps the β-subunit has a function in maintaining the structure of the α-subunit to enable effective binding of K^+ ion to the outside face of the α-subunit. The H^+, K^+-ATPase β-subunit has the sequence Phe-Arg-His-Tyr in its cytoplasmic domain. This tyrosine has been shown to be important for the retrieval of the H^+, K^+-ATPase from the apical membrane of the parietal cells and to ensure its return to the tubulo-vesicular compartment in order to terminate the process of acid secretion. The participation of a tyrosine-based signal in the retrieval of the H^+, K^+-ATPase suggests that this process involves interactions with adaptins and is mediated by clathrin-coated pit formation. In knockout mice deficient in the H^+, K^+-ATPase β-subunit, cells that express the H^+, K^+-ATPase α-subunit had abnormal canaliculi and were devoid of typical tubulo-vesicular membranes.

Regions of Association in the Oligomeric Structure

There has been much suggestive evidence that the $\alpha-\beta$ heterodimeric H^+, K^+-ATPase exists as an oligomer. Such evidence includes target size by irradiation and unit cell size of the enzyme in two-dimensional crystals. Using Blue native gel separation and cross-linking with Cu^{2+}-phenanthroline, it was shown that the enzyme did indeed exist as an $(\alpha\beta)_2$ heterodimeric dimer. Membrane-bound H^+, K^+-ATPase reacted with Cu-phenanthroline to provide an $\alpha-\alpha$ dimer. The site of Cu^{2+}-oxidative cross-linking was either at cys^{565} or cys^{616}. Hence, this region of the α-subunit is in close contact with its neighboring α-subunit. No evidence was obtained for $\beta-\beta$ dimerization. ATP prevents this Cu-phenanthroline-induced $\alpha-\alpha$ dimerization. The M7/loop/M8 sector of the α-subunit is tightly associated with the β-subunit. An antibody mAb 146-14 recognizes the region of the α-subunit at the extra-cytoplasmic face of the M7 segment as well as the β-subunit, a finding consistent with the association found by column chromatography. Using a yeast two-hybrid analysis, a fragment Leu855 to Arg922 of the α-subunit was identified to bind the β-subunit. This is at the entrance of the TM8 into the membrane domain.

Kinetics and Conformational Changes of the Gastric H^+, K^+-ATPase

The gastric H^+, K^+-ATPase exchanges intracellular hydrogen ions for extracellular potassium ions by consuming ATP. The H^+ for K^+ stoichiometry of the H^+, K^+-ATPase is not clear. There are reports of two different stoichiometries, one or two H^+ per ATP hydrolyzed. In ion-tight vesicles studied at pH 6.1, the stoichiometry is $2H^+$:1ATP but at full pH gradient where the pH reaches 1.0, this has to fall to 1:1. Probably protonation of a carboxylic acid at the lower luminal pH is then maintained.

There are several steps in the reaction scheme of the H^+, K^+-ATPase. The enzyme is phosphorylated by ATP at asp^{386}. The rate of formation of the phosphoenzyme (EP) and the K^+-dependent rate of phosphoenzyme breakdown are sufficiently fast to allow the phosphoenzyme to be an intermediate in the overall ATPase reaction. The initial step is the reversible binding of ATP to the enzyme in the absence of added K^+ ion, followed by an Mg^{2+} (and proton) dependent transfer of the terminal (gamma) phosphate of ATP to asp^{386} of the catalytic subunit (E_1-P·H^+). The Mg^{2+} remains occluded until dephosphorylation. The addition of K^+ to the enzyme-bound acyl phosphate results in a two-step dephosphorylation. The faster initial step is dependent on the concentration of K^+, whereas the slower step is not affected by K^+ concentration. The second phase of EP breakdown is accelerated in the presence of K^+ but, at K^+ concentration exceeding 500 μM, the ratio becomes independent of K^+ concentration. This shows that two forms of EP exist. The first form E_2P is K^+ sensitive and converts spontaneously in the rate-limiting step to E_1P, the K^+ insensitive form. ATP binding to the H^+, K^+-ATPase occurs in both the E_1 and the E_2 state, but with a lower affinity in E_2 state (2 000 times lower compared to E_1). The effects of H^+ and K^+ on formation and breakdown of phosphoenzyme were determined using transient kinetics. Increasing hydrogen ion concentrations on the ATP-binding face of the vesicles accelerate phosphorylation, whereas increasing potassium ion concentrations inhibit phosphorylation. Increasing hydrogen ion concentration reduces this K^+ inhibition of the phosphorylation rate. Decreasing hydrogen ion concentration accelerates dephosphorylation in the absence of K^+, and K^+ on the luminal surface accelerates dephosphorylation. Increasing K^+ concentrations at constant ATP decreases the rate of phosphorylation and increasing ATP concentrations at

constant K^+ concentration accelerates ATPase activity and increases the steady state phosphoenzyme level. Therefore, inhibition by cations is due to cation stabilization of a dephospho form at a cytosolically accessible cation-binding site. The reaction mechanism is similar to that of the Na^+, K^+-ATPase.

The ions transported from the cytoplasmic side are H^+ at high pH. Since Na^+ is transported as a surrogate for H^+, it is likely that the hydronium ion, rather than the proton per se is the species transported. The ions transported inwards from the outside face of the pump are Tl^+, K^+, Rb^+, or NH_4^+. Presumably the change in conformation changes a relatively small ion-binding domain in the outward direction into a larger ion-binding domain in the inward direction.

The E_1 conformation of the H^+, K^+-ATPase binds the hydronium ion from the cytoplasmic side at high affinity. With phosphorylation, the conformation changes from $E_1P{\cdot}H_3O^+$ to $E_2P{\cdot}H_30^+$ form, which has high affinity for K^+ and low affinity for H_3O^+ allowing release of H_3O^+ and binding of K^+ on the extra-cytoplasmic surface of the enzyme. The rapid breakdown of the E_2P form requires K^+ or its congeners on the outside face of the enzyme. With dephosphorylation, the E_1K^+ conformation is produced with a low affinity for K^+, releasing K^+ to the cytoplasmic side, allowing rebinding of H_3O^+.

Fluorescein isothiocyanate (FITC) binds to the H^+, K^+-ATPase, inhibiting ATPase activity but not pNPPase activity. Fluorescence of the FITC-labeled enzyme, representing the E_1 conformation, was quenched by K^+, Rb^+, and Tl^+. The quenching of the fluorescence by KCl reflects the formation of E_2K^+. FITC binds at lys^{516} in the hog enzyme sequence. This FITC-binding site apparently becomes less hydrophobic when KCl binds to form the $E_2{\cdot}K$ conformation. In the E_1 form, the FITC region is relatively closer to the membrane and the extra-cytoplasmic loop relatively hydrophilic. With the formation of the $E_2{\cdot}K^+$ form, the FITC region is more distant from the membrane. These postulated conformational changes are therefore reciprocal in the two major conformers of the enzyme. When the gastric H^+, K^+-ATPase was cleaved by Fe^{2+}-catalyzed oxidation under various ligand, cleavage patterns were different between the different conformations. There are two Fe^{2+} cleavage sites. In Fe^{2+} site1, the parallel appearance of the fragments at ^{230}ESE, near ^{624}MVTGD, and at ^{728} VNDS upon transition from E_1 to E_2(Rb) conformations were observed. Meanwhile, in Fe^{2+} site2, the fragment near ^{299} HFIH was cleaved independent of conformational changes. These cleavage patterns were the same as those of the Na^+, K^+-ATPase. The cleavage data showed that the structural organization and changes in the cytoplasmic domains, association with E_1/E_2 transitions, are essentially the same for the H^+, K^+-ATPase, the Na^+, K^+-ATPase, and sr Ca-ATPase. N-domain where ATP binds inclines nearly 90° with respect to the membrane and the A-domain rotates by about 110° horizontally during the E1 to E2 conformation.

Functional Residues of the H^+, K^+-ATPase

When the gastric H^+, K^+-ATPase was digested by trypsin in the presence of high concentration of KCl, the tryptic membrane digest showed the presence of Rb^+ occlusion, i.e., stable binding of Rb^+ in the membrane domain of the catalytic subunit as does the Na^+, K^+-ATPase. Some regions near the membrane such as the region between gly^{93} and glu^{104} near the M1 segment, the region between asn^{753} and leu^{776} near the cytoplasmic side of the M5 segment, and the region after the M8 segment, especially the region between ile^{945} and ile^{963} containing five arginines and one lysine, were K^+ protected against digestion. Furthermore, when K^+ was removed from this membrane digest, the M5/M6 hairpin was released from the membrane, showing that M5M6 membrane hairpin is stabilized by K^+ ions. Proton pump inhibitors such as omeprazole, pantoprazole, lansoprazole, and rabeprazole all bind to Cys813 of M5M6, giving inhibition of activity.

Using site-directed mutagenesis of the gastric H^+, K^+-ATPase transfected in HEK293 cells, M5M6 luminal loop was studied in terms of K^+ access to the ion-binding domain. Mutations of M5, M5–M6, and M6 regions such as P798C, Y802L, P810A, C813A or S, F818C, T823V, and mutations of M7–M8 and M8 such as E914Q, F917Y, G918E, T929L, F932L, reduced the affinity for SCH28080, a reversible proton pump inhibitor, up to tenfold without affecting the nature of the kinetics. The L809F substitution in the loop between M5 and M6 resulted in about 100-fold decrease in inhibitor affinity. C813T mutant showed ninefold loss of SCH28080 affinity. All these data suggest that the binding domain for SCH28080 contains the surface between L809 and C813, where M5–M6 loop and the luminal end of M6 locate. Mutations of C813 and I816 in M6 and M334 in M4 also showed that the inhibitor binds close to the luminal surface of the enzyme. Mutations of the negatively charged amino acid residue in the α-subunit showed that the carboxyl group of the membrane-spanning domain is important for cation binding. Mutation of E820Q showed decreased K^+ sensitivity and the dephosphorylation was not stimulated by either K^+ or ADP, indicating that E820 might be involved in K^+ binding and transition to the E_2 form of the H^+, K^+-ATPase. Mutation of E795 showed a decrease of the phosphorylation rate and the apparent ATP affinity, indicating that E795 is involved in both K^+ and H^+

binding. Mutation of E795 and E820 in M5 and M6 resulted in a K^+-independent, SCH28080-sensitive ATPase activity, caused by a high spontaneous dephosphorylation rate. Thus the sixth transmembrane (M6) segment of the catalytic subunit plays an important role in the ion recognition and transport in the type II P-type ATPase families. When all amino acid residues in the M6 segment of gastric H^+, K^+-ATPase α-subunit were singly mutated with alanine, four mutants, L819A, D826A, I827A, and L833A, completely lost K^+-ATPase activity. Mutant L819A was phosphorylated but barely dephosphorylated in the presence of K^+, whereas mutants D826A, I827A, and L833A were not phosphorylated from ATP. Amino acids involved in the phosphorylation are located exclusively in the cytoplasmic half of the M6 segment and those involved in the K^+-dependent dephosphorylation are in the luminal half. Several mutants such as I821A, L823A, T825A, and P829A partly retained the K^+-ATPase activity accompanying the decrease in the rate of phosphorylation. Substituting three residues in the Na^+, K^+-ATPase sequence with their H^+, K^+-ATPase counterparts (L319F, N326Y, T340S) and replacing the TM3–TM4 ectodomain sequence with that of the H^+, K^+-ATPase result in a pump that gives 50% of ATPase activity in the absence of Na^+ at pH 6. The cation selectivity of the Na^+, K^+- and H^+, K^+-ATPase would be generated through a cooperative effort between residues of the transmembrane segments and the flanking loops that connect these transmembrane domains. A model that results from these studies and the 3D structure of the SR Ca-ATPase suggests that ion transport occurs between TM4, 5, 6 and perhaps TM8 and that the vestibule around cys813 is the binding domain of both compounds such as omeprazole and SCH28080.

Acid Secretion and the Gastric H^+, K^+-ATPase

The H^+, K^+-ATPase is present only in the gastric parietal cell and the intercalated cell of the distal renal tubule. In the resting parietal cell, it is present in smooth surfaced cytoplasmic membrane tubules. Upon stimulation of acid secretion, the pump is translocated to the microvilli of the secretory canaliculus of the parietal cell. This morphological change results in a several fold expansion of the canaliculus. There are actin filaments within the microvilli and the subapical cytoplasm. In the cytoskeleton system, there is abundance of microtubules among the tubulovesicles. Some microtubules appeared to be associating with tubulovesicles. A large number of electron-dense coated pits and vesicles were observed around the apical membrane vacuoles in cimetidine-treated resting parietal cells, consistent with an active membrane uptake in the resting state. Cultured parietal cells also undergo morphological transformation under histamine stimulation, resulting in great expansion of apical membrane vacuoles. Immunogold labeling of H^+, K^+-ATPase was present not only on the microvilli of expanded apical plasma membrane vacuoles but also in the electron-dense coated pits.

There is activation of a K^+ and Cl^- conductance in the pump membrane which allows K^+ to access the extra-cytoplasmic face of the pump. This allows H^+ for K^+ exchange to be catalyzed by the ATPase.

The covalent inhibitors of the H^+, K^+-ATPase that have been developed for the treatment of ulcer disease and esophagitis depend on the presence of acid secreted by the pump. They are also acid activated prodrugs that accumulate in the acid space of the parietal cell. Hence their initial site of binding is only in the secretory canaliculus of the functioning parietal cell. These data show also that the pump present in the cytoplasmic tubules does not generate HCl.

The upstream DNA sequence of the α-subunit contains both Ca and cAMP responsive elements in the case of the rat H^+, K^+-ATPase. There are gastric nuclear proteins present that bind selectively to a nucleotide sequence, GATACC, in this region of the gene. These proteins have not been detected in other tissues. Stimulation of acid secretion by histamine increases the level of mRNA for the α-subunit of the pump. Elevation of serum gastrin, which secondarily stimulates histamine release from the enterochromaffin-like cell in the vicinity of the parietal cell, also stimulates the mRNA levels in the parietal cell. H_2 receptor antagonists block the effect of serum gastrin elevation on mRNA levels. It seems therefore that activity of the H_2 receptor on the parietal cell determines in part the gene expression of the ATPase. It might be expected therefore that chronic stimulation of this receptor would up-regulate pump levels whereas inhibition of the receptor would down-regulate levels of the ATPase.

However, chronic administration of these H2 receptor antagonists, such as famotidine, results in an increase in pump protein, whereas chronic administration of omeprazole (which must stimulate histamine release) reduces the level of pump protein in the rabbit. Regulation of pump protein turnover downstream of gene expression must account for these observations.

P-Type Pumps: Na^+/K^+ Pump

Peter L. Jorgensen
University of Copenhagen, Copenhagen, Denmark

The Na^+/K^+ pump transforms the chemical energy in ATP to electric or osmotic work and maintains electrochemical Na^+ and K^+ gradients across cell membranes. At rest, the pump converts 20–30% of the current ATP production in mammals to active Na^+/K^+-transport in kidney, intestine, muscle, heart, central nervous system, and other cells of the body where Na^+/K^+ gradients are required for maintaining membrane potential and cell volume. The Na^+/K^+ pump is the largest protein complex in the family of P-type cation pumps. The minimum functional unit is an $\alpha\beta$-heterodimer of the calytic α-subunit containing the Na^+/K^+, ATP, and phosphate binding sites, and the glycosylated β-subunit required for the correct folding of the complex in the endoplasmic reticulum. The $\alpha\beta$-unit can also be coexpressed with small ion transport regulators of the FXYD family. Individual genes of four α-isoforms and at least three β-isoforms of the Na^+/K^+ pump are expressed in a tissue- and cell-specific manner to cover the demands for the specific physiological functions in epithelia, skeletal and heart muscles, nerves, and the reproductive system.

The Na^+/K^+ Pump Reaction Cycle

The Na^+/K^+ pump is a molecular machine which binds ATP in the cytoplasmic protrusion and couples the scalar processes of phosphorylation and dephosphorylation to the vectorial extrusion of $3Na^+$ ions and uptake of $2K^+$ ions. The reaction is specifically inhibited by high-affinity binding of cardiac glycosides like digoxin or ouabain. The driving force of the reaction is the free energy of ATP hydrolysis, which depends on the cytoplasmic concentrations of ATP, ADP, and Pi. In normal cells containing mitochondria, the free energy of ATP hydrolysis is close to $-60\,kJ\,mol^{-1}$ and the electrical driving force of the Na^+/K^+ pump is close to -600 mV ($-\Delta G/F$; where F is Faradays constant ($96\,485\,C\,mol^{-1}$)). Most of the electrochemical work (~ 390 mV) is used for the outward translocation of three Na^+ ions per cycle against the inside negative membrane potential and the tenfold-steep chemical gradient for Na^+ ions. Less energy (~ 40 mV) is used for the inward transport of two K^+ ions per cycle since potassium in most cells is close to electrochemical equilibrium.

In the first step of the reaction cycle of the Na^+/K^+ pump in Figure 1, ATP acting with low affinity accelerates inward transport of $2K^+$ ions coupled to the E_2 [2K] $\leftrightarrow$ E_1ATP transition. After dissociation of $2K^+$ ions, binding of $3Na^+$ ions at sites oriented towards the cytoplasm promotes phosphorylation of Asp-369 from ATP and occlusion of $3Na^+$ ions in the E_1-P[3Na] form. Outward transport of $3Na^+$ ions is coupled to the E_1-P $\leftrightarrow$ E_2-P conformational transition. Binding of $2K^+$ ions at extracellularly oriented sites of the E_2P form activates dephosphorylation and $2K^+$ ions are stably occluded in the E_2 [2K] form.

In normal cells, the extracellular $[K^+]_e$ activities (4–5 mM) exceed those required for full activation, since the $K_{1/2}$ value is 1 mM. At cytoplasmic ATP concentrations of 2–3 mM, the rate of turnover depends on the $[Na^+]/[K^+]$ activity ratios. In most cells the $[Na^+]/[K^+]$ activity ratios in the cytoplasm are in the range of 10/140–30/120 mM and below the $K_{1/2}$ value for activation of the pump at 37/113 mM. For the renal $\alpha 1\beta 1\gamma$-Na^+/K^+ pump, the rate at 10 mM $[Na^+]_i$ and 140 mM $[K^+]_i$ in the cytoplasm is less than 5% of the maximum velocity ($V_{max} = 7500\,ATP\,min^{-1}$). Due to the cooperativity of Na^+ activation, the rate raises steeply with the $[Na^+]_i$ activity in the cytoplasm to 10% at 16 mM $[Na^+]_i$ and 134 mM $[K^+]_i$ or 20% of V_{max} at 22 mM $[Na^+]_i$ and 128 mM $[K^+]_i$ in the cytoplasm. This autoregulatory mechanism is very important since regulatory processes, in particular coexpression with FXYD proteins, can alter the affinity for Na^+ ions and thus become very efficient regulators of Na^+/K pump rate.

E_1- and E_2-Conformations of the Na^+/K^+ Pump

The E_1- and E_2-conformations differ with respect to orientation and specificity of intramembrane cation sites for Na^+ and K^+. In the E_2 [2K] form there is a 3000-fold preference for binding of K^+ over Na^+ at the extracellular surface and this requires that K^+ binding

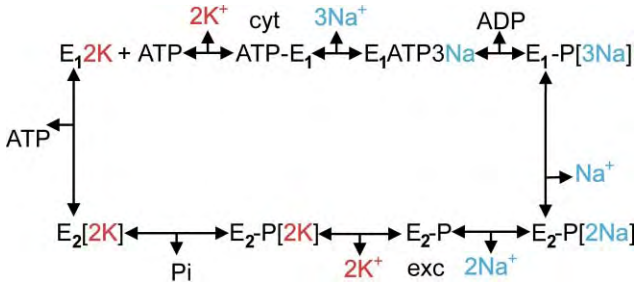

FIGURE 1 E_1–E_2 reaction cycle of the Na^+/K^+ pump with ping-pong sequential cation translocation. $[Na^+]$ or $[K^+]$ ions within brackets are occluded or tightly bound and prevented from exchanging with medium cations.

is 18 kJ mol^{-1} more stable than binding of Na^+. In the E_1ATP form, the affinity for Na^+ ions at the cytoplasmic surface is 16-fold higher than that for K^+ ions and this requires that binding of Na^+ is 6 kJ mol^{-1} more stable than binding of K^+. These adjustments of the cation sites are accompanied by changes of both the number of coordinating groups and their distances from the bound cations. The protein structure of the intramembrane domain of the Na^+/K^+ pump has not yet been solved at atomic resolution, but homology models based on the high-resolution structure of the Ca^{2+} pump of sarcoplasmic reticulum are efficient tools in interpretation of structure–function relationships of both the E_1- and E_2-conformations of the Na^+/K^+ pump, Figure 2. Modeling of the intramembrane domain shows that the structural changes accompanying the adjustments from an E_2-form with specificity for K^+ to an E_1-form with specificity for Na^+ can be achieved by twisting or tilting of the intramembrane helices to adapt the distances between the oxygen atoms of the coordinating groups of cation sites I and II in the intramembrane domain, Figure 2.

The overall structure of the α-subunit of the Na^+/K^+ pump is that the cation sites and transport path is made up of a bundle of transmembrane helices connected to a cytoplasmic protrusion consisting of three domains: the actuator or anchor (A), the phosphorylation (P) and the nucleotide-binding (N) domains. The N-domain is inserted between two Rossmann folds ($\alpha\beta\alpha\beta\alpha$) of the P-domain, which is directly connected to the extensions of the M4 and M5 transmembrane domains. The A-domain consists of the N-terminal portion of the α-subunit peptide chain and an insertion between M2 and M3. As seen from Figure 2, the $E_1P \rightarrow E_2P$ transitions are accompanied by large movements of the cytoplasmic A-, N-, and P-domains. The P-domain is rotated with reorientation of the catalytic site, including the important phosphorylated residue, Asp369, and the Mg^{2+} coordinating residue, Asp710. Movement of the N-domain is due mainly to the rotation of the P-domain. To stabilize the E_2P form, the A-domain rotates ~90°

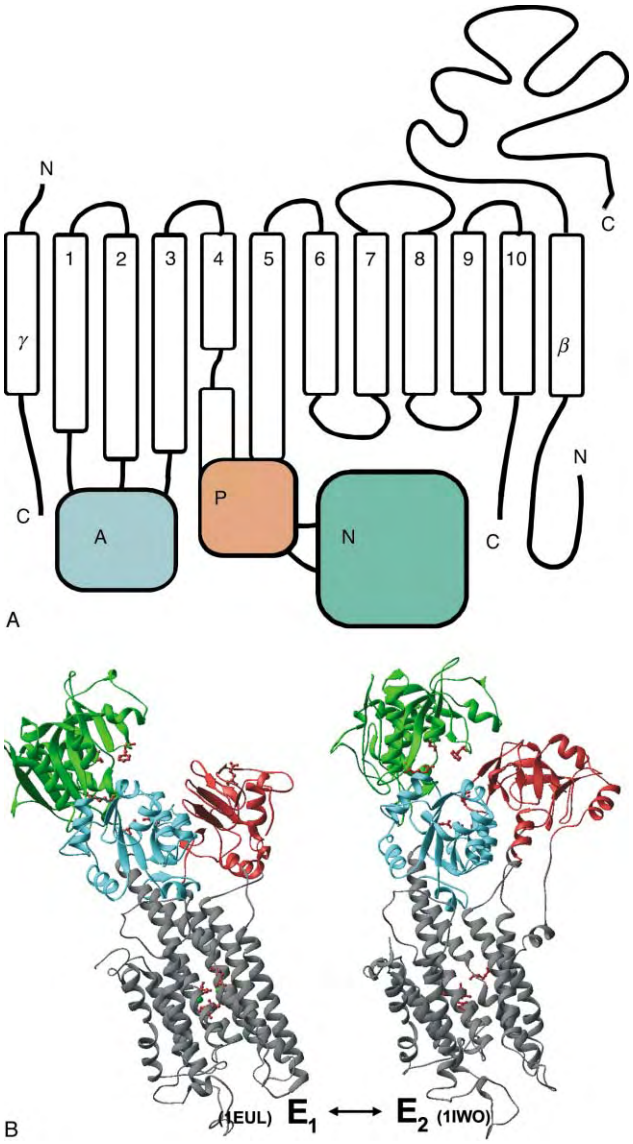

FIGURE 2 (A) Topology of the $\alpha\beta\gamma$-Na^+/K^+ pump. The β- and γ-subunits are single-pass membrane proteins. The α-subunit has ten transmembrane segments and the cytoplasmic protrusion is split in three domains: A, the anchor or attenuator domain; P, the phosphorylation domain, and N, the nucleotide binding site domain. (B) Models of E_1- and E_2-forms of the α-subunit of the Na^+/K^+ pump based on the high-resolution structure of Ca-ATPase in the E_1[2Ca] form (1EUL) and in the E_2-form (1IWO) stabilized by thapsigargin and Mg^{2+}. Side chains in ball and stick are shown for Phe475, Lys501, and Arg544 in the N-domain, for D369 and D710 in the P-domain, and for Glu327, Glu770, Asp804, and Asp808 in the cation binding domain. The position of the N-domain has been adjusted to allow spanning of an ATP molecule over the N- and P-domains.

about a vertical axis, thus docking the segment around Glu183 onto the P domain. These movements of the cytoplasmic domains are transmitted to tilting and twisting of the intramembrane helices and adjustment of the cation sites from a specificity for Na^+ in the E_1-form to a specificity for K^+ in the E_2-form.

Regulation of the E_1-E_2 Conformational Equilibrium

Physiological short-term regulation of the complex reaction cycle of the Na^+/K^+ pump is often directed towards rate limiting steps of the catalytic reaction, the long-range E_1-E_2 conformational changes which are linking the catalytic reactions to cation movements.

In the Na^+/K^+ pump, the conformational equilibria of both the phosphoforms (E_1P-E_2P) and dephosphoforms are poised heavily in direction of the E_2-forms. Thus in presence of K^+, the equilibrium constant (K_c) for the ratio E_2K/E_1K approaches a value of 1000. Changes of the conformational equilibrium may therefore have a strong influence on the turnover rate of the enzyme. Deletion of the N-terminal 30 residues by tryptic cleavage at 30Leu-Lys (T2) causes a 3–4-fold shift of the conformational equilibrium towards the E_1-form with reduction of Na^+/K^+ pump turnover to 45–50% of V_{max} values and the affinities for Na^+ or ATP are increased, while the apparent affinity for extracellular K^+ is reduced without interference with the capacity of the binding sites. Similar changes are seen after PKC mediated phosphorylation in the positively charged segment of the N terminus of the α1-subunit. The most pronounced structural variability between α-subunit isoforms occur at the N terminus. Comparison of the properties of α-isoforms shows that the maximum turnover rate is lower for the $\alpha2\beta1$-Na^+/K^+ pump ($4600\ min^{-1}$) than for the $\alpha1\beta1$-Na^+/K^+ pump ($7600\ min^{-1}$). The apparent affinities for Na^+ and ATP are two- and fourfold higher for α2- than for α1-isoforms, whereas the apparent affinity for K^+ is twofold lower for α2- than for α1-isoforms. These data are consistent with a shift of the E_1-E_2 conformational equilibrium toward E_1 in the α2-isoform. The properties of the α2-isoform are similar to those seen for the α1-isoform after deletion of 30 amino acid residues from the N terminus and they can be regarded as E_1-E_2 conformational isoforms. The rate of $\alpha3$-Na^+/K^+ pumps is about twofold lower than that of isoforms containing the α2-subunit.

Na^+/K^+ Pumps in Epithelial Cells of Kidney, Intestine, Lung, and Glands

The $\alpha1\beta1$-Na^+/K^+ pump is constitutively expressed in most cells and it maintains the Na^+ gradients driving the active transcellular transport in kidney, intestine, lung, and various glands. There is a close relationship between the capacity for reabsorption of Na^+ in these tissues and the abundance of $\alpha1\beta1$-Na^+/K^+ pumps in the basolateral membranes of the epithelial cells. The Na^+/K^+ pumps in human kidneys hydrolyze over 2 kg of ATP per day and over 600 g sodium is reabsorbed per day. Accordingly, ouabain binding data reveal 40–50 million Na^+/K^+ pumps per cell in thick ascending limbs of Henle (TALH) or distal convoluted tubules (DCT) as compared to a few hundred in red cells or a few thousand pumps in other nonpolarized cells. In all tubular cells the Na^+/K^+ pump maintains electrochemical gradients for sodium ($\Delta\mu Na^+$), the driving force for secondary active transport of other solutes and ions, such as H^+, Ca^{2+}, and Cl^-. In the TALH, the Na^+/K^+ pump functions in concert with the Na, K, $2Cl^-$ cotransporter and channels for K^+ or Cl^- to bring about transcellular NaCl transport, Figure 3. NaCl is reabsorbed at very high rates, while lumenal and cytoplasmic [Na^+] activities remain relatively high, 20–40 mM in the lumen of TALH.

The γ-subunit belongs to the FXYD family of small ion transport regulators. They are small single pass membrane proteins which share a 35 amino acid

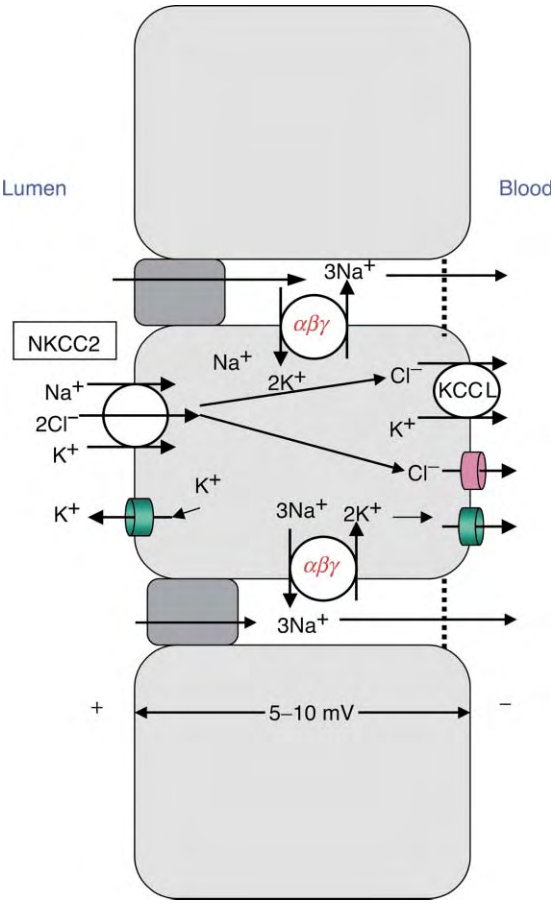

FIGURE 3 Mechanism of transcellular NaCl transport in thick ascending limb of Henle (TALH). The functions of the $\alpha1\beta1\gamma$-Na^+/K^+ pump are integrated with those of NKKCC2, the Na,K,Cl-cotransporter, KCCL, the K,Cl-cotransporter, and channels for K^+ and Cl^-.

TABLE I

Human Genes of Na^+/K^+ Pump Proteins: Isoforms of α and β Subunits are Expressed from Individual Genes[a]

Isoform	Gene	Human chromosome	Amino acid residues	Cell or tissue specific expression
$\alpha 1$	ATP1A1	1p13.1	1023	Constitutive, ubiquitous, dominant in epithelia of kidney, glands, and intestine
$\alpha 2$	ATP1A2	1q23.2	1020	Brain, muscle, heart
$\alpha 3$	ATP1A3	19q13.2	1013	CNS, brain
$\alpha 4$	ATP1A4	1q21–q23	1029	Testis, spermatozoa
$\beta 1$	ATP1B1	1q24.2	303	Ubiquitous, like the $\alpha 1$-subunit
$\beta 2$	ATP1B2	17p13.1	290	Brain, adhesion molecule (AMOG), liver
$\beta 3$	ATP1B3	3q23	279	Mostly in neural tissue, heart, kidney, lung

signature sequence domain, beginning with the sequence FXYD and containing seven invariant and six highly conserved amino acids. The approved human gene nomenclature for the family is listed in Table I. Coexpression of the γ-subunit (FXYD2) with the $\alpha 1\beta 1$-Na^+/K^+ pump modifies the enzymatic properties with respect to the affinity for cytoplasmic $[Na^+]$. The $\alpha 1\beta 1\gamma$-Na^+/K^+ pump complex has a relatively low affinity for $[Na^+]_{cyt}$ and it is expressed at very high densities in the basolateral membranes of the TALH.

In the IMCD, the inner medullary collecting duct, Na^+/K^+ pump functions are integrated with those of the sodium channel, ENAC, and K^+-channels to drive reabsorption of Na^+ under the regulation of aldosterone. In the IMCD, the expression of FXYD4 or CHIF is stimulated by aldosterone and the CHIF-$\alpha 1\beta 1$-Na^+/K^+ pump complex has a relatively high affinity for $[Na^+]_{cyt}$, thus enabling the pump to reduce the activity of $[Na^+]$ to 2–5 mM in the tubular lumen and in the cytoplasm of the principal cells of the IMCD.

Aldosterone also regulates Na^+ reabsorption driven by the $\alpha 1\beta 1$-Na^+/K^+ pumps in epithelia of lung, glands, and colon, thus providing a major force in the regulation of Na^+ metabolism and extracellular fluid volume.

Na^+/K^+ Pump Isoform Expression and Regulation in Muscle and Central Nervous System

Extensive analyses have been performed to clarify the tissue specific gene expression and the molecular mechanisms of the regulation of the α- and β-subunit genes, Tables I and II. Experiments on animal models allow reverse genetic strategy to analyze the function of transport proteins. Targeted disruption of the $\alpha 1$- and $\alpha 2$-subunit isoforms in mice confirm that the Na^+/K^+ pump is essential for life of all mammalian cells. Egg cells lacking both copies of the ubiquitous $\alpha 1$-isoform do not pass the blastocyst stage. Homozygote knockouts of the $\alpha 2$-isoform results in death few minutes after birth of the mice apparently due to malformation of neural connections in the medulla oblongata. Knockout of one of

FXYD7		19q13.13	80	In brain, reduces K^+ affinity of Na,K-pump

the genes shows that α1- and α2-isoforms have different physiological functions. An increased force of contraction of the heart is seen in animals lacking one copy of the α2-isoform, whereas the force of contraction is reduced after elimination of one copy of the α1-isoform. There is a correlation between the expression of the α2-Na^+/K^+ pump and the Na^+/Ca^{2+} exchanger in plasma membrane domains overlaying the endoplasmic reticulum. Elevation of local activities of $[Na^+]_{cyt}$ may therefore increase the $[Ca^{2+}]_{cyt}$ activity in the space of the cytosol near the endoplasmic reticulum and thus amplify the force of contraction. This may explain the specific role of the α2-isoform as a regulator of calcium and the force of contraction in the heart.

In skeletal muscle, long-term regulation involves thyroid hormone-mediated changes of the expression level of Na^+/K^+ pumps. Short-term regulation of the Na^+/K^+ pump is mediated either by changes in intracellular Na^+ activity or by hormone-mediated protein kinase reactions leading to changes of the Na^+/K^+ pump transport properties or in its cell surface expression. Insulin causes translocation of α2-Na^+/K^+ pumps to the cell surface and the α2-Na^+/K^+ pumps in skeletal muscle are involved in specific regulation in response to hypokalemia. Exercise stimulates exocytosis of α1- and α2-Na^+/K^+ pumps to the plasma membranes of muscle cells and this response is important for recovery of K^+ after repetitive muscle contractions. Phospholemman (FXYD1) interacts with α1- and α2-isoform Na^+/K^+ pumps and modulates their properties to cause a decrease in the affinity to Na^+. The presence of Na^+/K^+ pumps with low affinity can also be important for the recovery process after muscle contractions. Skeletal muscles are the main intracellular store of K^+, and the Na^+/K^+ pumps in the sarcolemma are important for maintaining plasma K^+ along with H^+/K^+ pumps in kidney and colon.

All three α1-, α2-, and α3-isoforms are expressed in the central nervous system. During embryogenesis, the α2-Na^+/K^+ pumps are expressed in most regions of the brain and they are important in the modulation of neuronal activity in the neonate. In the adult, α2-Na^+/K^+ pumps are expressed primarily in astrocytes, where glutamate is transported in a sodium- and potassium-dependent fashion. FXYD7 has been identified as an isoform-specific regulator of the Na^+/K^+ pump in brain. The properties of α3-Na^+/K^+ pumps may allow reuptake of K^+ at low extracellular activities in the brain.

The α4-isoform is exclusively expressed in spermatozoa in the testis. In the mid-piece containing the flagellar motor, the α4-Na^+/K^+ pumps are tightly coupled to Na^+/H^+ exchange of primary importance for generation of ATP and thus for the mobility of spermatozoa.

Glossary

digoxin Cardiac glycoside, also known as digitalis. It is derived from the leaves of the foxglove plant (*Digitalis purpurea*) and is a classic drug which increases the force of contraction of the incompensated heart, probably by increasing the $[Ca^{2+}]$ activity in the cytoplasm of heart muscle cells.

E_1P The phosphorylated intermediate that is formed by Na^+-stimulated transfer of the γ-phosphate from ATP to form an acyl bond with the carboxylate group of Asp369 of the α-subunit. $E_1P[3Na]$ occludes $3Na^+$ ions and it is a high-energy intermediate as it can transfer its phosphate to ADP and form ATP.

E_2P It is formed in the conformational transition $E_1P \leftrightarrow E_2P$. The E_2P conformation has two cation sites with preference for K^+ over Na^+. The $E_2P[2Na]$ form may react with Na^+ and ADP to form ATP. In the forward reaction, K^+ will replace Na^+ and stimulate hydrolysis and release of inorganic phosphate. The $E_2P[2K]$ form is insensitive to ADP and can only react with water to release inorganic phosphate.

Na, K-ATPase The enzymatic equivalent of the Na^+/K^+ pump is the *in vitro* $Na^+ + K^+$ stimulated ATPase activity which is inhibited by ouabain.

ouabain Strophanthin G, a plant alkaloid from *Strophantus gratus*, a fast acting cardiac glycoside that binds with high affinity to the α-subunit of the Na^+/K^+ pump.

Biography

Peter L. Jorgensen is a Professor of Molecular Physiology at the August Krogh Institute of the University of Copenhagen, Denmark. He holds a degree as medical doctor and a doctorate of medical sciences from the University of Aarhus, Denmark. He determined the physiological functions of the Na^+/K^+ pump in kidney and developed procedures for purification of the Na^+/K^+ pump from mammalian kidney and crystallization of the protein in the membrane plane. This led to detection of the distinct proteolytic cleavage patterns of the E_1- and E_2-conformations of the Na^+/K^+ pump and Ca^{2+} pump proteins. Recently, he contributed to solving the structure–function relationships of the binding sites for Na^+, K^+, Mg^{2+}, and ATP in the Na^+/K^+ pump protein.

P-Type Pumps: Plasma-Membrane H^+ Pump

A. Brett Mason and Carolyn W. Slayman
Yale University, New Haven, Connecticut, USA

Plasma-membrane H^+ pumps (also known as H^+-ATPases) are widely distributed throughout the fungal and plant kingdoms. They use the energy from ATP hydrolysis to generate a sizeable electrochemical gradient across the surface membrane, which in turn drives nutrient uptake into the cell via a series of H^+-coupled cotransporters (Figure 1A). The proton-pumping activity of the ATPase also contributes to the regulation of intracellular pH. Representative pumps have been cloned from budding (*Saccharomyces cerevisiae*) and fission (*Schizosaccharomyces pombe*) yeast, *Neurospora crassa*, several pathogenic fungi, and numerous plant species including *Arabidopsis thaliana*, *Nicotiana plumbaginifolia* (tobacco), and *Lycopersicon esculentum* (tomato).

Introduction

The fungal and plant plasma-membrane H^+-ATPases belong to a ubiquitous family of cation pumps known as P-type ATPases, so named because they hydrolyze ATP via a covalent aspartyl–phosphate reaction intermediate. When the P-ATPases are classified based on sequence alignments, membrane topology, and the nature of the transported cation(s), H^+-ATPases fall into a category designated as P_2 or type III.

Since 1986, when the *PMA1* genes of *S. cerevisiae* and *N. crassa* were cloned and sequenced, these two H^+-ATPases have served as prototypes for the group as a whole. Yeast in particular has proven to be an extremely useful model system. By virtue of the ease with which site-directed mutants can be made and analyzed, a large collection of *pma1* mutants has been generated which are providing molecular details as to the structure and function of the H^+-ATPase. The abundance of the ATPase in the yeast plasma membrane, where it may constitute up to 25% of total protein, is another feature of considerable value in the molecular characterization of the enzyme. Finally, the use of yeast as a vehicle for heterologous expression of other ATPases such as the individual isoforms of plant H^+-ATPase is providing information as to specific features of these enzymes that cannot be analyzed in their natural setting.

In addition to its utility in a comparative sense, the fungal ATPase has emerged as a potentially valuable target for the development of antifungal drugs. Most of the antifungals commonly used in the treatment of systemic fungal infections are either fungistatic compounds that inhibit the biosynthesis of ergosterol (the principal sterol in fungal membranes), or fungicidal compounds that interact with ergosterol directly, leading to disruption of the plasma membrane. Many pathogenic fungi are either innately resistant to existing antifungals, or are able to acquire resistance by developing mechanisms based on limitation of drug uptake, active drug efflux, or target resistance. In this regard, the H^+-ATPase has several properties that render it a promising new antifungal target: (1) it is an essential cell component, which favors the chances of fungicidal rather than fungistatic effect and simultaneously decreases the chances of resistance; (2) its cell surface location allows for targeting by drugs which do not enter the cell, thus avoiding multi-drug resistance (MDR) pumps and reducing the likelihood of toxic effects on host cells; and (3) it is structurally and functionally conserved across a wide range of fungal genera, promising broad-spectrum antifungal activity.

Structure

At the structural level, the fungal and plant plasma-membrane H^+-ATPases are composed of a 100 kDa polypeptide that is deeply embedded in the lipid bilayer, requiring detergents for solubilization. The predicted transmembrane topology of the 100 kDa polypeptide is shown in Figure 1B. As in other P_2-type ATPases, four hydrophobic segments at the N-terminal end of the polypeptide (M1–M4) and six hydrophobic segments at the C-terminal end (M5–M10) serve to anchor the ATPase in the membrane, while a large (340 amino acid) cytoplasmic loop in the center of the polypeptide

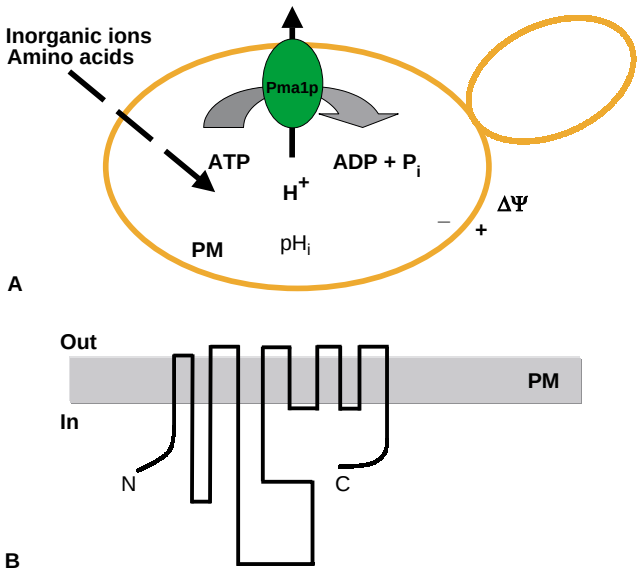

FIGURE 1 (A) The plasma membrane H^+-ATPase plays an essential role in yeast cell physiology. The pumping of protons (H^+) across the membrane at the expense of ATP hydrolysis establishes the membrane potential ($\Delta\Psi$) required for nutrient import and helps to regulate intracellular pH (pH_i). PM, plasma membrane. (B) Transmembrane topology of the fungal and plant H^+-ATPases. The ATPase has 10 transmembrane α-helices. Both N and C termini as well as the large catalytic domain of the enzyme are located in the cytoplasm. PM, plasma membrane.

contains the critical catalytic sites that bind ATP and form the aspartyl–phosphate intermediate.

The first three-dimensional glimpse of H^+-ATPase structure came from cryoelectron microscopic maps of the *Neurospora* enzyme at 8Å resolution. Ten transmembrane segments could be discerned clearly, connected by a narrow stalk to the multi-lobed, cytoplasmic headpiece of the enzyme. This low-resolution view has recently been confirmed and extended by comparison with X-ray crystallographic structures of the related mammalian sarcoplasmic reticulum Ca^{2+}-ATPase in two different conformations. In the first structure, with two Ca^{2+} ions bound, the headpiece of the Ca^{2+}-ATPase displayed a relatively open structure consisting of three well-separated domains: N (nucleotide-binding), P (phosphorylation), and A (actuator). In the second structure, obtained in the presence of a specific inhibitor known as thapsigargin, the three cytoplasmic domains had shifted towards one another to produce a relatively closed structure. Kühlbrandt and colleagues have demonstrated that the amino acid sequence of the *Neurospora* H^+-ATPase can be overlaid upon the Ca^{2+}-ATPase template to give a three-dimensional structure that agrees well with the earlier cryoelectron microscopic maps. Thus, structural information is now in hand that will serve as a valuable framework for mechanistic studies.

Reaction Mechanism

Like the intensively studied mammalian Na^+-, K^+-, and Ca^{2+}-ATPases, the fungal and plant plasma-membrane H^+-ATPases are considered to alternate between two major conformational states (E_1 and E_2) during their reaction cycle (Figure 2A). In E_1, the enzyme binds and hydrolyzes ATP to form a phosphorylated intermediate (E_1P), accompanied by protonation of the membrane-embedded transport site. It then undergoes a conformational change from E_1P to E_2P, during which the proton is extruded into the extracellular medium. After the release of inorganic phosphate, the E_2 conformation shifts back to E_1 to complete the cycle. The physical scale of these molecular movements can be appreciated by comparing the two crystal structures of Ca^{2+}-ATPase, where the top of the N-domain moves more than 50 Å and the A-domain rotates 90° to interact with the P-domain. A simple representation of this E_1 to E_2 conformational shift for a general P_2-type ATPase is depicted in Figure 2B. A stretch of 13 consecutive residues in stalk segment 4 of the yeast H^+-ATPase has

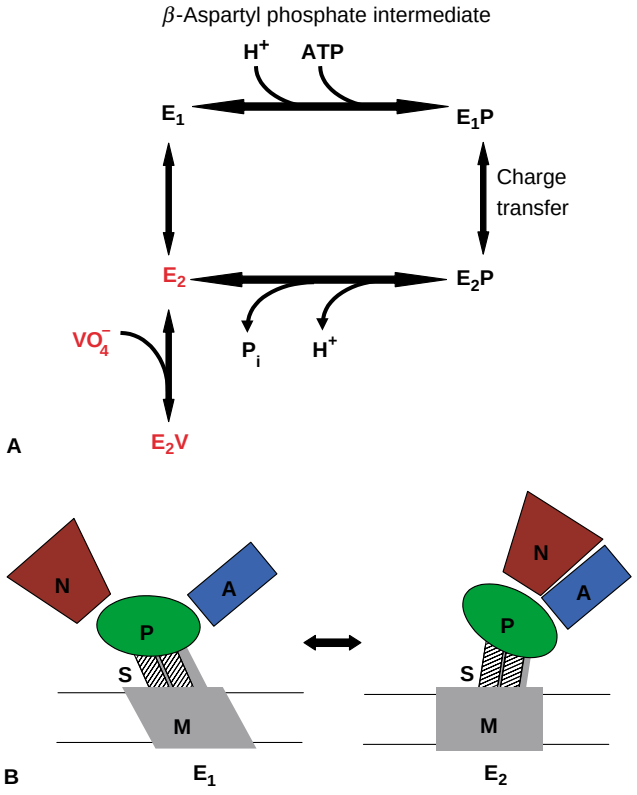

FIGURE 2 (A) The H^+-ATPase reaction cycle. See text for explanation. VO_4^-, vanadate, a potent P-type ATPase inhibitor. (B) Major domain movements that occur during conversion of the ATPase from the E_1 (cation-bound) to the E_2 (cation-free) conformation. recently been shown to play a key role in the E_1-E_2 conformational change.

Given the similar arrangement of membrane-spanning α-helices (M1–M10) in the Ca^{2+}- and H^+-ATPase crystal structures, the cation pathway through the H^+-ATPase is probably formed by M4, M5, M6, and M8 as it is in the Ca^{2+}-ATPase. Consistent with this idea, site-directed mutations in three of these segments (M5, M6, and M8) have been shown to alter the stoichiometry of proton transport. These studies were carried out with inside-out secretory vesicles, using the fluorescence quenching of acridine orange to measure H^+ transport into the vesicle. When such measurements were made over a range of MgATP concentrations, and the initial rate of quenching was plotted as a function of the initial rate of ATP hydrolysis, wild-type ATPase and most mutant forms of the enzyme displayed a linear relationship, with a slope corresponding to a stoichiometry of $1H^+$ translocated per ATP hydrolyzed. By contrast, several mutants in M5, M6, and M8 exhibited a decreased slope indicating partial uncoupling, and two mutants in M8 exhibited an increased slope reflecting an apparent increase in transport stoichiometry.

Considerable efforts are currently being made to obtain higher-resolution crystal structures of the H^+-ATPase. Information from these studies, in combination with further site-directed mutagenesis experiments, will soon provide more insight into the proton's path across the membrane bilayer.

Biogenesis

Biogenesis of the H^+-ATPase begins with its synthesis in the rough endoplasmic reticulum (ER), from which it travels to the plasma membrane via the secretory pathway (Figure 3). Because of its abundance in the membrane, together with the ease of making site-directed mutants, the yeast H^+-ATPase has served as a valuable model for studying this process.

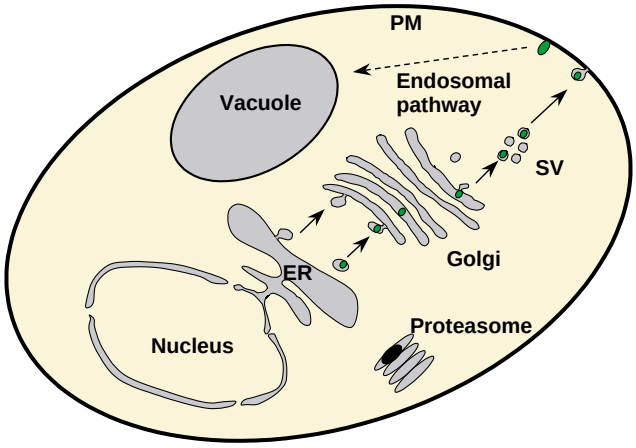

FIGURE 3 The yeast secretory pathway. ER, endoplasmic reticulum; SV, secretory vesicles; PM, plasma membrane.

While still in the ER, the ATPase adopts a fully folded structure that has the protease-resistant characteristics of the mature enzyme at the plasma membrane. The folded molecule is then incorporated into coat protein complex II (COPII) vesicles and shuttled to the *cis*-Golgi. Of considerable interest, a subpopulation of COPII vesicles has recently been identified that preferentially recruits and packages the H^+-ATPase by virtue of a specific coat protein, Lst1p. At least in principle, this mechanism provides a way to regulate biogenesis, underscoring the significance of the ATPase to the functioning of the cell as a whole.

Recent research has begun to shed light on the form of the ATPase as it exits the ER. Oligomeric forms of the *Neurospora* H^+-ATPase have been known for many years, and were originally thought to be by-products of detergent treatment. In the past several years, however, oligomers of the yeast H^+-ATPase have been detected early in biogenesis by three different methods: blue native gel electrophoresis, sucrose gradient centrifugation, and cross-linking of epitope-tagged polypeptides. In addition, oligomer formation provides a logical explanation for the existence of dominant negative *pma1* mutants, which cause coexpressed wild-type H^+-ATPase to be retained in the ER. The functional significance of the oligomers is not yet clear, given an earlier demonstration that the *Neurospora* H^+-ATPase is fully active when solubilized and reconstituted as a monomer. There has been speculation that the oligomers may play a special role in biogenesis and/or as a storage form of the ATPase, but further work will be required to test these ideas.

Parallel studies have been carried out recently to explore the association of the yeast H^+-ATPase with lipid rafts, sterol-, and sphingolipid-rich structures that are believed to segregate certain plasma-membrane proteins en route to the cell surface. Based on its insolubility in 1% Triton X-100 at 0°C, wild-type ATPase becomes associated with rafts prior to exiting the ER. Preventing the association by means of a mutation in sphingolipid biosynthesis does not block export, however, indicating that rafts do not play an obligatory role in this process.

Many mutations in the *PMA1* gene that lead to misfolding of the H^+-ATPase result in arrest of the polypeptide in the ER and massive accumulation of internal membranes. This represents the first level of quality control in biogenesis and, in most instances, is followed by redirection of the offending ATPase via the ER-associated degradation (ERAD) pathway for digestion in the proteasome. Quality

control screening is maintained, however, as the H^+-ATPase progresses through the secretory pathway. There are now several examples of mutant ATPases that escape the ER quality control mechanism only to be recognized as aberrant and differentially processed at later stages of the secretory pathway by vacuolar proteases.

Regulation

In addition to the major H^+-ATPase gene (*PMA*1), *S. cerevisiae* and *S. pombe* each have a second gene, *PMA2*, that encodes a nearly identical protein. The expression level of *PMA2* is so poor that it is unable to support growth, however, and the physiological function of the second ATPase remains unclear.

By contrast, plants possess multiple H^+-ATPase genes. In *A. thaliana*, for example, whole-genome sequencing has identified a family of 11 such genes, most or all of which are expressed in a tissue-specific way. Where tested, the corresponding H^+-ATPase isoforms differ detectably in their catalytic behaviors, suggesting that enzyme characteristics may be matched to the physiological requirements of individual tissues.

A diversity of environmental conditions and stress factors influence the biosynthesis and the activity of fungal and plant plasma-membrane H^+-ATPases (Figure 4). In yeast, two mechanisms have been identified, both resulting in up-regulation of the H^+-ATPase by glucose. At the transcriptional level, addition of glucose to the growth medium leads to a rapid increase in mRNA for the H^+-ATPase, and analysis of the promoter region of the *PMA1* gene has revealed active binding sites for several recognized transcription factors including Tuf1/Rap1/Grf1 and Gcr1. It is almost certainly significant that the same factors promote transcription of genes encoding glycolytic enzymes, pointing to a coordinated set of mechanisms that enable rapid, efficient growth on glucose.

Because the yeast H^+-ATPase has an unusually long half-life at the plasma-membrane (~11 h), posttranslational mechanisms are required to modulate its activity rapidly. Indeed, within minutes of glucose addition, the yeast ATPase displays an increased V_{max}, a lowered K_m, and a more alkaline pH optimum. There is growing evidence that this ensemble of changes results from posttranslational phosphorylation near the C terminus of the 100 kDa polypeptide. Truncation of the C terminus leads to constitutive activation, suggesting that the domain normally behaves in an autoinhibitory fashion. Detailed mutational analyses have linked the glucose-induced change in V_{max} with amino acids Arg^{909} and Thr^{912} and the change in K_m with Ser^{899} and Glu^{901}. Both pairs of residues constitute potential phosphorylation sites, and two novel phosphopeptides have been observed (though not yet sequenced) in proteolytic digests of H^+-ATPase from glucose-metabolizing yeast cells. Studies using site-directed mutagenesis of the yeast H^+-ATPase, coupled with suppressor analysis, suggest that the C terminus interacts with the stalk region near the cytoplasmic surface of the membrane and also with the ATP-binding (N) domain.

In plants, a variety of physiological conditions can affect the expression of specific ATPase isoforms, but

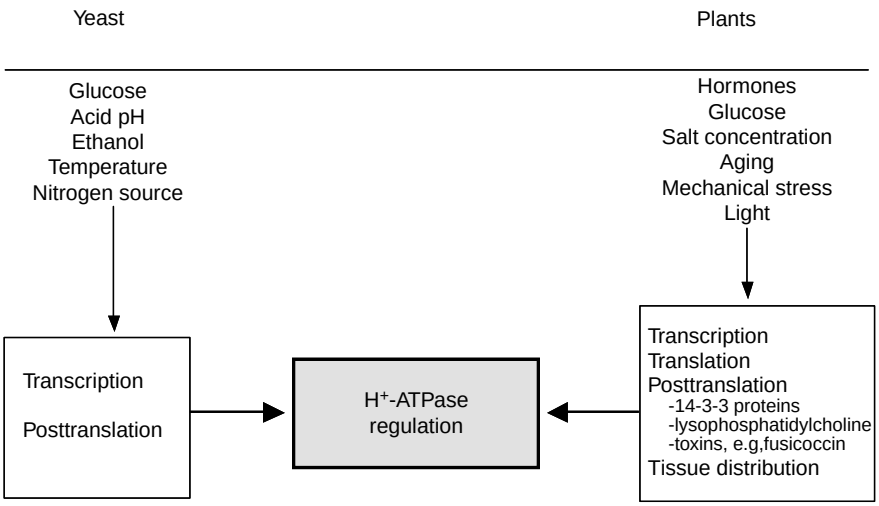

FIGURE 4 A comparison of the major environmental factors and mechanisms that regulate yeast and plant plasma membrane H^+-ATPase activity.

precise transcriptional mechanisms have not yet been elucidated. Translational mechanisms may also exist, possibly involving an untranslated leader sequence on the mRNA transcript that contains a short open reading frame (ORF). As in yeast, however, the primary modulator of plant H^+-ATPase activity is the C terminus of the enzyme, again acting in an autoinhibitory fashion. Growing evidence indicates that regulation is mediated by the binding of 14–3–3 proteins, a highly conserved family of acidic proteins expressed ubiquitously in eukaryotic cells. 14–3–3 proteins interact with many phosphoproteins, probably acting as dimers. A recent study of the Aha2p isoform of *Arabidopsis* H^+-ATPase expressed in yeast suggests that phosphorylation of Thr^{947} leads to the binding of 14–3–3 proteins, activating the enzyme. In the same study, the removal of two inhibitory sequences from the carboxyl terminus was also able to activate the Aha2p ATPase.

Regulation of H^+-ATPase activity is achieved through the coordinated action of multiple pathways. Our appreciation of the significance and complexity of this network will increase as our ability to explore cell physiology on a genome-, transcriptome-, and proteome-wide basis improves.

Summary

Research into the structure, function, biogenesis, and regulation of fungal and plant plasma-membrane H^+ pumps continues to provide a wealth of scientific information about the physiology of their host cells. Moreover, these pumps are invaluable as protein models not only for P_2-type ATPases but for complex integral membrane proteins in general.

And finally, with the continued increases in the incidence and variety of life-threatening fungal infections, particularly in immunocompromised patients, the fungal H^+-ATPase has assumed added significance as a viable target for the development of antifungal drugs.

Biography

Carolyn W. Slayman, Sterling Professor of Genetics and Cellular and Molecular Physiology at Yale University School of Medicine, has studied the plasma membrane H^+-ATPases of yeast and Neurospora for many years, focusing on the structure–function relationships that underlie proton transport.

A. Brett Mason, Associate Research Scientist in the Department of Genetics at Yale, began research on the yeast H^+-ATPase 10 years ago in New Zealand and joined the Slayman laboratory in 2000 to investigate the mechanism of ATPase biogenesis.

Purple Bacteria: Electron Acceptors and Donors

Evaldas Katilius and Neal W. Woodbury
Arizona State University, Tempe, Arizona, USA

Cyclic electron transport in the purple photosynthetic bacteria is facilitated by several soluble and integral membrane proteins. These proteins contain redox active cofactors serving as electron acceptors or donors. The cofactors are bacteriochlorophyll, bacteriopheophytin, quinone, or heme molecules. The electrochemical properties of these molecules are strongly affected by their protein environment allowing their midpoint potentials to be tuned to different values appropriate for their role in the cyclic electron transfer process.

General Description of the Cyclic Electron Transfer Chain

Generation of an electrochemical membrane gradient in purple nonsulfur bacteria involves light-driven electron transfer across the intracytoplasmic membrane followed by cotransport of electrons and protons in the opposite directions. The cycle starts with light-induced charge separation in the reaction center protein, where the electron transfer results in double reduction of a quinone molecule to quinol (see Figure 1) accompanied by proton uptake. Quinol then leaves the reaction center protein and is oxidized in the ubiquinol–cytochrome *c* oxidoreductase (also called cytochrome bc_1 complex). The quinol oxidation involves electron transfer both to a soluble cytochrome c_2 and to heme cofactors in the cytochrome bc_1 complex. This heme-mediated electron transfer in the cytochrome bc_1 complex results in the reduction of one quinone molecule bound in the Q_i site for every two quinol molecules oxidized in the Q_0 site (see Figure 1). The protons taken up from the cytoplasm during quinone reduction to quinol in the reaction center and cytochrome bc_1 are released to the periplasm during oxidation. Cytochrome c_2 in turn reduces the oxidized initial electron donor in the reaction center. The cyclic electron transfer results in the translocation of four protons from the cytoplasm to the periplasm for every two photons of light absorbed by the initial electron donor in the reaction center (Figure 1).

Reaction Center

The reaction center is an integral membrane protein, consisting of 3–4 protein subunits. In all species of purple bacteria, the reaction center contains two membrane-spanning protein subunits, called L (light) and M (medium), and the third subunit, called H (heavy), which is positioned on the cytoplasmic side of the membrane. Many species also contain a fourth subunit, a permanently associated cytochrome. The two membrane-spanning subunits bind the redox-active cofactors: four bacteriochlorophyll, two bacteriopheophytin, and two quinone molecules (see Figure 2). The protein also contains a redox inactive, nonheme iron atom and carotenoid molecule. Depending on the species, reaction centers contain either bacteriochlorophyll *a* or *b*, bacteriopheophytin *a* or *b*, and ubiquinone or menaquinone cofactors. The bacteriochlorophylls, bacteriopheophytins, and quinones are arranged in two nearly C_2 symmetric branches (see Figure 2). However, only one of these branches (usually called the A-branch), made up from cofactors mostly associated with the L protein subunit, is photochemically active *in vivo* (Figure 2). Upon the excitation with light, the initial electron donor P (a pair of bacteriochlorophyll molecules on the periplasmic side of the protein) donates an electron to a monomer bacteriochlorophyll, B_A, in ~3 picoseconds (ps), forming the charge-separated state $P^+B_A^-$, and then in ~1 ps the electron is further transferred to the bacteriopheophytin, H_A, forming the state $P^+H_A^-$. Electron transfer then proceeds to a primary quinone acceptor, Q_A, in ~200 ps, creating the charge-separated state $P^+Q_A^-$. From Q_A, the electron is transferred to a secondary quinone acceptor, Q_B, in 10–100 microseconds (μs). The semiquinone form of Q_B remains tightly bound to the reaction center. It is reduced to the quinol form after a second electron transfer event, which is coupled to proton uptake. The second electron transfer cycle is initiated when oxidized P^+ is reduced by cytochrome c_2, allowing light-induced charge separation to occur from P for a second

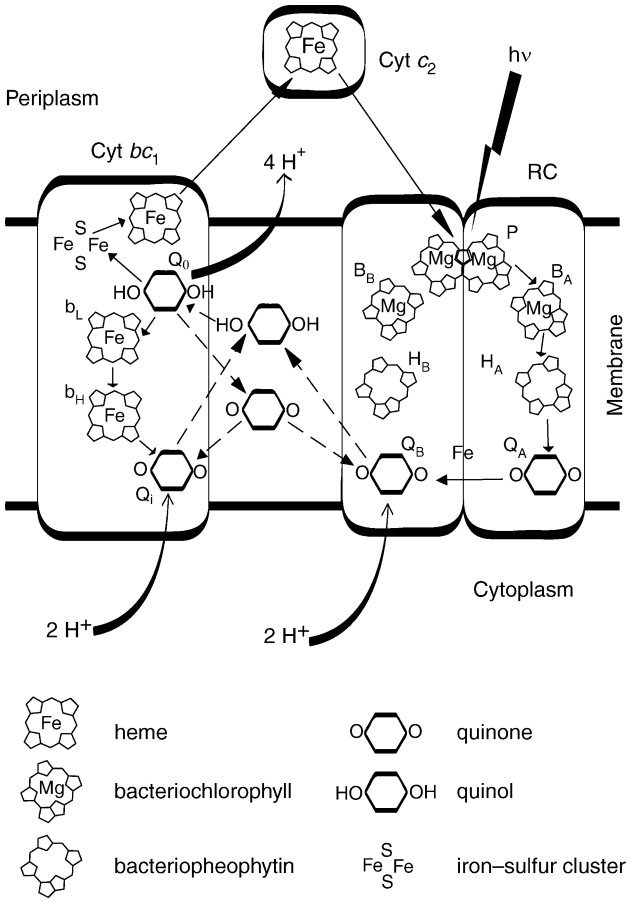

FIGURE 1 Cartoon diagram of the cyclic electron transfer reactions in photosynthetic purple bacteria. The main proteins involved in the reactions and their cofactors are shown schematically. RC stands for reaction center, Cyt c_2 – cytochrome c_2, Cyt bc_1 – cytochrome bc_1 complex. Q_0 and Q_i label two different quinone-binding sites in the cytochrome bc_1 complex. P, B_A, B_B, H_A, H_B, Q_A, Q_B label different cofactors in the reaction center (see Figure 2 for detailed explanation). Movement of the electrons is shown by solid arrows, dashed arrows depict movement of quinone and quinol cofactors.

time. The proton-coupled reduction of Q_B to a quinol occurs in ~1 millisecond (ms). The doubly reduced Q_B, Q_BH_2, then leaves the reaction center and enters the quinone pool (later binding to the cytochrome *bc*1 complex).

Properties of Reaction Center Cofactors

The initial electron donor, P, in purple bacteria consists of an excitonically coupled pair of bacteriochlorophyll molecules. The cation of P is a rather strong oxidant, with a P/P^+ midpoint potential of 0.50 V. On the other hand, the excited state of P, P^*, is a strong reductant with an estimated P^*/P^+ midpoint potential of ~ − 0.9 V, as the P to P^* transition energy is ~1.4 eV. The standard free energy of the first charge-separated state $P^+B_A^-$ is ~0.05 eV below P^* and the standard free energy of the state $P^+H_A^-$ is in the range of 0.15–0.25 eV below P^* (see Figure 2C). Further electron transfer from H_A to the quinone Q_A is driven by a larger free energy gap; $P^+Q_A^-$ is ~0.85 eV below P^*. The reduction potential of Q_A is ~ − 0.05 V, and therefore the free energy captured in the state $P^+Q_A^-$ is ~0.55 eV, or ~40% of the P to P^* transition energy (Figure 2C). The last charge-separated state $P^+Q_B^-$ is only slightly lower in free energy than $P^+Q_A^-$, given that the reduction of Q_B to the semiquinone has a midpoint potential ($E_m(Q_B/Q_B^-)$) of 0.02 V, while the reduction potential of semiquinone forming the quinol has an $E_m(Q_B^-/Q_BH_2)$ of ~0.1 V.

The fact that the reaction center has a symmetric arrangement of cofactors, yet an asymmetric electron transfer pathway, has intrigued researchers ever since the crystal structure was determined. Experimental results answering the question of what determines the electron transfer directionality have been presented over

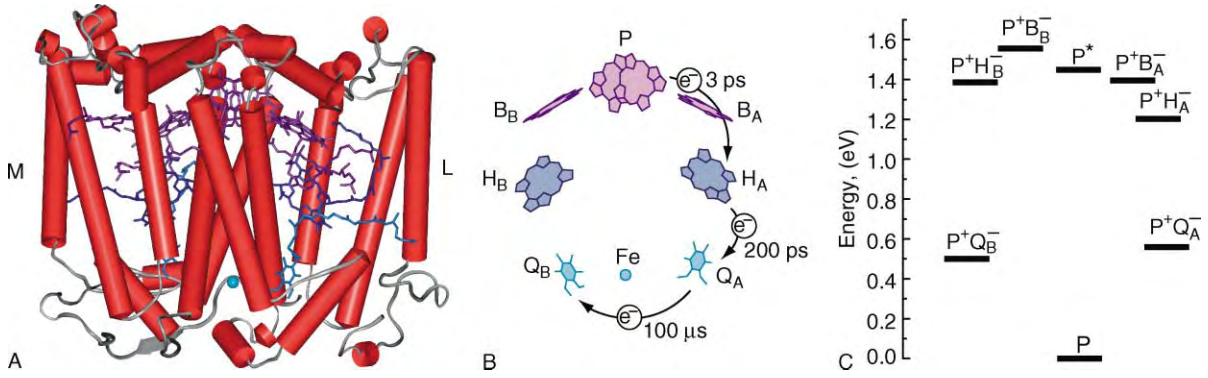

FIGURE 2 (A) Structure of the core subunits of the purple bacterial reaction center. The α-helices of the two subunits, L and M, are shown as red barrels. Bacteriochlorophyll, bacteriopheophytin, and quinone cofactors are shown inside the protein. This figure was created using the 1PCR entry from the Protein Data Bank. (B) Schematic arrangement of the symmetric branches of the bacteriochlorophyll (P and B), bacteriopheophytin (H), and quinone (Q) cofactors. The two branches, usually called A and B, are depicted as the subscripts. The asymmetric electron transfer reactions and their lifetimes are also shown. (C) The energetics of the charge-separated states in the reaction centers of purple bacteria. The free energies of the states are presented relative to the ground state of P, which was set at 0 eV.

the last few years. From site-directed mutagenesis studies, it has been deduced that the main factor limiting the electron transfer along the inactive B branch is the lower midpoint potential of the monomer bacteriochlorophyll cofactor B_B, which makes the standard free energy of the state $P^+B_B^-$ above the state P^* by ~ 0.1 eV (see Figure 2C). This high energetic barrier essentially blocks the electron transfer along the inactive branch, even though the standard free energy of the other charge-separated state, $P^+H_B^-$, is apparently slightly below P^*. The ability of the normally inactive branch (the B-side) to take part in charge separation has been demonstrated in various mutants of the reaction center in which the free energies of the charge-separated states involved were adjusted such that B-side electron transfer could effectively compete with A-side transfer.

Cytochromes

Light-induced charge separation in the reaction center generates both a reduced and an oxidized cofactor. While the doubly reduced quinone, Q_BH_2, has the ability to leave the reaction center to join the quinone pool, oxidized P (the cation free-radical P^+) has to be re-reduced to the neutral state by an external electron donor. This is accomplished by a *c*-type cytochrome. Purple bacteria can be categorized into two groups based on the type of the cytochrome *c* donor used and how it is associated with the reaction center.

The first and major group of bacteria has reaction centers that have permanently associated *c*-type heme-containing cytochrome subunits. These permanent RC-cytochrome complexes are best characterized in the purple bacteria *Blastochloris (Bl.) viridis* (previously named *Rhodopseudomonas viridis*), as this is the strain of bacteria from which the first crystal structure of reaction centers was determined. The cytochrome subunit, which is attached to the periplasmic side of the reaction center, is ~ 40 kDa and contains four heme cofactors. A separate water-soluble cytochome c_2 provides the electrons for the "fixed" cytochrome and mediates the cyclic electron flow between the reaction center and cytochrome bc_1 complex.

Another group of purple bacteria have simpler reaction centers with no permanently attached cytochrome subunit. Instead, a water-soluble cytochrome c_2 acts directly as the donor to oxidized P^+ as well as the acceptor of electrons from the cytochrome bc_1 complex. This group of bacteria includes such strains as *Rhodobacter (Rb.) sphaeroides* and *Rb. capsulatus*. Cytochrome oxidation and P^+ reduction in these strains occur through transient complexes that are formed between the reaction center and cytochrome c_2. The association of the two proteins is mediated mostly by electrostatic interactions, involving negatively charged residues on the periplasmic surface of the reaction center and positively charged residues on the surface of cytochrome c_2.

Properties of the Redox Active Centers in the Cytochromes

Cytochrome c_2 is a small protein containing only one covalently attached heme group. The redox potential of the heme cofactor ranges from 280 to 360 mV in various strains of purple bacteria. Electron transfer between cytochrome c_2 and P occurs with biphasic kinetics, with the major reaction phase having a reaction time constant of 1–4 μs and a slower phase with a 100–400 μs time constant. The first phase reflects the fast electron transfer from the cytochromes that are already associated with the reaction centers, while the slower phase represents the diffusion-limited second-order reaction.

Reduction of P^+ in the other group of the purple bacteria is performed by the permanently attached cytochrome. This cytochrome subunit contains two high and two low midpoint potential heme cofactors. As the best-studied example, the cytochrome from *Bl. viridis* has two hemes with low midpoint potentials of -60 and 20 mV and two high potential hemes, with midpoint potentials of 320 and 380 mV, respectively. The heme arrangement in the cytochrome is such that the heme with the highest midpoint potential is closest to the primary electron donor in the reaction center; the order (from proximal to distal) is: 380 mV → 20 mV → 320 mV → -60 mV. The reduction of P^+ in this cytochrome–reaction center complex is much faster than electron transfer between the soluble cytochrome c_2 and the reaction center. P^+ is reduced by the highest midpoint potential heme; the actual reaction rate depends on the redox state of the other hemes in the subunit and its time constant is on the order of a few hundred nanoseconds. Upon electron donation to P^+, the oxidation of heme 1 is followed by its reduction by heme 3 (with the midpoint potential of 320 mV) in several microseconds. The re-reduction of the oxidized hemes in the reaction center-associated cytochrome is again mediated by soluble cytochrome c_2; this reaction occurs in several hundred microseconds.

Ubiquinol–Cytochrome *c* Oxidoreductase (Cytochrome bc_1 Complex)

Ubiquinol–cytochrome *c* oxidoreductase (or the cytochrome bc_1 complex) is an integral membrane protein

involved in cyclic light-driven electron transfer as well as dark respiration. This complex both oxidizes and reduces quinones and reduces oxidized cytochrome c_2. The simplest of the cytochrome bc_1 complexes are found in the purple bacteria. In most species, this complex consists of only three subunits – cytochrome b, cytochrome c_1, and the "Rieske" iron–sulfur protein. Cytochrome b binds two redox-active heme molecules, called b_L and b_H, with the subscripts referring to the relatively low (~ -100 mV) and high (50 mV) redox midpoint potentials of the two hemes. Cytochrome c_1 binds only one heme molecule, which has a much higher midpoint potential of 290 mV. The "Rieske" iron–sulfur protein contains a $[Fe_2S_2]$ cluster with a relatively high midpoint potential of $\sim$280 mV.

The cytochrome bc_1 complex completes the electron transfer cycle in purple bacteria by re-reducing the cytochrome c_2 that was oxidized by the reaction center and performing the net oxidation of the quinol molecules released by the reaction center. First, the high potential iron–sulfur cluster is oxidized by cytochrome c_2 in $\sim$150–200 μs. Then, quinol binds to the Q_0 site at the interface of cytochrome c_1 and the "Rieske" protein on the complex and re-reduces the iron–sulfur cluster in a one-electron transfer. The second electron from the quinol is used to reduce the b_L cofactor and subsequently is transferred to b_H in $\sim$700 μs. The resulting oxidation of quinol in the Q_0 site results in release of two protons to the periplasmic side of the photosynthetic membrane. Heme b_H then reduces a quinone molecule bound in the second quinone-binding site Q_i, followed by proton uptake to form a semiquinone. This cycle repeats resulting in reduction of a second cytochrome c_2 and oxidation of a second quinol molecule in the Q_0 site, accompanied by release of two more protons on the periplasmic side of the membrane. The semiquinone molecule bound in the Q_i site is then reduced to quinol and released into the quinone pool. The reduction of the quinone molecule to quinol in the Q_i site results in uptake of two protons from the cytoplasmic side of the membrane. Thus, in total four protons are transferred from the cytoplasm to the periplasm, but the net number of quinol molecules oxidized in the cytochrome bc_1 complex is only one. This proton pumping creates the electrochemical gradient needed to drive ATPsynthase.

Purple Bacteria: Photosynthetic Reaction Centers

C. Roy D. Lancaster
Max Planck Institute of Biophysics, Frankfurt am Main, Germany

Located within photosynthetic membranes, reaction centers (RCs) are defined as the minimal functional units that can catalyze light-induced electron transfer reactions, thus stabilizing the separation of charged species across the membrane. The RC essentially functions as a ferrocytochrome c_2:quinone photo-oxidoreductase. The absorption of two photons of light leads to two one-electron oxidations of cytochrome c_2 in the periplasm and to the two-electron reduction of a quinone, which is coupled to the uptake of two protons from the cytoplasm. The resulting quinol then leaves its binding site, diffuses in the photosynthetic membrane and is reoxidized by a second membrane protein complex, the cytochrome bc_1 complex, which results in proton release to the periplasm. The electrons are transferred to re-reduce the cytochrome c_2 in the periplasm. This net proton transport produces a transmembrane electrochemical proton potential that can drive ATP synthesis through a third membrane-spanning complex, the ATP synthase.

Photosynthetic Reaction Centers

Virtually all life on Earth ultimately depends on the ability of photosynthetic organisms to convert solar energy into biochemically amenable energy. Photosynthesis is performed by higher plants, algae, and photosynthetic bacteria. Photosynthetic organisms absorb photons for the generation and storage of energy and for the production of biomass. A large proportion of photosynthetically active organisms consists of anoxygenic photosynthetic bacteria. In contrast to the higher plants, algae, and cyanobacteria of oxygenic photosynthesis, which contain the two membrane-bound photosystems I and II, each of the anoxygenic photosynthetic bacteria has only one type of reaction center. While the iron–sulfur type RCs of heliobacteria and anaerobic green sulfur bacteria resemble that of photosystem I, the pheophytin-quinone type RCs of purple bacteria are more similar to the RC of photosystem II.

Purple bacteria find their ecological niche in deeper layers of stagnant bodies of water. In all purple bacteria, the photosynthetic pigments and the photosynthetic apparatus are located within a more or less extended system of invaginated intracytoplasmic membranes. Unlike photosystem II, however, the purple bacterial RC is incapable of extracting electrons from water. Instead it must oxidize inorganic or organic molecules available in the environment. According to their electron donor requirements, sulfur and nonsulfur purple bacteria have traditionally been distinguished. In contrast to sulfur purple bacteria (*Chromatiaceae*, *Ectothiorhodospira*), nonsulfur purple bacteria (*Rhodospirillaceae*) do not require inorganic sulfur compounds, such as hydrogen sulfide, but instead use organic electron donors such as malate or succinate as electron donors. Most of what is known today about purple bacterial RCs results from studies on RCs from nonsulfur purple bacteria. These are currently the best-characterized membrane protein complexes.

Subunit Composition and Molecular Characterization

Most purple bacterial reaction centers contain four protein subunits (Figure 1), referred to as H, M, L, and C (a tetraheme cytochrome *c*). Some, however, such as the RCs of *Rhodobacter* (*Rb.*) *sphaeroides*, *Rb. capsulatus*, and *Rhodospirillum* (*Rs.*) *rubrum*, contain only the H, M, and L subunits. The related RC of the green aerobic thermophilic bacterium *Chloroflexus* (*Cf.*) *aurantiacus* lacks the H subunit.

Generally, RCs from purple bacteria have been isolated and characterized from *Rhodopseudomonas* (*Rp.*) *viridis* (suggested by Hiraishi in 1997 to be to referred to as *Blastochloris viridis*), *Rb. sphaeroides*, *Rb. capsulatus* and a number of other purple bacteria. Variant RCs have been created by site-directed mutagenesis as well as classical herbicide-resistance selection procedures and have been isolated and characterized from *Rb. capsulatus*, *Rb. sphaeroides*, and *Rp. viridis*.

RC preparations have a nonheme iron and four magnesium-containing bacteriochlorophyll cofactors

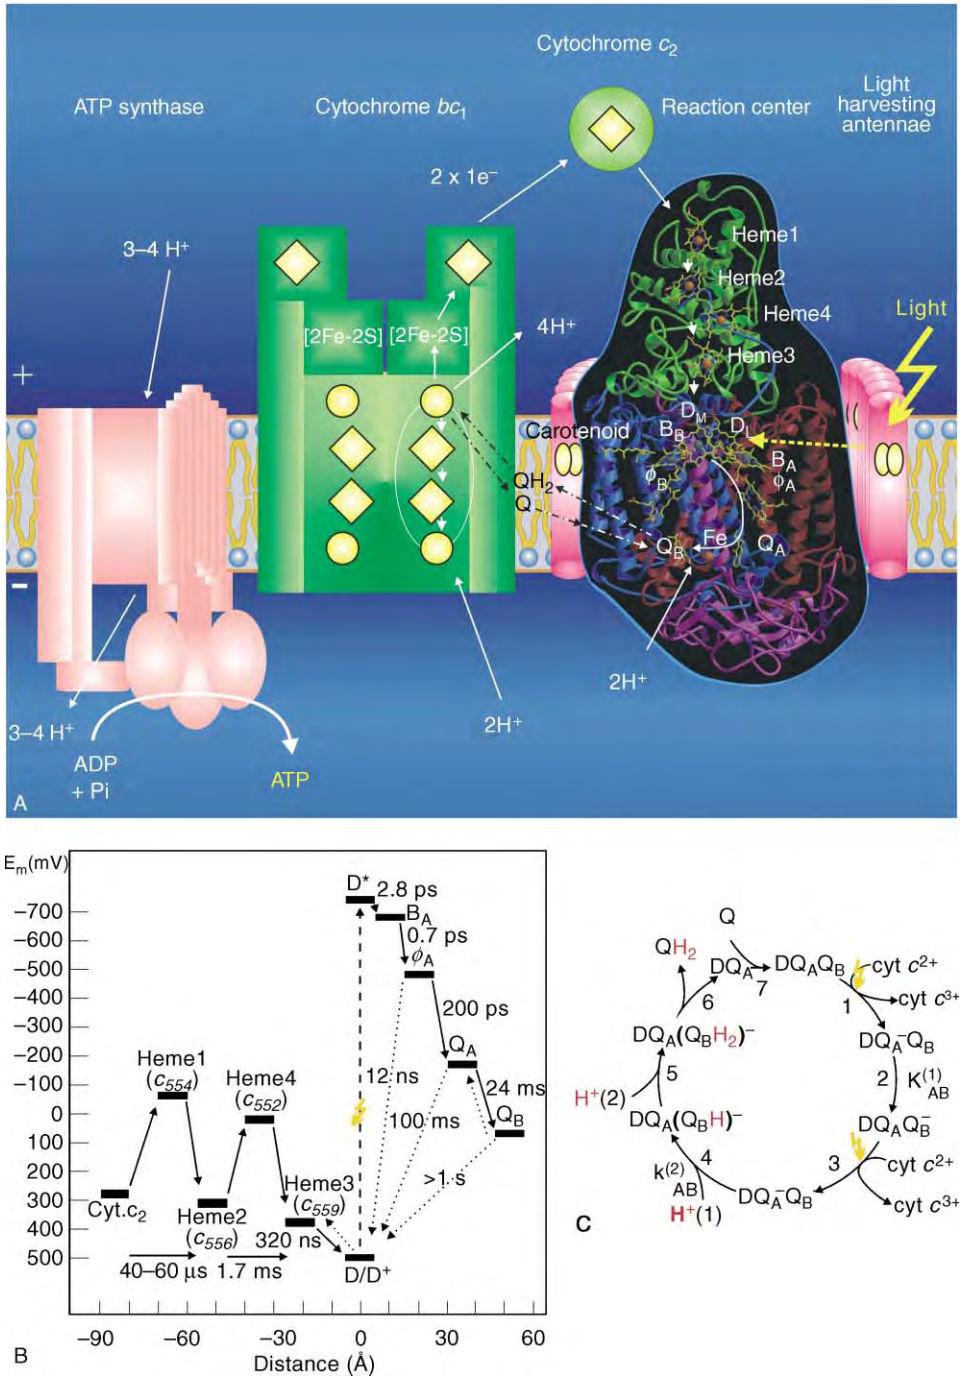

FIGURE 1 Structure and function of the photosynthetic RC. (A) Light-induced cyclic electron flow and the generation and utilization of a transmembrane electrochemical potential in the purple bacterium *Rp. viridis*. The structure of the *Rp. viridis* RC is represented schematically showing the heterotetramer of C, L, M, and H subunits as Cα traces in green, brown, blue, and purple, respectively, plus the fourteen cofactors, which have been projected on to the molecule for better visibility. Also for the sake of clarity, the quinone tails are truncated after the first isoprenoid unit and the phytyl side chains of the bacteriochlorophyll and bacteriopheophytin molecules have been omitted, as have those atoms of the carotenoid molecule, which were not observed in the electron density and assigned zero occupancy in the PDB entry 2PRC. Carbon, nitrogen, and oxygen atoms are drawn in yellow, blue, and red, respectively. (B) Equilibrium oxidation–reduction potentials of the *Rp. viridis* RC cofactors (as compiled by Lancaster, C. R. D., and Michel, H. (2001). Photosynthetic reaction centers. In *Handbook of Metalloproteins* (A. Messerschmidt, R. Huber, T. Poulos and K. Wieghardt, eds.) Vol 1, pp. 119–135. Wiley, Chichester, UK and references therein) as a function of inter-cofactor distance. The soluble electron donor protein cytochrome c_2 has been included as suggested in Figure 4A. Reaction halftimes indicated are taken from the references cited by Lancaster, C. R. D., and Michel, H. (2001). Photosynthetic reaction centers. In *Handbook of Metalloproteins* (A. Messerschmidt, R. Huber, T. Poulos and K. Wieghardt, eds.) Vol 1, pp. 119–135. Wiley, Chichester, UK. The photochemical excitation is indicated by a dashed arrow and unphysiological charge recombination reactions are shown as dotted arrows. (C) Quinone reduction cycle. Steps 2, 4, 5, and 6 are reversible. See text for details.

per RC, as measured by atomic absorption spectroscopy. In *Rb. sphaeroides* and *Rp. viridis*, these are bacteriochlorophyll *a* and bacteriochlorophyll *b*, respectively (Figures 1A and 2A). Those preparations with a tightly bound C subunit have four iron-containing heme groups, which are covalently bound to the protein via thioether bonds formed with the Cys residues of the heme attachment site sequences Cys-X-Y-Cys-His and the His is the fifth ligand to the heme iron. In the *Rp. viridis* RC, the sixth ligands to heme1, heme2, and heme3 are Met residues (His-Met-ligated hemes), whereas the sixth ligand to heme4 is a second His (*bis*-His ligation). Apart from these four hemes, all other cofactors are noncovalently bound by the L and M subunits. The six-coordinated nonheme ferrous iron is coordinated by the Nε atoms of four His residues and the two Oε atoms of a Glu residue. The fifth ligands to the five-coordinated bacteriochlorophyll-magnesium ions are provided by the Nε atoms of His side chains. In addition to these metal-containing cofactors, there are two bacteriopheophytin groups, a carotenoid, and two quinones bound by the RC. In *Rb. sphaeroides*, these are bacteriopheophytin *a*, spheroidene, and ubiquinone-10, respectively, whereas *Rp. viridis* contains bacteriopheophytin *b*, 1,2-dihydroneurosporene, menaquinone-9, and ubiquinone-9 (Figures 1A and 2A–2C).

Apart from the availability of high resolution crystal structures discussed, one major reason why, despite its complexity, the purple bacterial RC has become the "hydrogen atom of protein electron transfer" (W.W. Parson), is the richness of its characterization by optical absorption, electron paramagnetic resonance

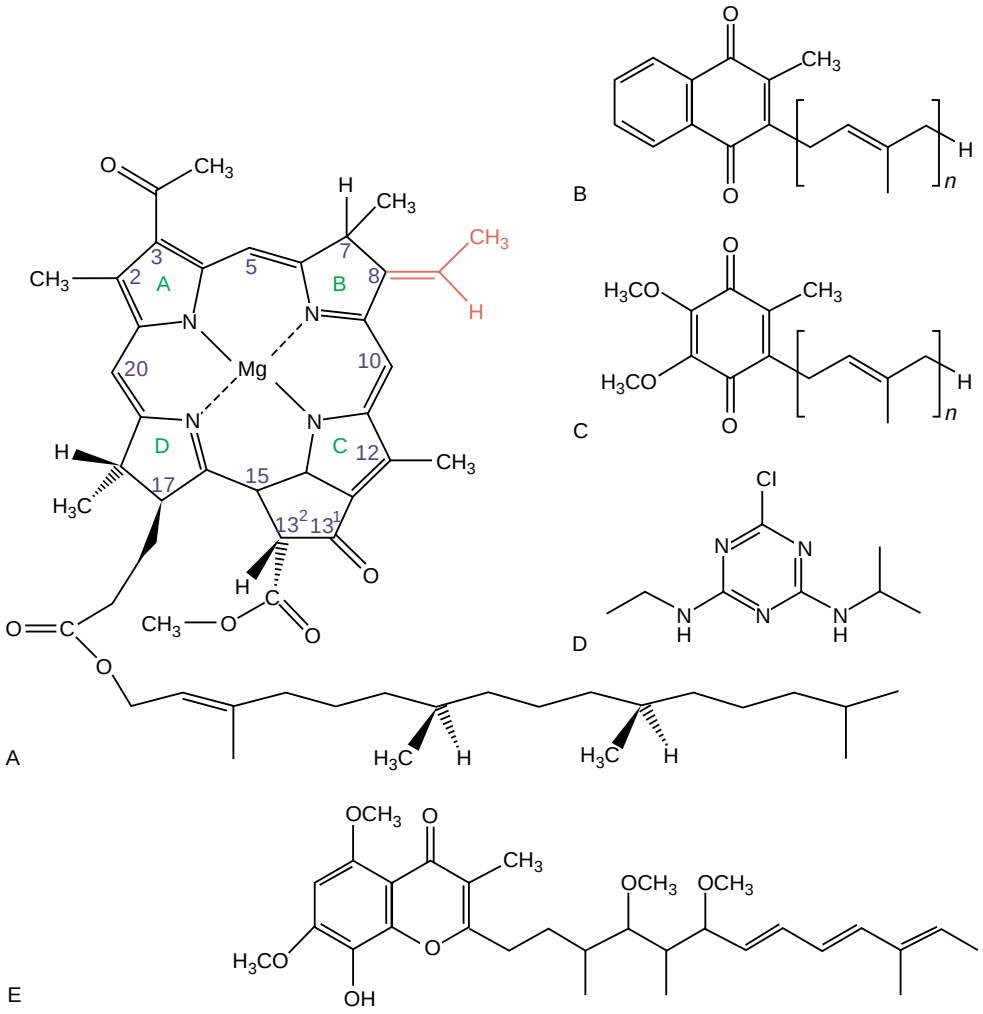

FIGURE 2 Chemical structures of RC cofactors (A–C) and inhibitors at the Q_B site (D–E). (A) Bacteriochlorophyll *b*, as bound in the *Rp. viridis* RC. The bacteriochlorophyll *a* bound in the *Rb. sphaeroides* RC differs by the presence of a C8 ethyl group instead of the C8 ethylidene group indicated in red. (B) Menaquinone-n. The native Q_A in the *Rp. viridis* RC is menaquinone-9. (C) Ubiquinone-n. The native Q_A in the *Rp. viridis* RC is ubiquinone-9. In the *Rb. sphaeroides* RC, both Q_A and Q_B are ubiquinone-10. (D) Atrazine (2-chloro-4-ethylamino-6-isopropylamino-*s*-triazine). (E) Stigmatellin A.

(EPR), electron-nuclear double resonance (ENDOR), Fourier transform infrared (FTIR), Resonance Raman (RR), fluorescence, Stark effect, and other types of spectroscopy.

X-Ray Crystal Structures of RCs from Purple Bacteria

The photosynthetic RC from *Rp. viridis* was the first membrane protein complex for which an atomic structural model could be determined by X-ray crystallography (Protein Data Bank (PDB) entry 1PRC). The structure of the four-subunit *Rp. viridis* RC is shown schematically in Figure 1A. The structure of the RC from *Rb. sphaeroides* (not shown) would appear almost identical except for the C subunit at the top, which would be missing. The recently determined structure of the RC from the sulfur purple bacterium *Thermochromatium tepidum* (PDB entry 1EYS) is very similar in overall architecture to that of *Rp. viridis*.

The *Rp. viridis* RC has an overall length of 130Å in the direction perpendicular to the membrane. Parallel to the membrane, the maximum width is ~70Å. The central core of the RC is formed by the L subunit and the M subunit, which possess five membrane-spanning segments each. Both subunits are closely associated and noncovalently bind ten cofactors as detailed above and shown in Figure 1A. Large parts of the L and M subunits and their associated cofactors are related by a two-fold axis of symmetry perpendicular to the plane of the membrane. The H subunit is anchored to the membrane by a single membrane-spanning helix and is attached to the LM core on the cytoplasmic side. On the periplasmic side, the C subunit with its four covalently bound heme groups is attached. The N-terminal diacylglycerol moiety which, in addition to the interaction with the LM core, anchors the C subunit in the membrane is not visible in the electron density map.

The pigments form two symmetry-related branches, also shown in Figure 1A, each consisting of two bacteriochlorophylls, one bacteriopheophytin and one quinone, which both cross the membrane starting from the "special pair" D of two closely associated bacteriochlorophylls (D_M and D_L) near the periplasmic side, followed by the "accessory" bacteriochlorophyll, B, one bacteriopheophytin, ϕ, and a quinone, Q. As shown in Figure 1A, only the branch more closely associated with L subunit is used in the light-driven electron transfer. It is called the A-branch, the inactive one the B-branch. The active branch ends with the primary quinone Q_A, the inactive one with the secondary quinone Q_B. Halfway between both quinones, the nonheme iron is located. The carotenoid is in van der Waals contact with B_B and disrupts the twofold symmetry. In both species, the crystallographic temperature factors, which are a measure for the rigidity of the structure, are considerably higher along the B-branch than along the A-branch.

Functional Aspects

Oxidation–Reduction Potentials

The oxidation–reduction midpoint potentials, E_M, of the four heme groups follow the order low, high, high, low in the sequence or low, high, low, high if the hemes are ordered with decreasing distance (see Figure 1B) from the primary electron donor D. Theoretical analysis by the application of continuum electrostatics to the crystal structure of the C subunit has provided quantitative estimations of the factors contributing to the equilibrium E_M values of the four hemes. Specific residues and the propionic side chains on the hemes are calculated to strongly modulate the E_M values. The correct division into low and high potential hemes can be obtained by taking only the protein into account. Consideration of heme–heme interactions is required to reproduce the experimental data quantitatively.

The redox potentials of the other *Rp. viridis* RC cofactors are also included in Figure 1B. The potential of the excited state D^* is derived from the free energy difference between the lowest vibrational levels of D and D^*. Estimated from the wavelength of the absorption maximum, the dimer of bacterichlorophyll *b* in *Rp. viridis* provides an energy of 1240 meV between D and D^*, that of the bacteriochlorophyll *a* dimer in *Rb. sphaeroides* one of 1380 meV. The redox potential of *Rb. sphaeroides* D has been increased from 505 to 765 mV by the introduction of three additional hydrogen bonds to the special pair bacteriochlorophylls by site-directed mutagenesis, thus destabilizing the oxidized state of the donor, D^+.

The redox potential of Q_A is higher in the *Rb. sphaeroides* RC than in the *Rp. viridis* RC because of the different chemical nature of the quinones (ubiquinone versus menaquinone). However, it is still 67 mV lower than that of *Rb. sphaeroides* Q_B, even though both cofactors are chemically identical, thus requiring a role of the protein in tuning the *in situ* redox potentials of the quinones.

Kinetics

Figures 1A and 1B show schemes of the electron transfer steps that occur in the purple bacterial reaction center. Light absorption leads to an excited primary donor D^*, from which an electron is transferred via the monomeric bacteriochlorophyll B_A (reaction halftime: 2.8 ps) and the bacteriopheophytin ϕ_A (700 fs) to Q_A in 200 ps, leading to the formation of $D^+Q_A^-Q_B$. Re-reduction of

D^+ by cytochrome c_{559} (heme 3) occurs in 320 ns. These processes are much faster than the subsequent proton uptake and inter-quinone electron transfer reactions. Therefore, the first step of quinone reduction in the RC can be viewed as a "photochemical cytochrome oxidation," giving rise to the radical state $DQ_A^-Q_B$ (Figure 1C). Re-reduction of cytochrome c_{559}^+ by cytochrome c_{556} (heme 2) occurs in 1.7 μs. The second step of quinone reduction involves the transfer of the first electron to Q_B in 17–25 μs, resulting in the state $DQ_AQ_B^-$. The one-electron reduction of Q_B is not associated with direct protonation and the semiquinone species is anionic. However, the $Q_A^-Q_B \rightleftarrows Q_AQ_B^-$ equilibrium constant is pH-dependent, as electron transfer is accompanied by substoichiometric proton uptake due to the protonation of amino acid residues. Cytochrome c_{556}^+ is re-reduced by cytochrome c_2 in 40–60 μs. In species that lack the C subunit, e.g., *Rb. sphaeroides*, the photoxidized special pair is directly re-reduced by cytochrome c_2 in a biphasic reaction. The fast phase of ~1 μs is attributed to intermolecular electron transfer, the slow phase of 100 μs is limited by docking and reorientation of the cytochrome c_2-RC complex. After a second "photochemical cytochrome oxidation," the diradical state $DQ_A^-Q_B^-$ is formed at rates similar to those for the first electron transfer. Coupled transfer of the first proton and the second electron to Q_B^- leads to the monoprotonated, doubly reduced state $DQ_A(Q_BH)^-$. Transfer of the second proton for the formation of Q_BH_2 is kinetically indistinguishable from the first proton transfer in the wild-type RC and can only be resolved in the case of mutants with significantly retarded second proton transfer rates.

Functional Derivatives

Substrate Analogue and Inhibitor Complexes

In the original *Rp. viridis* RC structure (PDB entry 1PRC), the Q_B site was poorly defined because it was only partially occupied with the native ubiquinone-9 in the standard RC crystals. However, ubiquinone-2-reconstitution experiments have yielded crystals with full quinone occupancy of the Q_B site. Subsequent X-ray diffraction analysis and refinement has led to a well-defined Q_B-site model (2PRC), with the quinone bound in the "proximal" position, i.e., close to the nonheme iron (hydrogen-bonded to its ligand His L190, see Figure 3A). In the RC structure with a Q_B-depleted Q_B site (3PRC, Figure 3B), refined at 2.4Å, apparently five, possibly six, water molecules are bound instead of the ubiquinone head group, and a detergent molecule binds in the region of the isoprenoid tail. Using the structures 2PRC and 3PRC as references, the original data set 1PRC was re-examined. A more quantitative analysis of the original data resulted in 20% of the Q_B sites being occupied with quinone in the proximal site, 30% having quinone bound in a more distal site, not hydrogen-bonded to His L190 and further away from the nonheme iron (see Figure 3A), and half of the Q_B sites being empty or having the quinone unaccounted for. A further structure, the RC complex with the inhibitor stigmatellin (see Figure 2E), refined at 2.4Å, indicates that additional hydrogen bonds stabilize the binding of stigmatellin over that of ubiquinone-2 (4PRC, see Figure 3C). The binding pattern observed for the stigmatellin complex can be viewed as a model for the stabilization of a monoprotonated reduced intermediate (Q_BH or Q_BH^-). This indicates that the Q_B site is not optimized for Q_B binding, but for Q_B reduction to the quinol. In combination with the results of electrostatic calculations, these crystal structures can provide models for intermediates in the reaction cycle of ubiquinone reduction to ubiquinol, as discussed next.

The Q_B site is also a well-established site of herbicide action. Over half of the commercially available herbicides function by inhibition of higher plants at the QB site of the D1 polypeptide of the photosystem II RC. A commercially very important class of herbicides are the triazines, which were introduced by J.R. Geigy S.A. in the 1950s. A prominent example is atrazine (Figure 2D), first reported in 1957. According to statistics from 1995, atrazine was used on ~67% of all US corn acreage, 65% of sorghum acreage, and 90% of sugarcane acreage. Another well-known triazine is terbutryn (2-*t*-butylamino-4-ethylamino-6-methylthio-*s*-triazine). X-ray crystal structures of complexes of the RC with atrazine (PDB entry 5PRC) and terbutryn (PDB entry 1DXR) have been determined at 2.35Å and 2.00Å resolution, respectively. In both cases, three hydrogen bonds bind the distal side of the inhibitors to the protein, and four additional hydrogen bonds, mediated by two tightly-bound water molecules are apparent on the proximal side, as shown for atrazine in Figure 3D. In contrast to the proximal binding of stigmatellin (Figure 3C), the triazine inhibitor partially overlaps with both the distal- and the proximal ubiquinone-binding sites (Figure 3D).

Mutants

Work on site-directed mutagenesis of photosynthetic reaction centers started with the RC from *Rb. capsulatus*. This species is genetically very well characterized and able to grow non-photosynthetically under aerobic conditions, as well as under anaerobic conditions using e.g., dimethylsulfoxide as an electron acceptor. Most importantly, under these latter conditions, the photosynthetic apparatus is fully induced. Unfortunately, the RC from *Rb. capsulatus* could not be crystallized, thus thwarting proper inspection for structural changes.

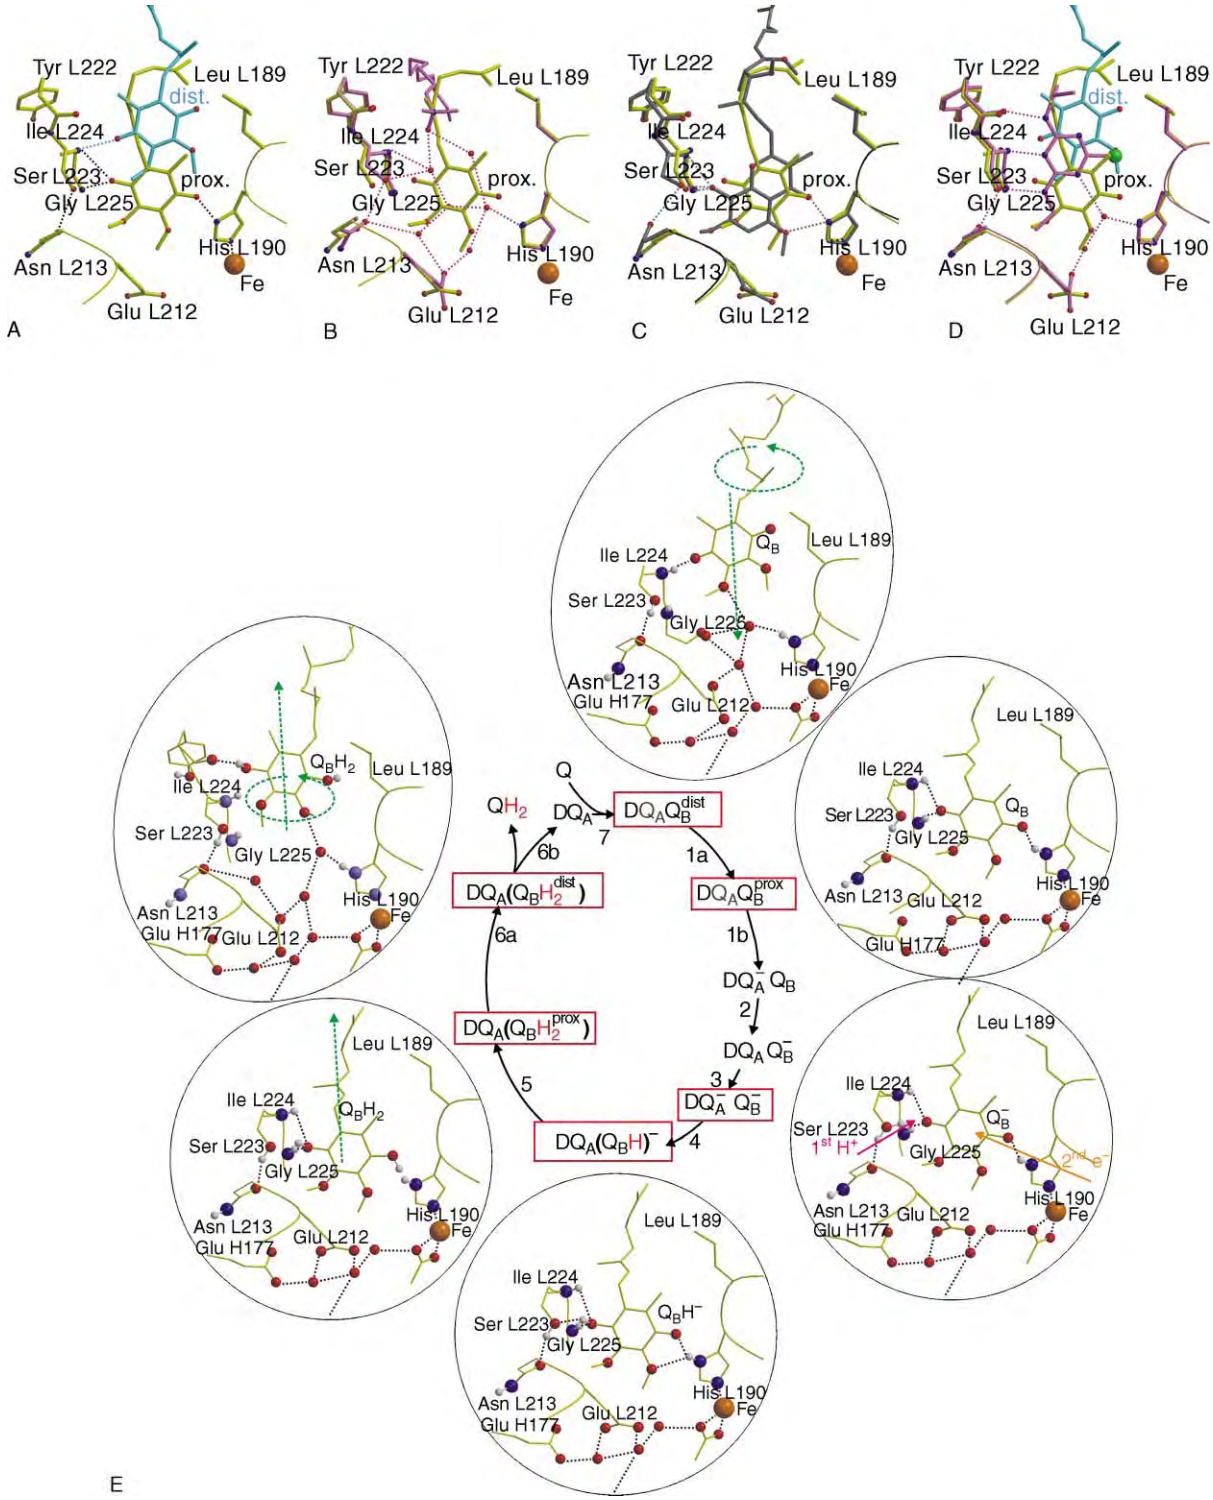

FIGURE 3 Derivatives at the Q_B site of the *Rp. viridis* RC. (A) Comparison of distal ($1PRC_{new}$, cyan) and proximal (2PRC, yellow) ubiquinone-binding sites. (B) Comparison of Q_B-depleted (3PRC, pink) and ubiquinone-2-occupied (2PRC, yellow) Q_B sites. (C) Comparison of stigmatellin binding (4PRC, gray) and ubiquinone-2 binding (2PRC, yellow). (D) Atrazine binding (5PRC, pink) compared to distal ($1PRC_{new}$, cyan) and proximal (2PRC, yellow) ubiquinone-binding sites. (E) Mechanistic implications of the structures 2PRC, 3PRC, 4PRC, and the revised model $1PRC_{new}$ for the events at the Q_B site within the reduction cycle of quinone to quinol. The numbering of the steps is analogous to that in Figure 1C. Hydrogen atoms are drawn as small light gray spheres. Dashed green arrows symbolize quinone movements.

The closely related *Rb. sphaeroides* can be grown under similar non-photosynthetic conditions, so that site-directed mutagenesis is also straightforward. As mentioned above, this RC is amenable to inspection by X-ray crystallography for structural changes. Many amino acids which were considered to be of importance for pigment binding, electron transfer or proton transfer were changed in *Rb. sphaeroides* RCs. In addition to mutagenesis, quinone or bacteriochlorin cofactors may be removed or replaced chemically with a wide range of similar compounds.

Site-directed mutagenesis of the RC from *Rp. viridis* is possible but more difficult. *Rp. viridis* can grow only under photosynthetic and, very slowly, under microaerophilic conditions. However, under microaerophilic conditions, the photosynthetic apparatus is hardly induced and photosynthetic growth conditions exert a selection pressure for revertants and suppressor mutants if the RCs are functionally impaired. On the other hand, very interesting herbicide-resistant mutants were obtained by classical selection procedures, with mutations some of which would not have been made by site-directed mutagenesis.

Some of these herbicide resistant mutants of the *Rp. viridis* RC have also been analyzed by X-ray crystallography. For instance, the mutation Tyr L222 → Phe unexpectedly leads to resistance against the herbicide terbutryn. In the wild type, Tyr L222 forms a hydrogen bond with the peptide carbonyl oxygen of Asp M43. Since this hydrogen bond is now missing, a stretch of the M subunit (M25–50) moves into a new position. The side chain of Phe L222 rotates by 90° into the herbicide binding site, thereby preventing the binding of terbutryn by steric hindrance, but at the same time introducing sensitivity to two other classes of photosystem II inhibitors normally inactive in bacterial RCs, the ureas and phenolics.

Using site-directed mutagenesis, the highly conserved Tyr L162, positioned halfway between D and the proximal heme3 (cytochrome c_{559}) in the *Rp. viridis* RC (see Figure 4A, below), was exchanged against a number of amino acids. All mutants grew photosynthetically. The redox potentials of D and c_{559} were changed by the mutations. The structures of two variant RCs (Tyr L162 → Phe and Tyr L162 → Thr) were determined and found not to differ significantly from the wild-type structure. Analysis of the kinetics of electron transfer led to the conclusion that the tyrosine residue at position L162 is not required for fast electron transfer from c_{559} to D^+.

Mutation of Arg C264 → Lys decreases the midpoint potential of heme3 (cytochrome c_{559}) from +380 mV to +270 mV, i.e., below that of heme2 (+320 mV, see Figure 1B). In the structure of the variant RC at 2.46Å resolution, no remarkable differences were found apart from the mutated residue itself. The halftime of electron transfer between heme2 and heme3 was the same as in the wild-type, indicating that the observed reaction rate is limited by the very uphill electron transfer from heme2 to heme4 (see Figure 1B).

Inter- and Intramolecular Electron and Proton Transfer and Catalytic Mechanism

Intramolecular Electron Transfer

The kinetics of light-induced electron transfer via Q_A to Q_B and of the re-reduction of the special pair have been detailed earlier. The reasons for the unidirectionality of electron transfer along the active A branch and not along the inactive B branch, despite the twofold pseudosymmetry of the LM core of the RC, have been the subject of numerous theoretical and experimental investigations. Slight differences in geometry, differences in rigidity, and differences in the amino acid composition of the L and M subunits have been suggested to contribute to unidirectionality. The latter aspect was specified by the theoretical identification of a large electrostatic field favoring charge separation along the A branch. A major contributor to the potential gradient is Arg L103, whose positive charge is stabilized by different sections of the polypeptide backbone. This dipolar stabilization leads to a much longer-range effect of the positive charge than if it were stabilized by a counter ion.

An experimental observation consistent with this electrostatic analysis is the finding that a site-directed double mutant in *Rb. capsulatus* RCs (Leu L212 → His; Gly L201 → Asp) appears to show significant electron transfer to ϕ_B. The first mutation leads to the incorporation of the β bacteriochlorophyll in the ϕ_A position and the second mutation introduces a negative charge close to B_A, thus making electron transfer down the A branch less favorable.

Quinone Reduction and Protonation

Both Q_A and Q_B sites are deeply buried within the photosynthetic reaction center complex, ~15Å from the cytoplasmic surface. Proton transfer to the reduced quinone within the Q_B site could occur by protons moving along a chain of proton donors and acceptors by a "proton wire," or hydrogen-bonded chain mechanism. Possible proton donors and acceptors are protonatable amino acid residues and water molecules. A number of the protonatable residues between the Q_B site and the cytoplasmic surface have been shown to be functionally relevant to the proton transfer process by analysis of site-directed mutations and second site revertants.

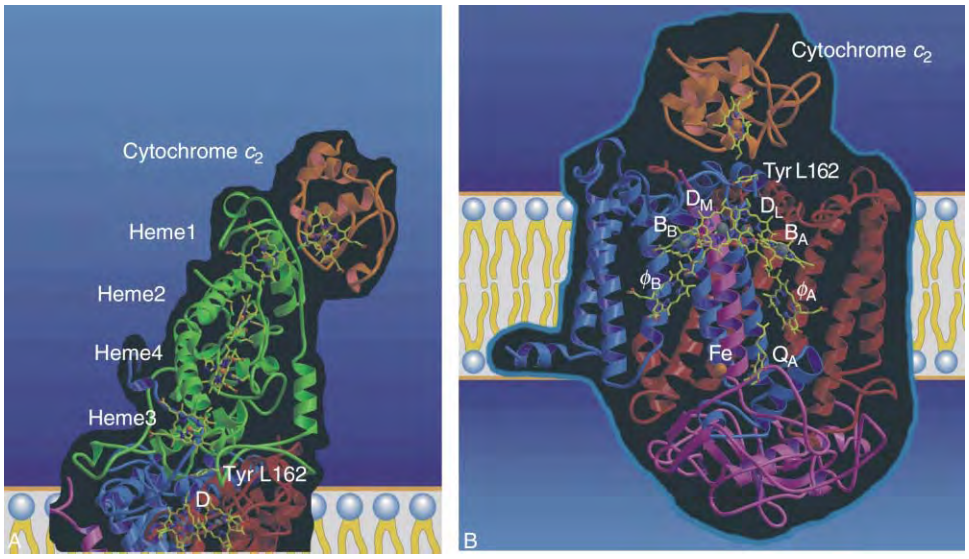

FIGURE 4 Cytochrome c_2 oxidation by the photosynthetic RCs of *Rp. viridis* and *Rb. sphaeroides*. (A) Reduction of the photo-oxidized tetraheme C subunit of the *Rp. viridis* RC (color-coding as in Figure 1A) by *Rp. viridis* cytochrome c_2 (orange). Theoretical docking as suggested from mutagenesis experiments. (B) Reduction of the special pair D in the *Rb. sphaeroides* RC (color coding of the L, M, and H subunits analogous to Figure 1A) by *Rb. sphaeroides* cytochrome c_2 (orange) as determined by X-ray crystal structure analysis (PDB entry 1L9B).

The observed effects can be due to the modification of the kinetics and thermodynamics of electron or proton transfer. Electrostatic calculations based on the X-ray structure coordinates of the RCs from *Rb. sphaeroids* and *Rp. viridis* led to the identification of residues that can contribute to the changes in equilibrium distributions of protons in the different redox states of the protein, thus helping to determine the role of the functionally important residues.

In combination with the results of electrostatic calculations, the crystal structures 3PRC, $1PRC_{new}$, 2PRC, and 4PRC already discussed (cf. Figures 3A–3D) can provide models for intermediates in the reaction cycle of ubiquinone reduction to ubiquinol (see Figure 3E). The binding of the incoming Q_B to the distal site displaces some of the water molecules present in the "empty" pocket. The quinone ring is flipped around the isoprenoid tail and further water molecules are displaced for the Q_B to occupy the proximal position (step 1a in Figure 3E). This is the position in which neutral Q_B accepts an electron from Q_A^-. The hydrogen bonds donated to the quinone will automatically lead to a tighter binding of the negatively charged semiquinone Q_B^- compared to the neutral Q_B (step 2). Additionally, the side chain of Ser L223 can reorient by rotation of its χ_2 (Cα–Cβ–Oγ–Hγ) torsional angle, thus establishing an additional hydrogen bond to Q_B^-. Coupled to the transfer of the second electron, the first proton is transferred, possibly via a transiently protonated Ser L223-OH_2^+, thus forming the monoprotonated, doubly reduced intermediate Q_BH^- (steps 3 and 4). After transfer of the second proton (step 5), movement of the quinol from the proximal to the distal position (step 6a) may be facilitated by increased stacking interactions of the aromatic ring systems with the Phe L216 ring and the diffusion of water molecules back into the pocket. The structures of these intermediates provide explanations for their relative binding affinities, as required for proper enzymatic function of the Q_B site. A rearrangement of hydrogen bonds, most prominently the reorientation of the Ser L223 side chain for Q_B reduction, as suggested by the scenario in Figure 3E, has also been calculated by Alexov and Gunner to be necessary to make Q_B reduction more favorable than Q_A reduction. These local rearrangements may constitute the conformational changes deduced to be required for function by a variety of experiments.

Cytochrome c_2 Oxidation

All four hemes of the *Rp. viridis* RC tetraheme C subunit are located close enough to the surface of the protein to accept electrons from soluble cytochrome c_2. Site-directed mutagenesis in another non-sulfur purple bacterium, *Rubrivivax gelatinosus*, has led to the identification of a patch of acidic residues immediately surrounding the distal low-potential heme1 of the tetraheme C subunit that apparently forms an electrostatically favorable binding site for soluble cytochromes. Thus all four hemes in the C subunit appear to be directly involved in the electron transfer toward the photo-oxidized special pair. Based on these findings, a model was proposed for the transient cytochrome c_2-RC complex for *Rp. viridis* (see Figure 4A).

In the case of the *Rb. sphaeroides* RC, which lacks the C subunit, the photo-oxidized special pair D^+ is directly re-reduced by cytochrome c_2. The structure of the co-complex of the *Rb. sphaeroides* RC and cytochrome c_2 has been determined by X-ray crystallography at 2.4Å resolution (cf. Figure 4B). In these crystals, D^+ is reduced by cytochrome c_2 at the same rate as measured in solution, indicating that the structure of the complex in the region of electron transfer is the same in the crystal and in solution. The binding interface can be divided into two domains. The first domain contributes to the strength and specificity of cytochrome c_2 binding and is a short-range interaction domain that includes Tyr L162 (cf. Figure 4B), and groups exhibiting non-polar interactions, hydrogen bonding, and a cation-π interaction. The second is a long-range, electrostatic interaction domain that contains complementary charges on the RC and cytochrome c_2. In addition to contributing to the binding, this domain may help steer the unbound proteins into the right orientation.

Relevance to Photosystem II

Based on the determined structure of the purple bacterial RC, very specific sequence homologies, and azidoatrazine labeling, the RC core of higher plant photosystem (PS) II was proposed to be similar to the LM core of the bacterial RC, with the D1 and D2 proteins corresponding to the L- and M subunits, respectively. This proposal could be verified experimentally. Recently, suitably designed, modified bacterial RCs have been shown to mimic tyrosine oxidation in PS II. In the absence of a high-resolution structure of the photosystem II RC, the purple bacterial RC still serves as the basis for models of PS II.

Glossary

cytochrome c_2 A heme-containing hydrophilic protein that functions as an electron carrier in both photosynthesis and respiration.

photosynthetic reaction center A membrane-intrinsic protein complex that carries out the primary photochemical event, the charge separation process.

purple bacteria Prokaryotes that catalyze photosynthetic electron transfer. Divided into *Rhodospirillaceae* (nonsulfur) and *Chromatiaceae* (sulfur).

ubiquinone (formerly called coenzyme Q) A quinone derivative with a variable length side chain of isoprene units (mostly 8–10). It occurs in the lipid core of the eukaryotic inner mitochondrial membranes and of bacterial cytoplasmic membranes and functions as a mobile, lipophilic carrier of electrons (and protons).

Biography

C. Roy D. Lancaster is a Group Leader in the Department of Molecular Membrane Biology at the Max Planck Institute of Biophysics in Frankfurt am Main, Germany. He holds an M.Sc. from McMaster University, Hamilton, Ontario, Canada, and a Dr. phil. nat. degree from J. W. Goethe University, Frankfurt am Main. He teaches Biochemistry and Biophysical Chemistry at J. W. Goethe University. His principal research interests are in the structure and mechanism of action of selected membrane protein complexes, including photosynthetic reaction centers.

Pyridoxal Phosphate

David E. Metzler
Iowa State University, Ames, Iowa, USA

Pyridoxal phosphate (PLP) is one of several small organic molecules known as coenzymes, compounds that are essential to all forms of life. PLP, together with over 60 different enzymatic proteins, acts to catalyze a variety of specific chemical reactions, many of which are steps in chemical pathways of synthesis or degradation of amino acids or of other nitrogen-containing compounds. PLP is the phosphoric acid ester of pyridoxal, a form of vitamin B_6. This vitamin is synthesized by plants and by many microorganisms, but humans must obtain it from dietary sources. The major form of vitamin B_6 in plants (and in vitamin pills) is the alcohol pyridoxol (pyridoxine). In tissues of our bodies (as well as of other organisms) this is converted to pyridoxol 5′-phosphate, which can be dehydrogenated (oxidized) to the aldehyde PLP (Figure 1). Some enzymes can convert PLP reversibly to pyridoxamine phosphate (PMP) by a process known as transamination (Figure 2). All organisms contain PLP and PMP, much of which is bound to enzyme proteins. Excess PLP is rapidly dephosphorylated to pyridoxal and oxidized to the corresponding carboxylic acid, pyridoxic acid.

Transamination

Transamination is a biologically important process by which living cells exchange the oxygen atoms of α-oxoacids with amino groups (and associated hydrogen atoms) of amino acids such as glutamic acid (Figures 1 and 2). The process occurs via two half-reactions. In the first the amino group is transferred from the amino acid to PLP to form PMP. In the second the PMP that is formed transfers the amino group to the carbon skeleton of the original oxoacid (Figure 2). During the reactions the PLP or PMP is held tightly in the active sites of the enzymes where it reacts rapidly and reversibly to form intermediates known as aldimines (Figure 3) or ketimines (Figure 4). The coenzymes function many times before the less tightly bound PMP loses its hold on the active site or the coenzyme is inactivated by a side reaction.

In the human body transaminases (aminotransferases) catalyze numerous steps in biosynthesis or breakdown of amino acids. For example, glutamic acid from the diet can donate nitrogen to oxoacids to form such amino acids as alanine and aspartic acid. In plants and other autotrophic organisms glutamic acid also donates nitrogen to additional oxoacids to synthesize amino acids that cannot be made in the human body.

The Variety of PLP-Dependent Reactions

Transamination is only one of many reactions of amino acids and other amines that are catalyzed by PLP-dependent enzymes. Some of these are listed in Table I. Groups *a*, *b*, and *c* in this table are defined by the cleavage of one of three possible chemical bonds, *a*, *b*, or *c*, in an amino acid substrate (see Figure 3). The enzymes in group *a*, which includes transaminases, initiate the reaction by removing the α-hydrogen as H^+. In this way each enzyme creates an intermediate chemical species, the quinonoid-carbanionic form (Figure 3). For transaminases and several other enzymes this intermediate has been identified by spectroscopic studies and X-ray crystallography. The quinonoid-carbanionic form reacts in different ways that depend upon the individual enzymes. Transaminases catalyze addition of an H^+ ion at a new position to create a ketimine form as illustrated in Figure 4. Subsequent hydrolysis yields PMP and the oxoacid product of the transamination.

Racemases, after removal of the α-hydrogen of the aldimine as H^+, add an H^+ ion back to the same carbon atom but from the opposite side of the planar quinonoid-carbanionic structure (Figure 3). The effect is to catalyze the interconversion of the two stereoisomers known as the L- and D-forms of the amino acid. Many bacteria form D-alanine from the predominate "natural" L-alanine using a PLP-dependent racemase. Bacteria utilize the D-alanine, as well as D-glutamic acid, formed by a special aminotransferase, in construction of their cell walls. The D-amino acids help provide protection from enzymes that act on L-amino acids. In a similar way small amounts of D-serine, which functions in the brain, are formed from L-serine by a racemase. A third type of reaction of a quinonoid-carbanionic species (Figure 3) is formation of the cyclic

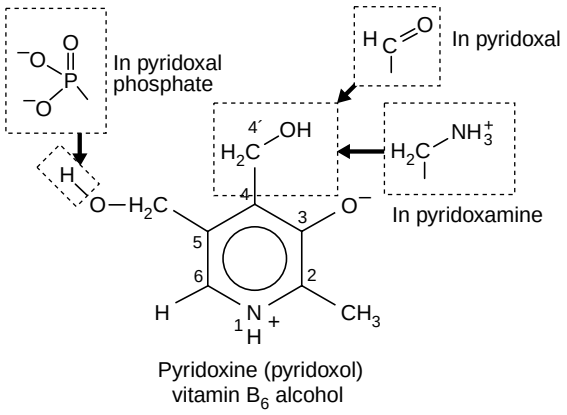

FIGURE 1 The vitamin B_6 (pyridoxine) family: pyridoxol, pyridoxal, pyridoxamine, and the coenzyme forms pyridoxal and pyridoxamine phosphates.

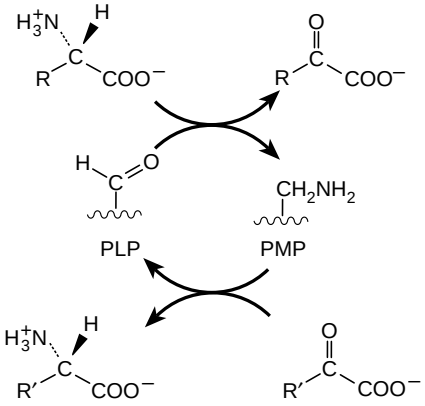

FIGURE 2 The transamination reaction by which amino groups are transferred from one carbon skeleton (in the form of an α-oxoacid) to another to form or to degrade an amino acid.

amino acid aminocyclopropane carboxylic acid, a precursor to the plant hormone ethylene. A large group of enzymes catalyze a fourth type of reaction, which involves elimination of a chemical group such as –OH, or –SH (designated – Y in Figure 3). This may be followed by a decomposition with liberation of NH_3 and other products or replacement of the eliminated group by a new group. These reactions play many roles in

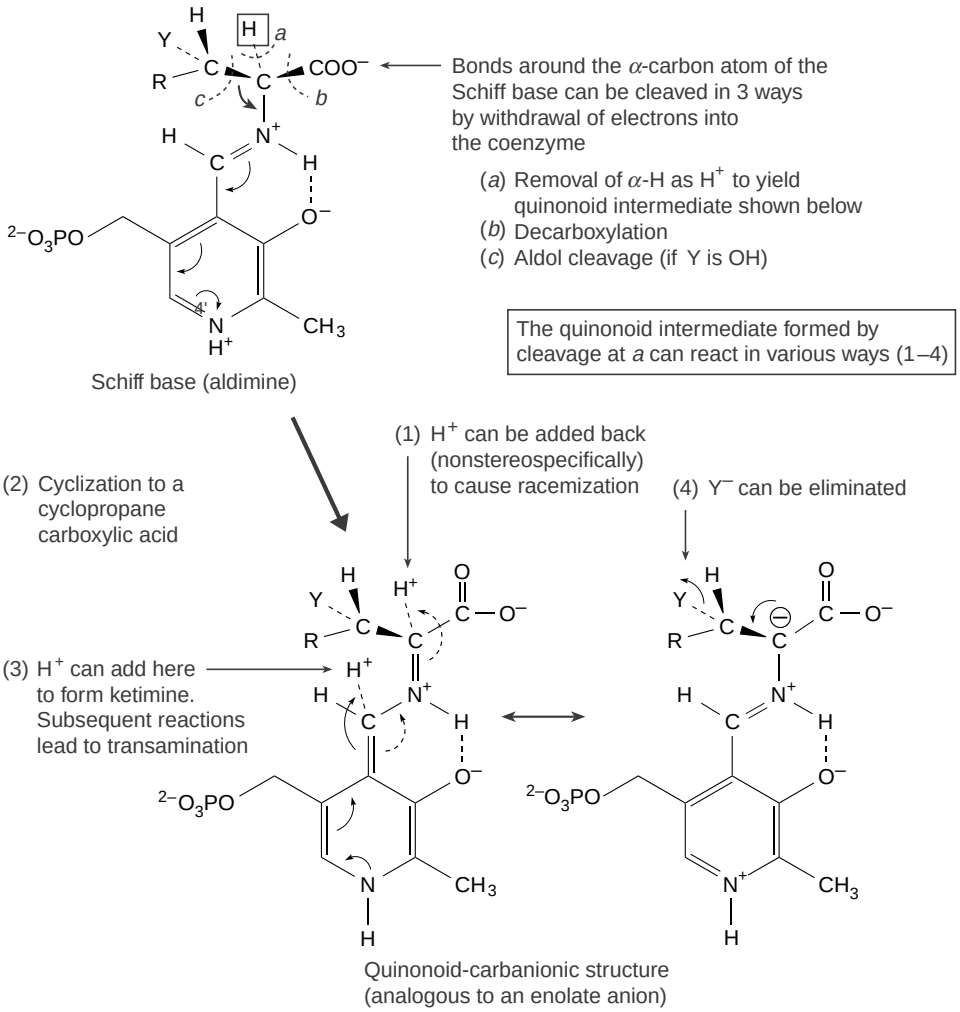

FIGURE 3 The action of pyridoxal phosphate in initiating catalysis of numerous reactions of α-amino acids. Completion of the various reactions requires a large variety of different enzyme proteins.

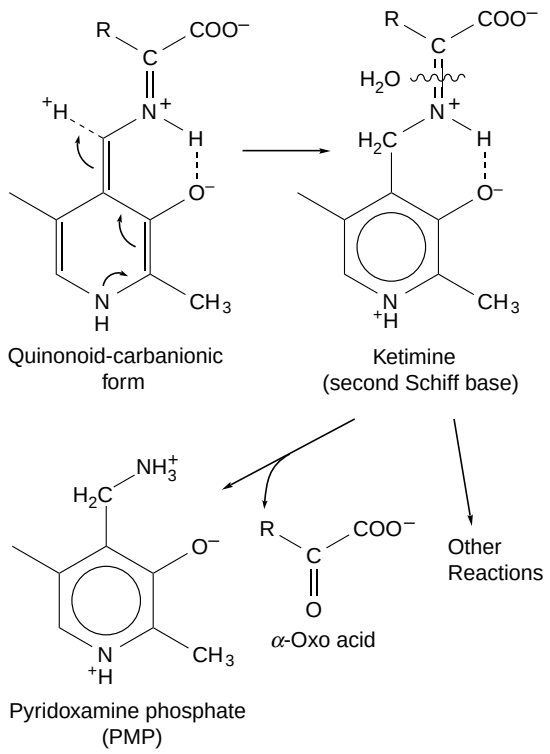

FIGURE 4 Conversion of the quinonoid-carbanionic intermediate into a ketimine which may give rise to PMP in a half-transamination reaction or may undergo alterations in the side chain (R–) to give other products.

TABLE I

Some Enzymes that Require Pyridoxal Phosphate as a Coenzyme

(a) Removing alpha hydrogen as H^+
- (1) Racemization
  - Alanine racemase
  - Serine racemase
- (2) Cyclization
  - Aminocyclopropane carboxylate synthase
- (3) Amino group transfer
  - Aspartate aminotransferase
  - Alanine aminotransferase
  - D-Amino acid aminotransferase
  - Branched chain aminotransferase
  - γ-aminobutyrate aminotransferase
  - ω-Amino acid:pyruvate aminotransferase
- (4) Beta elimination or replacement
  - D- and L-Serine dehydratases (deaminases)
  - Tryptophan indole-lyase (tryptophanase)
  - Alliinase
  - O-Acetylserine sulfhydrylase (cysteine synthase)
  - Tryptophan synthase

(b) Removal of alpha carboxylate as CO_2
- Diaminopimelate decarboxylase
- Glycine decarboxylase (requires lipoyl group)
- Glutamate decarboxylase
- Histidine decarboxylase
- Dopa decarboxylase
- Tyrosine decarboxylase

(c) Removal or replacement of side chain (or —H) by aldol cleavage or condensation
- Serine hydroxymethyltransferase
- δ-aminolevulinate synthase
- Serine palmitoyltransferase

(d) reactions of ketimine intermediates
- Aspartate γ-decarboxylase
- Selenocysteine lyase
- *Nif S* protein of nitrogen-fixing bacteria
- Gamma elimination and replacement
  - Cystathionine γ-synthase
  - Cystathionine γ-lyase
  - Threonine synthase

metabolism, both decomposing amino acids and forming new amino acids. A familiar example of such a decomposition reaction initiates the release of compounds giving the characteristic odor to crushed garlic.

A second major group of PLP-dependent enzymes (*b* in Figure 3 and Table I), the decarboxylases, remove a CO_2 molecule from a substrate. These enzymes also function in both catabolic and biosynthetic pathways. In each case the loss of CO_2 helps to drive the pathway in the needed direction. The most familiar decarboxylases participate in the formation of neurotransmitters such as γ-aminobutyrate, dopamine, adrenaline, and serotonin. A third major group of PLP-dependent enzymes (*c* in Figure 3 and Table I) catalyze cleavage or formation of carbon–carbon bonds in amino acids. These reactions resemble aldol-type reactions of organic chemistry. An example is formation of serine from glycine and formaldehyde. The latter, being a toxic compound, is carried as a derivative of another coenzyme tetrahydrofolic acid. The enzyme serine hydroxymethyltransferase (Table I), which catalyzes this reaction, allows bacteria and plants to form serine from glycine and also allows our bodies to form glycine from serine.

A fourth large group of enzymes (d in Table I) have more complex mechanisms that involve initial formation of ketimines followed by additional steps. One of these is a bacterial enzyme that converts the selenium-containing selenocysteine into L-alanine and elemental selenium (Se^0). Related enzymes in all organisms transfer sulfur, as S^0, into important metal–sulfur clusters such as Fe_4S_4 or the $MoFe_7S_9$ cluster, which participates in conversion of N_2 to HN_3 by nitrogen-fixing bacteria.

Chemical Mechanisms

Some details of mechanism have been indicated in Figures 3 and 4. However, many individual chemical steps performed in sequence are required of each enzyme. For several enzymes details have been established by use of spectroscopic techniques and by determination of

structures at atomic resolution by X-ray crystallography. In the first step of a reaction the enzymes must "recognize" a substrate molecule that repeatedly bumps against it as a result of the random movements of the molecules in the liquid environment in which it acts. Each protein, which is much larger than its substrate, contains a specifically constructed cavity that permits close contacts with the substrate molecule in the "active site." Close contact allows van der Waals attractive forces and electrostatic forces between oppositely charged ionic groups to hold the substrate if the latter has the appropriate structure. The PLP, which is also held by the protein, forms part of the binding cavity. In the free enzyme the PLP has a structure similar to that in Figure 3. However, the Schiff base linkage is not to the substrate, as in Figure 3, but to the $-NH_2$ group of a side chain of a lysine unit in the protein structure. This "internal aldimine" is the "resting form" of the PLP in the active site. Notice the positive charges provided by H^+ ions bound to the PLP at top and bottom and the negative charge provided by the oxygen atom attached to the ring (Figure 3). These charges provide electrostatic interactions that function both in the binding of substrates and in subsequent reactions. The reaction steps must occur rapidly, each step setting the stage for the next and permitting the whole sequence to be completed in a millisecond or less in some enzymes.

Recognition of a substrate often induces some movement in the protein. In some proteins a chemical group moves into a new position or a flap of protein folds over to partially cover the substrate. At some point in the sequence an H^+ ion must be removed from the $-NH_3^+$ group of the substrate. The resulting $-NH_2$ group, sometimes aided by a tilting of the bound PLP, moves toward the 4′-carbon atom of PLP and reacts via a chemical addition to form a transient geminal diamine (not shown here). Additional rapid steps release the lysine $-NH_2$ group and form the "external aldimine" shown at the top of Figure 3. The released lysine $-NH_2$ then serves as a "catalytic base" able to remove the α-H to form lysine $-NH_3^+$. In a transaminase the resulting lysine $-NH_3^+$ can place the H^+ that it carries onto the 4′ position of the PLP to form a ketimine (Reaction 3 of Figures 3 and 4). A water molecule then reacts to release the α-oxoacid product (Figure 3) and to leave PMP bound weakly to the protein. This represents the first of the two half reactions (Figure 2) occurring in transamination. The same sequence in reverse, using a different oxoacid, completes the transamination. This also illustrates the fact that every step catalyzed by transaminases is reversible, the overall reaction being driven by differences in concentration of reactants and products. The individual structures, chemical groups involved, and individual steps vary from one enzyme and one reaction type to another. Most do not form PMP as an intermediate. However, virtually all PLP-dependent enzymes use an active site lysine and multiple H^+ transfers.

The fundamental importance of the ring nitrogen at the bottom of the structure in Figure 3 lies in its action as an electron-attracting center. This is indicated by the curved arrows in the figure. The flow of electrons in this manner is thought to be coordinated with the major bond-breaking reactions catalyzed by these enzymes. In many of the enzymes a negatively charged carboxylate ($-COO^-$) side chain of the protein forms a hydrogen bond to the N^+-H at the bottom of the PLP ring. This carboxylate helps keep the H^+ on the ring and may also modulate the electron flow. At the same time the $-O^-$ group on the 3-position of the ring opposes the electron withdrawal from the substrate, perhaps assisting in other steps in the reaction. The $-O^-$ also helps to hold a proton onto the Schiff base nitrogen as shown in Figure 3. Each specific enzyme must hold its substrate in such a way that one of the bonds to the α-carbon atom (*a*, *b*, or *c* in Figure 3) is perpendicular to the plane of the pyridoxal phosphate ring. This is the bond that will be broken in the key step of the reaction sequence.

David E. Metzler is Professor Emeritus in the Department of Biochemistry, Biophysics, and Molecular Biology at Iowa State University, Ames, Iowa. He holds a Ph.D. from the University of Wisconsin. His research area is the chemistry of coenzymes, mechanism of their reactions, and the chemistry and structures of transaminases.

Pyrimidine Biosynthesis

Monika Löffler and Elke Zameitat
Philipps-University, Marburg, Germany

Pyrimidines are structural components in many natural compounds, such as nucleotides, nucleic acids, vitamins, pterins, and antibiotics. In all organisms pyrimidine nucleotides serve essential functions in cell metabolism as well as in nucleic acids such as the activation of sugars for polysaccharide and phospholipid synthesis, and glycosylation of proteins and lipids. In mammals pyrimidines are crucial to detoxification reactions in the liver. They are regarded as modulators of blood flow and have functions in the peripheral and central nervous system. The size of the pyrimidine nucleotide pools in cells is determined by the relative contributions of *de novo* synthesis and the interconversion reactions, together with salvage and presence or absence of enzymes of catabolic degradation. Some inherited disorders of pyrimidine biosynthesis and degradation have been diagnosed. Synthetic pyrimidine analogs act as antimetabolites and by selective interference in metabolic pathways, RNA and DNA synthesis, these and synthetic or natural enzyme inhibitors can combat infection, virus, tumor, and autoimmune diseases.

De novo Synthesis

Formation of UMP

Chemically, pyrimidines are heterocyclic six-membered ring structures containing two nitrogen atoms. The pyrimidine bases of nucleic acids possess an amino or hydroxyl group at position 4, and always an oxygen function at position 2. Thymine, in addition, has a methyl group at position 5. This gives rise to tautomeric structures for the bases uracil, cytosine, and thymine. The first pyrimidine nucleotide in cells, uridine monophosphate (UMP), is synthesized from CO_2, the glutamine amide group, aspartate, and phosphoribosyl-1-pyrophosphate (PRPP) (Figures 1 and 2). In contrast to the biosynthesis of purine nucleotides, the pyrimidine ring is assembled first and then linked to ribose phosphate to form a pyrimidine nucleotide. In higher eukaryotes, the cytosolic enzyme catalyzing formation of carbamoyl phosphate, carbamoylphosphate synthetase II (CPSase, Figure 1, no. 1), is distinctly different from carbamoylphosphate synthetase I, which is found in mitochondria as the first reaction of arginine biosynthesis and urea cycle in mammalian liver, and thus CPSase II is the first step committed to pyrimidine metabolism in higher animals (Figure 2). The formation of N-carbamoylaspartate (ATCase, no. 2) is the committed step for pyrimidine synthesis in prokaryotes, but is unregulated in eukaryotes. Next, the pyrimidine ring is cyclized by dihydroorotase (DHOase, no. 3). In higher animals the first three enzymes together with glutaminase (which provides the amino group from the side-chain amide group of glutamine) have been fused together (exon shuffling) during evolution to form a single polypeptide, CAD. This protein is located mainly in the cytosol and to some extent in the nucleus. Plants, such as prokaryotes, possess these enzymes individually encoded and located in chloroplasts. Formation of orotate from dihydroorotate is catalyzed by the mitochondrial flavoenzyme dihydroorotate dehydrogenase (DHODH, no. 4) transferring the reducing equivalents to the proximal acceptor ubiquinone and final acceptor molecular oxygen in the respiratory chain. Thus, the energy of dihydroorotate oxidation can be stored in ATP. Orotate phosphoribosyltransferase (OPRTase, no. 5) and orotidine decarboxylase (ODCase, no. 6) are fused on one bifunctional polypeptide, UMP synthase, operating in the cytosol of higher eukaryotes except in plants. Thus, only three genes (chromosomal location in Man: 2p21(CAD), 16q22 (DHODH), and 3q13 (UMP synthase)) code for the enzymes catalyzing the reaction of *de novo* UMP synthesis.

Regulation

Pyrimidine *de novo* synthesis is a demonstration that compartmentation within different parts of the cell – cytosol, mitochondria, chloroplasts – enhances the mode of regulation and flexibility of a metabolic pathway. Because of gene duplication, eukaryotes now have the potential to compartmentalize the synthesis of carbamoylphosphate for either pyrimidines (cytosol), or arginine and urea (mitochondria). In humans, urea synthesis takes place in liver only. The location of DHODH (Figure 2) in the inner mitochondrial membrane and its connection to the functional respiratory chain ensures the most efficient oxidation of

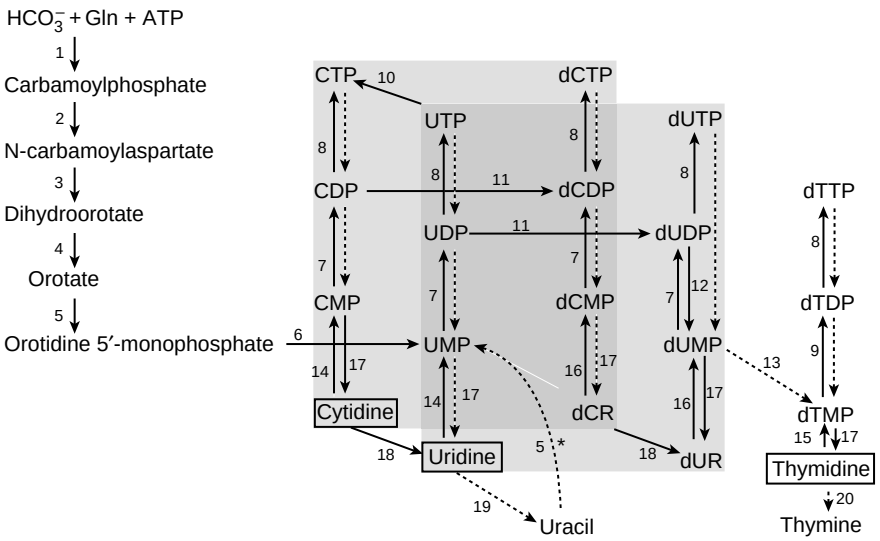

FIGURE 1 Biosynthesis and interconversion of pyrimidine nucleotides. The enzymes (given by numbers in the scheme) perform the *de novo* synthesis (1–6), interconversion of UMP to other ribonucleotides and deoxyribonucleotides (7–13), the salvage of preformed metabolites from dietary products or catabolism of nucleic acids (14–18), and the first steps of catabolism (19–20): 1, carbamoyl phosphate synthetase; 2, aspartate transcarbamoylase; 3, dihydroorotase; 4, dihydroorotate dehydrogenase; 5, orotate phosphoribosyltransferase; 6, orotidine 5′-monophosphate decarboxylase; 7, uridine(pyrimidine) monophosphate kinase; 8, pyrimidine diphosphate kinases; 9, thymidine monophosphate kinase; 10, cytidine triphosphate synthetase; 11, ribonucleoside diphosphate reductase; 12, dUDP phosphohydrolase; 13, thymidylate synthase; 14, uridine/cytidine kinase; 15, thymidine kinase; 16, deoxycytidine/uridine kinase; 17, 5′-nucleotidase; 18, (deoxy)cytidine deaminase; 19, uridine phosphorylase; and 20, thymidine phosphorylase. → (Pyro)Phosphohydrolases, not specified here. 5 * Uptake of 5′-fluoruracil by OPRTase.

dihydroorotate in aerobes. In turn, pyrimidine biosynthesis becomes a pacemaker for cell growth and proliferation under limited oxygen tension. Patients with acquired or inherited defects in mitochondria energetics, however, may suffer from a concomitant pyrimidine nucleotide starvation or imbalance. The two multienzyme polypeptides (CAD and UMP synthase) achieve a micro-compartmentation of pyrimidine *de novo* synthesis. Encoding five activities on two polypeptides simplifies the coordination and regulation of gene expression and activity. In addition, the direct transfer of a product from one active site to the next enzyme (channelling) considerably increases the efficiency of pyrimidine biosynthesis in higher eukaryotes. The first evidence for the location of CAD and UMP synthase close to the mitochondria surface has been obtained in a recent electron microscopic study. A metabolonlike complex facilitating the movement of substrate and product between cytosol and mitochondrion would allow a rapid increase in *de novo* synthesis when needed. The molecular regulation of pyrimidine *de novo* synthesis occurs at step 1 of CAD. The CPSase specific activity is low relative to that of the subsequent enzymes. It is allosterically activated by PRPP and feedback inhibited by UTP. The CAD activity is tuned by phosphorylation at two sites: MAP kinase action reduces the efficacy of UTP and increases that of PRPP, and phosphoylation by protein kinase A abolishes UTP inhibition but also makes PRPP less effective. Hence, by loosing feedback inhibition, carbamoyl phosphate synthesis is activated rapidly and sensitively in response to external growth-promoting signals. A modulation of ATCase activity is assured by a cooperative binding of carbamoyl phosphate and aspartate. An overflow into pyrimidine biosynthesis can occur from overabundant carbamoyl phosphate production in the case of urea cycle defects in liver: the carbamoyl phosphate leaves the mitochondria and is used by the ATCase of CAD. Under these conditions UMP synthase is the limiting enzyme, presumably because of an insufficient supply of PRPP for OMP synthesis, causing orotate to accumulate and to be excreted (secondary orotic aciduria).

Deficiency and Interference

The only hereditary but rare defect of pyrimidine *de novo* synthesis diagnosed so far in living humans is that of one or both activities in UMP synthase (OPRT domain or ODC domain) with different clinical manifestations, such as anemia or megaloblastic changes in bone marrow, immunodeficiency and gross orotate excretion in type 1 deficiency or orotidine plus orotic acid excretion, neurological deficits, and intellectual impairment, but no megaloblastic anemia in type 2 deficiency. There are

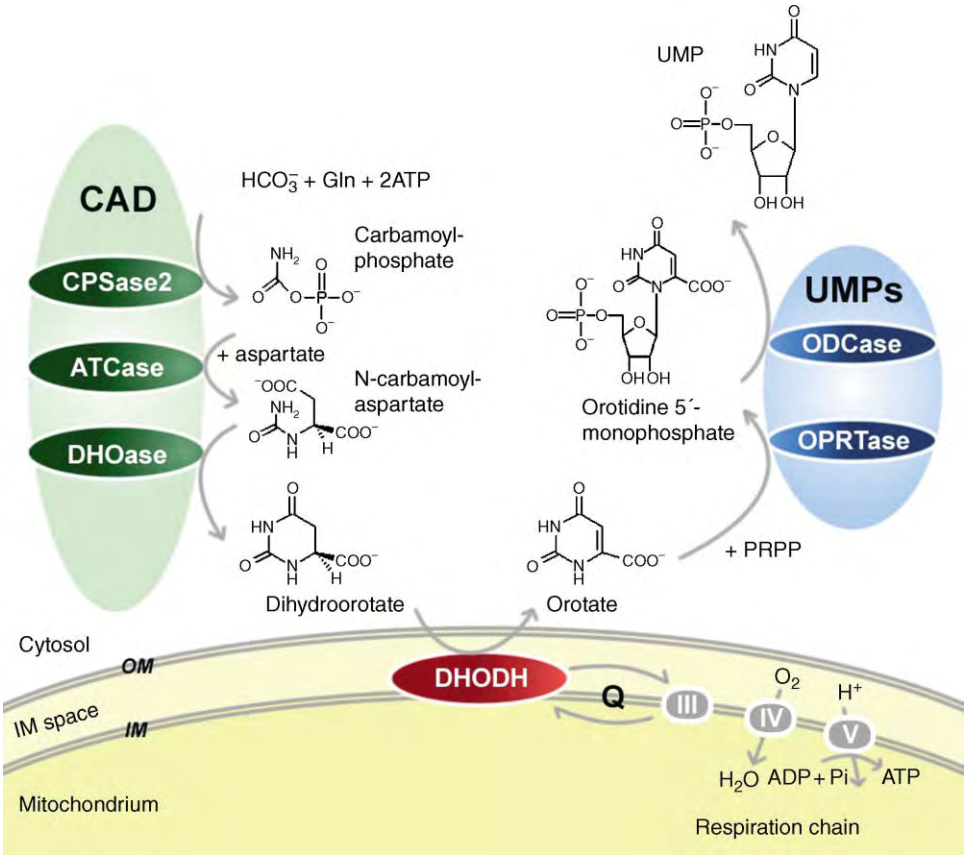

FIGURE 2 Compartmentation of pyrimidine *de novo* synthesis. In higher eukaryotes the multifunctional enzyme CAD (CPSase II + ATCase + DHOase, no. 1 + 2 + 3) and UMP synthase (OPRTase + ODCase, no. 5 + 6) are cytosolic, the monofunctional DHODH (no. 4) is in mitochondria and connected via ubiquinone (Q) to the functional respiratory chain at the stage of complex III (III). Electrons are transferred to oxygen via cytochrome oxidase (IV). ATP synthetase (V). Note that in plants no. 1,2,3 and no. 5 + 6 are in chloroplasts. In Gram-negative bacteria the quinone-dependent DHODH is attached to the plasma membrane. In Gram-positive bacteria and anaerobic yeasts all enzymes are cytosolic.

no specific inhibitors of CPSase of chemotherapeutic interest. N-phosphonoacetyl-L-aspartate (PALA), a model inhibitor of ATCase in prokaryotes, was clinically disappointing because gene amplification leading to overproduction of CAD caused resistance of human cancer cells. Current drug design for DHOase focuses on its Zn^{+2} center. Natural and chemical ubiquinone analogs, potent inhibitors against DHODH, failed to get clinical approval as anticancer drugs. The naphthoquinone atovaquone, a competitor for ubiquinone-dependent reactions, has been applied for treatment of opportunistic infections and malaria. The inhibition of DHODH by the isoxazol leflunomide, which was licenced recently, is central to the efficacy of this drug in treating rheumatoid arthritis and other autoimmune diseases. Antimetabolites of UMP synthase with anticancer activity but limited by toxicity at high dosage to patients (e.g., 6-azauracil, pyrazofurin) have been shown to suppress reproduction of *Toxoplasma gondii* and *Plasmodium falciparum*, because *de novo* pyrimidine synthesis is obligatory for these organisms to grow. Some widely used drugs, e.g., the calcium channel blockers nifedipine and nimodipine, were shown to suppress murine OMP decarboxylase and uridine kinase; barbiturates and aspirin interfered in the DHODH reaction. This emphasizes that the direct inhibition of pyrimidine biosynthesis is a potential side effect of drugs.

Interconversions in Pyrimidine Biosynthesis

Formation of Cytidine and Thymidine Nucleotides

Pyrimidine nucleotide di- and triphosphates are produced by ATP-dependent kinases (Figure 1, no. 7–9). CTP synthase (no. 10) catalyzes the formation of CTP from UTP using the amide group of glutamine – a GTP-dependent reaction (Figure 3A). Only at the time of DNA replication, do deoxynucleotide pools increase noticeably. Nucleoside 5′-diphosphate reductase

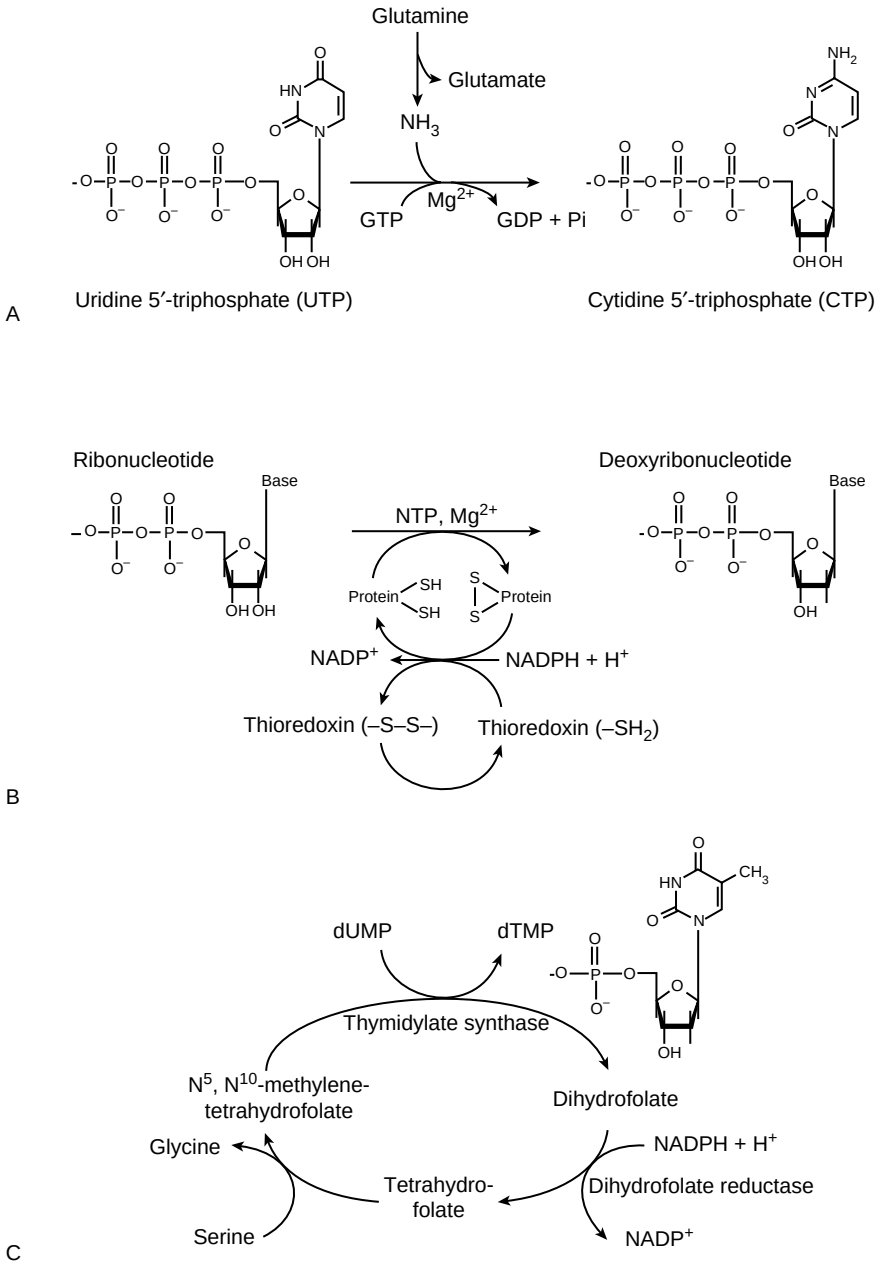

FIGURE 3 Formation of cytidine and thymidine nucleotides. (A) The synthesis of CTP from UTP by CTP synthase. (B) Conversion of UMP to dUMP by ribonucleotide reductase, schematic presentation of the enzyme. (C) The thymidylate synthase catalyzed reaction and regeneration of methylenetetrahydrofolic acid (THF) by means of dihydrofolate reductase.

(ribonucleotide reductase, no. 11) catalyzes the formation of deoxyribose (exchange of H for OH at C2′) of pyrimidine as well as purine ribonucleotides using NADPH and thioredoxin or glutaredoxin (Figure 3B). The product dUDP is dephosphorylated to dUMP (no. 12). In case of dUTP formation, this can effectively be reconverted to dUMP by the deoxyuridine triphosphate nucleotidohydrolase (pyrophosphohydrolase, Figure 1) in order to prevent its incorporation into DNA. dUMP is used by thymidylate synthase (no. 13) to form dTMP by means of (N^5, N^{10}-) methylenetetrahydrofolic acid (THF) as a one-carbon donor and reducing agent (Figure 3C).

Regulation

The enzymes of this part of pyrimidine synthesis are cytosolic. Their activity is strictly controlled by availability of substrates or by their products and other ribonucleotides and deoxyribonucleotides, respectively. This is a well-understood mechanism to ensure well-balanced pools of pyrimidine and purine

(deoxy)ribonucleotides in cells. For example, CTP is a negative effector of CTP synthase. This enzyme and CAD are connected with the cytoskeleton, hence are able to move around according to change in cell shape. Ribonucleotide reductase (no. 11) consists of two nonidentical protein subunits, one containing different effector binding sites, the other a nonheme iron and a tyrosyl radical generated by oxygen, giving the second control point for nucleic acid synthesis by O_2 in aerobes. This enzyme is subject to a sophisticated control mechanism, in which an excess of one deoxyribonucleotide inhibits reduction of all other ribonucleotides. Effective inhibition by dATP, dGTP, or dTTP explains the intrinsic toxicity of deoxyadenosine, deoxyguanosine, and thymidine to many organisms and the immunodeficiency in adenosine deaminase and purine nucleoside phosphorylase deficiency. dCTP and dTTP are major positive or negative effectors for the interconversion and salvage of deoxyribonucleosides. The key regulatory mechanism for thymidylate synthase is the delivery of THF by dihydrofolate reductase (Figure 3C). In plants and parasitic protozoa only, this enzyme is fused as a bifunctional polypeptide with thymidylate synthase.

Deficiency and Interference

Effective inhibitors of ribonucleotide reductase (e.g., hydroxyurea, HU) are potent inhibitors of DNA synthesis and hence of replication. HU also exerts a synergistic effect with nucleoside analogs used in the treatment of HIV-1. This is attributed to reduction in intracellular deoxyribonucleotides coupled with interference in antigen-dependent T-lymphocyte activation. However, the clinical application is disputed. It is noteworthy that healthy human lymphocytes do not pick up exogenous orotic acid, nor do they convert UTP to CTP. However, both these pathways are up-regulated in malignancy. Most of the CTP synthase inhibitors that have been developed and tested with experimental tumors are synthetic pyrimidine analogs (e.g., deazauridine and cyclopentenyl cytosine). Thymidylate synthase and dihydrofolate reductase are well-established target enzymes in cancer therapy using 5-F-UMP (from 5-fluoruracil which can be activated by OPRTase) and folate analogs (e.g., methotrexate) preventing THF regeneration.

Salvage

Phosphorylation and Dephosphorylation

The fact that hereditary orotic aciduria does respond to life-long supply with uridine but not to uracil indicated that pyrimidine nucleoside salvage can compensate for the lack of *de novo* synthesis in Man, if the dosage as food additive is in grams per day and increasing from child to adulthood. This is in direct contrast to purines where the gut mucosa contains a complement of enzymes which degrades all dietary purines to the end-product uric acid. Prominent salvage capacity is expressed in lymphoid cells, polymorphonuclear cells, and the central nervous system. Uridine, (deoxy)cytidine, and thymidine originating from daily nutrients or intracellular breakdown from nucleic acids are rescued from circulation by cytosolic (deoxy)ribonucleoside kinases that show a high level of specificity with respect to the base and sugar moieties, with ATP as the major phosphate donor (no. 14–16). In contrast to purines the salvage of free pyrimidine bases at the expense of PRPP does not occur in any mammalian tissue. Orotate as a natural component of dairy food is taken up and converted to UMP only by liver and erythrocytes. It can also stem from food additives such as zinc orotate and magnesium orotate, which are used for metal ion substitution therapy. Salvage of deoxycytidine is important in DNA repair. Deoxycytidine kinase is also responsible for activating some nucleoside analogs as well as natural deoxyribonucleosides – such as deoxyadenosine in adenosine deaminase deficiency. Pyrimidine and purine deoxyribonucleoside kinases seem to have evolved from a common progenitor multisubstrate kinase. Multisubstrate deoxyribonucleoside kinases were found in several insect species and shown to phosphorylate pyrimidines as well as purine (deoxy)nucleosides with high efficiency. The dephosphorylation of pyrimidine(deoxy)ribonucleoside monophosphates is catalyzed by 5′-nucleotidases (no. 17) which are found to occur as specific isoforms in different tissues. This reaction is a prerequisite for transport and delivery of pyrimidines by the circulation. In cells uridine and deoxyuridine can be formed from cytidine and deoxycytidine by cytidine deaminase (no. 18). The cleavage of uridine and thymidine by phosphorylases (no. 19–20) to the appropriate bases and ribose-1-phosphate would initiate the catabolic pathway.

Regulation

The balance between excretion and uptake is set by intracellular substrate cycles involving 5′-nucleotidases, kinases, and nucleoside transport through the plasma membrane of cells. Uridine is taken up effectively by a carrier-mediated concentrated transport process or by cotransport, by all human cells except erythrocytes.

Deficiency and Interference

Different mutants of the pyrimidine-5′nucleotidase are known causing enzyme deficiency. This is inherited as an

autosomal recessive trait. The symptoms include nonspherocytic hemolytic anemia, splenomegaly, and hepatomegaly; gross elevation in erythrocyte UTP/CTP are characteristic findings. A different deficiency of 5′-nucleotidase associated with hemolytic anemia has been described in patients with lead poisoning or thalassemia. Deficiency of the mitochondrial form of thymidine phosphorylase has major effects on many systems in humans. Patients with mutations in the mitochondria-specific thymidine kinase-2 develop myopathy and depletion of muscular mitochondrial DNA. Pyrimidine(deoxy)ribonucleoside kinases are critical constituents for interference by pharmacological agents: they are of key importance for the channelling of nucleoside analogs (such as arabinosyl cytosine, azidothymidine, 2′3′-dideoxycytidine) in cell metabolism of human and pathogens; mutants of thymidine kinases from virus and other organisms are proposed as "suicide agents" for gene therapy of cancers. On the other hand, strategies for inhibition of pyrimidine biosynthesis by drugs can be anticipated in cells with high activities in the salvage reactions. This aspect underlies current research on structure and function of pyrimidine (deoxy)ribonucleoside transporters in plasma and mitochondria membranes and their connection with salvage and biosynthesis of pyrimidines.

Monika Löffler is a Professor for Biochemistry at Philipps-University, Marburg, Germany. Her present research interest is enzymology of pyrimidine biosynthesis, its crosstalk to functional mitochondria. Further work of the group, metabolomics of pyrimidine metabolism in Man, is devoted to improve diagnosing and treating inherited and acquired disorders.

Elke Zameitat, having secured a diploma and degree in human biology, and presently a Ph.D. student, is involved in cloning, expression, and characterization of recombinant dihydroorotate dehydrogenase from different organisms, also for structure–activity relationship studies with inhibitors.

Pyruvate Carboxylation, Transamination, and Gluconeogenesis

Sarawut Jitrapakdee
Mahidol University, Bangkok, Thailand

John C. Wallace
University of Adelaide, Adelaide, Australia

The processes of transamination and pyruvate carboxylation combine to provide the pathway of gluconeogenesis with one of its principal substrates. For example, in transamination, a single amino acid (e.g., alanine) transfers its amine group to a ketoacid (typically α-ketoglutarate or oxaloacetate) to form their corresponding amino acids (i.e., glutamate and aspartate) while it is converted to its corresponding ketoacid (viz., pyruvate). Pyruvate carboxylation yields oxaloacetate, essential for gluconeogenesis in liver and kidney, for glyceroneogenesis in adipose tissue, and for the continuing operation of the Krebs tricarboxylic acid cycle. Gluconeogenesis is essential in maintaining normal blood glucose concentration during the postabsorptive state and especially in starvation, enabling brain, blood cells, and renal medulla to continue functioning properly.

Gluconeogenesis

Overview

Glucose occupies a central role in metabolism, both as a fuel for certain tissues and as a precursor of essential structural and other biomolecules in most tissues. The maintenance of a supply of glucose is essential for brain, renal medulla, and both red and white blood cells. These tissues rely exclusively on glucose as their energy source under normal circumstances, yet unlike liver and muscle do not store glucose as glycogen. When carbohydrate is not available from dietary sources in adequate amounts the blood glucose level is maintained within relatively narrow limits by a combination of glycogenolysis and gluconeogenesis. Liver glycogen can be broken down to release glucose into the blood circulation to other tissues, but it is usually depleted within 18–72 h after meals, depending on the species. Liver and kidney cortex cells circumvent this situation, especially during prolonged starvation, by having the pathway to synthesize glucose from substrates such as lactate derived from glycolytic tissues like skeletal muscle and red blood cells, glycerol from the breakdown of triglycerides stored in adipose tissue, and certain amino acids derived from the breakdown of muscle and other tissue proteins. The conversion of these precursor molecules to glucose is known as "gluconeogenesis." Gluconeogenesis, in part a reversal of glycolysis occurs exclusively in liver and kidney cortex utilizing most of the glycolytic enzymes except for three steps: (1) the conversion of pyruvate to phosphoenolpyruvate (PEP) via oxaloacetate, (2) fructose 1,6-bisphosphate to fructose-6-phosphate, and (3) glucose-6-phosphate to glucose. These reactions cannot be simply reversed by pyruvate kinase, phosphofructokinase and hexokinase, respectively, due to the large negative free energy changes in the direction of glycolysis. However, liver and kidney cortex cells overcome this situation by having another four enzymes including pyruvate carboxylase (PC) working in tandem with phosphoenolpyruvate carboxykinase (PEPCK) to form PEP, along with fructose-1,6-bisphosphatase and glucose-6-phosphatase which bypass the energy barriers as shown in Figure 1.

Control of Gluconeogenesis

As these three steps (often known as three "substrate cycles") are catalyzed by four separate enzymes, they are the targets to be controlled by short- and long-term mechanisms. Short-term regulation (seconds to minutes) of hepatic gluconeogenesis can be achieved through hormonal changes which in turn alter the enzymatic activities of the bifunctional enzyme 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase (PFK-2/F2,6BPase), and also of 6-phosphofructo-1-kinase (PFK-1), fructose-1,6-bisphosphatase (F1,6BPase) and pyruvate kinase (PK). Plasma glucagon and catecholamines, elevated during fasting, trigger an increase in cAMP levels leading to a rise in protein kinase A activity that results in the phosphorylation of pyruvate kinase and thus a

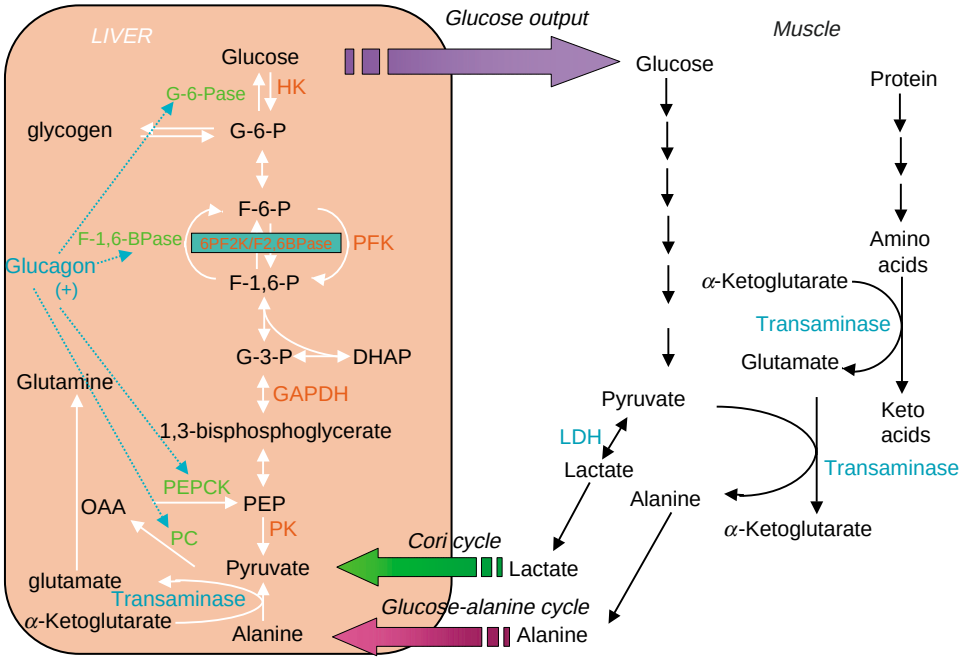

FIGURE 1 Glycolytic and gluconeogenic pathways. Also shown are the Cori cycle and glucose–alanine cycle. In glycolysis, glucose is oxidized by various enzymes to produce pyruvate, while in gluconeogenesis pyruvate is reconverted to glucose using most of the glycolytic enzymes plus four different enzymes, i.e., PC, PEPCK, fructose-1,6-bisphosphatase (F-1,6-BPase), and glucose-6-phosphatase (G-6-Pase). Lactate produced by anaerobic glycolysis in muscle can be converted to pyruvate by lactate dehydrogenase (LDH) in liver as part of the Cori cycle, while alanine produced by the breakdown of muscle protein can also be converted to pyruvate by transaminase in liver as part of glucose-alanine cycle. DHAP, dihydroxyacetone phosphate; HK, hexokinase; PFK, phosphofructokinase; GAPDH, glyceraldehyde-3-phosphate dehydrogenase; PC, pyruvate carboxylase; PEPCK, phosphoenolpyruvate carboxykinase.

decrease in its activity. Glucagon also exerts its effects on 6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase through the same mechanism as for pyruvate kinase, resulting in the phosphorylation of this bifunctional enzyme. This leads to an increase in its F2,6BPase activity and a concomitant loss of its PFK-2 activity. The resulting reduction in the level of fructose-2,6-bisphosphate derepresses fructose-1,6-bisphosphatase activity while also reducing the activities of both phosphofructokinase and pyruvate kinase. These events therefore represent a major force in driving glucose metabolism in a gluconeogenic direction.

Long-term regulation (minutes to hours) of glucose metabolism can also be effected via hormonal changes. These occur when the dietary intake is low in carbohydrate, during starvation or prolonged exercise – all conditions which lead to low levels of insulin and high levels of plasma glucagon, catecholamines, and glucocorticoids. Glucagon and catecholamines act via cAMP to exert their effects by stimulating the transcription of genes encoding gluconeogenic enzymes. Therefore, it is not surprising to see the presence of cAMP-responsive elements in the promoters of the genes encoding PEPCK, fructose-1,6-bisphosphatase, and glucose-6-phosphatase. Glucocorticoids, acting via the glucocorticoid receptor, bind to the responsive element on promoters of PEPCK and glucose-6-phosphatase, and up-regulate transcription of both genes. These changes also drive glucose metabolism in the direction of gluconeogenesis. However, the opposite effect occurs when animals are fed a carbohydrate-rich diet that causes an increase in plasma insulin levels. The insulin signaling cascade results in the inhibition of transcription of genes encoding gluconeogenic enzymes. The very fine control of these enzymes' genes via hormones is a hallmark of long-term regulation in gluconeogenic tissues.

It is noteworthy that gluconeogenesis does not begin in the liver of rodents until immediately after birth as the maternal circulation provides glucose for the developing fetus. Of the four gluconeogenic enzymes present in liver, pyruvate carboxylase, PEPCK, and glucose-6-phosphatase are present in the liver at negligible levels before birth but appear rapidly after birth consistent with the onset of gluconeogenesis. The hormonal mechanism which mediates the increase in these three enzymes in liver at birth is not clearly defined. At least one of the following events that occur within a few hours after birth is likely to regulate gluconeogenesis: (1) a rapid and marked fall in the concentration of blood glucose which was hitherto supplied to the fetus from the maternal circulation via the placenta, and a low portal glucose concentration caused by a low

carbohydrate diet. This results in an increase in the cAMP level via elevated levels of glucagon and epinephrine and a low level of insulin. (2) An increased supply of plasma fatty acids to the liver caused by the hydrolysis of triglycerides in dietary milk.

Pyruvate Carboxylation

The carboxylation of pyruvate is a very important anaplerotic reaction to provide oxaloacetate for the Krebs cycle to operate continuously, as oxaloacetate and other intermediates are withdrawn from the cycle for a number of biosynthetic pathways including gluconeogenesis in liver and kidney, production of neurotransmitter substances in the glial cells of the brain, glyceroneogenesis in adipocytes, and fatty acid synthesis in liver, adipocytes and lactating mammary glands (see Figure 2). Therefore, oxaloacetate must be replenished at all times by the activity of PC (EC 6.4.1.1) that catalyzes the carboxylation of pyruvate to oxaloacetate as described in the following equation:

$$\text{Pyruvate} + HCO_3^- + \text{ATP} \overset{Mg^{2+},\text{acetyl-CoA}}{\rightleftharpoons} \text{oxaloacetate} + \text{ADP} + \text{Pi}.$$

PC contains covalently bound biotin as a prosthetic group that acts as a swinging arm to convey CO_2 between the two catalytic domains, i.e., the biotin carboxylation domain and the transcarboxylation domain. In mammals, PC is located in the mitochondrial matrix where its anaplerotic activity can be directly applied to the Krebs cycle. The control of pyruvate carboxylation can be achieved by three different ways: (1) control of substrate supply, (2) control by the enzyme's allosteric regulator(s), and (3) transcriptional/posttranscriptional control (see Table I).

Control by Substrate Supply

The first step to regulate pyruvate carboxylation is to control the availability of substrates to be converted to pyruvate and enter the mitochondria. These substrates are lactate, and gluconeogenic amino acids, principally alanine but also serine and several others indirectly. Due to a limiting O_2 supply to the muscle cells during intense exercise, skeletal muscle glycogen is metabolized anaerobically by the glycolytic pathway for ATP production. The pyruvate derived from glycolysis is reduced to lactate with the concomitant oxidation of NADH by the action of lactate dehydrogenase. This lactate is exported from muscle cells to the liver via the blood circulation. Lactate once taken up by liver cells is converted back to pyruvate and subsequently carboxylated to oxaloacetate for gluconeogenesis. In what is known as the Cori cycle, glucose produced from liver cells is then circulated to muscle to replenish its glycogen after the exercise. Therefore intense exercise enhances gluconeogenesis via pyruvate carboxylation. Breakdown of muscle protein during starvation yields gluconeogenic amino acids that also contribute to the supply of pyruvate. Glycerol derived from the hydrolysis of triglyceride in adipose tissue during prolonged fasting and in

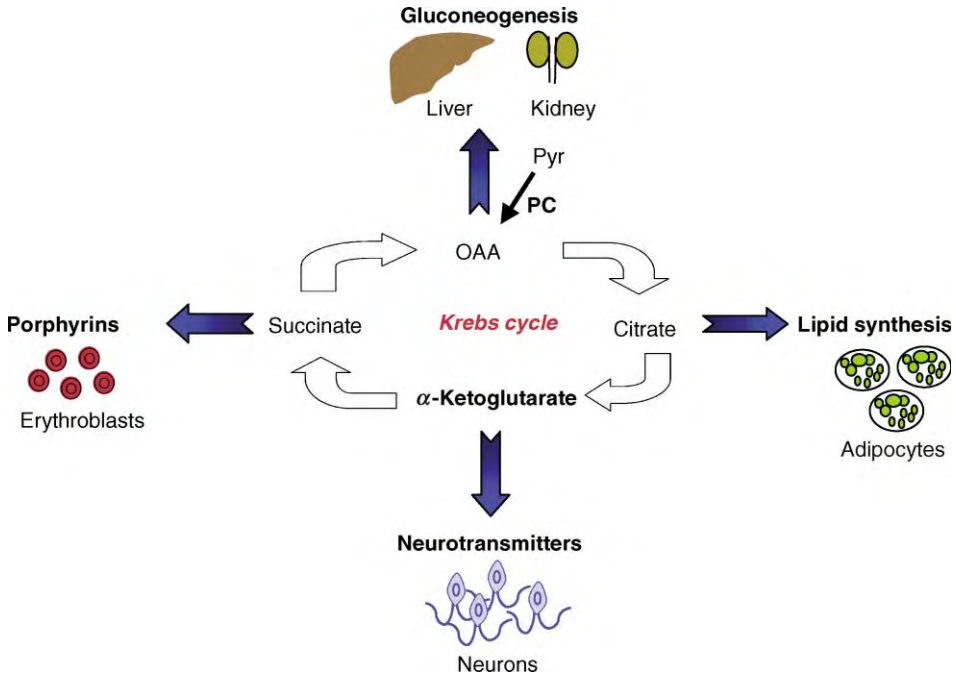

FIGURE 2 The anaplerotic function of PC in mammalian tissues in which oxaloacetate is withdrawn from the Krebs tricarboxylic acid cycle for various biosynthetic pathways. OAA, oxaloacetate; Pyr, pyruvate.

TABLE I

Factors Affecting Pyruvate Carboxylation

Factor	Mechanism of action
Insulin	Inhibits PC gene expression; inhibits protein breakdown and hence restricts substrate supply
Thyroid hormone	Stimulates PC synthesis
Glucocorticoids	Increases substrate supply
Glucagon	Increases ATP/ADP ratio
Acetyl-CoA	Allosteric activation

diabetes is another substrate that is converted to glucose. It has been estimated that ~15% of hepatic glucose production are derived from the Cori cycle while ~12% are derived from the glucose–alanine cycle. Glycerol accounts to only 2% of hepatic glucose production in the postabsorptive state but can become more significant (~10–15%) in prolonged fasting or in diabetes.

Control by Allosteric Regulator

Short-term regulation of pyruvate carboxylation is principally controlled by its allosteric activator, acetyl-CoA. The β-oxidation of free fatty acids during fasting results in an elevated level of acetyl-CoA in the mitochondria, and the binding of acetyl-CoA by PC results in its allosteric activation thereby enhancing pyruvate carboxylation.

Control by Transcriptional/ Posttranscriptional Mechanisms

Long-term regulation of pyruvate carboxylation is a slow response process taking several hours or days and involves alteration of transcriptional and posttranscriptional mechanisms. In rat, two tissue-specific promoters of the PC gene are activated differentially to mediate the production of mRNA transcripts bearing different 5′-noncoding regions with distinct translational efficiencies. Pathophysiological conditions including diabetes, hyperthyroidism, and obesity are known to affect pyruvate carboxylase activity in the long term.

Link between Pyruvate Carboxylation and Insulin Secretion

It is known that pancreatic islets contain high concentrations of PC mRNA and protein, and that the latter's specific activity is equivalent to that in liver and kidney. However, the islets lack PEPCK activity and its mRNA. This provides us with a clue that here PC does not serve the purpose of gluconeogenesis. It has been shown that there are two alternative routes for using oxaloacetate produced by PC, i.e., the pyruvate/malate and the pyruvate/citrate shuttles operating across the mitochondrial membrane. These routes are essential for glucose-induced insulin secretion as specific inhibition of PC activity also reduces the secretion of insulin in response to glucose, further suggesting a role for PC in insulin secretion.

Transamination

Breakdown of Amino Acids in Liver

Dietary proteins are digested by enzymes in the stomach and small intestine to yield various amino acids. This process provides both nitrogen and carbon sources for various biosynthetic pathways. Once transported to liver, these amino acids are subjected to a variety of enzymatic reactions, some are anabolic while others are catabolic. Of the latter the first is called "transamination." This process removes the NH_2 group from each amino acid to produce an α-keto acid. The α-amino group is most frequently transferred to α-ketoglutarate to form glutamate. This reaction is catalyzed by enzymes called a "transaminase" or an "aminotransferase." For example, alanine aminotransferase or aspartate aminotransferase transfers the α-amino group from alanine or aspartate to α-ketoglutarate:

$$\text{Alanine} + \alpha\text{-ketoglutarate} \leftrightarrow \text{pyruvate} + \text{glutamate}.$$

$$\text{Alanine} + \alpha\text{-ketoglutarate} \leftrightarrow \text{oxaloacetate} + \text{glutamate}.$$

Transaminases or aminotransferases are known to require pyridoxal phosphate (a derivative form of vitamin B6) as a cofactor of the reaction. Glutamate is then converted back to α-ketoglutarate by glutamate dehydrogenase in liver. This reaction yields NH_3, which enters the urea cycle.

Breakdown of Amino Acids in Muscle and the "Glucose–Alanine Cycle"

At rest, muscle can utilize fatty acids, ketone bodies, or blood glucose as carbon sources, depending on their availability, while during intense exercise muscle utilizes glycogen as an energy source via anaerobic glycolysis to produce lactate. However, vigorously contracting muscle or prolonged starvation triggers protein breakdown thereby producing amino acids which either can be oxidized or in some cases used as gluconeogenic substrates. As mentioned above, transamination of most amino acids prior to the oxidation of their ketoacid derivative produces

glutamate as the end product. The α-amino group of glutamate can be transferred to pyruvate, the readily available product of glycolysis in muscle, to form alanine. The alanine is then transported through the blood circulation to the liver where alanine is converted back to pyruvate by alanine aminotransferase. This reaction is exceptionally important in liver as it provides pyruvate to be used for gluconeogenesis. Glucose produced in liver is then circulated back to the muscle where it is utilized for glycogen synthesis or as an energy source during rest periods. The transfer of an amino group from glutamate to pyruvate to form alanine in muscle and the conversion of alanine back to glucose via pyruvate is known as "glucose–alanine cycle"(see Figure 1). The operations of the glucose–alanine cycle and the Cori cycle in liver provide an economic means to produce glucose from the end products of muscle metabolism.

Biography

Sarawut Jitrapakdee has studied the regulation of pyruvate carboxylase in liver and pancreatic islets with particular reference to glucose-induced insulin secretion by β-cells and the relevance of this to obesity and type 2 diabetes. He has been awarded several distinguished prizes for his graduate studies at the University of Adelaide and subsequently since taking up a Faculty position at Mahidol University, Bangkok.

John C. Wallace undertook postdoctoral studies on gluconeogenesis with Sir Hans Krebs (Oxford), and with the codiscoverers of pyruvate carboxylase, Professor Merton Utter (Cleveland) and Dr. Bruce Keech (Adelaide). He has published 70 papers on structure/function studies of pyruvate carboxylase, and has been awarded the LKB Medal and the Lemberg Medal by the Australian Society for Biochemistry and Molecular Biology. His other research interests include the insulin-like growth factor system with 69 publications and several international patents in this area.

Pyruvate Dehydrogenase

Sam A. Johnson
Salk Institute, La Jolla, California, USA

James G. McCormack
OSI Pharmaceuticals Ltd., Oxford, UK

The Pyruvate dehydrogenase (PDH) complex (EC 1.2.4.1 + 2.3.1.12 + 1.8.1.4) is a multi-enzyme complex, which in eukaryotes is located within the mitochondrial matrix associated with the inner mitochondrial membrane. PDH catalyzes the oxidative decarboxylation of pyruvate with the concomitant formation of carbon dioxide, acetyl CoA, and NADH (reaction [1]), and thus forms the link between the glycolytic and Kreb's citric acid cycle (TCA) pathways.

$$\text{Pyruvate} + \text{CoA} + \text{NAD}^+ \rightarrow \text{Acetyl-CoA} + \text{NADH} + \text{H}^+ + \text{CO}_2 \quad [1]$$

This reaction is essentially irreversible ($\Delta G^{o'} = -39$ kJ) and, as it represents the "point-of-no-return" for carbohydrate utilization in mammals, it is highly regulated. This is primarily achieved by regulation of the amount of PDH in the active state by reversible phosphorylation by multiple dedicated kinases and phosphatases, and also by end-product inhibition.

Components and Structure of PDH

The known components of the PDH complex and its associated regulatory enzymes are listed in Table I. PDH complex isolated from mammalian tissues has an overall molecular weight of 7–10 MDa (i.e., ~2 times that of a eukaryotic ribosome) and can be visualized using an electron microscope.

The structure of the mammalian PDH complex is based around a core 60-mer of 6 E3-BP and 54 E2-subunits arranged as a pentagonal dodecahedron (E3-BP has previously been called component (or protein) X). The inner domains of the E2 and E3-BP-subunits interact to produce the core frame of the complex. The lipoyl domains protruding from the core contain flexible linkers allowing the outer domains some mobility with respect to the core. Both E2 and E3-BP have subunit-binding domains that bind other proteins in the complex and anchor them to the core 60-mer (see Figure 1). The lipoyl groups (covalently attached to E2 lysines) participate in catalysis and their flexibility relative to the core is essential for this function. The E3 component is also present in two similar complexes, the 2-oxo-acid dehydrogenase and the branched chain oxo-acid dehydrogenase complexes, as well as in the glycine-cleavage system, all of which are also located within the mitochondrial matrix.

It is thought that the six E3-BPs are located at the faces of the pentagons where they each bind an E3 homodimer. The $\alpha_2\beta_2$ heterotetramers of E1 (20–30 per complex) are thought to be localized to the edges of the pentagons. The regulatory kinases and phosphatases associate with the E2-subunits and act on serine residues in the E1α-subunits. The precise stoichiometry of the regulatory proteins in the complex is unknown but there are estimated to be approximately three molecules of kinase per complex. This is obviously fewer than the number of E1-subunits and it is thought the kinase moves over the surface of the core by utilizing the mobility of the lipoyl groups.

The structure of the bacterial form of PDH has been studied more extensively than the mammalian form; it is based on a 24-mer core of E2 with 24 E1 and 12 E3-subunits attached. No E3BP is present and the complex is not regulated by phosphorylation. The yeast *Saccharomyces cerevisiae* form of the complex is based on a 60-mer core, possibly with the E3-subunits located inside of the hollow E2 core at the 12 holes. The yeast complex, although more like the mammalian form in structure, is not regulated by reversible phosphorylation, a fact supported by the lack of homologues of PDK or PDP in the complete yeast genome sequence.

There are a number of inherited metabolic defects which have been described where various components of the PDH system, or their expression, have been shown to be defective, and interestingly, the auto-immune response which is thought to be the basis of primary biliary cirrhosis appears to be directed primarily against the E3BP and E2 components of the PDH complex.

TABLE I

Components of the PDH Complex and its Regulatory Enzymes

Components	EC reference	Full name	Subunit M_R (kDa)	Cofactors	Stoichiometry in mammalian complex
E1	1.2.4.1	Pyruvate dehydrogenase	α 42 β 36	TPP, Mg^{2+}	20–30 α_2 β_2 heterotetramers
E2	2.3.1.12	Dihydrolipoamide acetyltransferase	52	Lipoate	54
E3	1.8.1.4	Lipoamide dehydrogenase	55	FAD	6 homodimers
E3BP	None	E3 binding protein	51	Lipoate	6
PDK	2.7.1.99	Pyruvate dehydrogenase kinase	45–48 (4 isoforms)	Mg^{2+}	?Few
PDP	3.1.4.33	Pyruvate dehydrogenase phosphatase	cat 50	Mg^{2+}	?Few
			r 90	FAD?	

Mechanism of the Reaction Catalyzed by PDH

The multi-step reaction catalyzed by the PDH complex involves sequential reactions with the intermediates being relayed between the subunits via the flexible lipoyl domains.

E1 catalyzes the decarboxylation of pyruvate forming 2-(1-hydroxyethyldiene)-TPP bound to E1 (TPP is thiamin pyrophosphate). E1 also catalyzes the transfer of the intermediate as an acetyl group to the lipoyl moiety of E2. Each E2-subunit contains two flexible lipoyl groups. The acetyl group is shuttled between them to achieve the transfer between reaction centers that are too distant to be connected by one lipoyl group. E2 catalyzes the transfer of the acetyl group from the attached lipoyl group to CoA forming acetyl-CoA, leaving the lipoate group in the reduced form. E3 (and possibly E3-BP) catalyzes the transfer of electrons from the reduced lipoyl group attached to E2 to NAD^+ generating NADH and an oxidized lipoyl group. Thus, the overall reaction has been catalyzed and the PDH complex is returned to its original state.

Role of PDH in Metabolism

The reaction catalyzed by the PDH complex is central within metabolic pathways, most importantly linking glycolysis to the TCA cycle. Pyruvate has multiple sources and the acetyl-CoA produced has multiple

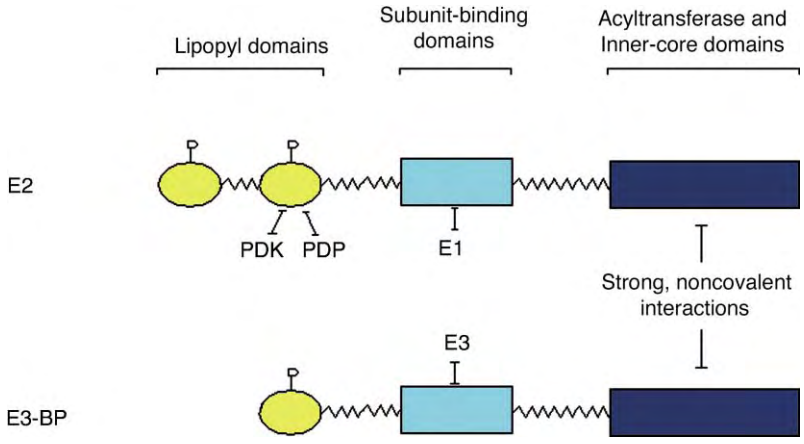

FIGURE 1 Schematic structures of the E2- and E3BP-subunits of the PDH complex. The acetyltransferase domains of the E2-subunits and the inner-core domains of the E3-BP-subunits interact to produce the dodecahedral core of the PDH complex. The subunit-binding domains and lipoyl domains (the majority of the proteins) are exterior to the core. The other major subunits (E1 and E3) are bound to the relevant subunit-binding domains. The regulatory proteins associate with the lipoyl domains of E2 and act to regulate the phosphorylation status of E1. Domains are linked by flexible linker regions composed of sequences rich in alanine and proline.

destinations, both catabolic and anabolic. The correct rate of flux through PDH is essential for the homeostasis of the cell. Coupled with the fact that the reaction catalyzed by PDH is irreversible in mammals and thus represents the point of commitment of carbohydrate metabolism, this means that the regulation of PDH is extremely important.

Regulation of PDH

Regulation of Activity by Phosphorylation

The major regulation of PDH is based on phosphorylation. The activity of the complex is modulated by phosphorylation of the E1α-subunits on three serine residues. The complex is inactive in the phosphorylated state (PDH-P) and active in the non-phosphorylated state (PDHa). The three phosphorylation sites (site 1 (S264), site 2 (S271), and site 3 (S203)) do not have equal importance in causing inactivation of the complex. Site 1 is the main inhibitory site and has been shown to account for at least 98% of the inhibition in rat heart mitochondria. Sites 2 and 3 are thought to reinforce the inactivating action of phosphorylation at site 1 and to make dephosphorylation more prolonged.

The phosphorylation status of PDH is regulated by dedicated kinases and phosphatases (Figure 2). The only other known phosphorylated protein within the mitochondrial matrix of mammalian cells is the related branched chain oxo-acid dehydrogenase complex which appears to have its own dedicated set of regulatory enzymes that are sequentially related to those for PDH.

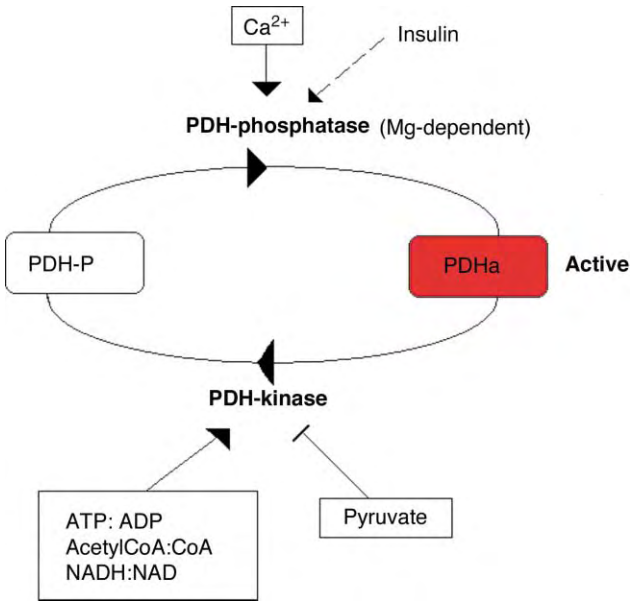

FIGURE 2 Regulation of PDH activity by phosphorylation-dephosphorylation. PDH is inactive in the phosphorylated form and active in the dephosphorylated form. Both intrinsic and extrinsic regulation is based on interconversion of the two forms by dedicated kinases and phosphatases.

Pyruvate Dehydrogenase Kinase

Currently, four isoforms of pyruvate dehydrogenase kinase (PDK) have been cloned from mammalian sources and studied (a fifth member of the family is present in the human genome sequence). These are expressed in a tissue-specific manner and differ substantially in their kinetics and allosteric modulation. Their expression is also altered differentially by hormones and nutritional status. The differences between the properties of the isoforms are substantial. For example, PDK3 has the highest specific activity and is virtually insensitive to NADH and acetyl-CoA inhibition, whereas PDK2 and PDK4 (which appears to be preferentially up-regulated in starvation and diabetes) have lower specific activities and are much more sensitive to NADH and acetyl-CoA. There is also evidence that different PDK isoforms have different activities towards the different phosphorylation sites in PDH E1α.

The kinases are strongly associated with the inner lipoyl domains of the E2-subunit of the PDH complex. The kinases act on the three serine residues on the E1α-subunit previously described. Their association with the E2-subunit increases the efficiency of phosphorylation of E1α.

The primary sequences of the PDKs are more like bacterial histidine kinases than eukaryotic serine/threonine kinases and evidence exists for the similarity of mechanism between PDK and a bacterial histidine kinase. However, the sites phosphorylated by the PDH kinases are situated in consensus sequences typical of eukaryotic serine/threonine phosphorylation sites. It is interesting to speculate that this situation arose by evolution from the endosymbiotic status of mitochondria in eukaryotic cells.

Pyruvate Dehydrogenase Phosphatase

Pyruvate dehydrogenase phosphatase (PDP) is a member of the PPM-family of phosphatases. PDP dephosphorylates the E1α-subunit and so causes the activation of PDH complex. PDP appears to act exclusively on PDH: no other substrates of PDP are known. PDP is also the only known phosphatase to act on PDH *in vivo*.

PDP has been cloned from a number of species. The phosphatase was originally cloned from bovine tissues, where the phosphatase is heterodimeric consisting of a catalytic (PDP_{cat}) and regulatory (PDPr) subunit. In rat, two isoforms of the catalytic subunit have been cloned, but as yet no regulatory subunit has been cloned.

The bovine phosphatase is the most extensively studied. It is Ca^{2+}-activated with Ca^{2+} causing a reduction in the $K_{0.5}$ for Mg^{2+}. Ca^{2+} also causes a reversible E2-PDP association and resultantly a 20-fold reduction in the $K_{0.5}$ of PDP for phosphorylated E1.

The two cloned rat isoforms of the phosphatase appear to differ in their regulation. PDP1 (orthologue of PDP_{cat}) is activated by Ca^{2+} but not by spermine. PDP2 has a much higher $K_{0.5}$ for Mg^{2+} (17.4 ± 2.7 mM versus 1.5 ± 0.5 mM for PDP1 in the absence of Ca^{2+}) and is not activated by Ca^{2+} but is activated by spermine. PDP1 appears to be the more strongly expressed form in skeletal muscle whereas PDP2 is the more strongly expressed in 3T3-L1 adipocytes and liver.

The role of the regulatory subunit of PDP is unclear. Studies in which recombinant PDP_{cat} and highly purified PDP are compared suggest several potential properties of PDPr. Firstly, it causes an increase in the $K_{0.5}$ of PDP_{cat} for Mg^{2+}. Secondly, the presence of PDPr confers spermine sensitivity to the phosphatase. Thirdly, differences in affinity of PDP to E2 were found with and without PDPr, so that it is likely that PDPr contributes to the binding and/or orientation with the core PDH complex via E2. PDPr was not found to have any native phosphatase activity and, despite the homology of PDPr to the enzyme dimethylglycine dehydrogenase, no enzymatic activity towards dimethylglycine or related molecules was found. Intriguingly, PDPr is a flavoprotein that binds a dissociable FAD, but it is not clear if this is involved in the function of the protein.

Intrinsic Regulation of PDH

Intrinsic regulation is predominantly based on the reversible phosphorylation mechanism of E1α-subunits as described above, and on end-product inhibition. Intrinsic regulation ensures that the rate of flux through PDH is appropriate for the metabolism of the cell. As illustrated in Figure 2, the kinase is activated by increased ratios of [ATP]/[ADP], [acetyl-CoA]/[CoA] and [NADH]/[NAD^+]. Thus, in the states where the ratios of [products]/[reactants] are high, the kinases are activated and so PDH is inactivated. This is reinforced by increased ratios of [acetyl-CoA]/[CoA] and [NADH]/[NAD^+] also causing end-product inhibition of the catalytic activity of PDH itself. This is also the principal regulatory mechanism by which the so-called glucose-fatty acid (or Randle) cycle operates, and ensures that carbohydrate is preserved when fatty acids are being oxidized (which will lead to increases in intramitochondrial NADH and acetyl-CoA levels). Conversely, high concentrations of pyruvate inhibit the kinase and so favor the active state of PDH where pyruvate will be metabolized. NADH also has an inhibitory effect on PDP, thus making the regulation more efficient by coordinate action on the activities of the kinase and phosphatase.

Extrinsic Regulation of PDH

Extrinsic (i.e., hormonal) regulation of PDH is also predominantly based on the modulation of complex activity by reversible phosphorylation. The localization of PDH exclusively within the mitochondrial matrix presents a problem to the cell in transmitting an extracellular signal to the PDH system: not only must the signal cross the plasma membrane, but also cross the largely impermeable mitochondrial inner membrane.

Calcium Regulation of PDH

Calcium has a physiological role in activating mitochondrial metabolism. For example, in muscle cells, increased cytosolic Ca^{2+} concentration stimulates contraction and so increases ATP usage. The increased cytosolic Ca^{2+} concentration is relayed into the mitochondrial matrix by a specific Ca^{2+}-uniporter in the inner membrane (where there are also specific Ca^{2+} export mechanisms). The increases in mitochondrial Ca^{2+} concentration cause activation of PDP and so an increase in PDHa as well as activation of two other intramitochondrial dehydrogenases that are sensitive to calcium (NAD^+-isocitrate dehydrogenase and 2-oxoglutarate dehydrogenase which are activated by Ca^{2+} causing decreases in their K_m values for isocitrate and 2-oxoglutarate respectively). The overall result is increased production of NADH for ATP generation by oxidative phosphorylation. This mechanism can thus override the intrinsic mechanisms described above and thereby increase metabolic flux whilst maintaining or even increasing key metabolite ratios such as [ATP]/[ADP] and [NADH]/[NAD^+]. Increases in cytosolic and mitochondrial Ca^{2+} can be brought about by several different hormones acting on several different tissues.

Insulin Regulation of PDH

Insulin causes an acute increase in the activity of PDH, so increasing the production of acetyl-CoA and the rate of lipogenesis in certain tissues. Insulin is not thought to cause an acute response in the PDKs, but long-term insulin stimulation down-regulates the transcription of these enzymes. Acutely, insulin acts via an increase in the activity of PDP. Insulin causes a reduction of the $K_{0.5}$ for Mg^{2+} and so an activation of PDP, and hence an activation of PDH. The precise mechanism by which insulin transduces a signal into the mitochondria to cause this effect is unknown.

Biography

Sam Johnson received his doctoral training in the laboratory of Professor Richard Denton at the University of Bristol, United Kingdom. He is currently undertaking postdoctoral work at the Salk Institute, La Jolla, California.

Jim McCormack also obtained his Ph.D. through Dick Denton's lab in Bristol, and later a D.Sc. from the same University. He is currently Vice President of UK Discovery for OSI Pharmaceuticals in Oxford, and was previously vice president for Scientific Affairs and for Target Cell Biology at Novo Nordisk in Denmark. Previously he was Director of Diabetes Discovery at Novo Nordisk, head of Biochemical Pharmacology at Syntex Research in Edinburgh, and a tenured lecturer in Biochemistry at Leeds University, where he was also a research fellow of the Lister Institute of Preventive Medicine.

Together, Sam and Jim estimate that the number of assays of PDH and its associated enzymes which they have carried out is well into six figures.

Pyruvate Kinase

Kosaku Uyeda
University of Texas Southwestern Medical School, Dallas, Texas, USA

Pyruvate kinase catalyzes the last step of glycolysis which is important for generating ATP. Mammals express four major pyruvate kinase isozymes, muscle (M1), liver (L), erythrocyte (R) and the ubiquitous M2 types. All but the M1 isozyme exhibit positive cooperative kinetic behaviors upon binding the allosteric activator fructose-1,6-diphosphate and in the presence of increasing phosphoenolpyruvate concentrations. All four isozymes are inhibited by phenylalanine. The L-pyruvate kinase isozyme activity also is inhibited by phosphorylation in response to glucagon. Consistent with its important role in regulating glucose metabolism and fat synthesis in liver, L-pyruvate kinase also is extensively regulated at the level of transcription. L-pyruvate kinase transcription increases in response to glucose and insulin and decreases in response to glucagon and high fat diets.

Pyruvate Kinase Reaction

Pyruvate kinase (PK) (EC 2.7.1.40) catalyzes the final step of glycolysis,

$$\text{P-enolpyruvate} + \text{ADP-Mg}^{2+} \rightarrow \text{Pyruvate} + \text{ATP-Mg}^{2+} + \text{H}^{+}$$

The enzyme requires two equivalents of divalent cation and K^+ for a full activity. One divalent cation complexes with ATP or ADP and the other cation binds to the protein and functional groups of pyruvate. The γ-phosphate of ATP bridges the two divalent cations.

Structure

All PKs from a variety of sources are tetramers (Mr = 240 kDa). Mammals express four isozymes designated as M1 and M2 for muscle type, L for liver, and R for erythrocytes. M1 muscle isozyme is the only PK exhibiting hyperbolic kinetics for phosphoenolpyruvate (PEP). However, in the presence of the allosteric ligand such as phenylalanine, it shows cooperative saturation for PEP. All other isozymes exhibit cooperativity with respect to PEP and are activated by fructose 1,6-diphosphate (Fru1,6-P_2) by lowering K_{PEP}.

PK has been isolated and characterized from a number of prokaryotes and from eukaryote tissues. Each consists of ~500 amino acid residues. Crystal structures of the enzymes from cat and rabbit muscle, yeast, *Escherichia coli* and *Leishmania mexicana* have been reported (1 and reviewed in 2). They all exhibit a very similar 3D structure (Figure 1A). Each subunit contains three domains: the A domain with the classic $(\alpha/\beta)_8$ structure; the B domain with an irregular fold; and the C domain with an α- and β-organization (Figure 1B). The eukaryotic enzymes contain additional short N-terminal peptides. The active site is situated on the C-terminal side of the A domain, facing the cleft between the A and B domains. The Fru 1,6-P_2 complex of yeast PK has revealed that the Fru 1,6-P_2-binding site is located in the C (regulatory) domain, which is 40Å away from the catalytic center.

Regulation of LPK *in vitro*

Effect of pH

In alkaline pH, LPK exhibits a sigmoidal saturation curve with PEP, but at lower pH the enzyme shows Michaelis–Menten kinetics. The transition between these two enzyme conformational states occurs at a narrow pH range between 6.8 and 7.3.

Allosteric Effectors

Fru 1,6-P_2 reduces the cooperative effects of PEP and converts the enzyme to a form exhibiting Michaelis–Menten kinetics with a higher affinity for the substrate. ATP and alanine are inhibitors of liver PK (LPK), and these ligands raise the apparent K_{PEP} to higher values. The inhibitory effect of ATP and alanine is counteracted by PEP and Fru 1,6-P_2. Pig LPK is inhibited by phenylalanine more strongly than alanine.

Phosphorylation/ Dephosporylation

LPK was first shown to be regulated by phosphorylation catalyzed by cAMP-dependent protein kinase (PKA), resulting in loss of the enzyme activity. The phosphate

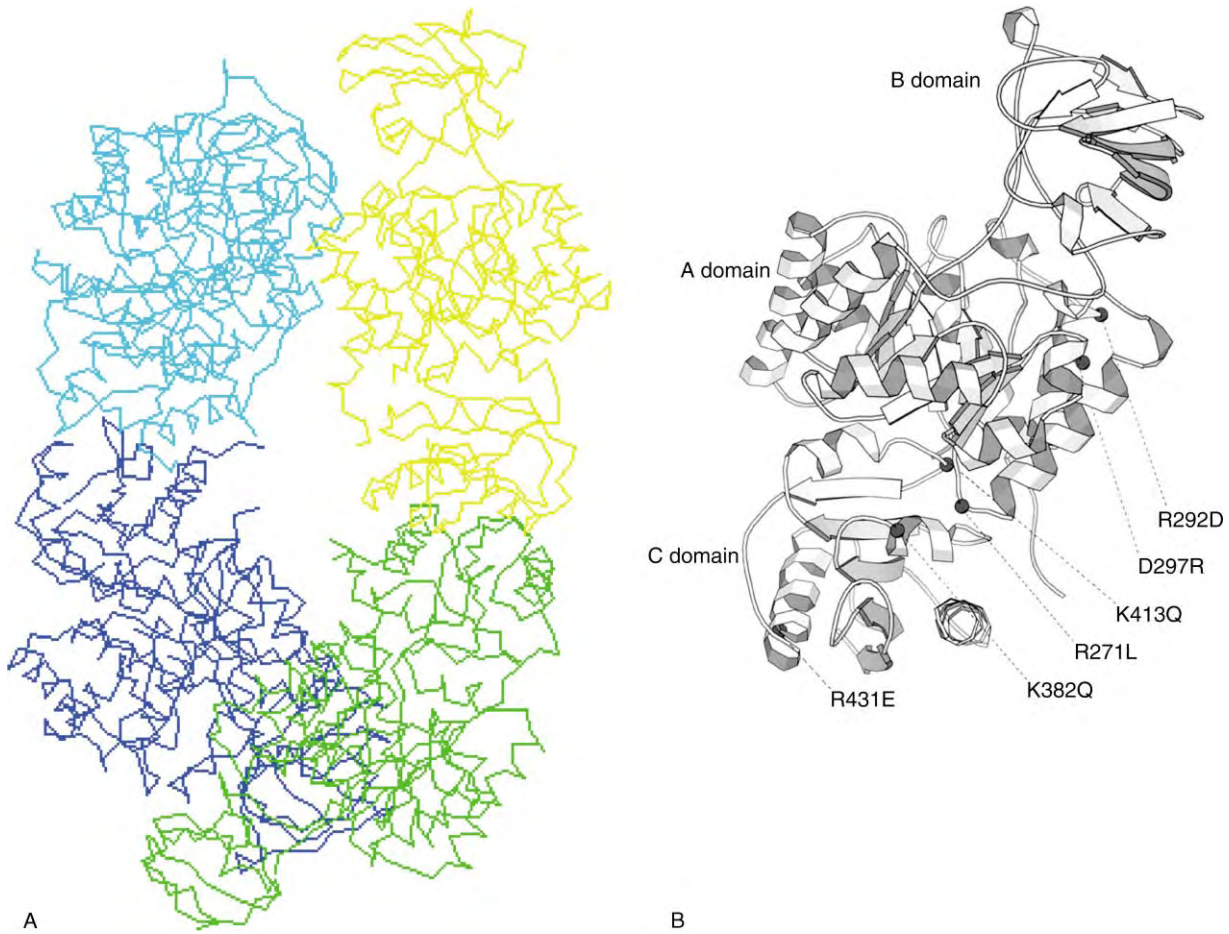

FIGURE 1 (A) Tetrameric *E. coli* PK in inactive T state. (B) *E. coli* PK subunit. The orientation is same as in A. (Reproduced from Valentini, G. *et al.* (2000). The allosteric regulation of pyruvate kinase. *J. Biol. Chem.* **275**, 18145–18152.)

incorporation is one mole phosphate per mole enzyme subunit on the N-terminal Ser within the consensus PKA target sequence (ArgArgAlaSerPVal). When the phosphorylated LPK was dephosphorylated by histone phosphatase, the enzyme recovered full activity.

The major effect of phosphorylation is to raise the apparent K_{PEP} approximately threefold (from 0.3 to 0.8 mM). It also increases the Hill coefficient from 1.1 to 1.5. V_{max} remains the same for both enzyme forms. This inhibitory effect of phosphorylation is counteracted by Fru 1,6-P_2 and H^+. Phosphorylation does not inhibit the rat LPK in the presence of 5 μM Fru 1,6-P_2 at pH 7.3, and the enzyme follows Michaelis–Menten kinetics with K_{PEP} of 0.04 mM. Phosphorylated LPK is more sensitive to inhibition by ATP and alanine than is the dephospho form.

Crystallographic Studies

Crystallographic and mutagenesis studies provided the mechanistic features for the allosteric transition in PK at the molecular level. The enzyme displays significant conformational changes involving all three domains of each subunit in the tetrameric enzyme in moving from the T- to R-state (Figure 2). This model is based on the X-ray structure determination of the allosteric *E. coli* PK in the inactive T-state and the M1 isozyme, which is an active R-conformation. In general, the allosteric transition involves two kinds of movements, (1) the rotation of the B and C domains (17° and 15°) within each subunit and, (2) a 16° rotation of each subunit within the tetramer. Thus, the allosteric activation of PK appears to involve rotation of both domain and subunit. This model is further supported by the observation that the 3D structure of each domain is not altered by their movement, suggesting that they rotate as rigid bodies connected by flexible hinges. The transition from R- to T-state also causes significant changes in the active site including distortion of the PEP-binding site, suggesting the poor substrate affinity of the T-state. It also shrinks the cleft between the A and C domains preventing effector binding.

These kinetic changes induced by various ligands and by phosphorylation are the acute regulation of PK activity by hormonal and nutritional states. Experiments performed on intact animals confirm the regulation of

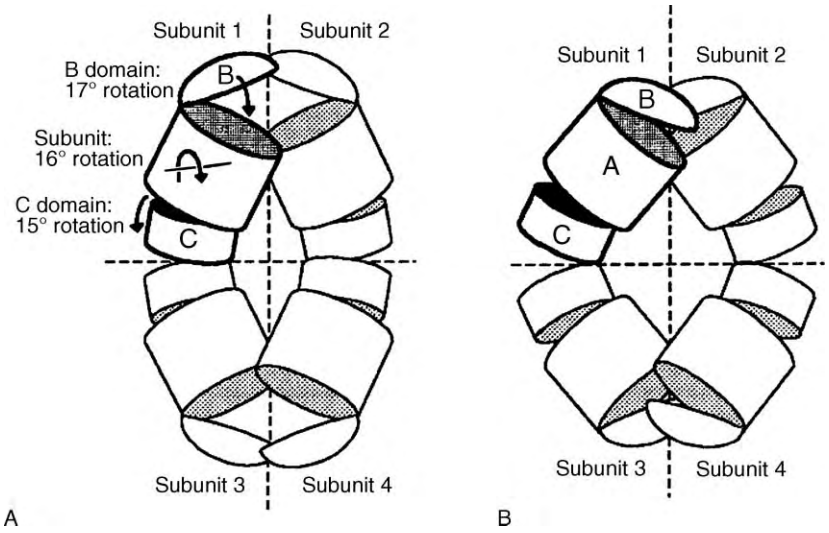

FIGURE 2 Schematic representation of the domain and subunit rotations in the T- and R-state transitions of PK.

PK *in vivo*. Intravenous administration of glucagon causes rapid inactivation of PK in liver. The effect of glucagon also raises cAMP concentration. Insulin causes rapid activation of PK.

Regulation of LPK Concentration by Gene Expression

Effect of Insulin, Glucagon, and Carbohydrate in Liver

In long-term regulation, LPK gene expression is controlled also by hormones and nutrients. Feeding mammals a diet rich in carbohydrate and low in fat leads to an increase in insulin levels and a fall in glucagon. Insulin and glucagon can activate and repress, respectively, the LPK transcription. These hormonal effects are mediated by direct response to the hormonal signals acting via membrane receptors.

In addition to increased insulin secretion, the excess glucose leads to activation of LPK gene transcription. This activation of gene expression is mediated by glucose, independent of insulin, and requires metabolism of glucose. Thus, glucose is not only a source of energy but also is able to stimulate glycolytic, and lipogenic enzyme genes.

Carbohydrate Response Element of LPK Promoter

The LPK gene promoter contains the glucose response element (−168 to −145 nucleotides upstream of open reading frame) and several other nuclear factor binding sites including nuclear factor (NF) and HNF4. The transcription factor binding to the glucose response element was identified recently and termed carbohydrate response element binding protein (ChREBP). In addition, it contains multiple phosphorylation sites, subject to regulation by protein kinase/phosphatase.

Carbohydrate Response Element Binding Protein

ChREBP is a large protein (Mr = 94.6 kDa) containing 846 amino acids. It consists of several functional domains including nuclear localization signaling (NLS) site, basic/helix-loop-helix/Zip region, polyproline, and Zip-like regions (Figure 3). ChREBP belongs to the MyoD family of transcription factors and binds to two consensus sequences (5′-CANNTG-3′) that are separated by five bases.

Regulation of ChREBP in Response to Glucose and cAMP

Inhibition by cAMP-Dependent Protein Kinase, PKA

ChREBP contains multiple phosphorylation sites including three sites for PKA, located at Ser196 (near NLS site), Ser626, and Thr666. ChREBP is controlled at two levels, nuclear entry and DNA binding. PKA-catalyzed

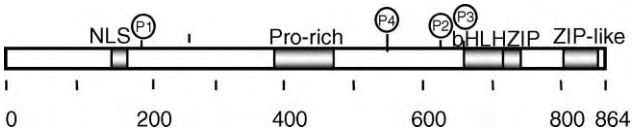

FIGURE 3 The domain structure of ChREBP. The locations of NLS, proline-rich stretch, bHLH/Leucine zipper, and Zip like domains are indicated. The locations of four phosphorylation sites of PKA are designated as P1, P2, and P3. The AMPK site is indicated as P4.

phosphorylation of Ser196 results in inhibition of nuclear import of ChREBP, while that of Thr666 leads to complete inhibition of the DNA binding. In low glucose, ChREBP is localized in the cytoplasm as the phosphorylated form, but in high glucose, it migrates to the nucleus as a dephosphorylated form.

Inhibition by AMP-Activated Protein Kinase, AMPK

Incubation of hepatocytes in fatty acids results in inhibition of glucose activated LPK transcription. This inhibition is mediated by phosphorylation of another site (Ser568) by AMPK. AMPK is activated by increased AMP generated by fatty acylCoA synthetase.

Activation by Glucose

Excess glucose activates the LPK gene expression by increased metabolism of glucose which activates ChREBP by dephosphorylation catalyzed by a specific protein phosphatase (PPase). A specific PP2A activated by Xu5P catalyzes the dephosphorylation and activation of phosphorylated/inactive ChREBP in liver in response to high carbohydrate. Xu5P is a metabolite in the pentose shunt pathway which increases with increased glucose metabolism, and serves as a glucose signaling compound. Thus, these results outline how glucagon/cAMP and high-fat diet repress ChREBP activity by phosphorylation. Glucose, however, activates the ChREBP activity and this activation of ChREBP leads to increased transcription of the LPK gene (and probably others), increasing glucose metabolism.

Glossary

carbohydrate response element A DNA sequence within the promoter of a gene to which a specific transcription factor binds in response to excess carbohydrate.

gene promoter A region of a gene that responds to glucose, hormones, and other stimuli and binds a number of transcription factors that affect transcription.

liver pyruvate kinase An isoenzyme of pyruvate kinase that occurs mainly in liver.

transcription Synthesis of mRNA transcribed from a specific sequence of DNA of a gene.

Biography

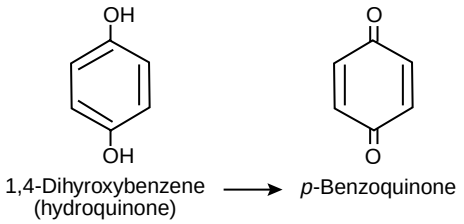
Kosaku Uyeda is a Professor in the Biochemistry Department of University of Texas Southwestern Medical School in Dallas. His principal research interests are in mechanism of regulation of carbohydrate metabolism and lipogenesis. He holds a Ph.D. from the University of California, Berkeley. His laboratory codiscovered an important allosteric activator of glucose metabolism (fructose 2,6-P_2). In addition, they isolated and identified a new transcription factor (ChREBP) which stimulates glucose metabolism and conversion to fat in liver in response to excess carbohydrate.

Quinones

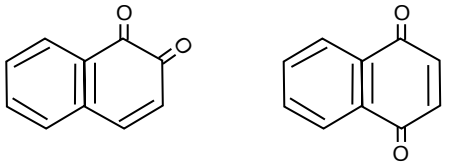
Giorgio Lenaz and Maria Luisa Genova
University of Bologna, Bologna, Italy

Chemistry of Quinones

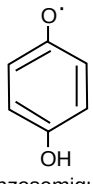
Quinones are diketones derived by oxidation of dihydroxyarenes; the simplest quinones are those derived by benzenediols (1,2- and 1,4-dihydroxybenzene:



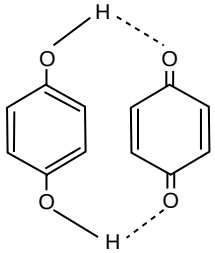
Also condensed arenes give quinones, e.g., the naphthoquinones:



The reversible oxidation of dihydroxyarenes to the respective quinones is a two-electron process with the intermediate formation of the radical form of semiquinones, e.g.,



The redox systems quinone/diphenol (or quinol) are widely present in nature. Also known is the charge transfer complex quinhydrone, where quinone is the electron acceptor while diphenol is the electron donor:



Biological Benzoquinones: Coenzyme Q and Plastoquinone

Chemistry and Distribution

Coenzyme Q was discovered in 1957 by F. L. Crane in Wisconsin as a yellow oily substance, extracted from bovine heart mitochondria, and having redox properties. It is also called ubiquinone, initially from the European nomenclature. The bovine compound is 2,3-dimethoxy-5-methyl-6-decaprenyl-1,4-benzoquinone (Coenzyme Q_{10}), but other homologues exist having polyprenyl chains of different lengths in the 6-position (Table 1). Also some analogues with different substitutions in the benzene ring have been found in nature or synthetized.

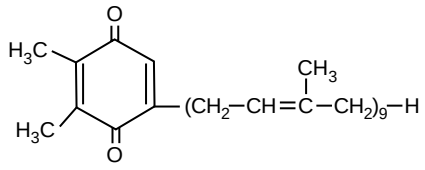
Coenzyme Q homologues were initially found in the inner membrane of mitochondria of eukaryotic cells and in the plasma membranes of aerobic and photosynthetic bacteria and they were discovered to be essential components of respiratory and photosynthetic chains. A different analogue, plastoquinone-9 (2,3-dimethyl-5-nonaprenyl-1,4-benzoquinone), was found in chloroplasts of higher plants and algae and in cyanobacteria and proven as an essential component of the photosynthetic apparatus (see structure below).

TABLE 1

Naturally Occurring Homologues and Analogues of Coenzyme Q

Homologue or analogue	Molecular weight	Occurrence
Coenzyme Q_6	590	*Saccharomyces cerevisiae* and other yeasts
Coenzyme Q_7	659	Minor component of some yeasts
Coenzyme Q_8	728	Some yeasts, *Escherichia coli*, and many other bacteria
Coenzyme Q_9	794	Rat, mouse, shark, some insects, protozoa, molds, yeasts, basidiomycetes, *Pseudomonas fluorescens*, and other bacteria
Coenzyme Q_{10}	862	Most mammals including man, birds, amphibia, most invertebrates, most photosynthetic bacteria, and some other bacteria
Rhodoquinone-10	847	*Rhodospirillum rubrum*
Ubichromenol-10	862	Accompanies Q_{10} in minor amounts as a cyclization product
Plastoquinone-9	747	Chloroplasts of higher plants and algae

See text for chemical structures.
Rhodoquinone-10 is 2-methoxy-3-amino-5-methyl-6-decaprenyl-1,4-benzoquinone.

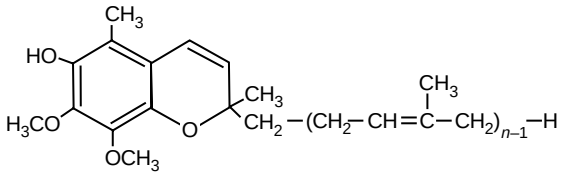


Plastoquinone-9

Soon after its discovery, Coenzyme Q was also found to be present in other cellular membranes of eukaryotic cells, including Golgi apparatus, lysosomes, and plasma membrane.

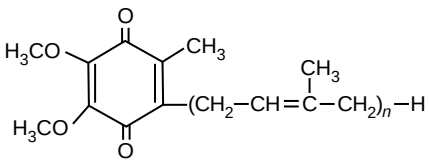
The major redox forms of Coenzyme Q, with their prevalent protonation states, are the following:

unit of the side chain forming the respective ubichromenols:

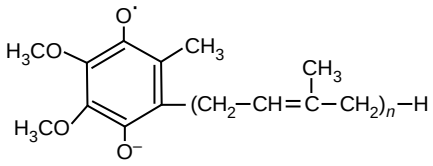


Ubichromenols

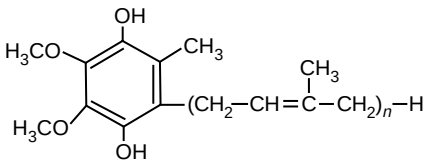
Coenzyme Q homologues 1–12 are soluble in most organic solvents but not in water due to their isoprenoid sidechains. Only homologues 6–12 are obtained in crystalline form at room temperature.



ubiquinone (Q)



ubisemiquinone anion (Q·)



ubiquinol (QH_2)

The standard redox potential of the ubiquinone/ubiquinol couple at pH 7 is $\sim +100$ mV. The semiquinone radical is intermediate in most redox reactions of Coenzyme Q; however, it is very unstable and is rapidly dismutated to the quinone and quinol forms:

$$2Q\cdot + 2H^+ \longleftrightarrow Q + QH_2$$

Under some conditions, ubiquinones undergo cyclization between the ring and the first isoprenoid

In water, Coenzyme Q homologues form micelles or aggregates. They are soluble in lipids and disperse in monomeric form in phospholipid bilayers as well as in biological membranes.

Coenzyme Q absorbs light in the UV with a maximum at 275 nm in ethanol and at 270 nm in hydrocarbons when in oxidized form (extinction coefficient 15 $mM^{-1}\,cm^{-1}$), and with a maximum at 290 nm in all organic solvents when in reduced form (extinction coefficient 4 $mM^{-1}\,cm^{-1}$). The ubisemiquinone anion

has a maximum at 318 nm (extinction coefficient 10.7 mM^{-1} cm^{-1}) and minor peaks also in the visible spectrum. The semiquinones are best detected by electron spin resonance techniques.

The lateral mobility of Coenzyme Q in phospholipid bilayers is very high: using the method of collisional fluorescence quenching with membrane-bound fluorescent molecules, a lateral diffusion coefficient was calculated $\sim 10^{-7}$ cm^2 s^{-1}. Such mobility seems essential for the function of the quinone in electron transfer chains in energy-transducing membranes.

Functions of Coenzyme Q

Electron Transfer Chains of Mitochondria and Bacteria

The best known function of Coenzyme Q is as a redox component of the mitochondrial respiratory chain, localized in the inner membrane. A standard scheme of the respiratory chain is depicted in Figure 1.

Coenzyme Q was first described as a mobile diffusible component localized between Complex I (NADH Coenzyme Q reductase) or Complex II (succinate Coenzyme Q reductase) and Complex III (ubiquinol cytochrome *c* reductase); in these systems, Coenzyme Q is reduced by Complex I or II and reoxidized by Complex III; it was then found that Coenzyme Q is also reduced by other mitochondrial enzymes, such as glycerol-1-phosphate dehydrogenase, electron transfer flavoprotein (ETF) dehydrogenase (an enzyme involved in fatty acyl CoA oxidation), and dihydro-orotate dehydrogenase.

Due to its extremely hydrophobic nature, Coenzyme Q is localized in the hydrocarbon interior of the lipid bilayer of the inner mitochondrial membrane, where its diffusion rate may be very high. In such way it behaves as a common pool of molecules, so that any molecule would be randomly reduced by any Complex I or II and reoxidized by any Complex III.

Besides the Coenzyme Q pool dissolved in the lipid bilayer, Coenzyme Q molecules bound to the individual complexes have also been described. These bound quinones may be important for the mechanism of outward proton translocation, required in the chemiosmotic mechanism of oxidative phosphorylation. The best-known mechanism is the Q-cycle, first proposed by the Nobel laureate Peter Mitchell (Figure 2).

Tight Coenzyme Q binding to proteins (Q-binding proteins) in the respiratory complexes is required to stabilize the semiquinone form that is an essential intermediate in the mechanism of proton translocation.

Moreover, a well-known example of bound quinones is represented by the reaction center of photosynthetic bacteria that has been crystallized and resolved by X-ray diffraction together with its bound prosthetic groups (Figure 3). In bacteria, besides ubiquinone, also menaquinone (a naphthoquinone) may participate in electron transfer.

In chloroplasts of photosynthetic algae and higher plants, the function of ubiquinone is exploited by plastoquinone, present in bound form in photosystem II and free as a pool in the lipid bilayer.

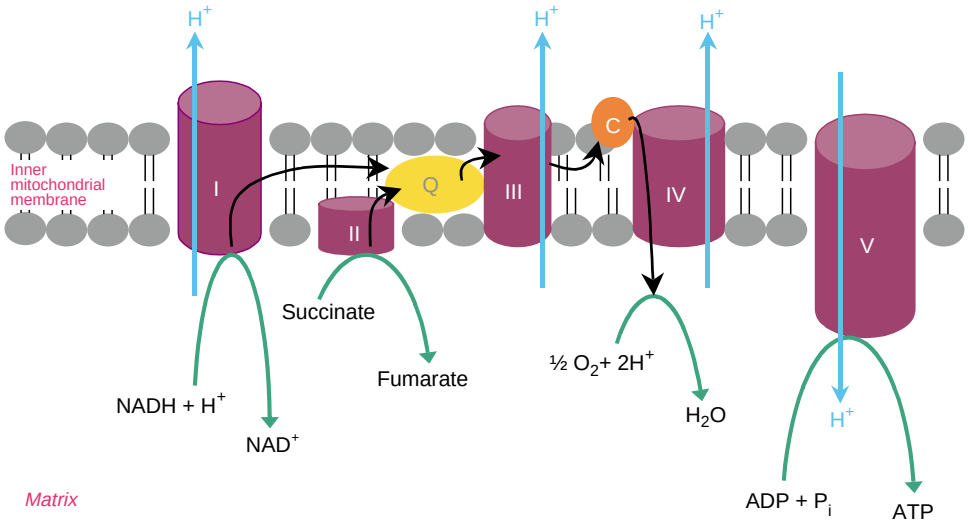


FIGURE 1 Schematic view of the mitochondrial oxidative phosphorylation system, showing the role of Coenzyme Q as a shuttle of electrons between Complex I or Complex II and Complex III. Other dehydrogenases using Coenzyme Q as acceptor are not shown for simplicity. Roman numbers refer to the respective enzyme complexes. Black arrows indicate the flux of electrons, green arrows indicate chemical reactions, and blue arrows indicate proton translocation. During redox reactions catalyzed by Complex I, III, and IV, protons are extruded forming a transmembrane gradient that is used by Complex V (ATP synthase) for synthesizing ATP.

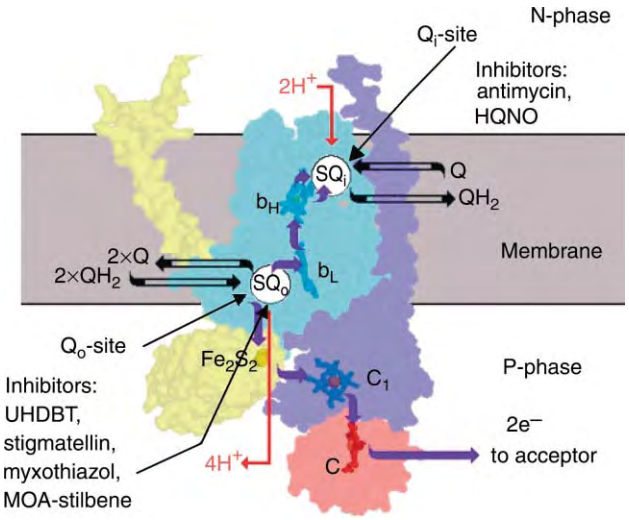

FIGURE 2 The Q-cycle as a mechanism of proton translocation in complex III of the mitochondrial respiratory chain. The scheme shows the Q-cycle in the context of the enzyme structure where the catalytic subunits are shown by their surfaces and made transparent so as to show the redox centers (cyan: cytochrome *b*; yellow: iron-sulfur protein; blue: cytochrome c_1). Quinol (QH_2) is oxidized in a bifurcated reaction at the Q_o-site of the complex located at the outer positive side of the membrane (P-phase): one electron is transferred to the high-potential chain, consisting of the Fe_2S_2 center and cytochrome c_1, and then to cytochrome *c* (red) that carries the electron to Complex IV. Since the semiquinone formed (SQ_o) is unstable, another electron is transferred through the low-potential chain of cytochrome hemes (b_L and b_H) to the Q_i-site where a quinone molecule is fully reduced to quinol. In order to provide the two electrons required at the Q_i-site, located at the inner negative side of the membrane (N-phase), the Q_o-site oxidizes two equivalents of quinol ($2 \times QH_2$) in successive turnovers. Information about inhibitor specificity of the above-mentioned reactions is shown in the figure. The integration of the redox reactions with the release or uptake of protons in the aqueous phases (red arrows) allow the complex to pump protons across the membrane. With permission of Dr. A. R. Crofts, University of Illinois at Urbana-Champaign, IL, USA.

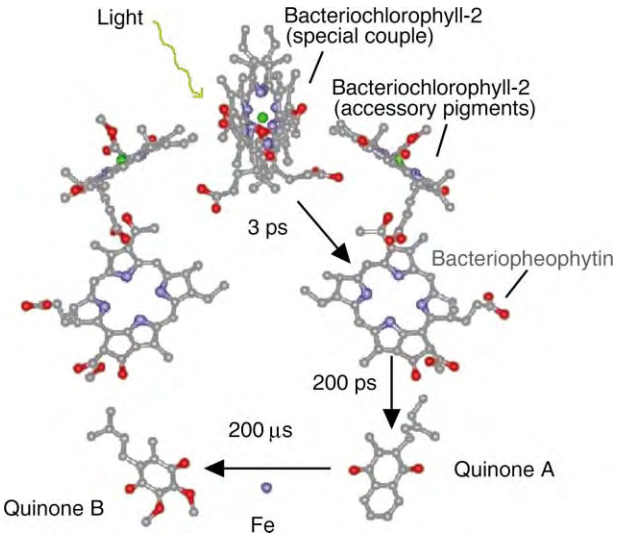

FIGURE 3 Bound quinones in the photosynthetic reaction center of Rhodopseudomonas viridis. Following excitation, the special pair of bacteriochlorophyll molecules donates an electron to a nearby bacteriopheophytin pigment (time constant: 3 ps). Subsequent transfer to the primary quinone (QA, a bound menaquinone) occurs with a half-time of 200 ps. Further electron transfer occurs from QA to the quinone acceptor QB, a bound ubiquinone occupying an active site near the cytoplasmic surface of the protein. QB accepts two electrons and two protons, then it undergoes exchange with the mobile pool of quinones in the lipid bilayer. With permission of Dr. R. Baxter, University of Chicago, IL, USA.

Other Electron Transfer Chains

Coenzyme Q of eukaryotic cells is present in most intracellular membranes and in the plasma membrane as well. Its function in these systems is better known in the plasma membrane oxidoreductase (PMOR) where the quinone appears to participate in transmembrane electron transfer between intracellular NADH or NADPH and extracellular acceptors including the ascorbic acid free radical, derived from the partial oxidation of ascorbic acid. This system may be involved in the antioxidant defenses of the cell since it regenerates ascorbic acid, an antioxidant.

Coenzyme Q as an Antioxidant

Coenzyme Q and other quinones are powerful antioxidants in their reduced form. The ubiquinol reacts with peroxide radicals, such as the lipid peroxide radical LOO·:

$$QH_2 + LOO\cdot \longrightarrow QH\cdot + LOOH$$

where LOOH is a lipid hydroperoxide.

In addition, it may be used to regenerate the reduced antioxidant form of vitamin E (α-tocopherol, T-OH) from the tocopheroxyl radical TO·:

$$T\text{–}OH + LOO\cdot \longrightarrow T\text{–}O\cdot + LOOH$$

$$T\text{–}O\cdot + QH_2 \longrightarrow T\text{–}OH + QH\cdot$$

The semiquinone form of Coenzyme Q, originated from its antioxidant action, is readily converted to the oxidized form by another radical:

$$QH\cdot + X\cdot \longrightarrow Q + XH$$

The cell contains several enzymatic systems to reduce oxidized Coenzyme Q (Q) back to its antioxidant form (QH_2). Among these are the cytosolic enzyme DT-diaphorase (NAD(P)H dehydrogenase (quinone) E.C.1.6.99.2), also found bound to the plasma membrane, a cytosolic NADPH quinone reductase, and microsomal NADH cytochrome b_5 reductase.

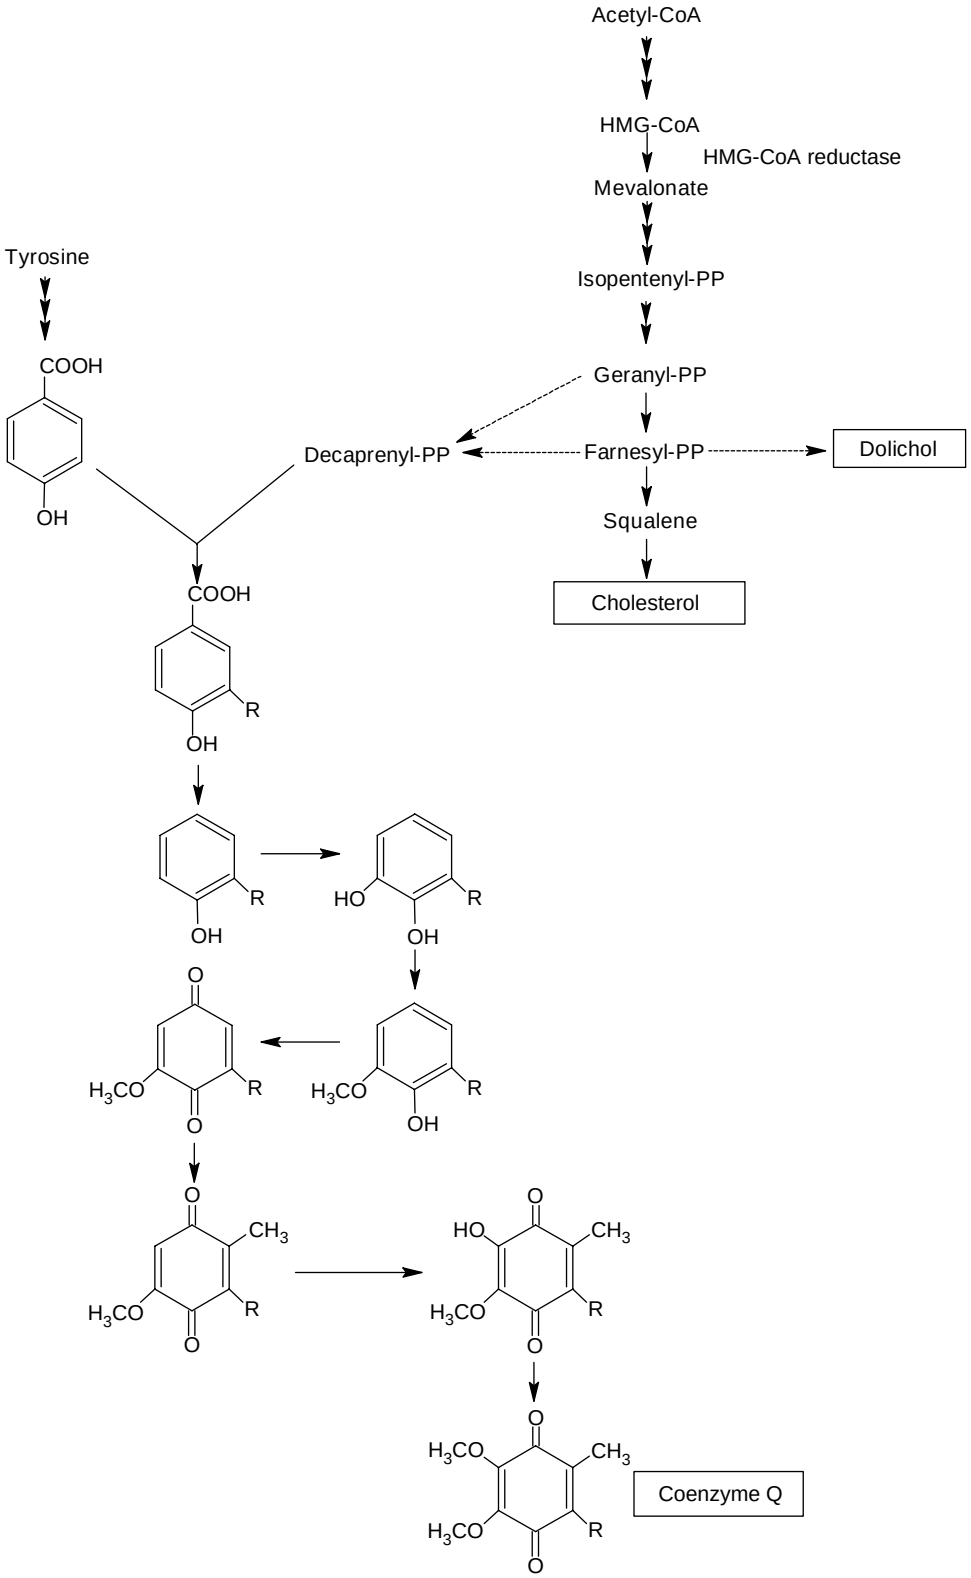

FIGURE 4 Simplified scheme of the biosynthesis of Coenzyme Q. R = isoprenoid side chain; HMG-CoA = 3-hydroxy-3-methyl-glutaryl Coenzyme A.

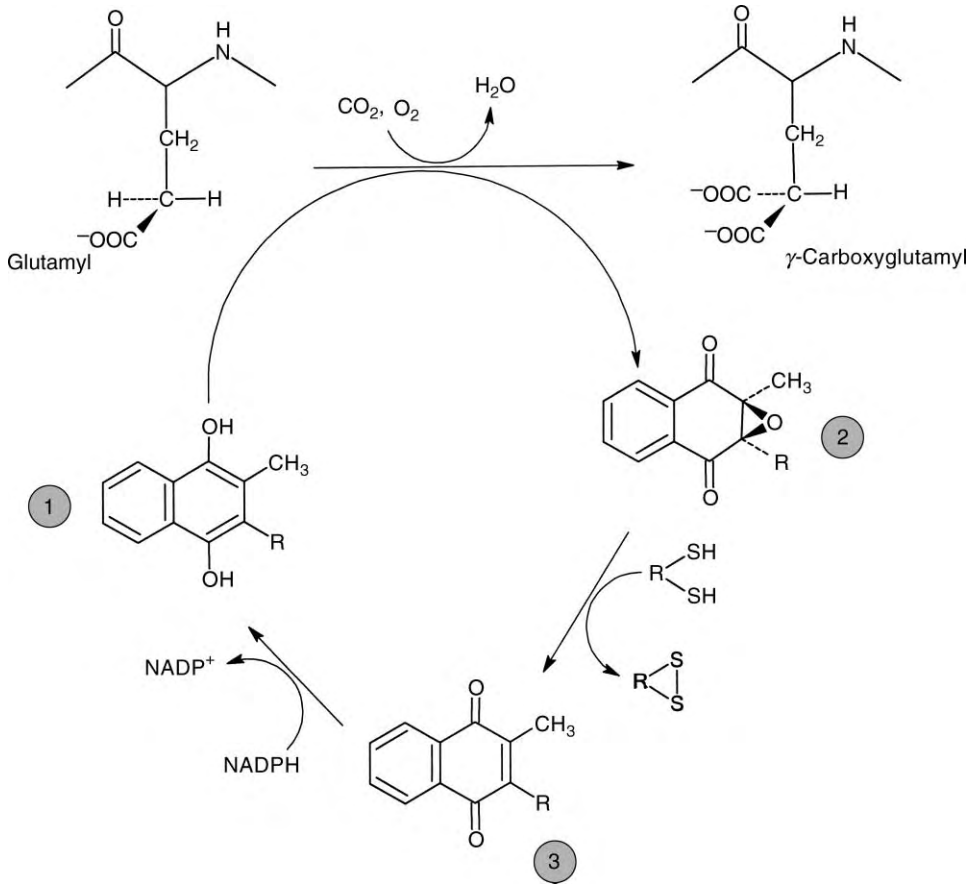

FIGURE 5 Mechanism of action of vitamin K in protein carboxylation. The γ-carboxylation reaction of protein-bound glutamate requires molecular oxygen and the reduced form of vitamin K (1); the hydroquinone is converted to the vitamin K epoxide (2) during the reaction. The vitamin K epoxide must be reconverted to the hydroquinone; this happens in two steps: in the first step the epoxide is converted to the quinone form (3) using the coenzyme thioredoxin [$R(SH)_2$]; the quinone is then reduced to the hydroquinone in an NADPH-dependent reaction.

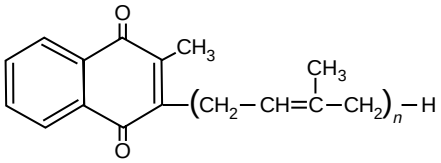
Biosynthesis of Coenzyme Q

Coenzyme Q is synthetized by animals starting from the amino acid tyrosine which is converted to *p*-hydroxybenzoate; after insertion of the isoprenoid side chain in the 6-position, the ring is completed by a complex series of reactions involving hydroxylations and O-methylations. The isoprenoid side chain is synthesized starting from acetyl CoA through the mevalonate pathway and isopentenyl pyrophosphate, which is common to the synthesis of cholesterol, dolichol, and other polyprenyl compounds (Figure 4). It was found that cholesterol-lowering agents acting on the enzyme 3-hydroxy-3-methyl-glutaryl CoA reductase, which converts 3-hydroxy-3-methyl-glutaryl CoA to mevalonate, besides lowering plasma cholesterol, also lower Coenzyme Q levels, suggesting caution in the use of these agents.

The biosynthesis of Coenzyme Q requires several vitamin-derived coenzymes and appears to be easily limiting on the normal levels of the quinone in the body. For this reason dietary intake of Coenzyme Q, as a vitamin-like supplement, has been recommended by many authors.

Biological Naphthoquinones: Menaquinone and Vitamin K

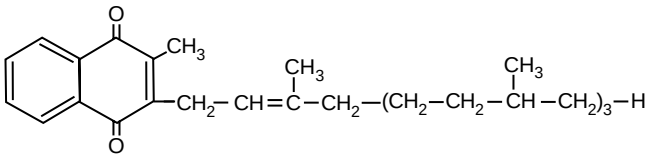
Menaquinone is the quinone used for electron transfer by many bacteria, either alone or together with ubiquinone (Figure 3).



Menaquinones ($n = 7–9$)

Vitamin K exists in two natural forms, phylloquinone (K1) and menaquinone (K2), with 4 and 6 isoprenoid units, respectively. In phylloquinone, three isoprenoid units are hydrogenated. Menadione (K3), without an

isoprenoid chain, is a synthetic derivative.



Vitamin K1

Vitamin K is involved in the process of blood coagulation, being required for the synthesis of prothrombin and factors VII, IX, and X. Vitamin K is involved in posttranslational modifications of these proteins consisting in the γ-carboxylation of glutamate residues. Vitamin K is the coenzyme of the carboxylase enzyme and acts in its reduced hydroquinone form. The mechanism of action is shown in Figure 5.

Glossary

antioxidants Molecules capable of preventing the propagation of free radicals and hence protecting cellular and extracellular biomolecules from free-radical-induced damage, such as lipid peroxidation and genetic mutations in DNA. There are water-soluble antioxidants, such as ascorbic acid (vitamin C), and lipid-soluble antioxidants such as α-tocopherol (vitamin E). Ubiquinol belongs to this latter category.

chloroplasts Organelles present in photosynthetic higher plants and in eukaryotic algae that carry out the process of oxygen-evolving photosynthesis by extracting electrons from water, in a complex electron transfer chain containing plastoquinone among other components, and reducing CO_2, thus yielding carbohydrates by a complex synthetic process (Calvin cycle).

coenzyme A nonprotein compound required for the catalytic action of an enzyme that can be strongly bound to the enzyme itself as a prosthetic group or participate as a substrate to the enzyme-catalyzed reaction. Several coenzymes cannot be synthetized *de novo* and derive from nutritionally supplied vitamins.

free radical An atom or molecule having one or more unpaired electrons. For this reason free radicals are usually very reactive, in the attempt to donate or receive an electron, and may damage biological molecules by establishing a chain reaction of propagation followed by permanent chemical modification of the attacked molecules. Among free radicals are some of the so-called reactive oxygen species, derived by partial reduction of molecular oxygen during mitochondrial respiration and other biological processes.

mitochondria Organelles present in most eukaryotic cells carrying out the process of oxidative phosphorylation and several other metabolic pathways. Mitochondria consist of two membranes, the inner membrane being the site of the respiratory chain, delimiting two aqueous compartments (called the intermembrane space and the matrix).

vitamin A biological molecule, acting in small amounts (therefore not a structural component), that cannot be synthetized by the body and therefore requires dietary supplementation. Many vitamins are part of coenzymes. Vitamins are classified as water soluble and lipid soluble.

Biography

Giorgio Lenaz is a Professor of biochemistry at the Medical School of the University of Bologna, Italy. After his medical degree at the University of Bologna he was a postdoctoral fellow at the University of Wisconsin. His main research interest is mitochondrial bioenergetics in health and pathology, in particular mitochondrial encephalomyopathies and aging. He is an expert in Coenzyme Q and related compounds and has published many experimental papers and reviews in leading journals on the subject. He is a member of the executive committee of the International Coenzyme Q_{10} Association.

Maria Luisa Genova is a postdoctoral fellow in biochemistry at the University of Bologna. She holds a Ph.D. in biochemistry, and was trained at Rice University in Houston, Texas; she has published several papers on the subject of Coenzyme Q and mitochondrial bioenergetics.

Rab Family

Mary W. McCaffrey and Andrew J. Lindsay
University College, Cork, Republic of Ireland

Rab proteins are monomeric small GTPases that function as key regulators of eukaryotic membrane trafficking. Specifically, they have been implicated in the budding, transport, docking, and fusion of lipid bilayer vesicles. The Rabs form the largest and most diverse branch of the Ras protein superfamily. They are evolutionarily conserved and are present in all eukaryotes investigated, localizing to specific organelles of the secretory and endocytic pathway. The human genome project has demonstrated the existence of at least 60 members in the human Rab family, which can be divided into 10 subfamilies. Members of each subfamily have similar subcellular localization and some functional overlap. Most Rab proteins are ubiquitously expressed; however, a number such as Rab3A, which is expressed neurons, and Rab27, expressed in melanocytes and platelets, are cell-type specific. Rab proteins are characterized by their functional cycle. As their name suggests they bind GTP, which results in their activation. The GTP can then be hydrolyzed to GDP resulting in the Rab adopting an inactive (GDP-bound) conformation and leading to its subsequent membrane dissociation. Several Rab-interacting proteins have been identified, which regulate either the Rab nucleotide-bound state, its localization, or act as "effectors" of Rab function.

Discovery

The first Rab GTPases were discovered in the late 1980s, through the pioneering work of the Tavitian group, in Paris, which set out to identify homologues of the Ras oncogenes. They screened a brain cDNA library with degenerate oligonucleotides designed against the most conserved regions of G proteins (the G boxes). Besides known G proteins, new ras-related genes were identified in this screen. These were sufficiently different from Ras and Rho to be placed in a new family of the Ras superfamily and were named the Rabs–*Ra*s homologue from *b*rain.

Sequencing revealed that these new Rab genes bore greatest similarity to two previously described yeast secretory mutant genes, *sec4* and *ypt1*. The fact that these two yeast orthologues had previously been implicated in membrane trafficking provided the first clues that the members of the Rab GTPase family function in membrane trafficking in higher eukaryotes. In the years that followed, several research groups (notably the Zerial group) extended the family to 11 then to between 30 and 40 distinct members. With the aid of information from the human genome project, 60 distinct human Rab GTPases have now been identified.

Primary Structure and Evolution

The Rab family members are the most divergent and extensive branch of the ras superfamily. They contain ~200 amino acids with a molecular mass between 20 and 25 kDa, and are hydrophilic in nature (see Figure 2 for a schematic representation of Rab functional domains). Like all G proteins, they contain well-conserved guanine nucleotide binding domains (G-boxes) but otherwise are quite divergent – particularly in their carboxy-terminal region. This region is known to be critical for specifying membrane localization.

Their extreme carboxy termini also possess a characteristic conserved CC or CXC motif (C = cysteine, X = any amino acid). This motif is post-translationaly modified, in a process known as isoprenylation, by the addition of geranyl groups. The addition of a hydrophobic moiety on the cysteine results in a protein that is chemically competent for insertion into the lipid bilayer (further details on post-translational modifications are discussed later in this article).

By analogy with the Ras proteins, a further domain has been identified in the Rabs – the "effector" domain. This domain of ~10 amino acids was found to be critical for transmission of the Ras signal to its downstream machinery. Mutation of this effector domain abolishes growth signaling, independent of Ras GTP binding. Thus, this region was named the effector domain of ras. The equivalent region in the Rabs, also termed the effector domain, is frequently mutated in studies that investigate Rab function.

By analogy with the oncogenic Ras mutants, a number of Rab mutations have been generated. The most frequently utilized activating mutant for the

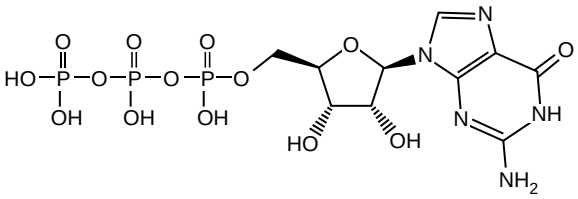

FIGURE 1 The structure of GTP.

Rabs is at amino acid position ~70 and is generated by the conversion of a glutamine (Q) to a leucine (L) at this position. Such Rab mutants are deficient in GTPase activity and thus remain in the 'activated' GTP-associated state (see Figure 1 for GTP structure). A serine (S) to asparagine (N) mutation, near amino acid 20, generates a dominant negative Rab mutant, that is constitutively GDP-bound and therefore inactive. Expression of these mutants in mammalian cells has revealed important Rab functional data.

In a study of the evolution and complexity of the core protein machinery involved in intracellular trafficking (coat complexes, Rab GTPases, SNAREs, and Sec1s) by the Scheller group, 60 distinct Rab genes were identified in humans. It was noted that there was a significant expansion of the Rab family from yeast to worms, and a further expansion from worms to mammals. A phylogenetic tree of the human Rab family is reproduced from Bock *et al.* (see Figure 3). Of the four core membrane-trafficking families compared, the Rabs were the only family that underwent such a significant expansion. It is likely that the higher degree of complexity in multicellular organisms is reflected by the greater requirement for Rabs, not only for more intricate regulation of intracellular trafficking but also for tissue specialization of membrane-trafficking functions.

The Rab family can be divided into ~10 subfamilies. Representative members of these subfamilies are Rab1, Rab3, Rab4, Rab5, Rab6, Rab8, Rab11, Rab22, Rab27, and Rab40.

Post-translational Modifications

Rab proteins are hydrophilic, thus, in order for membrane binding they must possess one, or two, C20 geranyl–geranyl lipid groups at their carboxy terminus. The process by which they gain these lipid moieties is known as isoprenylation. Newly synthesized, unprenylated, Rab GTPases are bound by Rab escort protein (REP) and delivered to Geranylgeranyl Transferase (GGTase). GGTase catalyzes the attachment of the lipid groups to two carboxy-terminal cysteine residues present on all Rab GTPases. REP appears to be a specialized Rab GDI that can deliver newly synthesized, GDP-bound, Rab proteins to GGTase for isoprenylation, and then transport the modified protein to its target membrane. It is thought that Rab-GDP binds its host membrane via a protein receptor, which 'senses' the Rab carboxy-terminal domain, however, very little evidence currently exists in the literature regarding the identity of such Rab receptors. Thus, while the amino acid sequence in the C-terminal region confers membrane specificity to a given Rab, the isoprenoid group confers chemical compatibility with the membrane, anchoring the otherwise hydrophilic protein in the hydrophobic lipid bilayer.

Cellular Localization

Rab proteins have now become standard markers for organelles of the secretory and endocytic pathways. Not all 60 human Rab GTPases have yet been sufficiently characterized such that the entire Rab localization pattern is known. However, for those that have been characterized, it is clear that they localize to distinct membrane organelles. For example, Rab1 localizes to the ER/*cis*-Golgi and Rab3 localizes to synaptic vesicles/chromaffin granules of the neuroendocrine system, while Rab5, Rab4, and Rab11 localize to distinct early endosomal membranes, Rab6 is located

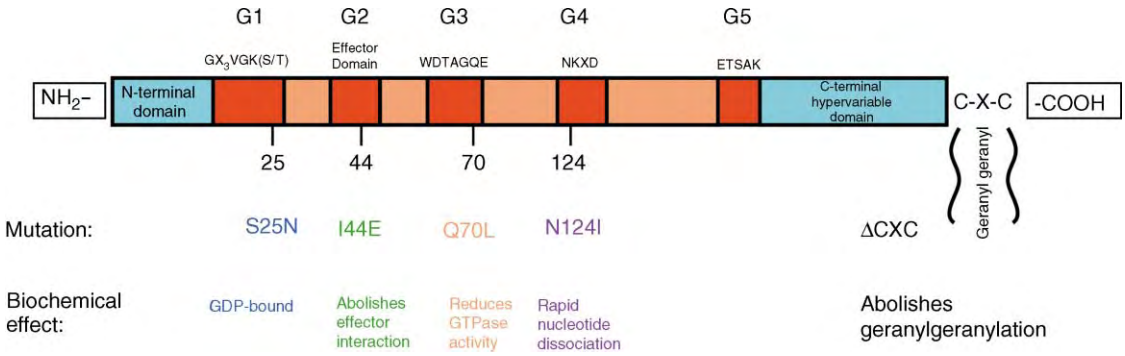

FIGURE 2 Schematic diagram of the general domain structure of Rab GTPases. Indicated are the commonly used Rab11 mutations and their biochemical consequences.

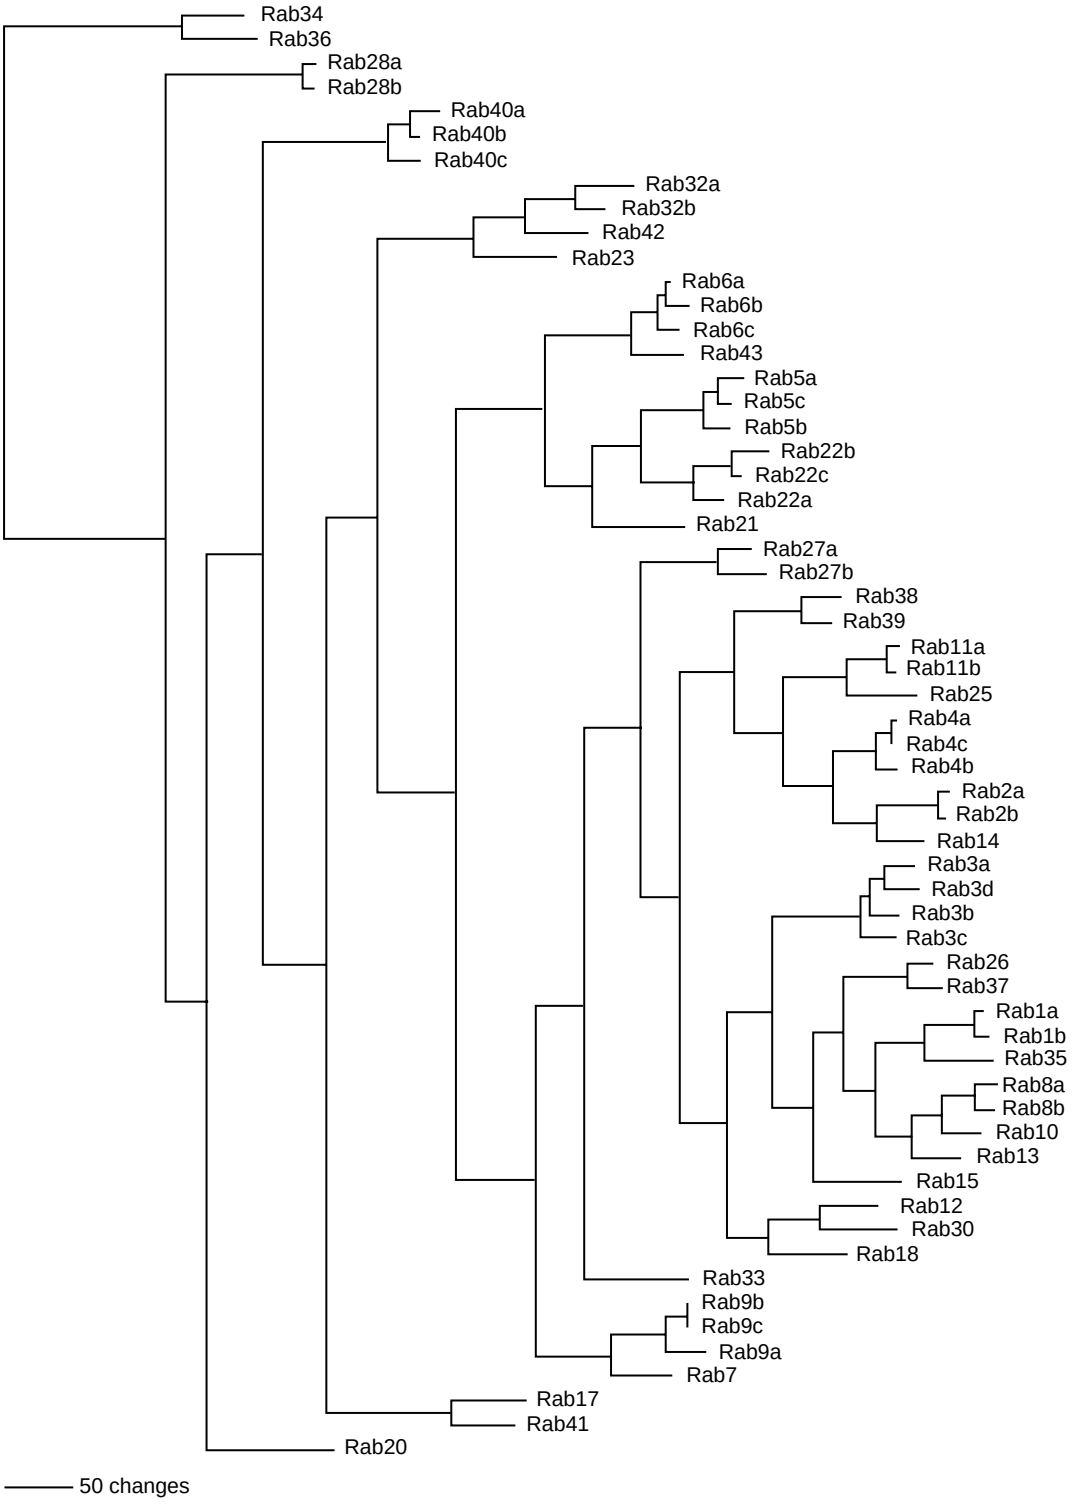

FIGURE 3 Phylogenetic tree of the human Rab GTPases. (Reprinted from Bock, J. B., Matern, H. T., Peden, A. A., and Scheller, R. H. (2001). A genomic perspective on membrane compartment organization. *Nature* **409**, 839– 841, by permission of Nature.)

on the Golgi apparatus, Rab7 is on late endosomes, Rab22 localizes to endosomes and the Golgi and Rab27 to melanosomes and lytic granules. Figure 4 and Table I indicate the known localization and trafficking steps controlled by Rabs characterized to date.

Functional Cycle

The functional cycle of Rab5 has been extensively characterized and is used here as a paradigm of all Rabs (see Figure 5 for generalized Rab GTPase cycle).

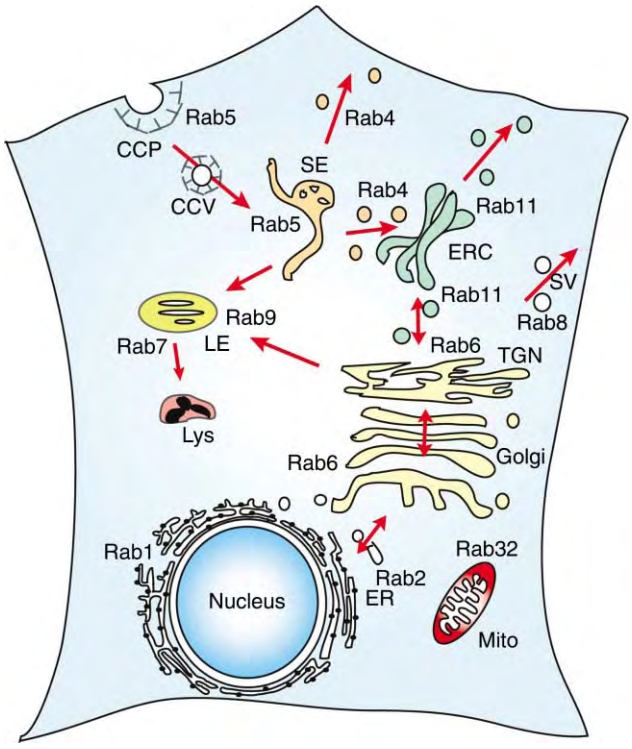

FIGURE 4 Localization of selected Rab GTPases and the membrane-trafficking pathways they regulate. The endocytic pathway involves internalization of cargo in clathrin-coated vesicles (CCV) and delivery to the early/sorting endosome (SE). Cargo is then either sorted for transport along the degradative pathway to the late endosomes (LE) and lysosomes (Lys), or directly recycled back to the plasma membrane from the SE, or indirectly, via the endocytic recycling compartment (ERC). The biosynthetic pathway transports proteins from the endoplasmic reticulum (ER) through the Golgi complex from where they are delivered to the cell surface in secretory vesicles (SV). The endocytic and secretory pathways communicate through the *trans*-Golgi network (TGN).

GDP-bound Rab5 is delivered to its target membrane by Rab guanine nucleotide dissociation inhibitor (Rab GDI). Rab guanine nucleotide exchange factor (Rab GEF) then catalyzes the exchange of the GDP for GTP, allowing Rab5 to adopt its active conformation. The GTP-bound Rab is now resistant to extraction by Rab GDI. Once membrane associated and in its active conformation the Rab protein is now competent to exert a controlling function on membrane trafficking. Rab5 mediates its function by recruiting a repertoire of specific effector proteins necessary for fusion of early endosomes. Upon completion of Rab function the GTP is hydrolyzed by the Rab GTPase enzymatic activity, releasing inorganic phosphate and resulting in an inactive Rab bound to GDP. This GTPase activity is stimulated by Rab GTPase *a*ctivating *p*rotein (Rab GAP).

Rabs have been variously implicated in vesicle budding from the donor membrane, transport along the cytoskeleton, docking to, and fusion with, the acceptor membrane. Though there is evidence for various Rabs of their involvement in these distinct events in membrane trafficking, it is not clear whether some Rabs function in vesicle budding exclusively, while others function in vesicle transport or docking, or whether a given Rab, in association with one specific set of effector proteins, functions in budding and in combination with other sets of effector proteins functions in transport, docking, or fusion.

Effectors

Several putative Rab effectors have been identified – primarily by two-hybrid library screening with GTPase deficient (dominant-positive) Rab mutants. While a survey of all of the Rab effectors reported in the literature is beyond the scope of this review, it is clear that there are likely to be many more Rab effectors than Rab GTPases. The GTP-bound form of Rab5 has been shown to interact specifically with at least 20 different proteins. Several Rab effectors have coiled-coil and/or phospholipid-binding domains (such as FYVE or C2 domains), while some are enzymes, or cytoskeletal (actin or tubulin) motor proteins. Identification of Rab effectors, and regulatory proteins, is a very important approach towards understanding the function of Rab GTPases and is likely to be an area of continued research for several years to come.

Rabs and Diseases

Sequencing of the human genome has revealed that a substantial number of disease-causing genes are involved in membrane trafficking. A proportion of these genetic diseases are the result of mutations in Rab GTPases, or their interacting proteins. Griscelli syndrome is an autosomal recessive disorder that results in pigmentation defects. There are two variants of this disease, one that results in immunological defects, and the other is associated with neurological dysfunction. The former is caused by missense mutations in the Rab27a gene, and the latter is the result of mutations in its putative effector, myosin Va. Both are located side-by-side on chromosome 15. Rab27a functions to regulate the transport of melanosomes to the periphery of melanocytes, also regulating the secretion of lytic granules in cytotoxic T lymphocytes. Hence, the lack of functional Rab27a results in the loss of pigmentation and in the uncontrolled activation of T lymphocytes. Mutation of myosin Va causes pigmentation defects, but since it is not involved in lytic granule movement, it does not cause immunological defects. Choroideremia is an X-linked disease that results in the degeneration of the pigment epithelium of the eye. It is caused by a defect in the REP-1 gene. REP-1 is one of the two

TABLE I

Localization, Tissue Distribution, and Function of the Human Rab GTPases

Rab GTPase	Localization	Tissue expression	Function
Rab34	Golgi	Ubiquitous	Lysosome positioning
Rab36	Golgi	Unknown	Unknown
Rab28	Unknown	Unknown	Unknown
Rab40	Unknown	Unknown	Unknown
Rab32	Mitochondria	Ubiquitous	A-kinase anchoring protein
Rab42	Unknown	Unknown	Unknown
Rab23	Unknown	Brain	Negative regulator of Sonic hedgehog pathway in mouse
Rab6	Golgi	Ubiquitous	Retrograde Golgi transport
Rab43	Unknown	Unknown	Unknown
Rab5	Plasma membrane, CCVs, and early endosomes (EE)	Ubiquitous	Transport from the plasma membrane to EE
Rab22	EE, LE, Golgi	Ubiquitous	Communication between biosynthetic and endocytic pathways
Rab21	Apical vesicles	Ubiquitous	Unknown
Rab27	Melanosomes and granules	Melanocytes, platelets, and lymphocytes	Transport of melanosomes and lytic granules
Rab38	Melanosomes	Melanocytes	Melanosome sorting
Rab39	Golgi-associated organelles	Ubiquitous	Endocytosis
Rab11/Rab25	Recycling compartment (RC) and TGN	Ubiquitous	Endocytic recycling and transport to TGN
Rab4	EE	Ubiquitous	Endocytic recycling and degradation
Rab2	Golgi	Ubiquitous	Golgi to ER transport
Rab14	ER/Golgi/Endosomes	Ubiquitous	Transport between Golgi endosomes
Rab3	Synaptic vesicles (SV)	Neurons	Regulation of neuro-transmitter release
Rab26	Secretory granules	Parotid gland	Regulated secretory pathway
Rab37	Secretory granules	Mast cells	Mast cell degranulation
Rab1	ER/*cis*-Golgi	Ubiquitous	ER to Golgi transport
Rab35	Unknown	Unknown	Unknown
Rab8	Transport vesicles	Ubiquitous	Regulates polarized membrane transport
Rab10	Golgi	Ubiquitous	Unknown
Rab13	Junctional complexes	Epithelial cells	Regulation of structure and function of tight junctions
Rab15	EE and RC	Ubiquitous	Inhibitor of endocytic recycling
Rab12	Granules/Golgi	Ubiquitous	Unknown
Rab30	Golgi	Unknown	Unknown
Rab18	Apical dense tubules	Epithelial cells	Unknown
Rab33	Unknown	Unknown	Unknown
Rab9	LE	Ubiquitous	LE to TGN transport
Rab7	Late endosomes (LE)	Ubiquitous	Transport from LE to lysosomes
Rab17	Epithelial cells	Apical RC	Transport through apical RC
Rab41	Unknown	Unknown	Unknown
Rab20	Apical dense tubules in kidney tubule epithelial cells	Epithelial cells	Unknown

isoforms of GGTase that prenylate Rab GTPases. It is essential for the prenylation of Rab27a in the retinal pigment epithelium. REP-2 appears to be sufficient for the efficient geranyl-geranylation of all other Rab GTPases. Thus, the lack of functional REP-1 results in nonfunctional Rab27a and the onset of the disease. The pathology of this disease may be caused by the degeneration of the retinal epithelium due to deficient melanosome transport, and hence lack of protection during light exposure.

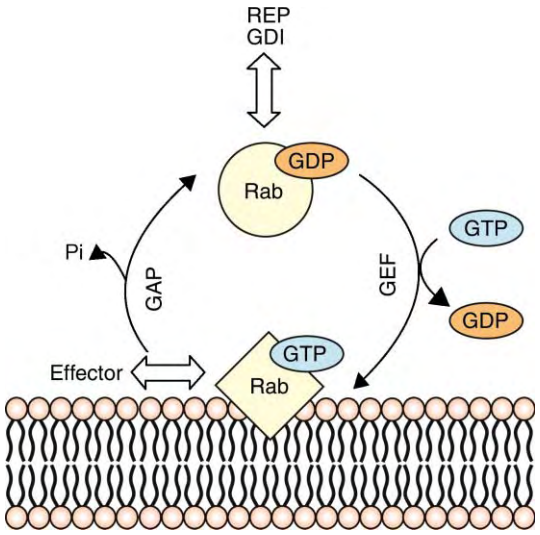

FIGURE 5 The Rab GTPase cycle. Rab GTPases cycle between GTP- and GDP- bound forms, allowing the Rab to adopt active and inactive conformations. The cycle is mediated by various accessory factors. A guanine-nucleotide exchange factor (GEF) exchanges the GDP for GTP. Conversion from the GTP- to the GDP-bound form is mediated by a GTPase-activating protein (GAP) which stimulates the Rab to hydrolyze bound GTP. The active GTP-bound form mediates its function through specific effector molecules. Newly synthesized cytosolic, GDP-bound Rab, interacts with Rab escort protein (REP) for membrane delivery. Subsequently, after each functional round, the GDP-bound Rab is extracted by the GDP dissociation inhibitor (GDI) from its host membrane and delivered to a new membrane location for another functional round.

Tuberin is a tumor suppressor protein that interacts with Rabaptin-5 and negatively regulates endocytosis by acting as a Rab5-GAP. Its inactivation causes tuberous sclerosis, a disease that results in malformations and tumors of the central nervous system. Finally, mutations in the GDI1 gene, which encodes GDI-α have been found in a subgroup of patients with X-linked nonspecific mental retardation. GDI-α is particularly abundant in brain tissue, thus defective membrane recycling of one or more Rab GTPases in brain synapses is likely to be the cause of this condition.

Biography

Mary W. McCaffrey is a Lecturer in Biochemistry and Science Foundation Ireland (SFI) Investigator in the National University of Ireland, Cork. Her principal research focus involves the functional characterization of Rab proteins in mammalian endosomal trafficking. She holds a Ph.D. from the University of London, England and received postdoctoral training in the Pasteur Institute, Paris, France. Her group is a world leader in the identification and characterization of the Rab11 effector machinery.

Ran GTPase

Mary Shannon Moore
Baylor College of Medicine, Houston, Texas, USA

Ran (Ras related nuclear protein) is a 25 kDa member of the Ras superfamily of small GTPases. To date, a Ran homologue has been found in every nucleated cell of every eukaryotic organism on Earth, and Ran is essential for the viability of all those cells. During interphase, Ran plays an essential role in driving and regulating the active transport of cargo between the nucleus and cytoplasm. Ran also has critical functions during mitosis when Ran is essential for mitotic spindle assembly and placement as well as re-assembly of the nuclear envelope.

Small GTP-Binding Proteins as "Molecular Switches"

Ran is called a GTPase because it binds and hydrolyzes GTP. All small GTPases of the Ras superfamily cycle between GTP- and GDP-bound states, and undergo a marked conformational change upon conversion from one state to the other. Thus, GTPases in the GTP-bound form can bind proteins that the GDP-bound form cannot, and vice versa. This key property confers on small GTPases the ability to function as "molecular switches" that cycle between active and inactive states, the GTP-bound form generally being the active form.

Ran represents its own family of small GTP-binding proteins in the Ras superfamily, of which it is the only member. The other families include the Ras, Rab, Arf, Rac, and Rho families that regulate signal transduction, vesicular transport, cytoskeletal organization, and cell proliferation. Ran's role is to act as a "switch" to regulate nuclear transport during interphase and spindle, and nuclear envelope assembly during mitosis.

Nucleocytoplasmic Transport

A basic necessity of the eukaryotic cell is the ability to transport macromolecules bidirectionally between the nucleus and cytoplasm. The traffic between these two compartments is both heavy and complex with multiple classes of cargo being actively transported in both directions (Figure 1). Nuclear proteins such as transcription factors and histones are, like all proteins, made in the cytoplasm and must cross the nuclear envelope into the nuclear interior to carry out their function. Conversely, ribosomal subunits, tRNAs, and mRNAs produced inside the nucleus must cross the nuclear envelope in the opposite direction into the cytoplasm in order to be used for protein translation.

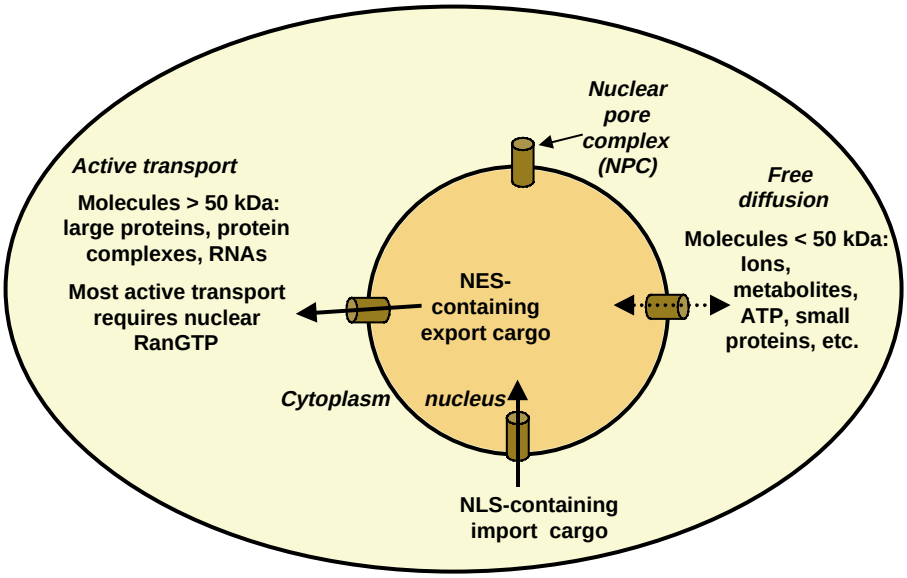
Nucleocytoplasmic traffic is restricted to nuclear pore complexes (NPCs), which are large proteinaceous structures that bridge the double membrane of the nuclear envelope to form aqueous channels linking the cytoplasm and nucleoplasm. The vertebrate NPC is composed of ~30 different proteins and a HeLa cell contains ~3000 NPCs. At present, all NPCs appear to be functionally identical with the same NPC capable of carrying out both import and export virtually simultaneously. While molecules up to ~50 kDa can diffuse through the NPC, the majority of nuclear proteins (both larger and smaller than 50 kDa) as well as the other classes of transport cargo appear to undergo signal-mediated active transport rather than diffusion.

There are two types of nuclear transport signals, NLSs (nuclear localization sequences) that mediate nuclear import and NESs (nuclear export sequences) that mediate nuclear export. There are multiple types of NLSs and NESs found on different types of cargo, and, in general, each type of signal is recognized by a different nuclear receptor/carrier. Most nuclear carriers are members of the karyopherin-β superfamily and there are over twenty members of this family in human cells. During nuclear import, a soluble carrier binds the NLS-containing cargo in the cytoplasm, then moves the cargo through the NPC and releases it in the nuclear interior. Nuclear export works essentially the same way in reverse, with an NES-containing cargo being recognized by its specific carrier inside the nucleus, movement of the export complex through the NPC, and disassembly of the complex and release of the cargo upon reaching the cytoplasm.

The Ran GTPase

The Cellular Gradient of RanGTP

A key player in the majority of the known nuclear transport pathways is the small GTPase Ran and, not



Some NLS-containing import cargo:	Some NES-containing export cargo:
Nuclear proteins	Shuttling proteins
Shuttling proteins	Newly formed ribosomal subunits
	tRNAs
	mRNAs

FIGURE 1 Overview of nucleocytoplasmic transport. Most nuclear transport requires nuclear RanGTP, however mRNA export does not. Carriers of the NTF2 family mediate mRNA export, and this transport pathway is Ran-independent. Active transport of the rest of the cargo listed does require nuclear RanGTP.

incidentally, the main region of homology between all the karyopherin-β nuclear carriers is a RanGTP-binding domain. Inside the cell, Ran is primarily nuclear in spite of the fact it does not appear to contain an NLS in its sequence. This is because Ran is actively imported into the nucleus by a small protein called p10/NTF2, which is a member of a second class of nuclear carriers, the NTF2 family.

Importantly, whether Ran is in the cytoplasm or nucleus determines whether it is RanGTP or RanGDP (Figure 2). Inside the nucleus, Ran is converted to the GTP-bound form by the RanGEF (guanine nucleotide exchange factor), which stimulates RanGDP to release GDP and bind GTP. In contrast, the RanGAP (GTPase-stimulating protein) is located in the cytoplasm. The RanGAP rapidly converts any RanGTP entering the cytoplasm to RanGDP by stimulating Ran to hydrolyze its bound GTP.

The resulting concentration gradient of low RanGTP in the cytoplasm to high RanGTP in the nucleus is vitally important for controlling the directionality of nuclear transport by regulating the assembly and disassembly of karyopherin-β containing transport complexes. Also, because the RanGEF is bound to chromatin, the concentration of RanGTP is highest near the chromatin where it is produced (Figure 2C). This location becomes important during mitosis, when chromatin-localized RanGTP stimulates mitotic spindle and nuclear envelope assembly in the correct location around chromatin.

Cellular Functions of Ran

Nuclear Transport

The increasing RanGTP concentration from the cytoplasm to the nuclear interior is the primary factor that triggers the disassembly of transport complexes at their correct final destination. Members of the karyopherin-β family preferentially bind RanGTP with a much lower affinity for RanGDP, and upon binding RanGTP, the karyopherin-β carrier undergoes a conformational change that alters its cargo-binding domain. NLS receptors of the karyopherin-β family can only bind their cargo when they do not have bound RanGTP, which is their probable state in the cytoplasm. After movement across the NPC into the nuclear interior where the import complex encounters RanGTP,

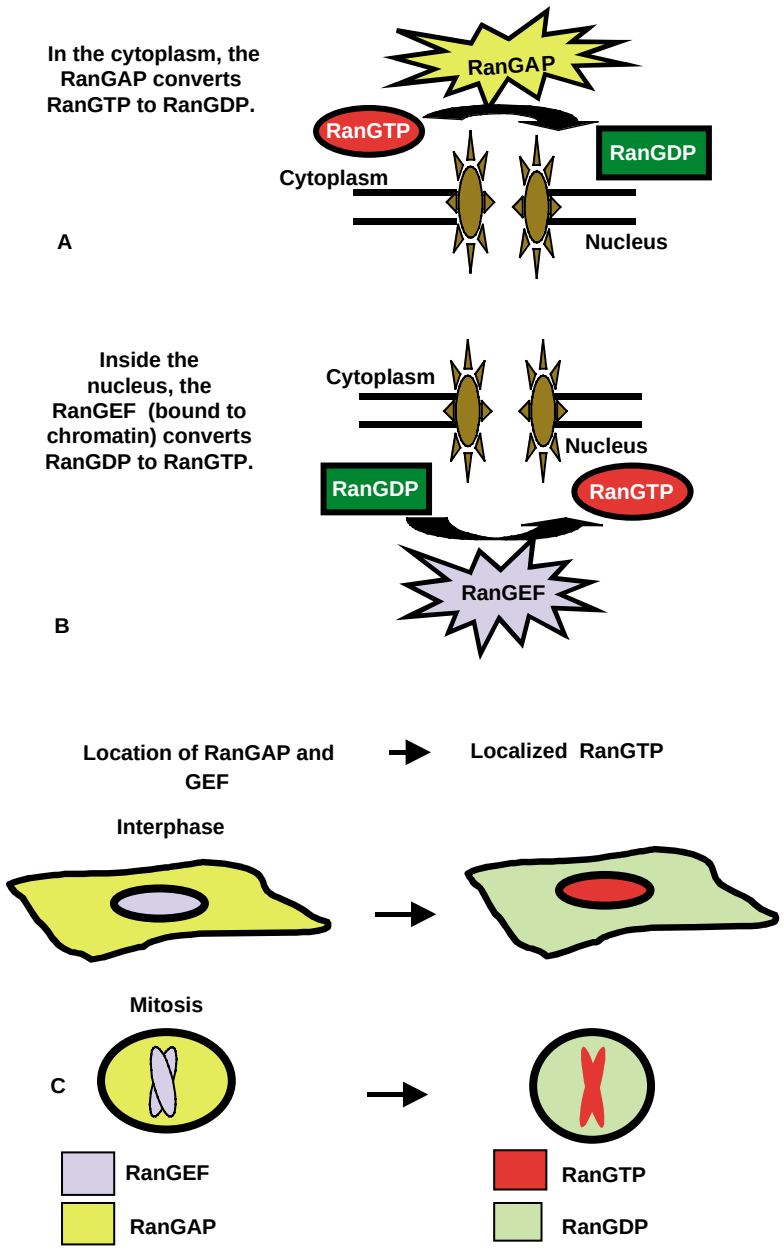


FIGURE 2 Establishment of the RanGTP gradient between the cytoplasm and nucleoplasm. (A) The RanGAP, which stimulates Ran to hydrolyze its bound GTP, is restricted to the cytoplasm. (B) The RanGEF, which stimulates Ran to release bound GDP and take up GTP, is found inside the nucleus bound to chromatin. (C) Restricting the RanGAP and the RanGEF to different compartments results in high levels of RanGTP inside the nucleus and low levels of RanGTP in the cytoplasm during interphase (top). The resulting gradient of RanGTP concentration between the cytoplasm and nucleoplasm is the key regulatory mechanism controlling the assembly and disassembly of nuclear import and export complexes in the correct cellular location (see Figure 3). Also, the RanGEF remains bound to chromatin throughout the cell cycle, and production of RanGTP at the chromatin surface in mitotic cells is required for proper placement of the mitotic spindle and re-assembly of the nuclear envelope around chromatin at the end of mitosis (bottom).

the carrier binds RanGTP, and as a result, releases its cargo into the nuclear interior (Figure 3A).

Export carriers of the karyopherin-β family behave just the opposite. These export carriers, in order to simultaneously bind their export cargo, must first bind RanGTP. After movement through the NPC, the cargo:export carrier:RanGTP complex encounters the RanGAP in the cytoplasm. Ran is stimulated to hydrolyze its bound GTP, and after hydrolysis, becomes RanGDP. The export carriers have a low affinity for RanGDP and, as a result, both RanGDP and an export cargo dissociate from the export carrier in the cytoplasm.

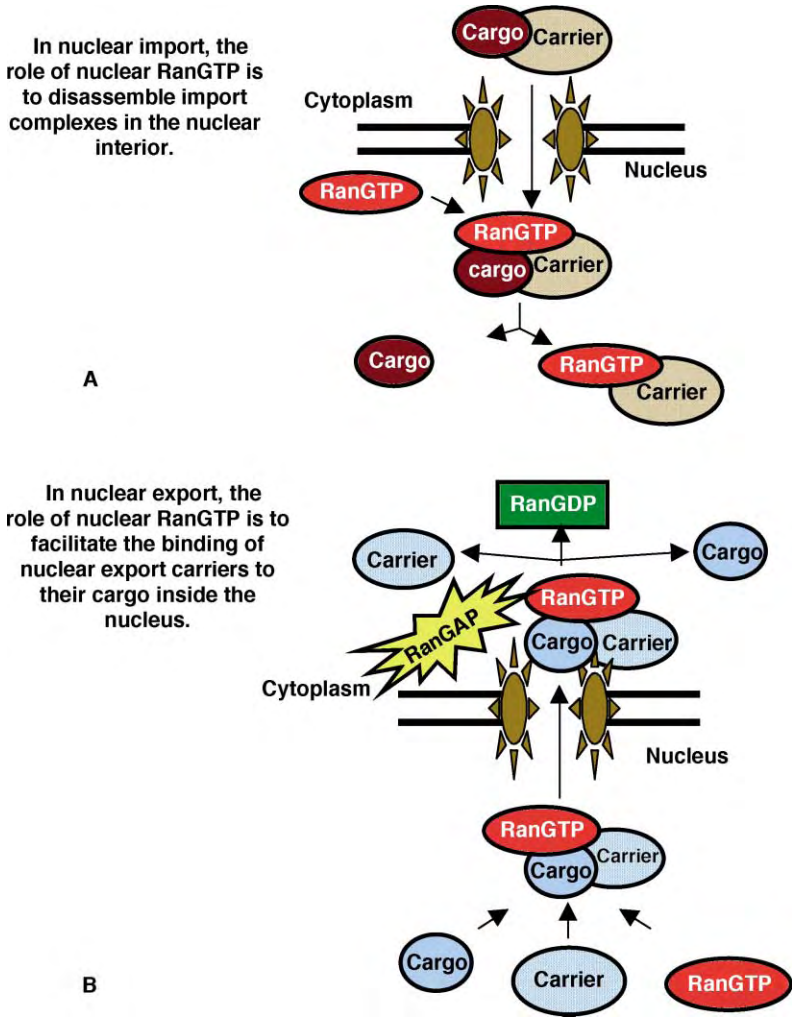

FIGURE 3 The RanGTP gradient across the NPC controls the assembly and disassembly of nuclear transport complexes. (A) Nuclear import carriers cannot bind import cargo and RanGTP simultaneously. After import of the import carrier:cargo complex through the nuclear pore complex (NPC), the carrier binds nuclear RanGTP. As a result of binding RanGTP, the import carrier releases the import cargo in the nuclear interior. (B) In contrast to nuclear import carriers, nuclear export carriers require bound RanGTP in order to bind their export cargo with high affinity. After export through the NPC, the export complex (RanGTP:export carrier:cargo) encounters the RanGAP in the cytoplasm that stimulates Ran to hydrolyze its bound GTP. Conversion of RanGTP to RanGDP results in the release of RanGDP and export cargo from the export carrier into the cytoplasm.

Regulation of Spindle and Nuclear Envelope Assembly at Mitosis

The nuclear envelope vesiculates and breaks apart during mitosis in vertebrate cells, and then reforms after the daughter cells are divided. Accordingly, no nuclear transport occurs during this time because there is no nuclear envelope and the cytoplasmic and nuclear contents are mixed. Ran however has additional functions critical to this period. Nuclear proteins containing an NLS are once again exposed to the NLS receptors and can be re-bound by them. However, as during nuclear import, RanGTP can break this complex apart, releasing the proteins.

Many of the proteins responsible for assembly of the mitotic spindle at mitosis are nuclear during interphase and contain an NLS. To be active for spindle assembly, RanGTP must first release these spindle assembly factors from NLS receptors. Because the concentration of RanGTP is highest, close to the chromatin due to the RanGEF located there; active spindle assembly factors (as opposed to inactive factors complexed with NLS receptors) are also most concentrated there. RanGTP is thus essential for spindle formation; both to release spindle assembly factors from NLS-binding carriers and for correct orientation of the spindle around chromatin.

As stated above, when a human cell enters mitosis at the beginning of cell division, the nuclear envelope fragments into vesicles. At the end of mitosis, after the two daughter cells have separated, these membrane vesicles bind to the decondensing chromatin and then

fuse together laterally to re-form an intact nuclear envelope. RanGTP is essential for this fusion step, as is one particular nuclear carrier of the karyopherin-β family (importin-β), however the exact mechanism is not yet known.

Other Roles of Ran

In addition to the cellular roles for Ran discussed above, Ran has also very recently been implicated in prevention of re-replication of chromatin during S phase and in regulation of kinetochore function throughout the cell cycle. It should be noted that in all of the multiple pathways in which Ran has been implicated, the general nature of the biochemical reaction carried out by Ran remain constant. Switching between RanGDP and RanGTP controls Ran's association with different proteins, and Ran's association with assorted proteins has different downstream effects depending on the protein involved, the cellular location where the interaction occurs, and the stage of the cell cycle when the interaction occurs. In summary, the Ran GTPase plays a powerful and irreplaceable role in the eukaryotic cell, both for constitutive viability and for cell division.

Biography

Mary Shannon Moore is an Assistant Professor in the Department of Molecular and Cellular Biology at Baylor College of Medicine, Houston. Her principal research interests are nuclear structure and function and nucleocytoplasmic transport. She received her Ph.D. from UT Southwestern Medical Center at Dallas, and did her postdoctoral work in Dr. Günter Blobel's laboratory at Rockefeller University in New York. In 1993, Drs. Moore and Blobel published the first paper showing a role for Ran in nucleocytoplasmic transport.

Ras Family

Lawrence A. Quilliam
Indiana University School of Medicine, Bloomington, Indiana, USA

Since the discovery of Ras activity in a cancer-causing retrovirus in 1964, it has become the prototype of a superfamily of over 100 GTP-binding proteins that regulate a myriad of biological functions in eukaryotic cells. This superfamily can be subdivided based on primary sequence or biological function into five major subfamilies; Ras, Rho, Rab, Ran, and ARF. This article will focus on the Ras subfamily of proteins that are primarily responsible for regulating cell proliferation and differentiation. These proteins function as molecular switches that alternate between active GTP and inactive GDP-bound conformations. Acquisition of the active GTP bound state and its hydrolysis to GDP are tightly regulated by guanine-nucleotide-exchange factors (GEFs) and GTPase activating proteins (GAPs) that in turn receive direction from the signal transduction pathways that are elicited by hormone and growth factor binding to cell surface receptors. Upon activation, Ras proteins bind specific downstream effector proteins, promoting their subcellular relocalization or conformational changes that result in their activation and transmission of a signal to induce events that include gene expression and cytoskeletal rearrangement. Mutations that prevent GTP hydrolysis result in constitutive signaling to downstream effectors and promote uncontrolled cell growth. These mutations are found in several common human cancers and can be used by researchers to understand their mechanism of action.

Physical Properties

Ras family proteins are often referred to as small or low-molecular weight GTPases. This is due to their 20–25 kDa size being smaller than the 38–52 kDa α-subunits of the heterotrimeric G proteins, another class of cell signaling molecules that bind and hydrolyze GTP. Ras proteins consist of a core GTP-binding/GTPase domain that encompasses ~160 amino acids, followed by a hypervariable domain that is thought to act as a flexible linker, and a C-terminal CAAX (cysteine-aliphatic-aliphatic-other amino acid) motif that is the signal for posttranslational lipid modification, see Figure 1. Addition of a 15 carbon farnesyl or 20 carbon geranylgeranyl isoprene group to the Cys, cleavage of the three C-terminal (AAX) residues, and methylation of the C-terminal COO- group help promote the membrane targeting of most Ras subfamily GTPases. Additional palmitylation of nearby cysteine(s) or presence of many basic (arginine, lysine) residues in the hypervariable region help maintain tight membrane association. Membrane association is essential for Ras protein function and mutation of the CAAX cysteine, preventing the series of posttranslational modifications, disables Ras function. Most of the Ras superfamily proteins are modified by a geranylgeranyl transferase that adds the 20 carbon lipid. However, H-, K-, and N-Ras are modified by a farnesyl transferase that recognizes a different CAAX sequence that adds a 15 carbon farnesyl lipid instead. Because of this specificity, drugs that mimic the C terminus of Ras and/or the farnesyl lipid can block posttranslational modification and clinical trials are being performed to evaluate their use in cancer chemotherapy.

The GDP/GTP Cycle and Ras Mutations

Ras binds GTP and GDP, but not GMP, with very high affinity. The intrinsic rates of nucleotide exchange and GTP hydrolysis by Ras *in vitro* are very slow (on the order of minutes to hours) and not practical for a signaling molecule that needs to rapidly respond to stimuli. However, this is by design. Each Ras protein is tightly regulated by one or more guanine-nucleotide-exchange factors (GEFs) that help turn it on and GTPase activating proteins (GAPs) that subsequently help to inactivate it, see Figure 2.

Ras GEFs contain a CDC25 homology domain that shares similarity with the yeast RAS1/2 GEF, CDC25. There are over 30 CDC25 homologues in the human genome. Some are highly specific for one Ras protein while others catalyze nucleotide exchange and multiple family members. GEFs promote the release of GDP, then stabilize the nucleotide-free protein until GTP can bind and displace them. This occurs very rapidly *in vivo* due to the high affinity of Ras for GTP. Also because GTP is in a 10–20-fold excess over GDP, the GEF is predominantly

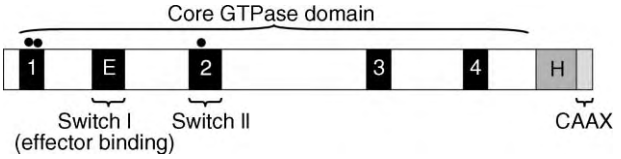

FIGURE 1 Linear diagram of Ras protein highlighting key sequences. Black areas are highly conserved across the entire Ras superfamily and form the guanine-nucleotide-binding pocket. Closed circles indicate sites of activating mutations found in human cancers. Switch I and II domains change conformation upon GDP versus GTP binding. E = effector binding loop that associated with downstream effectors. H = hypervariable domain, a 10–20 amino acid linker that also contributes to membrane binding. CAAX represents the terminal four residues that signal for posttranslational lipid modification of the cysteine residue. The identity of residue X dictates whether the G protein receives a 15 or 20 carbon lipid tail.

displaced by GTP. Because of the ability of nucleotide-free Ras to bind tightly to GEFs, dominant inhibitory mutants have been designed that have low affinity for nucleotide. These bind tightly to GEFs and prevent them from activating the endogenous wild type Ras, so blocking signaling pathways. These are useful tools for implicating Ras proteins or Ras pathways in the control of cellular events.

Although Ras is a GTPase, it has a poorly designed catalytic site. However, GAPs help stabilize the catalytic site and contribute a critical arginine residue that greatly accelerated nucleophilic attack of the GTP. One reason the α-subunits of heterotrimeric G proteins are bigger than Ras proteins is that they have an extra domain that contributes an "arginine finger" resulting in their typically having a higher intrinsic GTPase activity than Ras. Mutations that block intrinsic and GAP-stimulated GTP hydrolysis result in Ras proteins being locked in their active GTP-bound state. Such mutations at residues 12, 13, and 61 are found in H-, K-, or N-Ras in various human tumors. To date only ~10 Ras subfamily GAPs have been characterized. These fall into two structurally distinct families; those that regulate Rap/Rheb and those that regulate Ras and other GTPases. One of the Ras GAPs, neurofibromin, is the product of the NF1 tumor suppressor and, upon its loss, Ras GTP levels become elevated contributing to increase signaling that results in cancer and other proliferative diseases. Information on the better-characterized Ras subfamily members is discussed next.

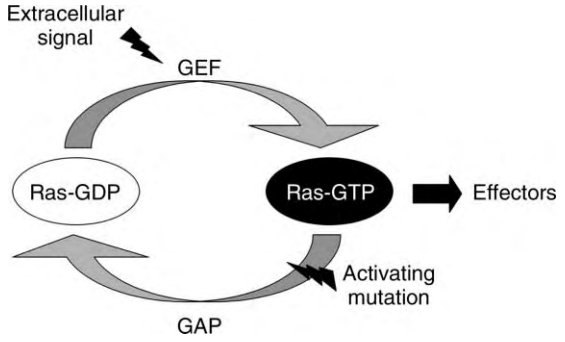

FIGURE 2 GDP/GTP cycle activity of Ras family GTPases. Ligand binding induce receptor-mediated activation or membrane-recruitment of guanine-nucleotide-exchange factors (GEFs) which promote the release of GDP from Ras and acquisition of GTP from the cytosol. GTP binding promotes a conformational change permitting Ras to associate with downstream effector proteins to elicit a biological response. GTPase activating proteins (GAPs) also recognize Ras-GTP and their binding promotes rapid acceleration of Ras' intrinsic GTPase activity. This converts Ras back to its inactive GDP-bound state from which the cycle can begin again. Mutations that block the intrinsic and GAP-stimulated GTPase activity lock Ras in its active, GTP-bound state.

H-, K-, and N-Ras

H-, K-, and N-Ras represent the original and best-studied/understood Ras proteins. Mutations of each of these proteins are found in human tumors with those in K-Ras being the most prevalent. K-Ras can have alternate splicing of its fourth exon with the 4B version being the most predominant.

It was long known that Ras was involved in growth control downstream of growth factor receptors and in 1993 an entire pathway from cell-surface receptor to the nucleus was delineated. The binding of growth factors to their protein tyrosine kinase receptors leads to phosphorylation of the receptors on tyrosine residues. This enables the binding of various adapter proteins that contain modular Src homology 2 or SH2 domains that recognize specific primary sequences that contain phospho-tyrosine. One such molecule is Grb2 that also has two SH3 domains that bind to proline-rich sequences like those found in the Ras GEF, Sos. Binding of a preformed Grb2-Sos complex to receptor tyrosine kinase results in recruitment of Sos to the plasma membrane where it promotes GTP-loading of Ras. In its active GTP-bound state, Ras now adopts a conformation that enables it to bind to the serine/threonine protein kinase, Raf. This in turn recruits Raf to the membrane, promotes a conformational change, and enables Raf to be phosphorylated by nearby kinase(s). Raf then phosphorylates MEK, which phosphorylates extracellular signal-regulated kinases (ERKs) 1 and 2. Phospho-ERKs dimerize and translocate into the nucleus where they phosphorylate transcription factors such as Elk1, leading to increased gene expression. It is now known that a number of additional signals activate Ras. For example, Ras GEFs (such as GRF1 in brain and GRP1 in T cells) and GAPs (Capri, Rasal) can be activated by Ca^{2+} elevation and/or diacylglycerol. Additionally, G protein-coupled receptors can trigger tyrosine phosphorylation to regulate the Grb2/Sos complex.

Ligand receptors reside on the plasma membrane and Ras also localizes there. However, recent studies indicate that Ras is also found on the Golgi membrane and that many of the events mediated by Ras occur at this intracellular site. One mechanism whereby activation of cell-surface receptors might signal to Ras at a remote intracellular membrane is via Ca^{2+} elevation, resulting in the activation of a $Ca2^{+}$-regulated exchange factor. This has been reported in T cells.

Binding of GTP triggers a conformational change in Ras in two regions called switch I and II. Switch I, which encompasses residues ~32–40 is the main determinant for effector binding. Conformation of this and switch II dictate which targets various Ras subfamily members associate with. A number of putative Ras effectors have been described however three have been best characterized. These include the protein kinase Raf, phosphatidylinositol 3 kinase, and RalGDS, an exchange factor for the Ras-related GTPase, Ral. There are several isoforms of each of these effectors that have different tissue distribution and affinities for various Ras family members. Each of these effectors has a related ~60 residue Ras association (RA) or Ras-binding domain (RBD). Since RA domains bind specifically to Ras-GTP, the isolated domains (typically fused to glutathione S-transferase and immobilized on glutathione-conjugated beads) can be used to precipitate Ras-GTP from cell lysates to gauge intracellular Ras activity. The Raf RBD is typically used to detect H-, K-, or N-Ras activity. While most Ras activity is associated with increasing cell growth and transformation, several recently characterized Ras targets that include RASSF1 appear to have tumor-suppressing properties.

Ral

As indicated above, a family of four Ral GEFs (RalGDS, Rgl, Rgl2/Rlf, Rgl3/RPM) possess Ras-binding domains and are downstream effectors of Ras. The primary function of Ras here is in recruiting Ral-GEFs to the membrane where they can activate Ral. In addition to being regulated by Ras/RalGDS, Ral is activated by Ca^{2+}, possibly due to its ability to bind calmodulin and by a second class of GEFs (the RalGPS or RalGEF2 family) that lack an RA domain.

Due to its regulation by Ras, initial studies focussed on its ability to regulate transformation. Recently RalGDS was found to be an important mediator of Ras-induced transformation in human epithelial cells. However, the downstream target(s) responsible for this effect remain to be identified. Ral or its GEFs have been reported to regulate various transcription factors including c-Fos, c-Jun, STAT3, and AFX (a member of the forkhead family). Interestingly, Ral-GEFs are often more potent at inducing biological effects than activated (GTPase-defective) Ral mutants. This may be because GTP/GDP cycling is required for Ral function or that binding of Ral-GEFs to additional proteins such as the serine/threonine kinase PDK1 or the scaffold protein, β-arrestin contributes to their biological activity.

Studies on Ral-binding proteins revealed the involvement of this GTPase in additional cellular functions that include vesicle sorting. This is not surprising since much of the Ral protein localizes to intracellular vesicles in both endocytic and exocytic compartments. Ral binds to and may assist in the formation of the exocyst, a complex of at least eight proteins, which directs vectorial targeting of vesicles from the Golgi to the basolateral but not apical membrane of epithelial cells. Ral is essential for this process in higher eukaryotes but, puzzlingly, Ral is not present in yeast where the exocyst was first identified. Ral also regulates receptor-mediated endocytosis but this is achieved via a distinct effector, RalBP1/RLIP76. RalBP1 binds to proteins associated with endocytosis but also contains a GAP-like domain for the Rho family GTPase, CDC42. It is via this activity that it may also regulate cell morphology. Given these myriad functions it is not surprising that Ral can contribute to cell proliferation and cancer.

R-Ras 1, 2, and 3

R-Ras, TC21 (R-Ras2), and M-Ras (R-Ras3) are closely related to Ras (Figure 3) and have overlapping signaling and biological function. However, although some activating mutations have been found in cultured cell lines, these GTPases appear to seldomly if ever be mutated in human cancers despite the transforming activity of laboratory-engineered mutants. R-Ras activates PI3K but does not regulate the Raf/ERK or RalGDS pathway. Distinct from H-Ras, it has been implicated in "inside-out" signaling, increasing the ability of integrin to bind extracellular matrix. This results in increased cell attachment and spreading. One study has implicated Rap1 as a mediator of R-Ras action, another example of a Ras protein cascade. The binding of R-Ras to focal adhesion kinase has also recently been reported, providing another avenue for it to regulate integrins and/or cell adhesion. Like R-Ras, TC21 and M-Ras also effectively activate PI3K. M-Ras preferentially activates B-Raf over the more common Raf-1 isoform. While M-Ras is most abundant in brain, the exact function of either M-Ras or TC21 is unclear.

Rap1 and 2

There are five members of the Rap cluster: Rap1A and 1B and Rap2A, 2B, and 2C. Rap1A/Krev-1 was isolated in 1988 due to sequence homology with Ras

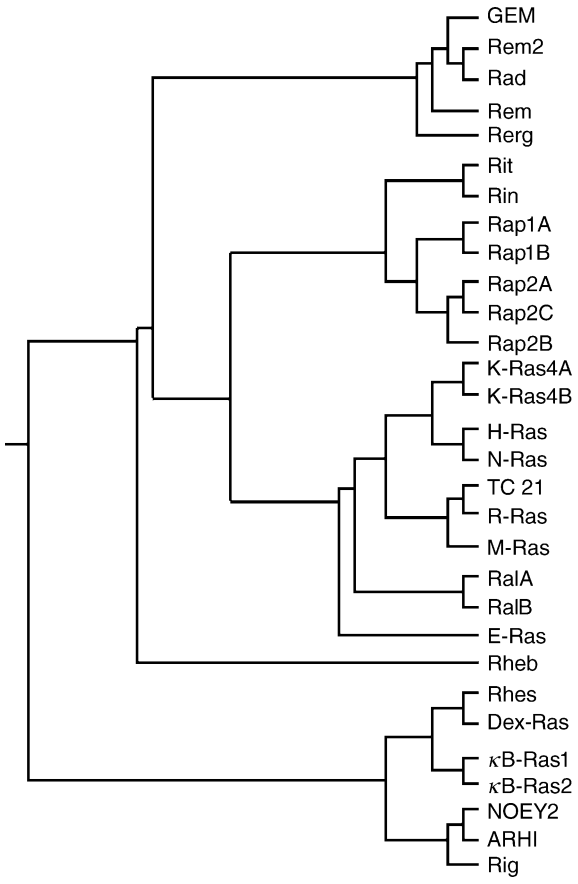

FIGURE 3 Dendrogram showing the relatedness of mammalian Ras subfamily GTPases.

(Ras proximate) and also due to its ability to revert the transforming activity of K-Ras. The revertant activity was believed due to Rap1A binding to Ras effectors and acting as a competitive antagonist of Ras. This indeed may be the true function of Rap in, e.g., T cells where Rap needs to be turned off by a costimulatory receptor such as CD28 in order for T cell receptor-induced activation of Ras to have its desired effect. However, the main role of Rap1 appears to be in the inside-out regulation of integrins. A Rap1 effector RAPL has recently been described in leukocytes that is responsible for promoting integrin clustering but how Rap regulated adhesion of cells in solid tissues has yet to be determined. While early studies described Rap1 and 2 localization to endocytic and Golgi membranes, recent studies have found Rap1 on epithelial cell junctions. It is likely that Rap1 and 2 plays multiple cell type-specific roles.

Rap1 and 2 are regulated by the same GEFs and GAPs. Strikingly, at least ten of the CDC25 family as well as the unrelated Smg GDS and DOCK4 proteins act as Rap GEFs suggesting that Raps play fundamental roles in cell biology that are triggered by a broad spectrum of extracellular stimuli. Signals from Ca^{2+}, diacylglycerol, receptor and nonreceptor protein tyrosine kinases, and cyclic AMP can all activate Rap. Indeed the protein kinase A-independent effects of cyclic AMP are due to activation of two Rap GEFs, Epac1 and 2 that contain cyclic nucleotide-binding domains. Several Rap GEFs contain RA domains, suggesting that they are recruited to membranes as downstream effector of other GTPases. This suggests that Rap activation may be a requisite for other Ras family members to execute their biological functions.

Rheb

Despite its name (Ras homologue expressed in brain), Rheb is found in many tissues. However it was discovered in 1995 as a protein whose expression was induced by synaptic stimulation. Although no Rheb GEFs have been found to date, Rheb's GTPase activity is regulated by TSC2, a tumor suppressor whose C terminus resembles Rap GAPs. Following loss of TSC2 or mutation of its GAP domain, the loss of GAP activity results in the accumulation of Rheb GTP. This activates a kinase cascade involving mTOR and ribosomal S6 kinase that promotes protein synthesis. Interestingly, Rheb is posttranslationally farnesylated similarly to H, K-, and N-Ras. It is therefore possible that Rheb represents an additional target of farnesyl transferase inhibitors designed to block Ras action and that these drugs might have use in the treatment of the proliferative disorders associated with tuberous sclerosis (TSC).

Other Ras Family Members

A number of additional GTPases exist (Figure 3) that are less well characterized but help exemplify the diversity of GTPase functions. These include ARHI/NOEY, Rig, and Rerg that have each been shown to play inhibitory roles. Critical conserved residues within their GTP-binding pockets diverge from those of most other Ras family members suggesting that these G proteins are constitutively GTP bound. The expression of these proteins can be induced by various agonists suggesting that they are regulated at the level of gene expression rather than by GEFs and GAPs. Further, it is their loss rather than mutation that contributes to cellular proliferation/transformation. Regulation at the level of transcription is not limited to these proteins; for example Dex-Ras expression is induced by corticosteroids, Rhes by thyroid hormone and as noted above Rheb by synaptic stimulation. Expression of many Ras family GTPases is also regulated by growth factors. Another branch of the Ras subfamily regulates transcription: κB-Ras binds to the IκB/NFκB complex and helps mask a nuclear localization sequence so that this transcription factor complex cannot translocate to the

nucleus and induce gene expression. The function of the Rad/Gem branch of the Ras family has until recently eluded investigators. However, they were recently shown to be negative regulators of the Rho–Rho kinase pathway, helping to explain their ability to modulate the actin cytoskeleton. Finally, several of the Ras family proteins lack the characteristic C-terminal CAAX box required for their posttranslational lipid modification. These include the closely related Rit and Rin proteins as well as Rerg and κB-Ras. While the former two proteins have been reported to regulate PC12, pheochromocytoma, cell differentiation, an event regulated by several Ras proteins via Raf and/or PI3K, Rit, and Rin appear to act via some alternative pathway(s). Interestingly, although Rit lacks any known recognition signal for C-terminal lipidation, Rit-transformed cell growth and survival in low serum is dependent on a farnesylated protein. Since most prenylated proteins are G proteins this suggests, once again, the existence of crosstalk between members of this subfamily of GTPases.

Glossary

effector Proteins (typically enzymes) that GTP-bound Ras proteins bind to elicit a biological response.

GTPase Describes the intrinsic GTP hydrolyzing enzymatic activity of Ras. Binds GDP or GTP with high affinity and catalyzes the hydrolysis of GTP to GDP and phosphate.

GTPase activating proteins (GAPs) Negative regulators of Ras that bind the GTPase and accelerate its ability to hydrolyze bound GTP.

Guanine-nucleotide-exchange factors Upstream positive regulators of Ras proteins that promote increased nucleotide exchange so that Ras can bind to GTP.

isoprenylation Process of irreversible post-translational covalent modification of the C terminus of proteins by 15 carbon farnesyl or 20 carbon geranylgeranyl isoprene-derived lipids.

Ras A high-affinity guanine nucleotide-binding protein with intrinsic GTPase activity that acts as a molecular switch or bio-timer by cycling between inactive GDP- and active GTP-bound states.

Lawrence Quilliam received his Ph.D. from the University of Sheffield, England and obtained postdoctoral training at the Scripps Research Institute, La Jolla, CA. He is currently an Associate Professor of biochemistry and molecular biology at Indiana University School of Medicine and a member of the Walther Oncology Center. His research focuses on the delineation of cellular signaling pathways involved in cancer with particular emphasis on Ras family proteins and their guanine nucleotide exchange factors.

Recombination: Heteroduplex and Mismatch Repair *in vitro*

Leroy Worth Jr.
National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina, USA

The methyl-directed repair pathway of *Escherichia coli* ensures genome stability by testing for the occurrence of mismatched base pairs. In addition to rectifying biosynthetic errors that occur through misincorporation during DNA biosynthesis, this pathway also controls the level of recombination between closely related sequences.

Mismatch Repair in Genetic Exchange

Early indications of the role of mismatch repair in genetic exchange were initially provided by the observation that null mutations in *mutS*, *mutL*, *mutH*, or *uvrD* genes result in a hyper-rec phenotype. Thus, in addition to replication error, DNA mismatches that arise during recombination are subject to the action of these activities. Specifically, the formation of hybrid or heteroduplex DNA during genetic exchange results in mispaired bases, which are formed at regions of sequence divergence between two homologous chromosomes. However, unlike mismatches produced during DNA replication, these mispairs are not necessarily promutagenic, but rather substrates for repair.

Homeologous recombination is defined as the genetic exchange between DNA sequences that are nearly identical. During this type of exchange, newly formed heteroduplex that failed to escape mismatch repair results in non-reciprocal exchange (gene conversion; non-Mendelian segregation), as one allele is replaced by the other.

Several studies have shown that as the level of divergence between DNAs decreases, so does the frequency with which they will recombine. Mismatch repair provides an efficient homology-sensing tool that assists in maintaining an energetic barrier to exchange between closely related sequences. Conversely, the low level of mismatches that happen to escape repair does not appear to be detrimental, but rather favors the appearance of newly formed recombinants, which may or may not be beneficial. Certainly, during meiotic recombination, a process required for proper chromosome segregation, a possible intolerable outcome of genetic exchange is imprecise chromosome disjunction.

The barrier to recombination caused by sequence divergence is most likely manifested at two distinct stages of recombination: the formation of heteroduplex joints and subsequent action of mismatch repair. The molecular steps of genetic recombination have been studied extensively in *Escherichia coli* and *Saccharomyces cerevisiae* and to a lesser extent in other systems. In *E. coli*, initial processing of the donor DNA is necessary to produce free single-stranded tails. The RecBCD enzyme unwinds and digests double-stranded DNA until a characteristic chi (χ) sequence (octanucleotide: 5′-GTCGGTGG-3′) is encountered. Once bound to chi, a cascade of events ensues, resulting in a free single-stranded 3′-end that is the substrate for RecA strand transfer. This free end is invasive and is able to displace one of the recipient strands in a RecA-dependent fashion.

In fact, no homologue of the RecD protein, which is necessary for DNA cleavage, is observed in *Bacillus*. All subsequent recombination functions are dependent on the function of RecA. The recombinant joint is subject to strand extension, branch migration mediated by the RuvAB (branch migration activity) complex, and editing. In *E. coli*, the editing process involves the methyl-directed mismatch repair system, controlled by the MutS and MutL proteins. In *Streptococcus pneumoniae*, the editing function is carried out by the homologous, nick-directed HexAB repair system. If mismatches are detected, the repair system may reject the entire donor strand and abort the recombination process.

RecA Strand Transfer

The level of homeologous recombination depends upon the degree of sequence divergence between the recombining sequences. It is known that independent of sequence identity, the degree of exchange is at least an order of magnitude lower than that between completely

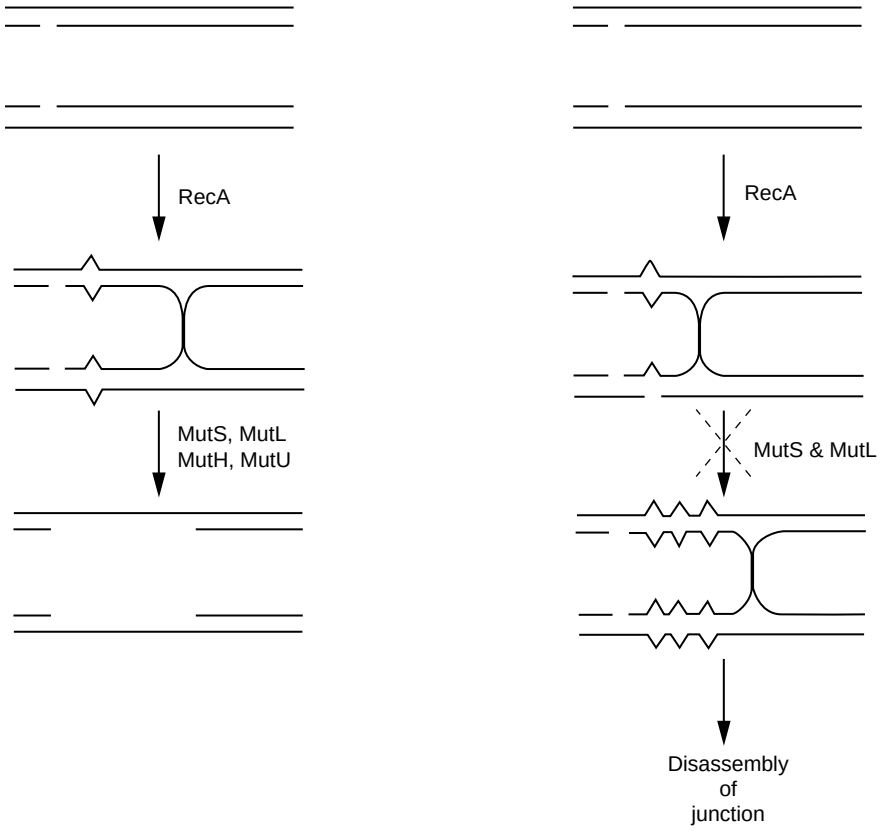

FIGURE 1 Potential mechanisms of DNA mismatch repair in modulating heteroduplex formation between divergent DNAs.

identical DNAs. This effect is remarkably independent of mismatch correction and can only be alleviated by the overproduction of proteins involved in recombination, specifically RecA protein.

The process of heteroduplex formation by RecA is associated with the initiation step of recombination and involves the formation of branched joints that proceed in a polarity-dependent fashion (Figure 1, top). These branched intermediates are stable and possess the ability to move through regions of lower sequence identity, thus the introduction of DNA mismatches. That near-perfect sequence identity is required for initiation is probably due to RecA-mediated homology search and the subsequent stability of the recombinant joint within the filament.

Mismatch Repair Mediates Heteroduplex Formation

DNA mismatch repair is able to recognize incorrect base pairs in DNA, but it is less known mechanistically as to how this pathway controls recombination between nearly identical DNAs. In terms of possible modes that could be envisioned, one might imagine that, as in replication fidelity, activities such as MutS and MutL could be involved in recognizing mismatches that are generated in newly formed heteroduplex. Indeed, these activities could act as a "mismatch sensing" and recognize regions of sequence divergence once they are encountered during the strand exchange process (Figure 1). Biochemical evidence for such a possibility was first demonstrated by studies of Worth *et al.* using purified *E. coli* repair activities. Both MutS and MutL proteins were shown to block RecA-mediated strand transfer between DNAs that shared more than 96% sequence identity. Specifically, using filamentous bacteriophage DNAs M13 and fd, whose DNAs share approximately 97% sequence identity, and the model three-strand *in vitro* transfer reaction, this study was able to show that RecA catalyzes the complete transfer of the complement strand, beginning with the 3′-end originating from a linear duplex molecule. The transfer of the complement results in a displaced linear single-strand that is formed from the 5′-end of the opposite strand, which in this case is identical in nature to the recipient DNA and the formation of full-length heteroduplex (Figure 1). This reaction requires the presence of single-stranded binding protein (SSB) and ATP. SSB acts to remove any secondary structure that might form and to aid in strand transfer by binding the growing displaced single-stranded DNA. Strand exchange between these DNAs (M13–fd) is not as efficient as those reactions carried out between identical DNAs

(e.g., M13–M13). This reduction in full-length heteroduplex suggests that the formation of mismatches, an indication of sequence divergence, acts as an energetic barrier to recombination.

MutS Inhibits Strand Exchange

Further data demonstrating the role of MutS in this process were provided by titration studies, which showed that increasing concentrations of this activity completely abolished heteroduplex formation between M13–fd DNAs. This process was shown to be dependent upon the formation of mismatches, as MutS had no effect on exchange reactions between identical DNAs. Because MutS is a known ATPase, and ADP is known to cause RecA to dissociate from DNA, it was thought that this inhibition could be due to an equilibrium shift in nucleotide, as more hydrolysis would occur for heteroduplex formation and therefore higher ADP pools. This possibility was shown not to be the case, however, as an ATP-regenerating system alleviated the potential to build up ADP and thus caused RecA to dissociate. Indeed, subsequent studies showed that mismatch recognition alone could act to block the heterologous reaction and thus partly explain the role of these activities in recombination.

MutL Enhances Inhibition

To test other components in the pathway, an additional *in vitro* study evaluated the role of MutL, if any, in this block. Studies involving equimolar MutS and MutL revealed an attenuated block of strand transfer between M13–fd DNAs beyond that exhibited by MutS alone. Although high concentrations of MutL alone failed to block strand transfer between these phage DNAs, it stimulated the inhibition afforded by MutS, as lower concentrations of this activity were required in eliminating full-length heteroduplex formation. This level of inhibition by mismatch repair was afforded when these individual activities were present in a 1:1 stoichiometry. Again, these activities did not inhibit DNA exchange as catalyzed by RecA when the donor and recipient DNAs were identical. This inhibition of the heterologous reaction thus demonstrates an act of synergy between these activities in sensing for the occurrence of DNA mismatches. Similar to replication fidelity, these components appear to act in concert to impose their anti-recombinogenic activity.

Recent studies have evaluated the role of mismatch repair in mediating downstream components of recombination, specifically RuvAB complex. These activities are involved in branch migration and are more efficient than RecA in extending newly recombinant DNA. Recent studies have shown that MutS and MutL also act to mediate branch migration as a consequence of the activities, which are not subject to the polarity restrictions associated with RecA. This observation suggests that mismatch repair might have a role in the resolution of DNA joints that are in the vicinity of DNA sequence divergence.

Alternative Role of Repair in Recombination

A second possibility to explain mismatch repair anti-recombination activity, which should not be viewed as mutually exclusive, is the removal of the invading strand through the recruitment of downstream components of the repair pathway (Figure 1). Indeed, similar to the proposed role of the *E. coli* system, these activities could react to the recombination intermediates by a mechanism similar to that for replication fidelity. The excision system could eradicate the newly formed intermediates by mismatch-dependent loading on the invading strand. In this case, mismatch detection along with a 3′-end would suffice as normal repair signals and thereby act to abort the recombining event through removal of the invading strand and full recovery of the recipient DNA through DNA synthesis. This process would require the unwinding activity of helicase II, which drives orientation-specific loading of the proper excision machinery.

The role of DNA repair in modulating heteroduplex formation is ongoing, and continued studies will seek to define how these activities regulate the frequency of genetic exchange as a function of sequence divergence.

Recombination: Strand Transferases

Floyd R. Bryant
The Johns Hopkins University, Baltimore, Maryland, USA

The recombination of homologous DNA molecules plays a central role both in gene rearrangement reactions and in the repair of damaged DNA. Genetic and biochemical studies have established that homologous recombination proceeds via the formation of intermediate structures in which the two recombining DNA molecules are joined together by single-stranded crossover connections. A continuing strand exchange between the two polynucleotide chains can then occur, leading to the generation of heteroduplex DNA. The formation of the recombinational intermediates is carried out by a class of proteins known as recombination strand transferases or DNA recombinases.

DNA Recombinases

The most well-studied members of this class of proteins are the bacterial RecA proteins and the eukaryotic Rad51 proteins. Other members of this class include the archaeal RadA proteins and the bacteriophage T4 UvsX protein.

Bacterial RecA Proteins

The prototypical DNA recombinase is the RecA protein of *Escherichia coli* (*E. coli*). Genetic studies have shown that the RecA protein is involved in virtually all aspects of homologous recombination in *E. coli*. Moreover, *E. coli recA* mutants are highly susceptible to DNA damaging agents (e.g., ultraviolet light or chemical mutagens), and in recent years the central role played by the RecA protein in recombinational DNA repair has been more clearly defined.

The *E. coli* RecA protein is composed of 352 amino acids (37 842 Da). The purified RecA protein binds to DNA, is a DNA-dependent ATPase, and promotes a variety of ATP-dependent DNA strand transfer reactions that are presumed to reflect *in vivo* recombination functions. In addition to its strand transfer activities, the RecA protein also promotes the autocatalytic cleavage of several proteins that are involved in the bacterial response to DNA damage. Although the *E. coli* RecA protein is the best characterized of the bacterial RecA proteins, RecA-like genes have been identified in all bacterial species that have been examined and RecA protein homologues have been analyzed from several other bacterial species, including *Bacillus subtilis* and *Streptococcus pneumoniae*.

Eucaryotic Rad51 Proteins

Eucaryotic homologues of the RecA protein, the Rad51 proteins, have been isolated and characterized from yeast and from human cells. The Rad51 proteins have been shown to play an essential role in DNA recombination and repair in eucaryotic cells.

The human and yeast Rad51 proteins are composed of 339 amino acids (36 966 Da) and 400 amino acids (42 961 Da), respectively. Although not as extensively investigated as the *E. coli* RecA protein, the human and yeast Rad51 proteins have been shown to promote ATP-dependent strand exchange reactions that are generally similar to those of the *E. coli* RecA protein.

A second group of eucaryotic RecA homologues which function specifically during meiosis, the Dmc1 proteins, has been isolated and characterized from yeast and human cells. However, the DNA strand exchange properties of the Dmc1 proteins have not yet been fully evaluated.

Other RecA Homologues

RecA-like proteins, known as the RadA proteins, have also been isolated and characterized from various archaeal cells, including *Sulfolobus solfataricus* and *Archaeoglobus fulgidus*. In addition, a RecA-like protein, the UvsX protein, is encoded by *E. coli* bacteriophage T4. The universal presence of RecA-like proteins suggests that functionally related homologous recombination and recombinational DNA repair systems are operative in all organisms.

Structure

The RecA and Rad51 proteins have been analyzed by a variety of structural methods. X-ray crystallography and electron microscopy have been especially useful in identifying the functional form of these proteins.

X-Ray Crystallography

The three-dimensional structure of the *E. coli* RecA protein has been determined by X-ray crystallography. The RecA protein consists of a central core domain (amino acids 34–240) which contains the ATP-binding site and possibly the DNA-binding site(s), and a smaller amino-terminal domain (amino acids 1–33) and carboxy-terminal domain (amino acids 241–352). Sequence comparisons indicate that a structurally similar central core domain is present in the Rad51 proteins. The Rad51 proteins, however, lack the carboxy-terminal domain found in the RecA protein, and have an extended amino-terminal domain that is not present in the RecA protein.

Electron Microscopy

Electron microscopy studies have shown that RecA protein monomers assemble on single-stranded DNA (ssDNA) in the 5′ to 3′ direction to form a right-handed helical nucleoprotein filament with one RecA monomer per three nucleotides of ssDNA, and approximately six RecA monomers per helical turn of the filament (Figure 1). The RecA protein forms a structurally similar filament on double-stranded DNA (dsDNA), with one RecA monomer per three base pairs of dsDNA.

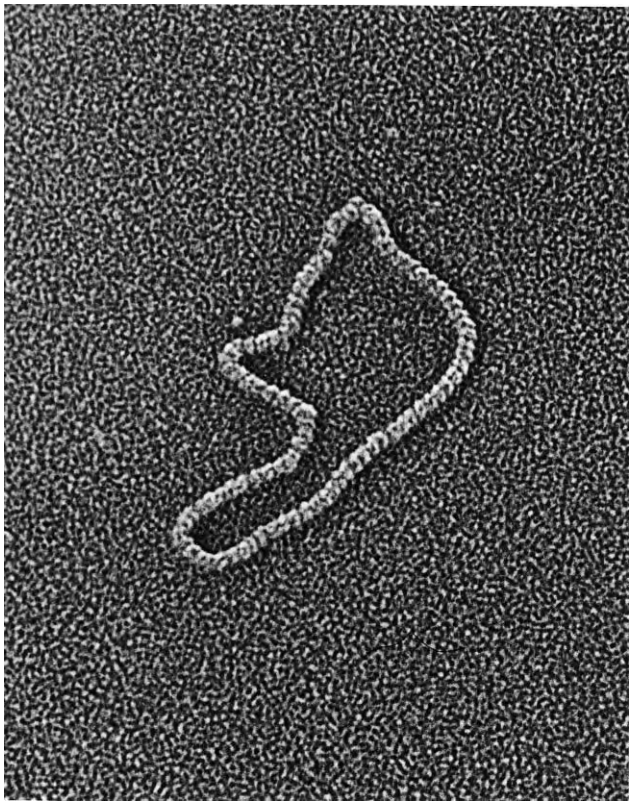

FIGURE 1 Circular ssDNA molecule covered by a helical filament of *E. coli* RecA protein (electron micrograph by Dr. Jack Griffith).

However, the binding to dsDNA is much slower than to ssDNA, and occurs only in the presence of ATP, whereas the binding to ssDNA occurs in either the presence or absence of ATP.

The conformation of the nucleoprotein RecA-DNA filament changes in response to the binding of nucleotide cofactors. In the absence of nucleotide cofactor, or in the presence of ADP, the filament adopts a compressed conformation with a helical pitch of ~70–85Å (seen on ssDNA only). In the presence of ATP, however, the filament assumes a more extended conformation with a helical pitch of 95Å (seen on ssDNA or dsDNA). In the ATP-activated state, the DNA inside the filament is stretched to 5.1Å per base/base pair (compared to 3.4Å per base pair in free dsDNA), and untwisted to 18.6 bases/base pairs per turn (compared to 10.5 base pairs per turn in free dsDNA).

The Rad51 proteins form filaments on DNA that are structurally similar to those formed by the RecA protein. This indicates that the altered conformation that is imposed on DNA in the ATP-activated state of the nucleoprotein filament is integral to the mechanism of action of the RecA and Rad51 proteins.

Model Reactions

The RecA and Rad51 proteins promote a variety of ATP-dependent DNA strand transfer reactions with defined DNA substrates. These reactions include D-loop formation and the three-strand exchange reaction.

D-Loop Formation

The RecA and Rad51 proteins can promote the pairing of a ssDNA with the complementary strand of a homologous covalently closed circular dsDNA to form a three-stranded structure known as a D-loop. However, because the dsDNA substrate lacks a free end, the invading ssDNA and the complementary strand from the dsDNA are unable to fully interwind, and the amount of strand transfer that can occur in this reaction is limited.

Three-Strand Exchange Reaction

The most extensively studied DNA strand transfer reaction is the three-strand exchange reaction, in which a circular ssDNA and a homologous linear dsDNA (typically from bacteriophage ϕX174 or M13 DNA; 5000–10 000 bases/base pairs in length) are recombined to yield a nicked circular dsDNA molecule and a linear ssDNA molecule. This reaction is a convenient model reaction for mechanistic studies because the substrates and products can be easily separated by agarose gel electrophoresis. Most of our understanding of the mechanism of action of the RecA

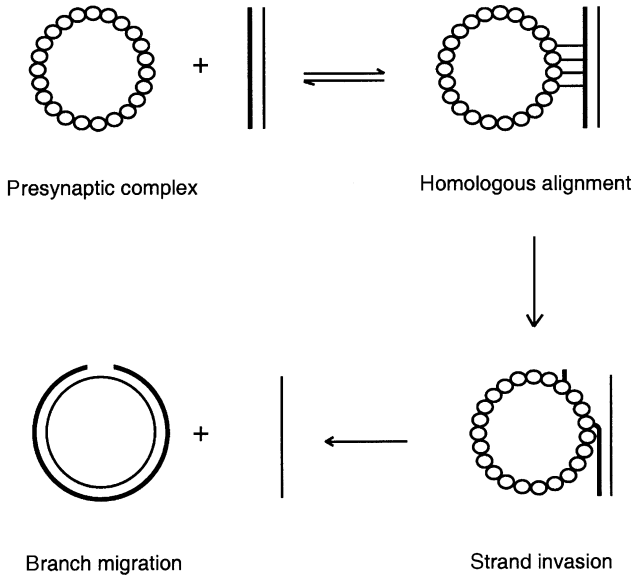

FIGURE 2 Schematic representation of the three-strand exchange reaction. A presynaptic complex (consisting of a circular ssDNA covered with a filament of RecA or Rad51 protein) interacts with a homologous linear dsDNA to produce a nicked circular dsDNA and a linear ssDNA. See text for details.

and Rad51 proteins has been derived from the study of this model reaction.

The three-strand exchange reaction proceeds in three distinct phases (Figure 2). In the first phase, stoichiometric amounts of RecA or Rad51 protein assemble onto the circular ssDNA substrate, forming a nucleoprotein filament known as the *presynaptic complex*. In the second phase, the presynaptic complex interacts with the linear dsDNA substrate, the homologous regions of the ssDNA and dsDNA are brought into register (*homologous alignment*), and new base-pairing interactions are formed between the circular ssDNA and the complementary strand of the linear dsDNA (*strand invasion*). In the third phase, strand exchange continues in a unidirectional manner, leading to the complete transfer of the complementary strand from the linear dsDNA to the circular ssDNA (*branch migration*).

ATP Hydrolysis

The RecA and Rad51 protein-promoted three-strand exchange reactions are absolutely dependent on ATP (or dATP) as a nucleotide cofactor. Curiously, however, the rate of ATP hydrolysis by the Rad51 protein ($0.1–1\ min^{-1}$) is much lower than that by the RecA protein ($20–30\ min^{-1}$). The mechanistic role of ATP hydrolysis in DNA strand exchange reactions is still poorly understood, and the functional significance of the difference between the RecA and Rad51 proteins is not clear. However, studies with nonhydrolyzable ATP analogues, and with mutant RecA proteins which bind but do not hydrolyze ATP, suggest that the homologous alignment and strand invasion reactions require ATP binding but not ATP hydrolysis, whereas the subsequent branch migration reaction may be coupled to the hydrolysis of ATP. These and other findings have led to the suggestion that the RecA protein may use the energy of ATP hydrolysis to actively drive branch migration. The Rad51 protein, in contrast, may stabilize the heteroduplex DNA formed by spontaneous branch migration in a process that is largely independent of ATP hydrolysis. Consistent with this view, it has been shown that RecA protein-promoted strand exchange proceeds uniquely in a 5′ to 3′ direction relative to the invading ssDNA (as expected for a coupled process), whereas the Rad51 protein-promoted reaction can proceed in either the 5′ to 3′ or 3′ to 5′ direction (as expected for a spontaneous process).

Accessory Proteins

The strand exchange activities of the RecA and Rad51 proteins are influenced by a host of recombination accessory proteins. These accessory proteins include the ssDNA-binding proteins and specialized recombination mediator proteins.

Single-Stranded DNA-Binding Proteins

The three-strand exchange activity of the RecA protein is stimulated by the *E. coli* SSB protein, a homotetrameric, non-sequence-specific, ssDNA-binding protein that is involved in many aspects of DNA biochemistry. SSB protein stimulates the strand exchange reaction both presynaptically (by removing secondary structure in the ssDNA substrate which otherwise impedes RecA binding) and postsynaptically (by binding to the displaced strand that is generated when the ssDNA substrate invades the homologous dsDNA). The strand exchange activity of the Rad51 protein is similarly stimulated by the heterotrimeric eucaryotic ssDNA-binding protein, replication protein A(RPA).

Mediator Proteins

The activities of the RecA and Rad51 proteins are also regulated by recombination mediator proteins. In bacterial systems, these mediator proteins include the RecO, RecR, and RecF proteins. The RecO and RecR proteins facilitate the binding of RecA protein to SSB protein-covered ssDNA and stabilize the resulting RecA-ssDNA filament, whereas the RecF and RecR proteins limit the extension of the RecA filament from an ssDNA gap or tail into an adjacent region of dsDNA. The best characterized

mediator of Rad51 protein activity is the Rad52 protein. The Rad52 protein, which may be a functional analogue of the bacterial RecO protein, stimulates Rad51 filament formation by facilitating the displacement of RPA protein from ssDNA.

Biological Reactions

The characterization of the biochemical activities of the RecA and Rad51 proteins has served to identify the mechanistic pathways that may occur in the cell during homologous recombination and recombinational DNA repair. The likely biological roles of the RecA and Rad51 proteins can be illustrated using the double-strand break repair model, which has emerged as a favored model for both the recombinational repair of fragmented DNA molecules and for programmed gene rearrangement reactions (Figure 3).

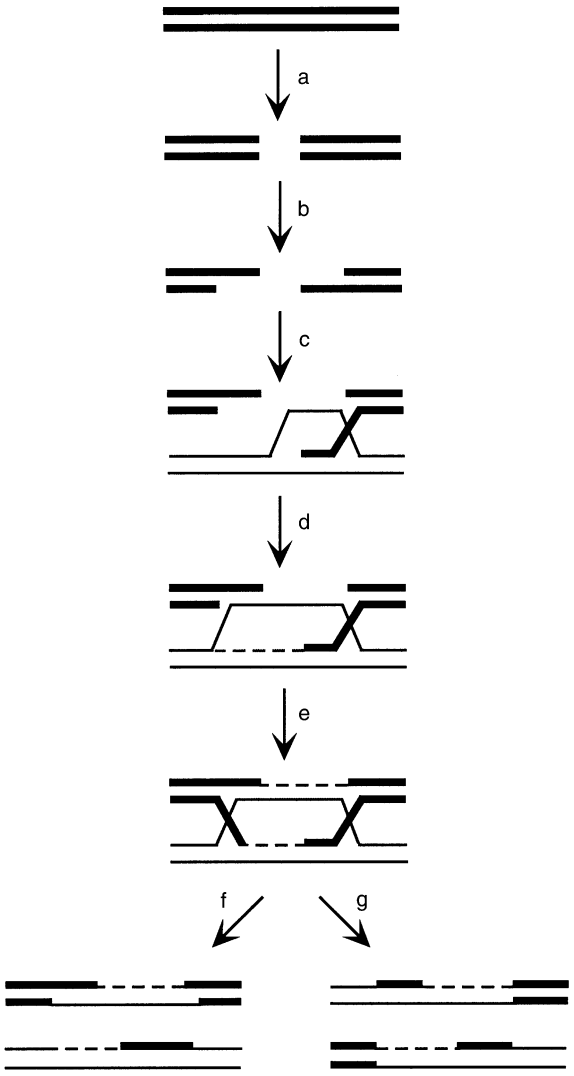

FIGURE 3 Schematic representation of the double-strand break repair model. The bold lines indicate a dsDNA undergoing a double-strand break, the thin lines indicate an intact homologous dsDNA, and the dashed lines indicate newly synthesized DNA. See text for details.

In this model, a double-strand break is introduced into a dsDNA molecule, either by a DNA-damaging agent or by a recombination-specific nuclease (*step a*). The ends of the two dsDNA fragments are then processed by specific nucleases so as to produce 3′-single-stranded "tails" (*step b*). RecA or Rad51 protein then assembles onto each of the single-stranded tails (with the assistance of various accessory proteins) to form active presynaptic nucleoprotein filaments. The single-stranded tail from one DNA fragment then pairs with an intact homologous dsDNA molecule (*step c*), forming a D-loop structure. The ssDNA tail from the second DNA fragment then pairs with the resulting displaced strand (*step d*). This sequence of strand transfer steps links the DNA molecules together by two single-stranded crossover connections, known as "Holliday junctions." A continuing strand exchange reaction, together with the synthesis of new DNA, results in the formation of regions of heteroduplex DNA in the linked DNA molecules (*step e*). Finally, cleavage of the crossover connections by a DNA junction-specific nuclease results in the separation or resolution of the two DNA molecules. Depending on direction of cleavage, the resolution step can produce either two DNA molecules that have been rejoined in the original linkages (*step f*), or two DNA molecules in new recombinant linkages (*step g*).

His principal research interests are in the mechanistic analysis of bacterial RecA proteins and in the role of DNA recombination in the development of antibiotic resistance in pathogenic bacteria.

Recombination-Dependent DNA Replication

Kenneth N. Kreuzer
Duke University Medical Center, Durham, North Carolina, USA

Over the last several decades, the processes of homologous genetic recombination and DNA replication have largely been studied in isolation from one another. However, beginning with a few studies of bacteriophages in the 1960s and 1970s, the possibility emerged that extensive DNA replication can sometimes be triggered by homologous genetic recombination. Over the last several years, scientists working with diverse organisms have shown that recombination-dependent DNA replication (RDR) is very common and that this process provides an important back-up mechanism for completing DNA replication when replication forks fail. Mutational inactivation of certain proteins that are involved in RDR or related processes can lead to genome instability and a predisposition to cancer in higher organisms.

Early Models of Homologous Recombination Invoke RDR

One of the early molecular models for homologous recombination, called break-and-copy, invoked *r*ecombination-*d*ependent DNA *r*eplication (RDR). One simple version of this model invoked a break in one molecule, with a resulting 3′ broken end being used as primer for DNA replication. Another DNA molecule, of different parentage, is used as the template, resulting in a genetic crossover in the resulting DNA molecule.

As the field progressed, evidence accumulated in a number of systems for break-and-rejoin models, without extensive DNA replication, and break-and-copy models fell into disrepute. We now understand that there are indeed many pathways of homologous recombination that do not involve extensive DNA replication, but also some very important recombination pathways that trigger extensive replication, as in the original break-and-copy models.

Modern versions of the break-and-rejoin model, such as the Meselson–Radding and double-strand-break repair (DSBR) models, invoke limited DNA replication events (e.g., gap filling) to fill in missing information. Such limited replication will not be considered here as RDR. Rather, the definition of RDR will be restricted to those events that are dependent on homologous recombination proteins and capable of replicating large portions of a chromosome.

RDR Pathways in Bacteriophage

Most of the early data arguing for the existence of RDR came from studies of bacterial viruses. For example, recombination-deficient mutants of well-known bacteriophages such as T4, T7, and lambda were found to be partially defective in DNA replication. The interpretation of that replication defect has not been straightforward, because recombination reactions can play indirect roles in viral DNA replication. For example, if recombination links multiple bacteriophage genomes together into a linear concatamer, a single initiation event from a conventional replication origin can result in much more DNA replication than if the genomes are not linked. Furthermore, recombination proteins might play a role in converting a theta-form replication intermediate into a rolling circle, resulting in numerous replication products rather than just two.

Studies with bacteriophage T4, however, demonstrated that the involvement of homologous recombination proteins in DNA replication is very direct. At early times of infection, T4 DNA replication initiates at replication origins by a mechanism that involves a persistent RNA–DNA hybrid (R-loop), but this origin-dependent replication is turned off after several minutes. For the remainder of the infection cycle, all DNA replication initiates by an RDR mechanism in which a fully functional replication complex is assembled on a displacement loop (D-loop; Figure 1). The D-loop is formed when the 3′ single-stranded end of one phage DNA molecule invades a homologous region of another phage DNA molecule, or the other end of the same molecule (since T4 DNA is terminally redundant).

Most or all D-loop formation depends on the phage-encoded UvsX and UvsY proteins, acting in concert with the T4 single-stranded DNA binding protein gene

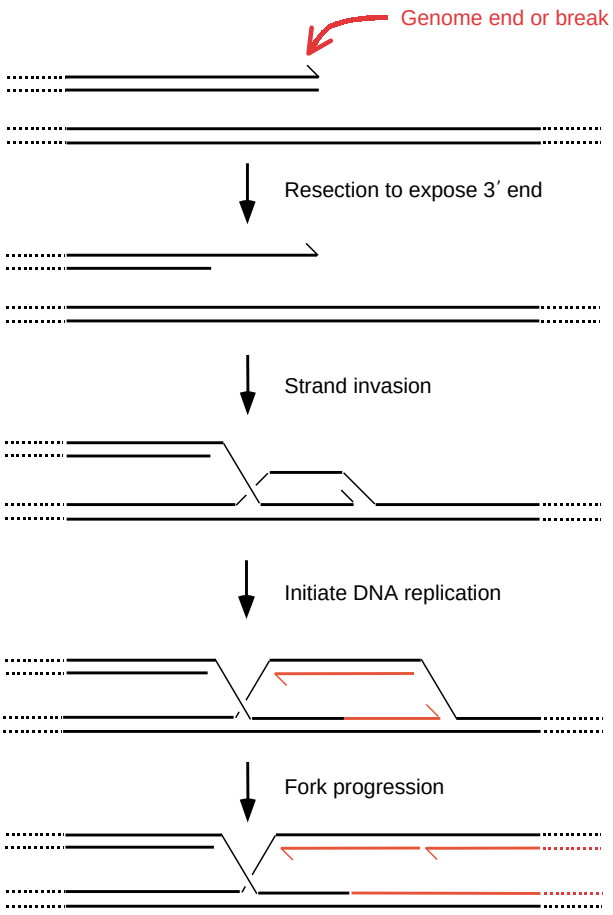

FIGURE 1 Model for bacteriophage T4 RDR. A single-stranded 3′ end is generated from a genomic end or break in the first step, either by exonuclease resection or by prior DNA replication up to the end (not shown in the figure). The strand invasion step creates a D-loop, upon which replication is initiated after assembly of the replication complex. The dotted lines indicate extended regions of the phage chromosome, and all newly replicated DNA is in red.

*p*roduct 32 (gp32). UvsX is a strand invasion protein, homologous to bacterial RecA and eukaryotic Rad51 protein, while UvsY plays the key role of loading UvsX onto gp32-coated single-stranded DNA (i.e., the 3′ end).

Once a D-loop is formed, the phage protein gp59 is the critical component that directs the replication machinery to the D-loop. The gp59 protein preferentially binds branched DNA and also gp32-coated DNA, and one or both of these preferences are thought to explain D-loop recognition. Gp59 has been first identified based on its ability to stimulate the loading of the replicative helicase (gp41) onto DNA during *in vitro* replication reactions. Once the replicative helicase is loaded, more extensive template unwinding, loading of additional replication proteins, and extensive DNA replication becomes possible. Proteins that allow the loading of replicative helicases onto recombination intermediates are central to the process of RDR, and the corresponding bacterial proteins will be discussed below.

There is now quite convincing experimental evidence for the T4 RDR pathway. A variety of physical and genetic experiments support the proposal that genome ends trigger DNA replication after a strand-invasion reaction. Furthermore, artificially introduced double-strand breaks (DSBs) dramatically stimulate the replication of homologous DNA *in vivo*. Finally, a robust *in vitro* system of RDR has been established using the T4 system, and recapitulates the major features of *in vivo* RDR.

Demonstration of RDR in *Escherichia coli* and Yeast

An apparent cellular RDR pathway, called inducible stable DNA replication (iSDR), was first uncovered by the late Tokio Kogoma and colleagues. They found that *E. coli* cells deficient in normal origin-directed replication can nonetheless replicate if their SOS system for DNA damage response is activated. This DNA replication required the strand invasion protein RecA, and a variety of results led to the proposal that iSDR also required chromosomal DNA breaks induced by some component of the SOS system. The simplest model is that the induced DNA breaks lead to invasive 3′ ends, and that resulting D-loops become the sites of assembly of new replication complexes (much like in Figure 1). More recent experiments have demonstrated that artificially induced DSBs can indeed trigger DNA replication in *E. coli*, providing strong support for a cellular pathway of RDR.

A key protein for *E. coli* RDR is PriA, which like T4 gp59, allows the loading of the replicative helicase (DnaB in this case) onto D-loop structures. Several other *E. coli* proteins, including DnaC, PriB, and PriC, can also participate in this reaction. The importance of PriA in the survival of *E. coli* will be discussed later, when we consider the role of RDR in completing genome replication. It is interesting to note at this point, however, that mutational inactivation of PriA dramatically reduces phage P1-mediated generalized transduction and also conjugal recombination. Therefore, these seemingly well-studied genetic pathways, which had been thought for decades to occur by a break-and-rejoin-like mechanism, may actually occur by a mechanism similar to RDR.

RDR is apparently not limited to prokaryotic systems such as T4 and *E. coli*. Indeed, genetic experiments have provided very strong evidence that RDR is a legitimate pathway of DNA break repair in the yeast *Saccharomyces cerevisiae*. Several different genetic approaches have revealed RDR in yeast. One approach used a diploid cell with a site that can be cleaved to create a DSB on one of the two copies of a particular chromosome (Figure 2). The arms of the two

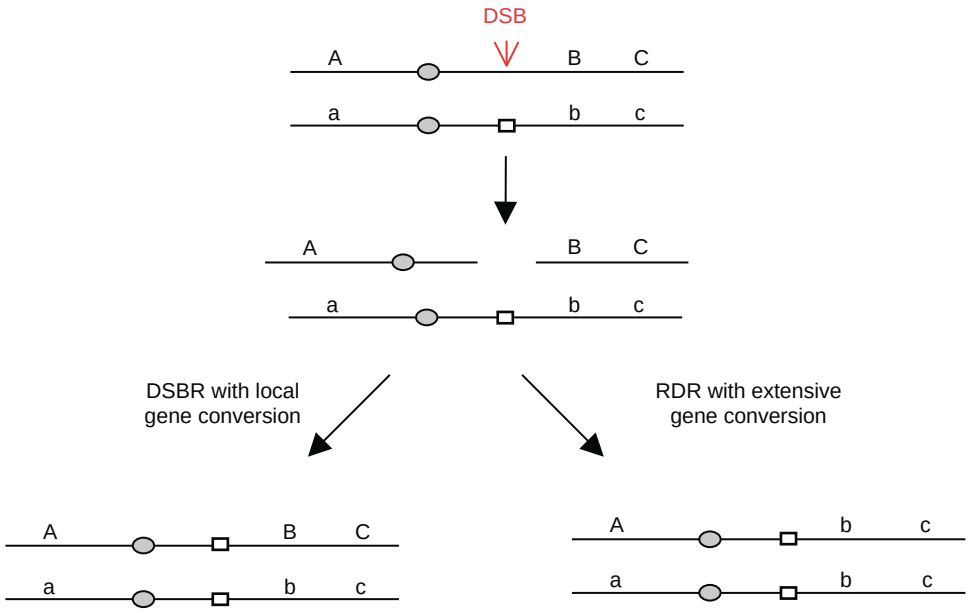

FIGURE 2 Two pathways for repair of a chromosomal DSB in yeast. Repair of a DSB occurs by a localized DSBR pathway on the left side; this pathway involves the reattachment of the two broken arms and a small region of DNA replication to replace any missing DNA near the break site. In the pathway on the right side, the smaller chromosomal fragment (containing alleles B and C) is lost. However, an intact chromosome is regenerated by an RDR reaction in which the broken end of the larger chromosomal fragment invades the intact homologous chromosome, and then triggers a DNA replication fork that travels to the end of the intact chromosome. This duplicates the chromosomal arm that contains alleles b and c, and with Holliday junction resolution, provides the cell with two complete and intact chromosomes to fulfill the diploid state. In this figure, each solid line is a DNA double helix, and gray ovals indicate centromeres. The downward pointing arrow indicates the site for the DSB, while the empty box indicates the DNA sequence at the corresponding site on the noncleavable chromosome (the sequences in this region of the two chromosomes are different from each other). Based on Malkova *et al.* (1996). *Proc. Natl Acad. Sci. USA* **93**, 7131–7136.

chromosomes were marked with a series of heteroalleles (indicated by the letters A/a, B/b and C/c in Figure 2). In wild-type cells, when the DSB is induced on the top chromosome, the diploid that resulted from DSB repair usually maintained each of the three pairs of heteroalleles, indicating a local DSBR event that caused gene conversion at the site of the DSB and that reattached the broken distal arm of the chromosome (Figure 2; left). At a low frequency, however, the resulting diploid cell experienced an extensive gene conversion event in which all alleles in the arm distal to the DSB had been converted to the form that was originally located on the unbroken (homologous) chromosome (Figure 2; right). Apparently, the distal chromosomal fragment with the "B" and "C" alleles had been lost, and replaced with a newly replicated copy of the distal arm from the unbroken chromosome.

While these RDR products were normally quite rare in wild-type cells, they became predominant when the cells had a mutation that inactivated the Rad51 protein (strand invasion protein, homologous to RecA/UvsX). Also, when the experimental setup was altered so that the distal fragment of the broken chromosome had no homology to the intact chromosome, wild-type cells efficiently utilized this RDR pathway to regenerate an intact chromosome. The only general mechanism to explain this extensive gene conversion of a large portion of a chromosome is that the centromere-proximal chromosomal end undergoes a strand-invasion reaction with the homologous chromosome, and the resulting D-loop triggers a new replication fork just as in the RDR pathways.

RDR as a Backup Mechanism to Complete DNA Replication

Nearly 30 years ago, Ann-Marie Skalka proposed that recombination could provide a mechanism for creating new replication forks after a previous fork encountered a template nick. Her proposal dealt with the complexities of phage lambda DNA replication, and has not been ascribed any broader significance for some time. However, many years later, scientists realized that a similar mechanism provides a means of restarting a replication fork that has been destroyed by a template nick. As diagrammed in Figure 3, when a replication fork encounters a template nick, one of the two arms can be broken off and replication thereby terminated. The broken end can be reconfigured into a replication fork by first forming a D-loop using a strand-invasion

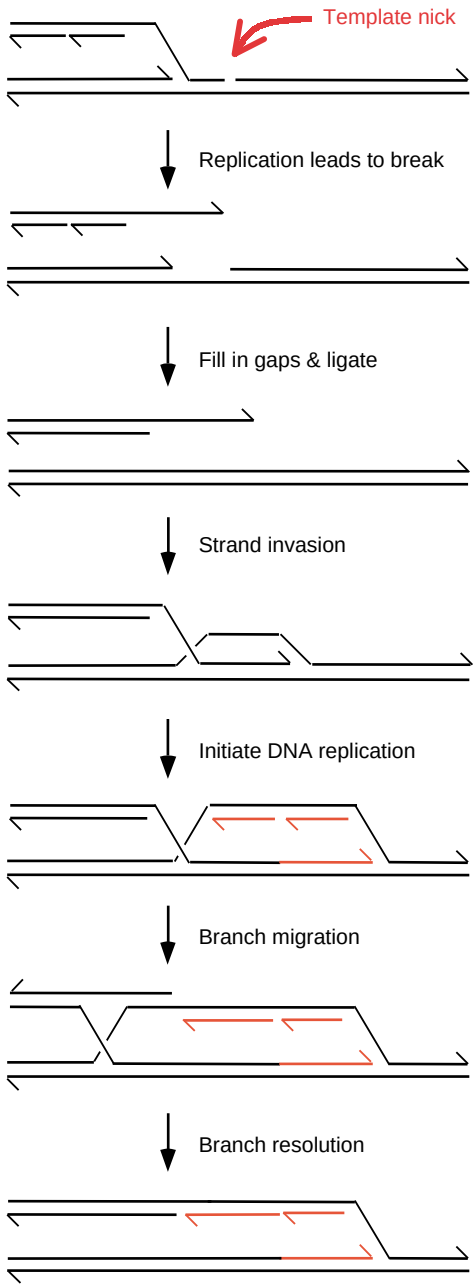

FIGURE 3 Replication fork breakage at a nick and restart by recombination. A template nick leads to a broken fork, which is then restarted by RDR. Note that one DNA strand has been flipped to the top in the molecule immediately after the arrow indicating branch migration (because DNA is a double helix but the drawing depicts only parallel lines, this flipping is just a convenience to make the drawing simpler).

reaction, and then assembling a replication complex onto the D-loop. Subsequent branch migration and junction resolution can thereby regenerate a simple replication fork and allow the completion of replication and normal segregation of the products at the next cell division (Figure 3).

We now believe that this pathway explains why many recombination-deficient mutants of bacteria and yeast grow poorly – they have great difficulty completing DNA replication due to problems at the fork. Notably, PriA-deficient mutants of *E. coli*, whose primary defect is in replication fork restart, are nearly inviable and quickly accumulate suppressor mutations that improve their viability.

In vivo experiments have demonstrated that replication forks are indeed broken when they encounter a template nick. It is not clear how often replication forks encounter template nicks, but broken replication forks also arise by another pathway that could be even more common. In bacterial and phage systems, it has been demonstrated that certain stalled or blocked replication forks are prone to breakage. This breakage depends on the branched-DNA-specific nucleases that normally resolve Holliday junctions (i.e., *E. coli* RuvC and T4 endonuclease VII). Results in eukaryotic systems also suggest that some blocked forks are broken, although the identity of the cleaving nuclease is uncertain.

It may seem strange that blocked replication forks would be actively cleaved by recombination nucleases, and this is indeed a dangerous reaction. However, this cleavage is apparently under strict control, and may only be used as a "last resort" when a stalled or blocked replication fork cannot be restarted by other mechanisms. By coupling fork cleavage with an RDR reaction, the replication fork can potentially be restarted and the cell saved from the dire consequences that result from trying to segregate a partially replicated DNA molecule in the next cell division.

With this new view that recombination provides a back-up mechanism to restart broken replication forks, it is worth reconsidering an interesting question from evolutionary biology—how and why did homologous recombination evolve? It is now clear that homologous recombination can play an important role at the level of single cell survival, namely the completion of DNA replication. Furthermore, it seems likely that DNA replication was even more prone to failure early in the evolution of cells, before very sophisticated replication machineries and repair pathways have been fully developed. Therefore, many scientists in the field now believe that homologous recombination first evolved as a means to complete cellular DNA replication, and that all the other wonderful benefits of recombination came later.

Replication Fork Failure and Direct Restart Pathways

The above description of replication fork restart is incomplete, focusing only on the restart of forks that end up being broken. As might be expected, other pathways

are able to directly restart stalled or blocked replication forks without the dangerous step of breaking the fork. Indeed, bacterial cells have multiple pathways for directly restarting forks. Although these pathways need not involve any recombination of the DNA molecules, some of the proteins that are involved in direct restart pathways are nonetheless recombination proteins that play roles in recombinational restart or other homologous recombination pathways.

One of the important unanswered questions is the fate of the various components of the replication machinery when forks are blocked or stall. It is clear that replication fork restart pathways require proteins that can load the replicative helicase, and so by inference, the replicative helicase seems to be lost when forks stop prematurely. We don't know which other components of the replication machinery are lost upon fork failure. Because the replicative helicase is thought to encircle the lagging-strand template, it is presumably lost whenever that strand is broken. In other cases (e.g., breakage of the leading strand and fork arrest without breakage), it remains to be determined how exactly the helicase is lost, and for that matter, whether the helicase is lost in only a subset of replication fork failures.

There are many possible reasons why a replication fork might stop prematurely. For example, a particular nucleotide might be temporarily limiting, a noncovalently bound protein might be encountered on the template duplex, or one of the key proteins of the replication machinery might become damaged or displaced from the replication fork. Sidestepping the question of how and why the replicative helicase and other proteins might be lost from such a fork, it is easy to see how direct restart pathways can solve the immediate problem and allow a completion of DNA replication.

However, the true complexities and benefits of replication fork restart pathways only become obvious when we consider other problems that a replication fork can encounter, particularly the many different forms of template DNA damage. The most obvious problem is when the replication machinery encounters a damaged base on the leading-strand template. In this case, one can easily see the advantage of disassembling the normal replication machinery—namely that an appropriate DNA repair complex can be recruited to fix the template damage or, if that fails, a translesion DNA polymerase can be recruited to incorporate something opposite the damaged base (Figure 4; left). After the repair or translesion synthesis event, the normal replication machinery would need to be assembled to resume replication, hence the need for a direct restart pathway (or an RDR event if the fork has become broken). This description of the behavior of the replication fork at sites of template DNA damage is very superficial and incomplete, in part because there are many forms of damage and multiple pathways of repair. The more serious limitation at this time, however, is that the field is just beginning to investigate what promises to be a very rich area, this interface where DNA replication, repair and recombination all intersect at troubled replication forks.

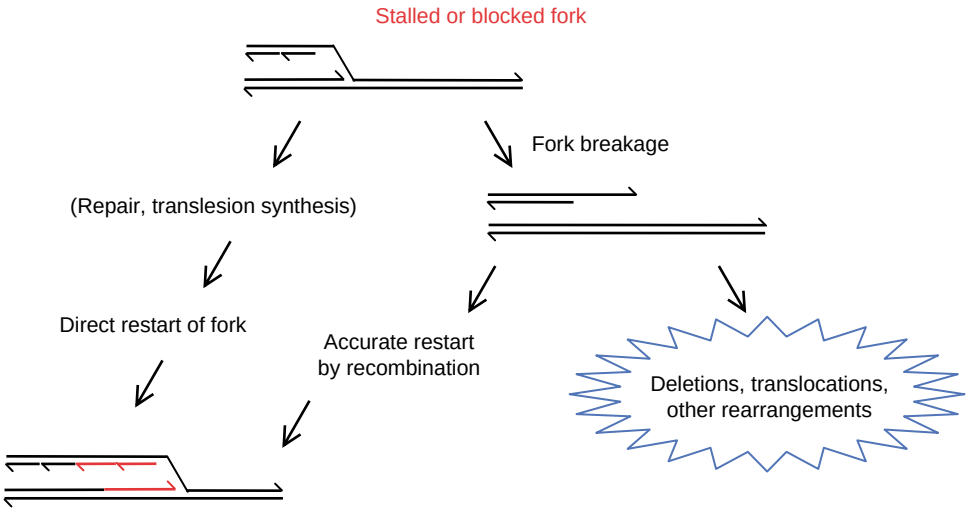

FIGURE 4 Pathways for restarting replication forks. Replication forks may stall due to the absence of nucleotides or problems with the replication machinery, or may be blocked due to template damage or bound proteins ahead of the fork. If the fork is blocked by template damage, repair of the damage or translesion synthesis may precede direct fork restart. If the fork is simply stalled, direct fork restart can occur without repair. In either case, some or all of the replication proteins need to be reassembled on the fork to reinitiate replication. In the pathway on the right, the stalled or blocked fork is broken, for example, by a recombination nuclease. Accurate restart of the fork by RDR (as in Figure 3) can lead to a normal cell without any genetic damage, but failure of this accurate pathway can lead to chromosomal rearrangements.

Disturbances in Fork Processing Lead to Genome Instability and Cancer Predisposition

DNA breaks are inherently dangerous. A broken fragment of a chromosome that lacks the centromere may be lost during mitosis to generate a terminal chromosomal deletion (assuming that the centromere-containing fragment acquires a new telomere). A broken end might engage in a non-homologous end joining reaction, or if the end is located within a repeat region, might undergo homeologous recombination with another copy of the repeat. In both cases, chromosomal deletions, inversions, and translocations can result.

With an understanding that DNA replication can lead to DNA breaks, it is therefore not surprising to find a strong association between disturbances in replication fork processing and genome instability. For example, studies in *S. cerevisiae* have shown that mutational inactivation of genes involved in the recombinational restart of replication forks (RDR) leads to genome instability. Apparently, when the normal pathway of restarting broken forks is disturbed, the broken DNA can result in chromosomal rearrangements (Figure 4).

Cells from individuals who suffer from certain human cancer predisposition syndromes (Werner's, Bloom's, and Rothmund–Thomson syndrome) show increased genome instability. Genetic analysis has traced these defects to genes that encode proteins that are suspected to be involved in replication fork integrity, recombinational restart of broken forks, and/or direct restart pathways. All three of these proteins belong to the RecQ family of DNA helicases (named after the founding member, bacterial RecQ). The precise role of any of these proteins is presently unclear, but it is easy to imagine that genome instability could result from a defect in recombinational restart of broken forks, or from a higher incidence of replication fork breakage. Increased fork breakage could potentially arise from a defect in a protein that is involved in direct restart pathways, or from any mutation that leads to more frequent fork arrest.

In summary, the period since the early 1990s has seen a remarkable merger of studies of DNA replication, recombination, and repair. These three processes apparently participate in an intricate choreography that is necessary for the accurate and complete replication of the genome, which in turn is important for genome stability and for the prevention of cancer in humans.

recQ DNA Helicase Family in Genetic Stability

Mary A. Risinger and Joanna Groden
University of Cincinnati College of Medicine, Cincinnati, Ohio, USA

Helicases are enzymes that use nucleoside triphosphate (usually ATP) hydrolysis to unwind nucleic acid duplexes (DNA–DNA, RNA–RNA, or DNA–RNA). Most helicases exclusively unwind either DNA or RNA duplexes, although some can unwind DNA duplexes and RNA duplexes as well as DNA–RNA hybrids. Because virtually all forms of DNA metabolism (including transcription, replication, recombination, and repair) require the unwinding of double stranded DNA (to allow access to the bases which encode the genetic information), DNA helicases are essential to the function and maintenance of the genome. This article deals with one family of DNA helicases, the recQ family, named for the similarity of family members to the prototype *Escherichia coli* recQ helicase, which participates in the recF genetic recombination pathway. Loss of recQ helicase function results in a loss of genomic stability that can be manifested in various ways. In humans, loss of function of certain recQ helicases results in cancer predisposition and variable degrees of premature aging. The study of these ubiquitous and highly conserved proteins promises to yield important information concerning tumorigenesis and the aging process.

Classification of Helicases

By primary structure comparisons helicases are divided into five superfamilies. The recQ family belongs to superfamily II (Sf2), one of the largest of the superfamilies. All Sf2 helicases contain seven conserved helicase motifs designated I, Ia, II, III, IV, V, and VI. Motifs I and II are the Walker A and B sequences characteristic of ATPases. Motif II of recQ helicases contains the DEXH motif (single-letter amino-acid code) that is a major characteristic of this family and is essential for ATP hydrolysis and, consequently, for helicase activity.

In *E. coli*, recQ is the sole member of its family. Most lower eukaryotic organisms also have a single recQ helicase. Examples are sgs1 from the budding yeast, *Saccharomyces cerevisiae*, and rqh1 from the fission yeast, *Schizosaccharomyces pombe*. However, higher organisms generally have multiple recQ helicases, presumably needed to maintain more complex genomes. Humans have at least five recQ helicases encoded by the *BLM*, *RECQ1* (also referred to as *RECQL*), *RECQ4*, *RECQ5*, and *WRN* genes.

Human Genetic Disorders Resulting from Defects in recQ Helicases

Defects in three of the five human recQ helicases result in defined clinical disorders known as chromosome breakage syndromes (autosomal recessive human disorders characterized by spontaneous genomic instability). Bloom syndrome, Rothmund–Thomson syndrome, and Werner syndrome are caused by germ-line defects in the *recQ* genes *BLM*, *RECQ4*, and *WRN*, respectively. Hallmarks of these rare diseases are genomic instability (apparent at the cellular level), cancer predisposition, and variable characteristics of premature aging.

Bloom Syndrome

Bloom syndrome (BS) persons (who lack the BLM protein due to various mutations in the *BLM* gene) are proportional dwarfs with sun-sensitive facial erythema (redness), impaired fertility, immune deficiency, and a high incidence of almost all forms of cancer with a very early age of onset (average 24 years). This makes BS a particularly interesting model for the study of tumorigenesis since most other hereditary cancer predisposition disorders result in the development of site-specific cancers. Cells cultured from BS persons demonstrate genomic instability in the form of a higher rate of the same types of chromosomal aberrations detected in cells cultured from normal individuals. Chromosomal breaks and rearrangements that are a result of increased homologous recombination are frequently observed. The classic feature of BS cells, which is considered diagnostic of the disease, is a several-fold increase in the frequency of sister chromatid exchanges (SCEs; reciprocal exchanges of DNA between sister

chromatids by homologous recombination). BS cells also demonstrate an abnormal profile of DNA replication intermediates.

Rothmund–Thomson Syndrome

Rothmund–Thomson syndrome (RTS) persons have progressive poikiloderma (a variegated hyperpigmentation and telangiectasia of the skin, followed by atrophy) that is apparent in early childhood. Common characteristics include numerous skeletal abnormalities, thin hair, cataracts, hypogonadism, and short stature. RTS persons are primarily susceptible to a single type of cancer, osteosarcoma (median age of onset 12 years), but skin malignancies and other forms of cancer have also been reported. Cells isolated from RTS persons reveal genomic instability in the form of chromosome translocations, rearrangements, and deletions.

Werner Syndrome

Werner syndrome (WS) is a hallmark premature aging disease. It is generally not detected until adolescence when WS persons fail to undergo the usual growth spurt and begin to display symptoms of premature aging including graying and thinning of the hair, wrinkling of the skin, cataracts, type II diabetes mellitus, osteoporosis, and atherosclerosis. WS persons are short in stature due to lack of the adolescent growth spurt and often have reduced fertility. They demonstrate a high incidence of malignancies, particularly sarcomas. The major causes of death are malignancy and vascular disease (average lifespan 47 years). Cells isolated from WS persons have a reduced replicative lifespan (they divide fewer times before becoming senescent) and are marked by increased genomic instability in the form of chromosomal alterations including chromosome translocations, rearrangements, and large deletions.

Structural Characteristics of recQ Helicases

In recQ family members, the helicase domain containing seven helicase motifs (I, Ia, III–VI) is generally centrally located (Figure 1). Most recQ helicases also have an recQ family C terminal (RQC) domain located just C terminal to the helicase domain. Since mutations of conserved residues in this region severely decrease ATPase activity, helicase activity, and single stranded DNA binding, it has been suggested that this domain may be involved in coupling DNA binding to ATP hydrolysis. More distal to the helicase domain is another conserved C-terminal domain designated as the helicase RNase D C-terminal (HRDC) domain. The HRDC domain is thought to be an auxiliary DNA binding domain. Unlike the RQC domain that is characteristic of recQ helicases, the HRDC domain is also found in other types of DNA-binding proteins (including other helicases, recombinases, and polymerases). With the exception of a nuclear localization signal identified in some recQ helicases, there is little additional C-terminal homology among recQ helicases. N-terminal domains vary greatly in length among recQ family members and there is generally little homology in this region. Several family members have N-terminal acidic regions and some have C-terminal acidic regions, which may be involved in protein–protein interactions.

Functional Characteristics of recQ Helicases

All recQ helicases studied to date are ATP- and Mg^{2+}-dependent 3–5′ helicases, i.e., they translocate along the DNA strand to which they bind in the 3–5′ direction as they unwind duplex DNA. Human *WRN* helicase and frog *FFA-1* helicase are unique in that they also have a 3–5′ exonuclease activity. It has been difficult to define the functions of recQ helicases at the molecular level *in vivo*. Since higher organisms have multiple recQ helicases and the loss of function of a single recQ helicase is compatible with survival, it is likely that recQ helicases have some overlapping functions where the remaining helicases can partially compensate for the loss. (RecQ helicases must also have some independent functions since diseases associated with the loss of a particular helicase have distinct characteristics.) The processes in which recQ helicases are likely involved (replication, recombination, and repair) are also closely intertwined. Clues to the *in vivo* functions of recQ helicases are provided by associated clinical syndromes (described above), *in vitro* studies, and *in vivo* localizations and associations.

Functional Clues Provided by *in vitro* Studies

RecQ helicases are unusual among helicases in their DNA substrate preferences. Although they are generally unable to unwind blunt-ended duplex DNA (unless a bubble is present), they efficiently unwind such non-Watson–Crick DNA structures as G-quadruplexes (extremely stable DNA secondary structures that can form in guanine-rich regions of DNA) and Holliday junctions (four-way crossover structures formed by DNA strand exchange during homologous recombination). They also unwind displacement loops (D-loops; intermediates formed during the strand invasion step of recombination).

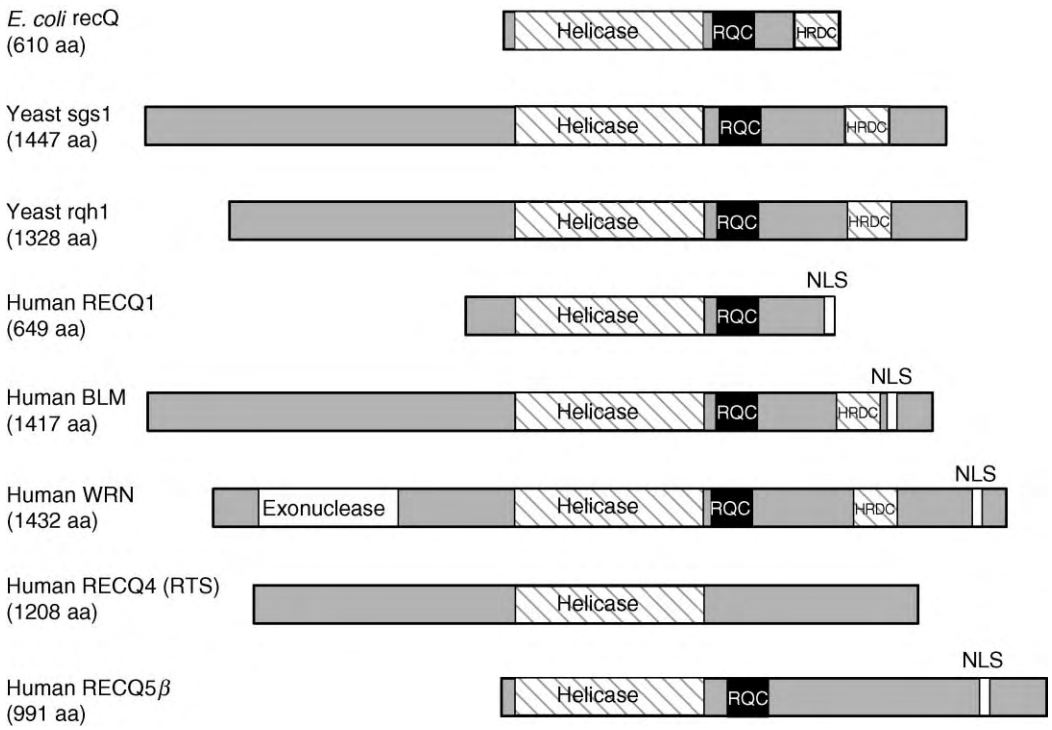

FIGURE 1 Schematic representation of domain structure of several recQ helicases. The names and sizes (numbers of amino acids) of the helicases are listed on the left. The positions of the conserved helicase, RQC (RecQ family C terminal), and HRDC (Helicase RNase D C terminal) domains are indicated on each diagram. The locations of the known nuclear localization signals (NLS) and the exonuclease domain of human WRN are also indicated.

Functional Clues Provided by Localizations and Associations

RecQ helicases undergo subnuclear relocalizations under various conditions. For instance, BLM generally has a punctate distribution within the nucleus that is at least partially associated with PML bodies (named for the presence of promyelocytic leukemia tumor suppressor protein). After treatment of cells with DNA damaging agents or inhibitors of DNA replication, BLM becomes associated with sites of DNA repair (defined by the presence of RAD51, required for the initial DNA strand pairing and invasion of homologous recombination). BLM directly binds to RAD51. BLM also associates with other proteins involved in DNA repair including ATM (ataxia telangiectasia mutated; serine/threonine kinase which phosphorylates BLM and other proteins involved in DNA damage repair), RPA (Replication Protein A; single stranded DNA binding protein involved in replication, recombination, and repair), BRCA1 (breast cancer susceptibility gene product), and MLH1 (mismatch repair protein). BLM (and most recQ helicases from lower organisms) binds topoisomerase III (relaxes negatively supercoiled DNA) and stimulates its activity. The tumor suppressor p53 binds to BLM and regulates its helicase activity.

WRN is generally associated with the nucleolus and/or is nucleoplasmic but undergoes translocation to DNA replication foci when DNA synthesis in inhibited. Potential roles for WRN in DNA replication, recombination, and repair are suggested by its association with a number of proteins involved in these processes including: RPA, FEN 1 (flap endonuclease 1; 5–3′ DNA structure-specific nuclease implicated in replication, recombination, and repair), EXO-1 (exonuclease 1; member of the RAD2 family of nucleases implicated in replication, recombination, and repair), pol-δ (DNA polymerase-δ; major DNA polymerase involved in replication), PCNA (Proliferating Cell Nuclear Antigen; pol-δ accessory factor), pol-β (DNA polymerase-β; major DNA polymerase involved in both short and long patch base excision repair), RAD52 (mediator of homologous recombination), the DNA-PK holoenzyme (DNA-PK_{CS} plus Ku70/80; serine/threonine kinase which phosphorylates WRN and other DNA repair proteins) and p53.

Potential Functions for recQ Helicases in Replication-Associated DNA Repair

Although loss of recQ helicase function leads to a number of phenotypic cellular changes, two consistent features are abnormal DNA replication and an increased occurrence of recombination. Distinctive characteristics of recQ helicases include their unusual substrate preferences

(G-quadruplexes, structures which resemble Holliday junction recombination intermediates, and D-loops) and their associations with other proteins implicated in replication, recombination, and repair. They also associate with what are presumed to be stalled replication forks after replication has been interrupted or DNA damage has occurred. These data suggest that the major function of recQ helicases is to maintain genomic stability by restarting stalled replication forks, although more than one mechanism could be responsible for this function. RecQ helicases may resolve DNA secondary structures such as G-quadruplexes ahead of the replication fork to allow the replication fork to proceed unimpeded. Indeed, WRN and *E. coli* recQ enable DNA polymerase-δ to traverse DNA tetraplex and hairpin structures *in vitro*.

RecQ helicases also may reset replication forks when they stall after encountering an area of DNA damage. One model that explains how this might occur is the "chickenfoot" model (Figure 2). In this case, leading strand synthesis is blocked by a lesion in the template while lagging strand synthesis continues for a short distance (Figure 2B). When replication stops, positive supercoiling surrounding the replication fork favors the formation of a four-way junction, the so-called chickenfoot that is analogous to a Holliday junction (Figure 2C). The shorter leading strand can now be extended to the end of the longer lagging strand with which it is now paired, past the lesion in the template (Figure 2D). RecQ helicases might then unwind these structures to restart the replication fork past the area of damage (Figure 2E). In the absence of a recQ helicase, the chickenfoot could be resolved by homologous recombination to re-establish the replication fork. RecQ helicases also may have a role in DNA repair by homologous recombination as suggested by their ability to unwind D-loops *in vitro* (disrupting less productive or inappropriate recombination intermediates). This could partially explain the observation of increased homologous recombination in cells lacking the BLM recQ-like helicase.

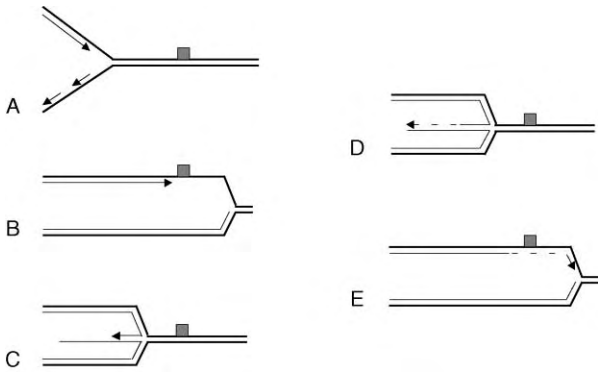

FIGURE 2 Chickenfoot model for the role of recQ helicases in restarting replication forks stalled by DNA damage. A replication fork is shown with the leading strand on top and the lagging strand on bottom (A). The long arrow represents leading strand synthesis, while the short arrows indicate lagging strand synthesis. When the fork encounters a lesion in the template on the leading strand (gray square), leading strand synthesis is halted but lagging strand synthesis can proceed for a short distance (B). When replication stops, positive supercoiling surrounding the replication fork favors the formation of a four-way junction, the chickenfoot (C). The shorter leading strand can now be extended to the end of the longer lagging strand with which it is now paired, past the lesion in the template (D). RecQ helicases would then unwind these structures to restart the replication fork past the area of damage (E).

Potential Function for recQ Helicases in Telomere Maintenance

Telomeres are structures composed largely of G,C-rich DNA repeat sequences that cap the ends of eukaryotic chromosomes and are required for chromosome stability. Telomeres become shorter each time a cell replicates its chromosomes. Stem cells and most immortal tumor cells overcome telomeric shortening using telomerase (a reverse transcriptase) to extend telomere ends. A relatively small proportion of human cancers use a telomerase-independent mechanism called alternative lengthening of telomeres (ALT) to extend telomeres and allow for continued cell division. Through recombination, long stretches of telomeric-repeat DNA are added to telomeres. Budding yeast strains that lack telomerase use a telomere maintenance pathway that resembles ALT and requires the recQ helicase sgs1. The human recQ helicases BLM and WRN have been localized to telomeres in ALT cells; both helicases bind to the telomere-associated protein TRF2 (Telomeric Repeat Factor 2). These data suggest that recQ helicases might have a role in telomere maintenance, at least in ALT cells. Since telomeres are G,C-rich structures in which G-quadruplexes are likely to form, recQ helicases might unwind these structures prior to replication of telomeric DNA. Additionally (or alternatively), recQ helicases might have a more direct role in the recombination process used for telomere lengthening.

Biography

Joanna Groden is a Professor in the Department of Molecular Genetics, Biochemistry, and Microbiology at the University of Cincinnati College of Medicine, and an Assistant Investigator of the Howard Hughes Medical Institute. Her principal research interest is inherited susceptibility to cancer. She holds a Ph.D. from Cornell University and received her postdoctoral training at the University of Utah. Her work resulted in the cloning and characterization of two human disease genes that determine cancer susceptibility, the *APC* tumor suppressor and the *BLM* helicase.

Regulated Intramembrane Proteolysis (Rip)

Jin Ye, Michael S. Brown and Joseph L. Goldstein
University of Texas Southwestern Medical Center, Dallas, Texas, USA

Regulated intramembrane proteolysis (Rip) is a newly recognized mechanism for signal transduction that involves the generation of regulatory molecules from membrane proteins. Such cleavage liberates cytoplasmic or lumenal/extracellular fragments from transmembrane precursor proteins, allowing the cleaved fragments to function at a new location. Rip influences processes as diverse as cellular differentiation, lipid metabolism, and the response to unfolded proteins, as originally addressed in a review article by Brown *et al.*. In addition to its occurrence in animal cells, Rip has been observed in bacteria, and, remarkably, the bacterial proteases are related evolutionarily to the ones used in animal cells. Proteins that are known to undergo Rip, span all the membrane bilayer at least once. In nearly all cases, the intramembrane cleavage does not take place until the bulk of the protein on the extracytoplasmic (lumenal or extracellular) face has been removed by a primary cleavage. This primary cleavage shortens the extracytoplasmic segment to less than 30 amino acids, which is a prerequisite for the secondary intramembrane cleavage. At least ten membrane proteins are currently known to undergo Rip, and their intramembrane cleavage is mediated by four different families of membrane-bound proteases (Figure 1).

Rip Mediated by Site-2 Protease (S2P) Family

S2P is a polytopic membrane protein with the characteristics of a membrane-embedded zinc metalloprotease (Figure 2). Genes similar to the one encoding mammalian S2P have been identified in DNA sequences from multiple species, including archaea, bacteria, plants, and animals. The encoded proteins share a similar hydrophobicity profile that predicts a highly hydrophobic structure with multiple membrane-spanning regions (Figure 2). The NH_2-terminal portion of all of these proteins contains a sequence conforming to the HE*xx*H consensus that is found in a large subfamily of zinc metalloproteases (where *x* is typically a noncharged amino acid). In these proteins, the two histidines of the HE*xx*H motif coordinate with a zinc atom, and the glutamate activates a water molecule, allowing it to make a nucleophilic attack on the peptide bond. Unlike its location in hydrophilic domains of classic zinc metalloproteases, the HE*xx*H sequence of S2P is embedded in a highly hydrophobic segment (Figure 2).

In addition to the HE*xx*H motif, classic zinc metalloproteases contain a remote residue (tyrosine or aspartate) that provides an additional coordination bound for the zinc. In the S2P-like proteins, this function is believed to be filled by the aspartate of the sequence LDG, which resides in a hydrophobic segment that shows a characteristic double peak in hydrophobicity plots and is located near the COOH terminus (Figure 2). The hydrophobic nature of S2P is consistent with its postulated role in cleaving a peptide bond that is located within a membrane bilayer.

Five membrane proteins, two in animals and three in bacteria, are known to be cleaved by the S2P family (Figure 2). In animal cells, both S2P substrates (SREBP and ATF6) contain one conserved asparagine and one conserved proline residue in the middle of the transmembrane domain, located about ten residues COOH-terminal to the cleavage site. Single amino acid substitution of either the asparagine or proline reduces cleavage only slightly, but substitution of both residues abolishes cleavage. The asparagine–proline sequence may serve as an NH_2-terminal cap that allows a portion of the transmembrane α-helix to unwind partially to expose the peptide bond for cleavage by S2P.

Sterol Regulatory Element-Binding Proteins (SREBPs)

SREBPs are membrane-bound transcription factors that regulate the synthesis of cholesterol, a major component of membranes in mammalian cells. As shown in Figure 1, SREBP is inserted in membranes of the endoplasmic reticulum (ER) in a helical hairpin fashion. The cytosolic NH_2-terminal domain is a transcription factor of the basic-helix-loop-helix-leucine zipper family. The COOH-terminal domain, also cytosolic, forms a

Membrane protein	Organism	Primary cleavage enzyme	Enzyme mediating Rip	Regulator of cleavage	Sites of cleavage	Function or consequence of cleaved protein
					Extracytosolic / Membrane / Cytosolic	
Rip by S2P family of proteases						
SREBP	Mammals/ *Drosophila*	S1P	S2P	Sterols/ phospholipids		Activates genes for lipid metabolism
ATF6	Mammals	S1P	S2P	Unfolded proteins		Activates genes for ER chaperones
RseA	*E.coli*	DegS	YaeL	Unfolded proteins		Releases σ^E, which activates stress induced genes
cAD1	*E. faecalis*	Signal peptidase	Eep	?		Stimulates mating
pro-σ^k	*B. subtilis*	None	SpoIVFB	SpoIVB		Activates genes for sporylation
Rip by γ-Secretase (Presenilin)						
APP	Mammals	β-Secretase	γ-Secretase	?		Generates Aβ peptide
Notch	Mammals/ *Drosophila*	TACE	γ-Secretase	Delta		Activates genes for differentiation
ErbB-4	Mammals	TACE	γ-Secretase	Heregulin		Phosphorylates nuclear proteins that inhibit cellular growth
Rip by Other Proteases						
MHC, class I	Mammals	Signal peptidase	Signal-peptide peptidase	?		Generates peptide for antigen presentation by HLA-E
Spitz	*Drosophila*	None	Rhomboid	Star		Generates ligand for EGF receptor

FIGURE 1 Membrane proteins that undergo regulated intramembrane proteolysis (Rip) categorized according to the Rip protease. The cleaved protein fragments are highlighted in red. For simplicity, proteins are not drawn to scale, and we do not show the alternate pathway for APP processing, which involves cleavage by TACE. For Notch, we show only the transmembrane subunit.

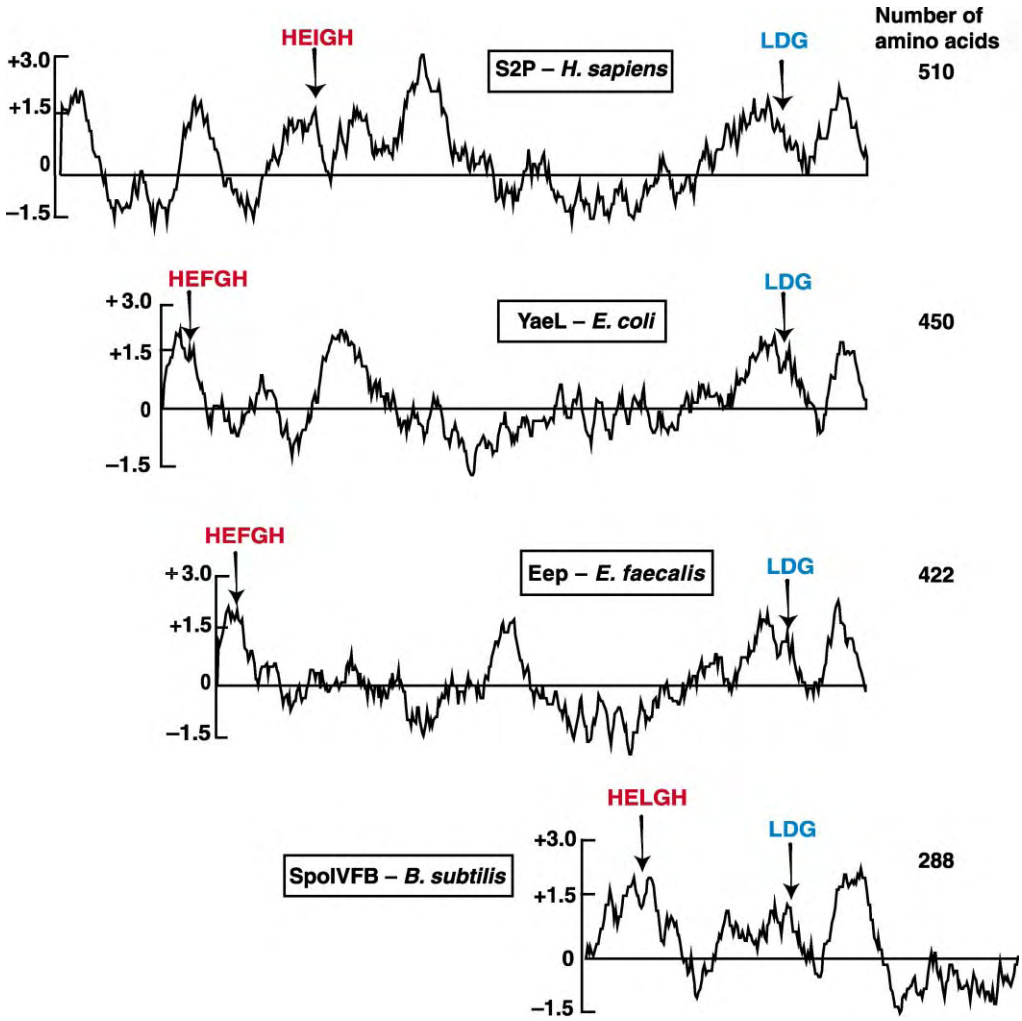

FIGURE 2 Hydropathy plots of human S2P and its bacterial family members. The HE*xx*H and LDG motifs (discussed in the text) are highlighted in red and blue, respectively. Each plot is drawn on the same scale and aligned by the position of the LDG motif. GenBank Accession numbers for the amino acid sequences are as follows: S2P, AAC51937; YaeL, AAC73287; Eep, AAD47948; and SpoIVFB, p26937.

complex with a polytopic membrane protein called SCAP. Upon deprivation of sterols, SCAP transports SREBP from ER to Golgi, where cleavage occurs. When cells are overloaded with sterols, the SCAP/SREBP complex is trapped in the ER and cleavage cannot occur. Inasmuch as SREBPs activate genes encoding enzymes of cholesterol synthesis, this sterol-mediated block in transport allows cholesterol to inhibit its own synthesis in a classic feedback fashion.

The first cleavage of SREBP is catalyzed by site-1 protease (S1P), a membrane-bound serine protease that is oriented with its active site in the lumen of the Golgi complex. Cleavage by S1P separates the two transmembrane helices of SREBP, but the NH_2-terminal fragment remains membrane-bound until it is cleaved by S2P at a site that is three residues within the transmembrane segment (Figure 1). Even though the activity of S2P is not regulated directly by sterols, S2P does not act until the two transmembrane segments have been separated by S1P, which effectively brings this reaction under cholesterol control.

In *Drosophila*, orthologues of SREBP, SCAP, S1P, and S2P are all expressed even though *Drosophila* cells do not produce sterols. *Drosophila* SREBP is processed by S1P and S2P in a reaction that requires SCAP and presumably requires ER to Golgi transport. The major SREBP targets in *Drosophila* S2 cells are enzymes required for synthesis of saturated fatty acids, which are incorporated into the major phospholipid, phosphatidyl ethanolamine (PE). PE, rather than sterols, is the feedback regulator of SREBP cleavage in these cells.

ATF6 AND RSEA

ATF6 is a type 2 membrane protein with a single transmembrane domain (Figure 1). Its NH_2-terminal

cytosolic domain is a transcription factor of the bZIP family. When mammalian cells produce unfolded endoplasmic reticulum (ER) proteins, ATF6 translocates from ER to Golgi, where it is cleaved sequentially by S1P and S2P, the same proteases that process SREBP. The intramembrane proteolysis carried out by S2P liberates the NH_2-terminal domain of ATF6 from the membrane, allowing it to activate transcription of *BiP/GRP78* and other genes whose products assist the folding of ER proteins. This regulatory pathway, called the unfolded protein response, helps cells to survive conditions of ER stress.

In *E.coli*, σ^E is the transcription factor that regulates extracytoplasmic stress response. Under nonstress conditions, σ^E is negatively regulated by RseA, an inner membrane protein with one transmembrane domain (Figure 1). The NH_2-terminal cytosolic domain of RseA binds to σ^E and is sufficient to inhibit σ^E activity. When unfolded proteins accumulate in the periplasmic space (similar to ER lumen in eukaryotic cells), RseA is first cleaved by DegS, a membrane-bound serine protease with its active site projecting into the periplasmic space. Cleavage by DegS removes the majority of the COOH-terminal periplasmic domain of RseA. YaeL, an orthologue of S2P, then cleaves the remaining part of RseA, after which RseA is rapidly degraded. This frees σ^E to associate with RNA polymerase and direct transcription of its target genes.

The similarity between mammalian and bacteria unfolded-protein response suggests that S2P-mediated Rip has been selected to cope with extracytoplasmic stress during evolution, although individual organisms use the mechanism in different ways: in mammalian cells Rip directly releases the active transcription factor from its substrate, whereas in bacteria Rip leads to degradation of a membrane-bound inhibitor of the responsible transcription factor.

Other Bacterial Proteins

Enterococcus faecalis, a Gram-positive bacterium, secretes an 8-amino acid peptide pheromone called cAD1, which induces a mating response in other enterococci that harbor a plasmid called pAD1 (Figure 1). Genomic sequencing revealed that the octapeptide pheromone is derived from a 143-amino acid precursor that contains a signal peptide at the NH_2-terminus and is inserted into the plasma membrane with a type 2 orientation. The pheromone corresponds to the COOH-terminal 8 amino acids of the signal peptide (Figure 1). The octapeptide is generated by cleavage of the precursor at two sites, at the extracellular side of the membrane in a reaction carried out by signal peptidase and at a site in the middle of the transmembrane signal peptide by Eep, an S2P orthologue. This system differs from the others in that the active fragment is released by S2P into the extracellular space rather than the cytosol.

Another prokaryotic relative of S2P is a *B. subtilis* protein called spoIVFB. This protein contains an HE*xx*H motif in a hydrophobic segment near the NH_2 terminus and an LDG motif in a double-peaked hydrophobic segment toward the COOH terminus (Figure 2). The overall hydrophobicity profile of SpoIVFB differs from those of the other family members. SpoIVFB is a much smaller protein, and it contains a hydrophilic extension on the COOH-terminal side of the hydrophobic LDG segment. SpoIVFB is the protease that removes a membrane-embedded NH_2-terminal hydrophobic peptide from a transcription factor, pro-σ^K, thereby releasing the factor into the cytosol and allowing it to activate gene transcription. This process is necessary for completion of spore formation in response to nutrient deprivation. The membrane orientation of pro-σ^K is opposite to the type 2 orientation of other known S2P substrates, and it is the only S2P substrate that does not require a primary cleavage (Figure 1). These differences in catalytic requirements may account for the differences in structure between SpoIVFB and the other members of the S2P family.

Rip Mediated by γ-Secretase

γ-Secretase is a membrane-bound complex consisting of several proteins, including presenilin and nicastrin. Presenilin contains two conserved aspartate residues that are located in 2 of its 8 transmembrane helices at positions that are predicted to place them at the same depth in the membrane. This property is reminiscent of soluble aspartyl proteases, which contain two closely apposed aspartates that are required for activity. Experiments with active-site-modifying agents specific for aspartyl proteases provide evidence that presenilin contains the active proteolytic site. The second component of γ-secretase, also required for catalytic activity, is a membrane protein called nicastrin. Nicastrin is believed to present substrates to presenilin, regulate its stability, and deliver it to the cell surface.

Several membrane proteins are believed to be cleaved by γ-secretase, but only three have been well characterized, as discussed here.

Amyloid Precursor Protein (APP)

APP is a type 1 membrane protein with an NH_2-terminal extracellular domain and a COOH-terminal cytosolic tail (Figure 1). Processing of APP generates a toxic amyloid β peptide that is responsible for Alzheimer's disease. APP is first cleaved at a site that is 28 amino acids from the transmembrane helix by β-secretase, a membrane-bound aspartyl protease with an extracytoplasmic active

site. This cleavage shears off the bulk of the extracellular domain of APP, which then allows the protein to be cleaved within the membrane by γ-secretase. Intramembrane cleavage can occur at either of the two sites separated by two amino acids, leading to two different amyloid β peptides, designated $A\beta_{1-40}$ and $A\beta_{1-42}$, which accumulate extracellularly. After the intramembrane γ-secretase cleavage, the cytosolic tail of APP enters the nucleus where it may affect transcription of genes that are not yet identified.

In addition to cleavage by β-secretase, APP can be cleaved by TNFα converting enzyme (TACE), a membrane-bound metalloprotease whose active site faces the extracellular surface. TACE cuts the extracytosolic domain of APP even closer to the membrane, leaving only 12 amino acids on the external surface. Like the β-secretase cleavage, TACE cleavage is followed by γ-secretase cleavage. In this case, the liberated fragment is too short to form an amyloid deposit, and thus cleavage by TACE does not lead to Alzheimer's disease.

Notch

The cell surface receptor Notch is synthesized as a type 1 membrane protein (Figure 1) that is processed constitutively by a furin-like enzyme in the secretory pathway. The enzyme cleaves the precursor to generate two subunits: an extracellular subunit and a transmembrane subunit, which remain associated as a noncovalent heterodimer. The heterodimer travels to the cell surface and remains intact until it binds its ligand Delta, a membrane protein that resides on the surface of an adjacent cell. Binding leads to cleavage of the transmembrane subunit of Notch by TACE, the same enzyme that cleaves APP. TACE cleavage releases most of the extracellular portion of the transmembrane subunit of Notch along with the attached extracellular subunit. The shortened transmembrane subunit is then cleaved by γ-secretase within the membrane-spanning helix, liberating a cytosolic fragment. The cytosolic fragment translocates to the nucleus where it activates several genes whose products influence the fate of cells during development.

ErbB-4

ErbB-4 is a transmembrane receptor tyrosine kinase that regulates cell proliferation and differentiation. It adopts a type 1 orientation with an NH_2-terminal extracellular ligand-binding domain and a COOH-terminal cytosolic tyrosine kinase domain (Figure 1). Upon binding to its ligand, heregulin, the ErbB-4 ectodomain is cleaved by TACE, followed by intramembrane proteolysis carried out by γ-secretase. The intramembrane cleavage results in the release of the cytosolic fragment, which travels to the nucleus where it phosphorylates substrates that regulate cell growth.

Rip Mediated by Signal-Peptide Peptidase (SPP)

SPP, a resident ER protein with 7 transmembrane domains, contains two conserved aspartate residues, each within adjacent transmembrane helices. As discussed above, such motifs are characteristic of the presenilin-type of aspartic protease. Similar to S2P, cleavage by SPP requires helix-breaking residues within the transmembrane domain of its signal peptide substrates.

The best-studied example of Rip mediated by SPP is the proteolytic processing of signal peptides from MHC class I molecules such as HLA-A, -B, -C, and -G. These molecules are expressed with a typical signal sequence for targeting to the secretory pathway. During their translocation through the ER membrane, the signal sequences are cleaved off from the pre-protein by signal peptidase. The cleaved signal peptides, which remain membrane-bound with a type 2 orientation, are then cleaved by SPP in the middle of the membrane to liberate the NH_2-terminal half of the signal peptides into the cytosol (Figure 1). These cytosolic fragments are then transported into the ER lumen where they bind to HLA-E, a nonclassical MHC class I molecule. The HLA-E/peptide complexes travel to the cell surface where they bind to CD94/NKG2A receptors on natural killer (NK) cells and inhibit NK cell-mediated lysis. This pathway protects cells expressing normal MHC class I molecules from killing by NK cells.

Rip Mediated by Rhomboid

Rhomboid, a Golgi membrane protein with 7 transmembrane domains, is a serine protease whose catalytic triad is buried within the membrane bilayer. Rhomboid belongs to a large gene family that is conserved throughout archaea, bacteria, yeast, plants, and animals, including humans. To date, rhomboid has only been characterized in *Drosophila* where it initiates epidermal growth factor receptor (EGFR) signaling.

Spitz is the main ligand for *Drosophila* EGFR. It is synthesized as a transmembrane precursor with an NH_2-terminal extracellular EGF-like domain and a short COOH-terminus cytosolic tail (Figure 1). Spitz is confined to the ER and is inert until it binds to another protein named star. Star escorts spitz from ER to Golgi where spitz is cleaved by rhomboid. The intramembrane cleavage liberates the extracellular

EGF-like domain from the membrane, allowing it to be secreted out of the cell.

Unlike Rip mediated by other proteases, a primary cleavage that sheds the extracytoplasmic domain of spitz is not required for the action of rhomboid, as rhomboid itself is directly responsible for the release of the extracellular domain of spitz (Figure 1). It remains unclear why spitz is subjected to Rip rather than being cleaved by an extracellular protease such as TACE.

Glossary

regulated intramembrane proteolysis (Rip) A process of signal transduction in which a membrane-bound protease cleaves its substrate within the lipid bilayer, thus allowing the cleaved protein fragment to function at a new location.

rhomboid An intramembrane serine-protease involved in the Rip of Spitz.

γ-secretase A protein complex containing an intramembrane aspartyl-protease catalytic subunit involved in the Rip of APP, Notch, and ErbB-4.

S2P An intramembrane metalloprotease involved in the Rip of SREBPs and ATF6.

SPP An intramembrane aspartyl-protease involved in the Rip of signal peptides released from certain MHC class I molecules.

Biography

The authors are members of the Department of Molecular Genetics at the University of Texas Southwestern Medical Center in Dallas. Dr. Ye is a postdoctoral fellow in the Department of Molecular Genetics at the University of Texas Southwestern Medical Center in Dallas. He delineated the role of S2P in cleaving membrane-bound SREBPs and ATF6 and advanced a provocative hypothesis to explain the mechanism by which intramembrane proteases cleave transmembrane proteins.

Brown and Dr. Goldstein are Professors in the Department of Molecular Genetics at the University of Texas Southwestern Medical Center in Dallas. They have worked together for 30 years on the genetics and regulation of cholesterol metabolism. They received the Nobel Prize in Physiology or Medicine in 1985 and the Albany Medical Center Prize in Medicine and Biomedical Research in 2003.

Respiratory Chain and ATP Synthase

David G. Whitehouse and Anthony L. Moore
University of Sussex, Brighton, UK

The respiratory chain and ATP synthase are, in eukaryotic cells, located in the inner membrane of mitochondria. Mitochondria are oval-shaped organelles, typically 1–2 μm long and 0.5 μm in diameter, whose principal cellular functions are to generate energy, in the form of ATP and carbon skeletons for biosynthetic purposes. The shape and appearance of mitochondria vary considerably and these organelles appear to be most numerous in mammalian tissues with a high-energy demand (heart, liver, muscle, and brain and in rapidly dividing plants cells). The respiratory chain functions to oxidize NADH ($+H^+$) and $FADH_2$ and reduce molecular oxygen to water. These functions are electron transfer (electronmotive) processes and result in a substantial release of energy, which generates a protonmotive force, that is used to drive the ATP synthase in the forward direction thereby synthesizing ATP for use in cellular reactions.

Components of the Respiratory Chain

The conversion of the electronmotive force (NADH and FADH oxidation) into a protonmotive force is carried out by three electron-driven proton-pumping respiratory chain complexes. These large transmembrane complexes contain numerous reduction–oxidation (redox) components that include flavins, iron–sulfur proteins, cytochromes, ubiquinone, and metal ions.

Flavins

Flavin mononucleotide (FMN) and flavin dinucleotide (FAD) are tightly bound (to their enzymes) cofactors that can accept (or donate) two electrons and two protons (to become fully reduced) or a single electron and proton to form the semiquinone intermediate.

Iron–Sulfur Proteins

Iron–sulfur (or nonheme iron proteins) contain iron atoms covalently bound to the apo-protein by cysteine sulfurs and to other iron atoms via acid labile sulfur bridges. In general, there are three types of Iron–sulfur proteins namely a single iron atom coordinated to the sulphydryl groups of four cysteine residues of the protein, a protein containing two irons and two inorganic sulfides (2Fe–2S) and four irons and four inorganic sulfides (4Fe–4S). Similar to the single iron cluster, both are coordinated by four cysteine residues. All three types of Iron–sulfur proteins can act as single electron carriers.

Cytochromes

Cytochromes are proteins containing a prosthetic group called a heme. The basis of the heme is a porphyrin, which consists of four pyrrole rings linked in a cyclic manner by methene bridges with a central coordinated iron atom that acts as a single electron carrier. There are at least four classes of cytochromes (cytochrome A–D) differentiated from each other by the ability to absorb light at different wavelengths (due to differences in the side chains on the porphyrin).

Ubiquinone

Ubiquinone or coenzyme Q is a hydrophobic quinone derivative that in mammalian mitochondria has a side chain of ten 5-carbon isoprene units (Q_{10}). Ubiquinone can be fully reduced to the quinol form by the acceptance of $2H^+$ and $2e^-$ (or the semiquinone derivative can be formed through the acceptance of a single proton and electron).

Respiratory Chain Complexes

The following respiratory chain complexes (I, III, and IV) are associated with proton translocation across the inner mitochondrial membrane.

Complex I (NADH-Ubiquinone Oxidoreductase)

NADH-ubiquinone oxidoreductase is the largest (750 kDa) and most complicated of the respiratory

chain complexes, having ~43 subunits. Although it is well established that complex I contains FMN and numerous Iron–sulfur proteins as redox centers, the exact route of electron transfer is uncertain. What is certain, however, is that the enzyme transfers two protons and two electrons from NADH ($+H^+$) to ubiquinone, and electron transfer is accompanied by the translocation of protons across the membrane with a stoichiometry of $4H^+/2e^-$. Enzyme activity is potently inhibited by rotenone and piercidin A. Electron microscopic studies suggest that complex I has an L-shape with the majority (if not all) of the redox centers being located within the peripheral part of the enzyme. The exact mechanism whereby protons are translocated across the membrane is uncertain.

Complex III (Ubiquinone–Cytochrome *c* Oxidoreductase or the bc_1 Complex)

Complex III is a large (250 kDa) multicomponent complex that catalyzes the oxidation of ubiquinol and the reduction of cytochrome c_1 and results in the vectorial transport of protons across the inner mitochondrial membrane. Redox centers include a 2Fe-2S protein (the Rieske center), two *b* cytochromes (cytochrome b_L and b_H) and cytochrome c_1. X-ray crystallography studies reveal that the enzyme is dimeric, with each of the two monomers being composed of at least 11 subunits (8 of which appear to have no catalytic role). Crystallography has also revealed that the monomers do not function independently but cooperate during electron transfer. Structural studies have also shown that the Rieske center shuttles between the quinone-binding site (of one of the monomers) in its oxidized state and cytochrome c_1 (of the second monomer) in its reduced state. Although the pathway of electron flow through complex III (known as the Q-cycle) is complicated, the net equation is:

$$QH_2 + 2\text{cyt}c_{1(\text{oxidized})} + 2H^+_N = Q + 2\text{cyt}c_{1(\text{reduced})} + 4H^+_P$$

where N and P refer to the negative and positive sides of the membrane (Figure 1).

The Q-cycle accommodates the fact that there is a mixture of two and one electron carriers and hence there must be a switch between ubiquinol (a two electron carrier), the cytochromes, and Rieske center (all of which are single electron carriers). It also explains the well-documented observation that the H^+/e^- stoichiometry for the bc_1 complex is 4. Complex III is inhibited by antimycin A, myxothiazol, and stigmatellin.

Complex IV (Ferrocytochrome *c* – Oxygen Oxidoreductase or Cytochrome *c* Oxidase)

Complex IV is a third large transmembrane enzyme (204 kDa) that catalyzes the oxidation of reduced cytochrome *c* and the reduction of molecular oxygen to water. It is also associated with the translocation of protons across the membrane and has at least 13 subunits of which only subunits I and II appear to play

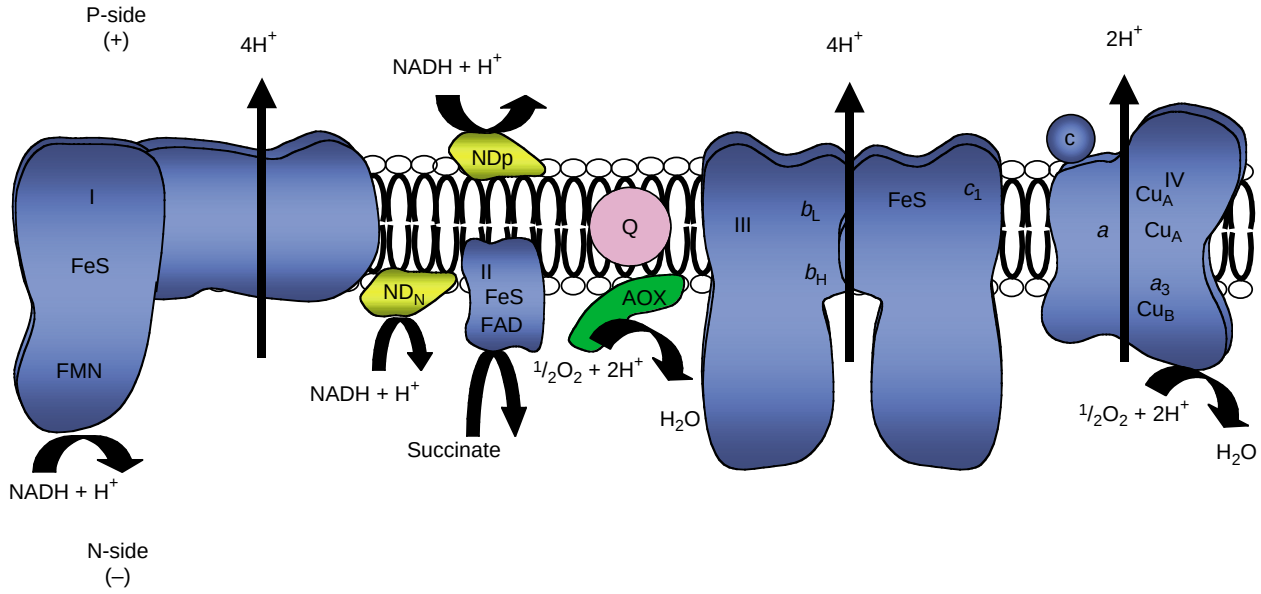

FIGURE 1 A schematic representation of the respiratory chain. The P- and N-sides of the membrane refer to the intermembrane space (positive) and matrix (negative), respectively. ND_P and ND_N refer to NADH dehydrogenases (such as the ETF, glycerol-3-phosphate and externally located NADH dehydrogenases) located on the P- and N-sides, respectively. AOX is the alternative oxidase.

a role in catalysis. The complex contains three Cu atoms and two heme *a* (cytochrome *a* and cytochrome a_3). High-resolution structural studies reveal that subunit II contains two of the Cu atoms complexed with sulfur atoms to form a binuclear center (known as Cu_A center). Subunit I contains the two cytochromes and the third Cu atom (Cu_B), which is closely associated with cytochrome a_3 forming a second binuclear center. Electron transfer through complex IV is from cytochrome *c* to the Cu_A center (which acts as a single electron receptor), then to heme *a* (which is slightly closer to the Cu_A center than heme a_3) onto the heme a_3–Cu_B center and finally onto oxygen bound to heme a_3. For every four electrons passing through the complex, one molecule of oxygen is reduced to two molecules of water, four protons are consumed from the matrix, and four protons are translocated across the membrane. It should be noted that the four electron reduction of molecular oxygen occurs as four single electron events and hence it is important that the potentially dangerous partially reduced intermediates such as superoxide anion are not released but remain tightly bound until completely reduced to water. Cytochrome *c* oxidase is potently inhibited by cyanide, azide, and carbon monoxide, which bind at the oxygen-binding site. Nitric oxide is also a reversible inhibitor of this complex.

Other Ubiquinone-Reducing Enzymes

Animal, plant, and a number of protest mitochondria also contain a number of membrane-bound enzymes that can reduce ubiquinone. These enzymes do not transfer charge across the membrane, i.e., protons are not vectorially transported across the inner mitochondrial membrane and are detailed in the following section.

Succinate Dehydrogenase

Succinate dehydrogenase is the only membrane-bound enzyme of the citric acid cycle that interacts directly with the respiratory chain. Succinate dehydrogenase is much smaller than complex I (140 kDa) being composed of four subunits. The two larger of these subunits are peripheral proteins that contain covalently bound FAD (on subunit I) and three Iron–sulfur centers (on subunit II). These two large subunits are anchored to the inner surface of the inner membrane by two integral membrane polypeptides (subunits III and IV) in which a single heme *b* is located. Although the exact route of electron transfer from succinate to ubiquinone is uncertain, it is known that the reduction of ubiquinone by succinate is not associated with any charge movement.

Electron-Transferring Flavoprotein (ETF)-Ubiquinone Reductase

The ETF-ubiquinone oxidoreductase is a globular protein located on the inner surface of the inner membrane and contains FAD, an Fe–S center and a ubiquinone-binding site. The enzyme can accept reducing equivalents from a variety of dehydrogenases including those involved in fatty acid oxidation or amino acid and choline catabolism.

Glycerol-3-phosphate Dehydrogenase

Glycerol-3-phopshate dehydrogenase is located on the outer surface of the inner membrane and catalyzes the oxidation of glycerol-3-phosphate to dihydroxyacetone phosphate and the reduction of ubiquinone. Although little is known about the structure or the route of electron transfer to ubiquinone, redox centers include FAD and probably an Iron–sulfur center.

External NADH Dehydrogenase

There are a number of rotenone-insensitive NADH dehydrogenases located on the outer and inner surface of the inner mitochondrial membrane in plant and yeast mitochondria. Again there is little structural information apart from the presence of FAD and possibly an Iron–sulfur center. Electron transfer is probably similar to that described for the ETF-ubiquinone oxidoreductase since the enzyme catalyzes the oxidation of NADH and the reduction of ubiquinone. In plants, the external NADH dehydrogenase (on the outer surface of the inner membrane) is regulated by cytosolic Ca^{2+}. These enzymes are not associated with proton pumping across the mitochondrial membrane.

Other Ubiquinol Oxidizing Enzymes (The Alternative Oxidase)

Although mammalian mitochondria do not possess any other ubiquinol-oxidizing enzymes apart from cytochrome oxidase (complex IV), most plants, some yeasts, fungi, and trypanosomes possess a cyanide- and antimycin-insensitive alternative oxidase that catalyzes the oxidation of ubiquinol and reduces molecular oxygen to water. Unlike cytochrome *c* oxidase, electron transfer does not result in proton translocation and redox energy is released as heat. Although no structural information is available, the enzyme is believed to contain two nonheme iron atoms linked by an oxygen atom as its only redox carrier (di-iron protein) and is probably globular with two of its amphiphilic helices lying parallel to the membrane plane. Enzyme activity is insensitive to all complex IV inhibitors but can be potently inhibited by salicylhydroxamic acid and the alkyl gallates.

Organization of the Respiratory Chain

The respiratory chain complexes in mammalian and plant mitochondria are generally considered to be free to diffuse laterally and independently of each other within the plane of the membrane. They are connected electronically to each other by ubiquinone and cytochrome *c* with electron transfer occurring by diffusion-based collisions between these components. There is also evidence to suggest that the numbers of complexes within the membrane are unequal with the following ratio: complexes I:II:III:IV: cytochrome *c*: ubiquinone = 1:2:3:7:14:63. Both cytochrome *c* and ubiquinone are considered to function as common pools and hence act as mobile carriers mediating electron transfer between freely diffusible large respiratory complexes.

For every $2e^-$ passing from NADH ($+H^+$) to oxygen to produce one molecule of water a total of ten protons are released at the P-side of the membrane. Since four protons are required to synthesize and export one ATP, then the amount of ATP formed by the oxidation of NADH is 2.5 (1.5 for succinate).

The ATP Synthase

The ATP synthase (or F_1F_0 ATPase and also referred to as complex V) uses the free energy of an electrochemical gradient of protons (or sodium ions) generated by the respiratory chain to synthesize ATP. The ATP synthases comprise a very large group of highly conserved enzymes that are found in the bacterial cytoplasmic membranes, the thylakoid membranes of chloroplasts, and the inner membranes of mitochondria. Most members of the group use H^+ as the coupling ion (the *Propionigenium modestum* enzyme is an example of the few ATP synthases that can use Na^+ as the physiological coupling ion).

Structure of the ATP Synthase

The ATP synthase is a miniature rotating motor and the simplest or prototype enzyme is that isolated from *E. coli*. The enzyme has a bipartite structure composed of a membrane-bound (hydrophobic) F_0 component crossing the inner mitochondrial membrane and a water-soluble (hydrophilic) F_1 component that protrudes into the mitochondrial matrix.

The F_0 Component

The F_0 entity is composed of three subunits (*a*, *b*, and *c*) with a stoichiometry of: *a*:2*b*:9–12*c* and it functions as a proton channel. The proton channel is a ring of 9–12 *c* subunits (the number of subunits may depend on the carbon source used for growth) positioned in the membrane and tightly bound to one *a*-subunit plus two *b*-subunits of F_0 and also bound to the γ, δ, and ε subunits of the F_1 component of the synthase.

The F_1 Component

The F_1 component has five types of subunits (α, β, γ, δ, and ε) with a stoichiometry of $3\alpha{:}3\beta{:}\gamma{:}\delta{:}\varepsilon$. The $\alpha_3\beta_3$ subunits are arranged as a hexamer of alternating α- and β-subunits with the γ-subunit projecting into the central cavity of this hexamer. The β-subunits contain the catalytic site for ATP synthesis/hydrolysis and bind the adenylates and inorganic phosphate.

ATP synthases from other sources all have very similar structures to the *E. coli* synthase except the mitochondrial enzyme. It contains an inhibitor protein and a mitochondrial oligomycin-sensitivity-conferring protein (OSCP factor). The mitochondrial δ-subunit is related to the ε-subunit of the *E. coli* synthase (Figure 2).

Mechanism of ATP Synthesis

ATP synthesis is driven by the rotation of the single γ-subunit, which extends into the center of the α_3/β_3 hexamer that contains the catalytic sites. As the single γ-subunit rotates so it alternately alters the conformation (and hence binding characteristics) of the catalytic sites. Changes in nucleotide affinity occur in the three β-subunits and arise from their interactions with the γ-subunit. This results in the sequential binding of ADP and Pi, followed by ATP synthesis and ATP release. This concept recognizes that the β-subunit can exist in three conformations: open, tight, or loose forms. These forms correspond to the binding, synthesis, and release of ATP and are driven by the rotation of the γ-subunit. The hydrolysis of ATP will drive the rotation of the γ-subunit in the opposite direction to that of synthesis.

Subunits c_{9-12}, γ, and ε constitute the rotor (rotating unit) and subunits α_3, β_3, δ, *a*, and b_2 constitute the stator (stationary unit). The protonmotive force drives rotation of the oligomeric ring of the *c*-subunits and of the γ-subunit in F_0 (since the γ-subunit is attached to the *c*-oligomer). Thus, protons moving from the P-side to the N-side of the inner membrane (i.e., down the electrochemical gradient are converted into rotational torque of γ, which alters nucleotide binding at the β-catalytic site and results in the synthesis/hydrolysis of ATP. It is not the synthesis of ATP but its release from the synthase that is driven by the protonmotive force. Subunits γ and ε rotate relative to the $\alpha_3\beta_3$ hexamer to alter the nucleotide affinities (and hence binding) in the β-catalytic sites. Probably subunit γ of F_1 and two copies of subunit *b* in F_0 stabilize the synthase complex.

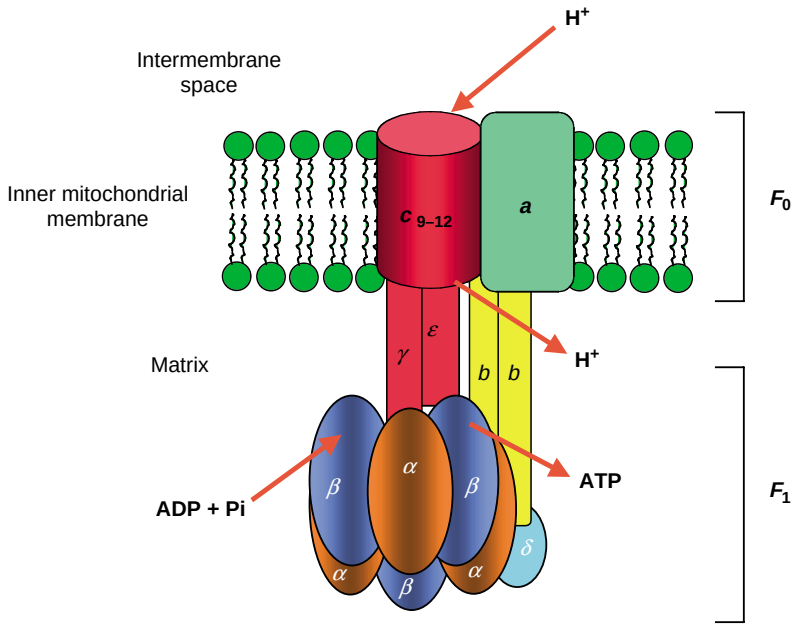

FIGURE 2 Diagram of the ATP synthase. Note that during ATP synthesis, subunits *c*, γ, and ε rotate as a complete unit with respect to the other (fixed) subunits.

A simplified mechanism suggests that it is the flow of protons through *c* via *a* channel (or two half channels) that protonates an aspartate residue and the proton is released through the channel (or second half channel). Conformational changes during this cycle of protonation–deprotonation provide the basis to explain rotation. This protonated *c* subunit then rotates through 360° during ATP synthesis/hydrolysis and both the subunits γ and ε rotate by 120° for each ATP synthesized (or hydrolyzed) with the rotation being coupled to the protonation-deprotonation of three–four *c* subunits.

Glossary

binuclear center A binuclear center comprises two redox-active components in close proximity, e.g., copper and cytochrome *a* or two iron atoms linked by an oxygen atom that function as a single entity to mediate electron transfer.

proton pump A transmembrane protein which mediates the active transport of protons across the inner mitochondrial membrane/thylakoid membrane.

protonmotive force The energy contained in an electrochemical gradient of protons across the inner mitochondrial membrane/thylakoid membrane and composed of two components, the membrane potential and pH gradient. It is the driving force for the transport of substrates across the membrane and for the synthesis of ATP.

respiratory chain An assemblage of electron carriers normally arranged as a multicomponent complex and located in the inner mitochondrial membrane.

Biography

Anthony L. Moore is a professor in the Department of Biochemistry at the University of Sussex, United Kingdom. His principal research interests are in the structure and function of plant mitochondrial respiratory chain proteins. He holds a Ph.D. from the University of Aberdeen and received his postdoctoral training at the University of Pennsylvania. He developed a procedure for measuring the steady-state redox poise of the ubiquinone pool in isolated mitochondria, which his laboratory has used to investigate the regulation of the alternative oxidase.

David G. Whitehouse is a research fellow in the Department of Biochemistry at the University of Sussex, United Kingdom. His principal research interests are in the structures and functions of both the plant mitochondrial and the chloroplast electron transport chains. He holds a Ph.D. from the University of London and received his postdoctoral training at Imperial College, London. He has published a number of research articles and chapters on the regulation of mitochondrial electron transport.

Respiratory Chain Complex I

Ulrich Brandt
Johann Wolfgang Goethe-University, Frankfurt, Germany

Complex I (EC 1.6.5.3) is a multi-subunit respiratory chain NADH:ubiquinone oxidoreductase that is found in the inner mitochondrial membrane of almost all eukaryotes and in the plasma membrane of many bacteria. It contains one molecule of flavine mononucleotide (FMN) and eight to nine iron–sulfur clusters as redox prosthetic groups.

Mammalian complex I couples the transfer of two electrons to the pumping of four protons across the mitochondrial inner membrane and thereby provides up to 40% of the driving force for ATP generation by oxidative phosphorylation (OXPHOS). Complex I is the target of numerous pathological human mutations in both the mitochondrial and the nuclear genomes. Since single electron transfer is part of its catalytic cycle and semiquinone radicals are natural intermediates, complex I is also considered a major source for reactive oxygen species that have been implicated in the etiology of neurodegenerative disorders and in aging.

Complex I Structure

Overall Shape and Subcomplexes

Till date there is no detailed structural information available for complex I. Electron microscopic analysis using single particles and 2D crystals have demonstrated that the enzymes from bovine heart mitochondria, the eubacterium *Escherichia coli*, and the fungi *Neurospora crassa* and *Yarrowia lipolytica* are L-shaped with a hydrophobic membrane integral arm and a hydrophilic peripheral arm that protrudes into the mitochondrial matrix (Figure 1).

When *N. crassa* is grown in the presence of the mitochondrial protein synthesis inhibitor chloramphenicol, a small form of complex I is made which consists of hydrophilic proteins only. Chaotropic agents such as NaBr or detergents can separate the two arms of complex I and also dissociate them further. Subcomplexes have been studied extensively for bovine heart, *N. crassa*, and *E. coli* complex I (Table I).

Central Subunits and Redox Clusters

A minimal form of complex I, consisting of 14 subunits, is found in bacteria such as *E. coli*. Seven of these make up the peripheral arm and contain all the known redox prosthetic groups, namely, one molecule of FMN and eight to nine iron–sulfur clusters. The remaining seven are hydrophobic proteins located in the membrane arm. All these 14 central subunits are also present in eukaryotic complex I. In most eukaryotes, the seven central subunits of the membrane arm (ND1-6, ND4L) are encoded by the mitochondrial genome (Figure 1).

Accessory Subunits

Eukaryotic complex I also contains a large number of additional subunits, resulting in a total number of more than 35 subunits in fungi and at least 45 subunits in mammals. While some may simply serve as a scaffold to increase the stability of the enzyme, there are indications that others may confer additional features specific to eukaryotic complex I. One such example is the acyl carrier protein (ACP) that carries a phosphopantheteine prosthetic group and may function in mitochondrial lipid biosynthesis. The AQDQ subunit seems to be involved in regulation. Phosphorylation at a cAMP-dependent protein kinase consensus site (RVS) was found to stimulate complex I activity. The B16.6 kDa subunit is identical with the programmed cell death regulatory GRIM19 protein and may link complex I function to apoptosis. The MWFE subunit of the membrane arm seems to be involved in complex I assembly. Overall very little is known about the function of the accessory subunits.

A nomenclature established for the bovine enzyme by John Walker and co-workers has been generally accepted for the subunits of complex I. Apart from some of the nuclear-coded subunits that were originally named by their molecular masses, the first four amino acids of the mature protein are used (see Table I). If the mature protein is N-terminally blocked, a number indicating the molecular mass preceded by the letter B identifies the subunit.

Assembly Factors

Two proteins, named CIA30 and CIA84 (for complex I associated), were found to be associated with peripheral

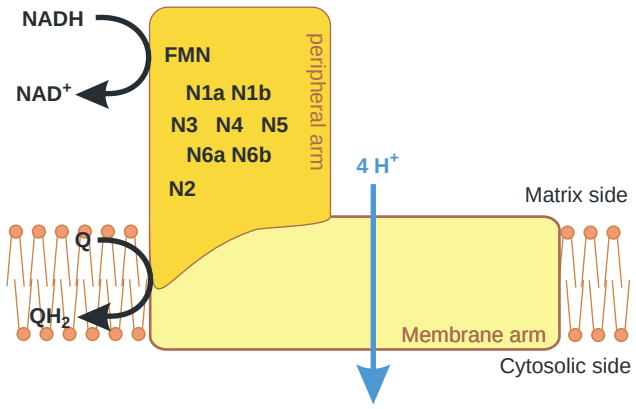

FIGURE 1 Schematic representation of mitochondrial complex I. The peripheral arm contains the seven nuclear-encoded central subunits and harbors all known redox prosthetic groups. The membrane arm contains the seven mitochondrially encoded subunits which are all highly hydrophobic. Eukaryotic complex I contains a number of additional "accessory" subunits distributed over both arms. The mechanism by which the transfer of electrons from NADH to ubiquinone is linked to proton translocation is essentially unknown. Q, ubiquinone; QH_2, ubiquinol.

arm subcomplexes in complex I mutants of *N. crassa*, but are not present in the fully assembled enzyme. Deletion of CIA30 or CIA84 led to complex I assembly defects in *N. crassa*. A CIA30 homologue is also present in mammalian genomes.

Complex I Evolution

Complex I was assembled from at least three pre-existing structural and functional modules during evolution. The homology to [NiFe] hydrogenases from various archae- and eubacterial sources has been especially useful for the understanding of complex I.

The Hydrogenase Module

Water-soluble hydrogenases from *Desulfovibrio* species consist of a large subunit which carries the [NiFe] site and is homologous to the 49 kDa subunit of complex I, and a small subunit which carries three iron–sulfur clusters and is homologous to the PSST subunit of complex I. In membrane-bound [NiFe] hydrogenases, exemplified by the enzyme encoded by the *ech* operon in *Methanosarcina barkeri*, the PSST homologue has suffered a C-terminal deletion abolishing two iron–sulfur clusters. Instead, an additional subunit carrying two iron–sulfur clusters in a ferredoxin-like fold has been acquired in this type of hydrogenase that is homologous to the TYKY subunit of complex I. It has been proposed that the hydrogenase structural fold has been conserved and shaped the catalytic core of complex I. According to this hypothesis, a significant part of the ubiquinone binding site of complex I has been derived

[c] NuoC and NuoD are fused to a single polypeptide in *E. coli*.

[d] These subunits are similar to each other and to a family of Na^+/H^+ or K^+/H^+ antiporters.

from the [NiFe] site in the large subunit, while cluster N2 corresponds to the proximal iron–sulfur cluster in the small subunit of water-soluble hydrogenases. Based on known X-ray structures of water-soluble [NiFe] hydrogenases, a structural model for the catalytic core of complex I was deduced by Brandt and co-workers and validated by site-directed mutagenesis in the yeast *Y. lipolytica*.

The Na^+/H^+ Transporter Module

One of the two transmembrane subunits of the Ech hydrogenase is homologous to the complex I subunit ND1, while the other exhibits similarities to the three complex I subunits ND2, ND4, and ND5. These three subunits are in turn related to a particular type of Na^+/H^+ or K^+/H^+ antiporter, exemplified by the MrpA and MrpD proteins of *Bacillus subtilis*. Recruitement of this transmembrane module by the water-soluble [NiFe] hydrogenases clearly was an important step toward development of complex I as it provided a component most likely critical for the development of a proton translocation machinery.

The NADH Dehydrogenase Module

The "electron input device" of complex I is related to the NAD^+-reducing [NiFe] hydrogenase from *Ralstonia eutropha*, encoded by the *hox* operon. The 24 and 51 kDa subunits are homologous to HoxF and the first 200 residues of the 75 kDa subunit are homologous to HoxU. The C-terminal half of the 75 kDa subunit shows sequence similarity to a formate dehydrogenase from *Methanobacterium formicicum*.

Variants of Complex I

Interestingly, several complex I variants are known that lack the 75, 51, and 24 kDa subunits of the NADH dehydrogenase module. Two archaebacterial proton pumping enzymes, $F_{420}H_2$:methanophenazine oxidoreductase from *Methanosarcina mazei* and $F_{420}H_2$:menaquinone oxidoreductase from *Archaeoglobus fulgidus*, accept electrons from coenzyme F_{420}, which is specific for methanogenic archaebacteria. The metabolic function of complex I from cyanobacteria and the chloroplasts of higher plants is not known. It may catalyze electron transfer from either NADH, NADPH, or ferredoxin to plastoquinone.

Complex I from the bacteria *Helicobacter pylori* and *Campylobacter jejuni* lack the 51 and 24 kDa subunits and contain a modified version of the 75 kDa subunit. Therefore, it is likely that the electron donor to these enzymes is also not NADH.

Complex I Function

The overall reaction of respiratory chain complex I is the transfer of electrons from NADH to ubiquinone or menaquinone in some bacteria and the concomitant buildup of chemiosmotic membrane potential that in mammalian mitochondria contributes ~40% to the total proton-motive force generated during oxidative phosphorylation.

Electron Transfer and Redox Centers

The physiological reaction of complex I involves electron transfer from NADH via FMN onto a series of iron–sulfur clusters with E_{m7} values between −370 and −250 mV. The tetranuclear iron–sulfur cluster N2 (E_{m7} −150 mV) is generally regarded as the last redox center in this electron transfer chain and there is evidence that it is the immediate electron donor for ubiquinone. Electron transfer from NADH to artificial acceptors such as ferricyanide or hexaammineruthenium(III) chloride does not involve the quinone binding site and can also be observed with a three-subunit subcomplex (flavoprotein, FP) of bovine heart complex I which consists of the peripheral arm subunits 51, 24, and 10 kDa.

Proton Pumping

Experimental data with intact mitochondria and submitochondrial particles indicate that complex I pumps protons with a stoichiometry of 4 $H^+/2\,e^-$. The mechanism how proton translocation is coupled to redox chemistry is still unknown. A large number of concepts and more or less detailed hypothetical mechanisms have been proposed over the last decades, but even the fundamental issue, whether there is just one integrated pumping device or two pumps transporting 2 $H^+/2e^-$ each are operational in complex I, remains unsolved. While FMN could be ruled out as a component of the proton pump, most researches in the field consider iron–sulfur cluster N2 as probable candidate to be directly involved in ubiquinone reduction and proton translocation. This view is supported by experimental evidence for the most part obtained by Tomoko Ohnishi and co-workers demonstrating for this redox center a pH-dependent midpoint potential and magnetic coupling to ubisemiquinone species. However, all known redox centers of complex I reside in the peripheral arm and it remains obscure how electron transfer drives proton translocation across the membrane part. In recent years, different directly linked mechanisms essentially inverting the proton-motive ubiquinone cycle of the cytochrome bc_1 complex have been put forward, but emerging

evidence seems to favor a more indirect mechanism based on conformational coupling.

Na^+ Pumping by Bacterial Complexes I

In some bacteria, complex I pumps sodium ions in addition or instead of protons across the plasma membrane generating a sodium motive force rather than a proton motive force. For the purified and reconstituted complex I of *Klebsiella pneumonia*, a pump stoichiometry of 1 Na^+/e^- was determined.

Inhibitors of Complex I

A plethora of structurally diverse hydrophobic compounds have been reported to inhibit complex I and are considered to interfere with ubiquinone binding. Among these inhibitors are naturally occurring antibiotics as well as synthetic insecticides and acaricides. Also a number of drugs such as amytal and meperidine, neurotoxins related to 1-methy-4-phenylmeperidinium, and even detergents such as Triton X-100 and Thesit inhibit complex I. Kinetic studies suggested that these inhibitors can be grouped into three different classes that are represented by the well known and widely used inhibitors DQA (2-decyl-4-quinazolinyl amine) and piericidin A (class I/A-type), rotenone (class II/B-type), and capsaicin (C-type). Except for capsaicin, all these inhibitors exert their inhibitory potential at I_{50} values in the nanomolar range. Competition experiments demonstrated that these inhibitors share one common binding domain with partially overlapping sites. In agreement with this observation, cross-resistance between DQA/piericidin A and rotenone is observed in inhibitor resistant mutants.

Complex I in Disease

Genetic defects in complex I typically result in multisystem disorders with a wide spectrum of severities ranging from adult onset exercise intolerance to fatal infantile lactic acidosis. Disease is often progressive.

Mitochondrial Mutations

Deletions within the mitochondrial genome or point mutations in mitochondrial tRNA genes affect the function of several respiratory chain complexes simultaneously. Skeletal muscle biopsies from such patients typically show ragged red fibers caused by mitochondrial hypertrophy. The typical clinical phenotype of mitochondrial point mutations in the ND genes is Leber's Hereditary Optic Neuropathy (LHON), characterized by optic nerve atrophy or LDYT (LHON plus dystonia), characterized by additional lesions in the caudate and putamen. Ragged red fibers are not commonly observed in patients with isolated complex I defects.

Nuclear Mutations

Due to the large number of potential target genes, mutations affecting nuclear-coded subunits of complex I have been described only recently. The typical clinical picture is Leigh syndrome, a severe, early onset neuromuscular disorder, associated with lactic acidosis, ataxia, hypotonia, spasticity, developmental delay, optic atrophy, and, in the terminal stage, degeneration of the basal ganglia. Sometimes, this is accompanied by hypertrophic cardiomyopathy. Such mutations were found in the 75 kDa, 51 kDa, 49 kDa, PSST, TYKY, and AQDQ homologues.

Mechanisms of Complex I Pathology

Complex I dysfunction has several biochemical consequences which may be relevant for producing disease symptoms. (1) Feedback inhibition of the NADH-producing citric acid cycle and pyruvate dehydrogenase complex results in elevated blood lactate levels. (2) Lowered OXPHOS efficiency will reduce ATP production. OXPHOS defects often show a remarkable degree of tissue- and organ specificity. This has been explained by assuming different energetic thresholds, in descending order for optic nerve, neuronal cells, heart muscle, skeletal muscle, and liver. (3) Increased generation of reactive oxygen species. Oxidative stress is evident from the induction of MnSOD mRNA in complex I patients. ROS damage of complex I and the ND genes in the mitochondrial genome may result in a vicious cycle of mitochondrial damage. (4) Reduced mitochondrial energy production and elevated oxidative stress may lead to the opening of the mitochondria permeability transition pore, release of pro-apoptotic factors, and apoptotic cell death.

Poisoning of Complex I

The neurotoxin 1-methyl-4-phenyl 1,2,3,6 tetrahydropyridine (MPTP), a synthetic meperidine analogue, is able to rapidly and persistently induce symptoms of acute Parkinsonism in humans and other primates. MPTP is metabolized to 1-methyl-4-phenylpyridinium (MPP^+) by the action of glial cell monoamine oxidase B. Since MPP^+ is a substrate for the dopaminergic re-uptake pathway, it accumulates in the nigrostriatal dopaminergic neurons, where it causes a specific reversible inhibition of complex I. Strikingly, highly selective neurodegeneration of the nigrostriatal dopaminergic system was also observed

following chronic exposure of rats to the common complex I inhibitor rotenone. These results support the view that complex I deficiency may also be involved in the etiology of idiopathic Parkinsonism.

Biography

Ulrich Brandt is Professor at the Gustav-Embden Center for Biological Chemistry of the Johann Wolfgang Goethe-University in Frankfurt am Main, Germany. His principal research interest is the structure and function of respiratory chain complexes and the molecular causes of mitochondrial disorders. He holds a Ph.D. from the University of Munich and received his postdoctoral training at the Dartmouth Medical School, New Hampshire and the Glynn Research Institute, Cornwall, United Kingdom. He has studied the mechanism by which mitochondrial cytochrome bc_1 complex is inhibited by strobilurins, a family of compounds now widely used as potent fungizides in agriculture. He serves as the General Secretary of the German Society for Biochemistry and Molecular Biology.

Respiratory Chain Complex II and Succinate: Quinone Oxidoreductases

C. Roy D. Lancaster
Max Planck Institute of Biophysics, Frankfurt am Main, Germany

Succinate:quinone oxidoreductases (SQORs) are enzymes that couple the two-electron oxidation of succinate to fumarate [Eq. (1)] to the two-electron reduction of quinone to quinol [Eq. (2)]:

$$\text{succinate} \leftrightarrows \text{fumarate} + 2H^+ + 2e^- \quad (1)$$

$$\text{quinone} + 2H^+ + 2e^- \leftrightarrows \text{quinol} \quad (2)$$

They can also catalyze the opposite reaction, the coupling of quinol oxidation to the reduction of fumarate. Depending on the direction of the reaction catalysed *in vivo*, the members of the superfamily of SQORs can be classified as either succinate:quinone reductases (SQR) or quinol:fumarate reductases (QFR). SQR and QFR complexes are anchored in the cytoplasmic membranes of archaebacteria, eubacteria, and the inner mitochondrial membrane of eukaryotes with the hydrophilic domain generally extending into the cytoplasm and the mitochondrial matrix, respectively. SQR (respiratory complex II) is involved in aerobic metabolism as part of the citric acid cycle (Krebs cycle) and of the aerobic respiratory chain (Figure 1A). QFR participates in anaerobic respiration with fumarate as the terminal electron acceptor (Figure 1B) and is part of the electron transport chain catalyzing the oxidation of various donor substrates (e.g., H_2 or formate) by fumarate. These reactions are coupled via an electrochemical proton potential (Δp) to ADP phosphorylation with inorganic phosphate by ATP synthase.

Succinate:Quinone Oxidoreductases Classification

Functional Classification

Succinate:quinone oxidoreductases (SQORs) can be divided into three functional classes based on the quinone substrate and the *in vivo* function of the enzyme. Subclass 1 contains those enzymes that oxidize succinate (with an oxidation–reduction potential at pH 7, $E_{M7,}$ of +25 mV) and reduce a high-potential quinone, e.g., ubiquinone ($E_{M7} = +90$ mV) or caldariella quinone ($E_{M6.5} = +103$ mV). The succinate:quinone reductases (SQRs) from mammalian mitochondria (respiratory complex II) and many prokaryotes belong to this group. Subclass 2 comprises those enzymes that catalyze the oxidation of a low-potential quinol, e.g., menaquinol ($E_{M7} = -74$ mV) or rhodoquinol ($E_{M7} = -63$ mV), and the reduction of fumarate. All quinol:fumarate reductases (QFRs) studied so far belong to this subclass. Subclass 3 includes those enzymes that catalyze the oxidation of succinate and the reduction of a low-potential quinone, e.g. menaquinone or thermoplasmaquinone. These subclass 3 enzymes are found in gram-positive bacteria (e.g., *Bacillus subtilis*, *Paenibacillus macerans*, *Bacillus licheniformis*) and archaebacteria (e.g., *Thermoplasma acidophilum*).

Structural Classification

SQORs generally contain four protein subunits, referred to as A, B, C, and D. Subunits A and B are hydrophilic, whereas subunits C and D are integral membrane proteins. Among species, subunits A and B have high sequence homology, while that for the hydrophobic subunits is much lower. Most of the SQR enzymes of gram-positive bacteria and the QFR enzymes from ε-proteobacteria contain only one larger hydrophobic polypeptide (C), which is thought to have evolved from a fusion of the genes for the two smaller subunits C and D. While subunit A harbors the site of fumarate reduction and succinate oxidation, the hydrophobic subunit(s) contain the site of quinol oxidation and quinone reduction.

Based on their hydrophobic domain and heme *b* content, SQORs are divided into five types (Figure 2A). Type A enzymes contain two hydrophobic subunits and two heme groups, e.g., SQR from the archaea *Archaeoglobus fulgidus*, *Natronomonas pharaonis*, and *T. acidophilum*. Type B enzymes contain one hydrophobic subunit and two heme groups, as is the case for SQR from the gram-positive bacteria *B. subtilis* and *P. macerans* and for QFR from the ε-proteobacteria *Campylobacter jejuni*, *Helicobacter pylori*, and

(2003). The role of electrostatics in proton-conducting membrane protein complexes. *Adv. Protein Chem.* **63**, 131–149. *FEBS Lett.* **545**, 52–60.

Wolinella succinogenes. Examples for type C enzymes, which possess two hydrophobic subunits and one heme group, are SQR from mammalian mitochondria and from the proteobacteria *Paracoccus denitrificans* and *Escherichia coli*, and QFR from the nematode *Ascaris suum*. The QFR of *E. coli* is an example of a type D enzyme, which contains two hydrophobic subunits and no heme group. Finally, type E enzymes, such as SQRs from the archaea *Acidianus ambivalens* and *Sulfolobus acidocaldarius*, but also from the proteobacterium *C. jejuni* and the cyanobacterium *Synechocystis*, also contain no heme, but have two hydrophobic subunits very different from the other four types and more similar to those of heterodisulfide reductase from methanogenic archaea.

SQOR Structure and Function

Overall Description of the Structure

The currently available crystal structures of SQORs (Figure 2B–2D) are those of two prokaryotic QFRs, both from 1999, and one prokaryotic SQR, from 2003. The *E. coli* QFR (Figure 2D), determined at 3.3Å resolution, belongs to the type D enzymes, and the QFR of *W. succinogenes* (Figure 2B), refined at 2.2Å resolution, is of type B. The structure of the SQR from *E. coli* (Figure 2B) was reported at 2.6Å resolution. Interestingly, *E. coli* QFR appears to be a monomeric complex of one copy each of the A, B, C, and D subunits, whereas

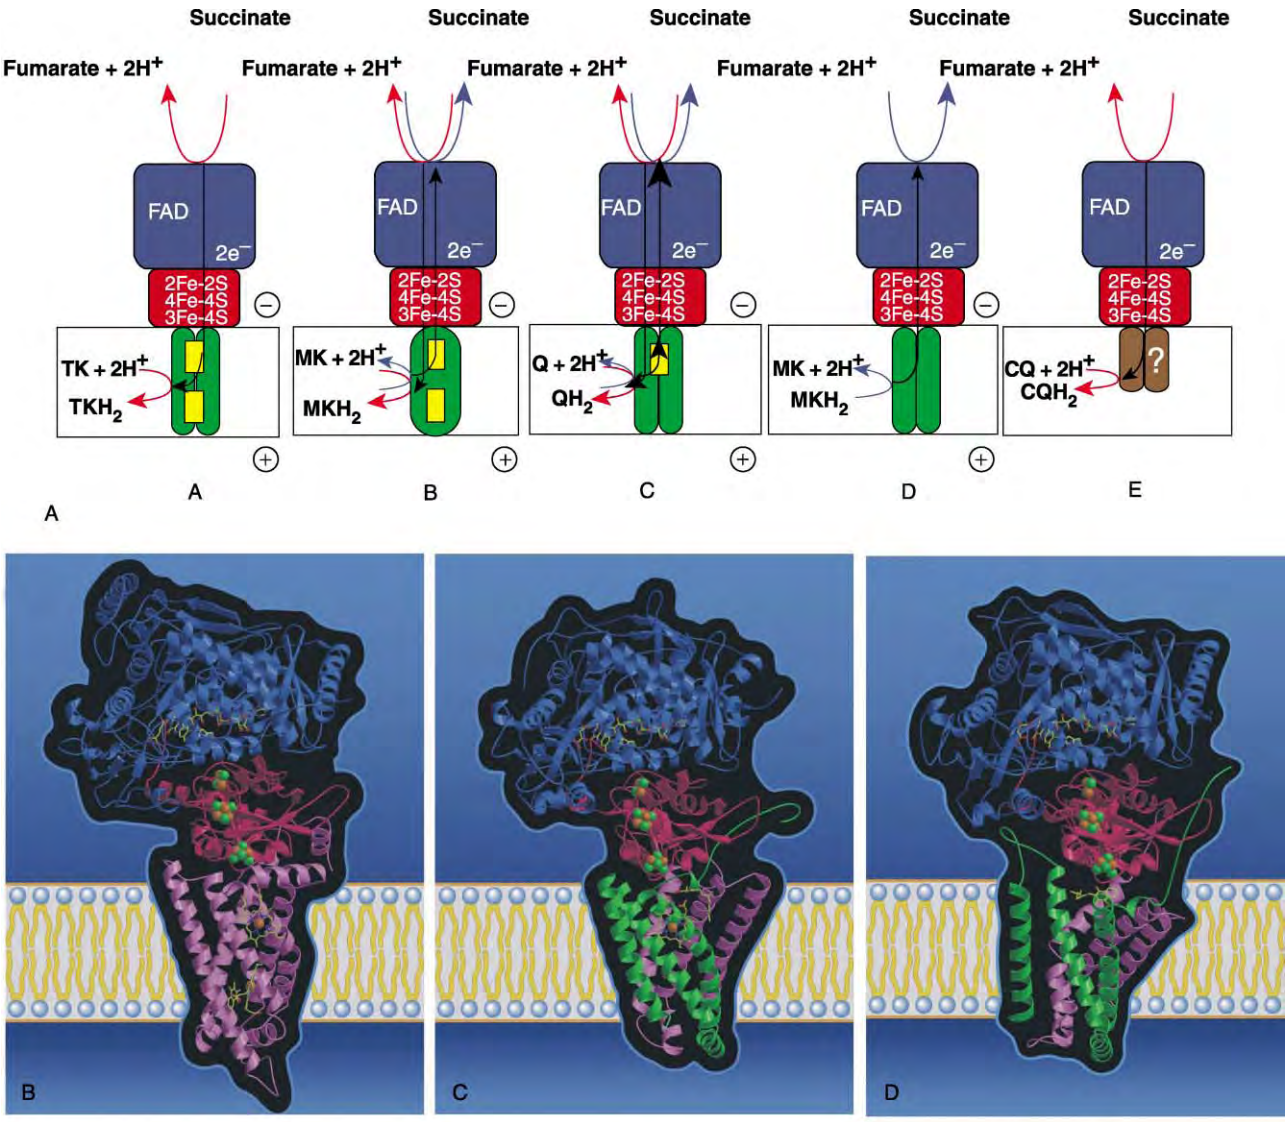

FIGURE 2 (A) Classification (A to E) of succinate:quinone oxidoreductases based on their hydrophobic domain and heme content. The hydrophilic subunits A and B are drawn schematically in blue and red, respectively; the hydrophobic subunits C and D in green. Heme groups are symbolized by small yellow rectangles. The directions of the reactions catalyzed by SQR and QFR are indicated by red and blue arrows, respectively. White rectangles symbolize the respective cytoplasmic or inner mitochondrial membrane bilayer. The positive (+) and negative (−) sides of the membrane are indicated. In bacteria, the negative side is the cytoplasm ("inside"), the positive side the periplasm ("outside"). For mitochondrial systems, these are the mitochondrial matrix and the intermembrane space, respectively. The type of quinone transformed in vivo is not necessarily unique for each type of enzyme. The examples given are thermoplasma-quinone (TK), menaquinone (MK), ubiquinone (Q), and caldariella quinone (CQ).(-B-D) Three-dimensional structures of *W. succinogenes* QFR, a B-type SQOR (B) (determined by Lancaster, C.R., Kroger, A., Auer, M., and Michel, H. (1999). Structure of fumarate reductase from *Wolinella succinogenes* at 2.2Å resolution. *Nature* **402**, 377–385), *E. coli* SQR, a C-type SQOR (C) (determined by Yankovskaya, V., Horsefield, R., Tornroth, S., Luna-Chavez, C., Miyoshi, H., Leger, C., Byrne, B., Cecchini, G., and Iwata, S. (2003). Architecture of succinate dehydrogenase and reactive oxygen species generation. *Science* **299**, 700–704), and *E. coli* QFR, a D-type SQOR (D) (determined by Iverson, T. M., Luna-Chavez, C., Cecchini, G., and Rees, D. C. (1999). Structure of the *Escherichia coli* fumarate reductase respiratory complex. *Science* **284**, 1961–1966). The Cα traces of the A subunits are shown in blue, those of the B subunits in red, those of the C subunits in pink, and those of the D subunits in green. The atomic structures of the prosthetic groups are superimposed for better visibility. From top to bottom, these are the covalently bound FAD, the [2Fe–2S], the [4Fe–4S], and the [3Fe–4S] iron–sulfur clusters, and (where present) the proximal and the distal heme *b* groups. Atomic color coding is as follows: C, N, O, P, S, and Fe are displayed in yellow, blue, red, light green, green, and orange, respectively. Figures with atomic models were prepared with a version of Molscript (Kraulis, P. J. (1991). MOLSCRIPT: a program to produce both detailed and schematic plots of protein structures. *J. Appl. Crystallogr.* **24**, 946–950) modified for color ramping (Kraulis, P. J. (1997). Esnouf Rm. An extensively modified version of MolScript that includes greatly enhanced coloring capabilities. *J. Mol. Graphics Mod.* **15**, 132–134) and rendered with the program Raster3D (Merrit, E. A. and Bacon, D. J. (1997). Raster 3D: Photorealistic molcecular graphics. *Meth. Enzymol.* **277**, 505–524).

W. succinogenes QFR is apparently a homodimer of two sets of A, B, and C subunits, and *E. coli* SQR is a homotrimer of three sets of A, B, C, and D subunits. For the *Wolinella* enzyme, analytical gel filtration experiments have shown that the homodimer is apparently also present in the detergent-solubilized state of the enzyme, implying that it is unlikely to be an artifact of crystallization. However, functionally all three enzymes appear to act as monomers, which is why only the monomeric complexes are shown in Figure 2B–2D.

The Relative Orientations of Soluble and Membrane-Embedded SQOR Subunits

The structures of all three enzymes shown in Figure 2B–2D can be superimposed on the basis of the Cα positions of the conserved hydrophilic subunits A and B. In this superimposition, large parts of the membrane-embedded subunits can be aligned in the case of *W. succinogenes* QFR and *E. coli* SQR, but not for *E. coli* QFR. However, as demonstrated by Lancaster and coauthors, in an alternate orientation the transmembrane subunits of *E. coli* QFR and of *W. succinogenes* QFR can be overlaid in spite of the respective absence and presence of the two heme groups. Consequently, the relative orientations of the hydrophilic subunits and the transmembrane subunits is similar in *W. succinogenes* QFR and *E. coli* SQR and different in *E. coli* QFR.

Subunit A and the Site of Succinate Oxidation/Fumarate Reduction

The flavoprotein or A subunit (64–73 kDa) of all described membrane-bound SQOR complexes contains a flavin adenine dinucleotide (FAD) prosthetic group covalently bound to a conserved His residue as an 8α-[Nε-histidyl]-FAD. The two most important domains of subunit A are the bipartite FAD-binding domain and the "capping" domain, which is inserted between the two parts of the FAD-binding domain. The capping domain contributes to burying the otherwise solvent-exposed FAD isoalloxazine ring from the protein surface.

The binding site of succinate/fumarate is located between the FAD-binding domain and the capping domain next to the plane of the FAD isoalloxazine ring. The structures and results from site-directed mutagenesis suggest that the *trans*-dehydrogenation of succinate to fumarate occurs via the combination of a hydride ion transfer from one succinate methylene group to the N5 position of the FAD and a proton transfer from the other succinate methylene group to the side chain of a conserved Arg residue of the capping domain (Figure 3). All residues implicated in substrate binding and catalysis are conserved throughout the superfamily

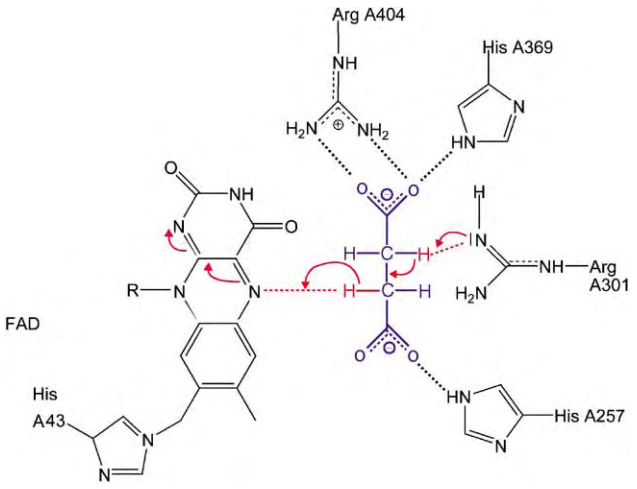

FIGURE 3 Possible mechanism of succinate oxidation. Modified from Lancaster C. R. D. (2001). *Eur. J. Biochem.* **268**, 1820–1827.

of SQORs, so that this reversible mechanism is considered generally relevant for all SQORs. Release of the product could be facilitated by movement of the capping domain away from the dicarboxylate site.

Subunit B: The Iron–Sulfur Protein

Generally, SQORs contain three iron–sulfur clusters, which are exclusively bound by the B subunit of 26–30 kDa. Enzyme types A–D contain one [2Fe–2S]$^{2+,1+}$, one [4Fe–4S]$^{2+,1+}$, and one [3Fe–4S]$^{1+,0}$ cluster, whereas an additional [4Fe–4S]$^{2+,1+}$ cluster apparently replaces the [3Fe–4S]$^{1+,0}$ in the type E enzyme. This subunit consists of two domains, an N-terminal plant ferredoxin domain, in contact with subunit A and binding the [2Fe–2S] cluster, and a C-terminal bacterial ferredoxin domain, in contact with the hydrophobic subunit(s) and binding the [4Fe–4S] and the [3Fe–4S] clusters. In general, these iron–sulfur clusters are coordinated by conserved Cys residues, although one of the ligands to the [2Fe–2S] cluster in *E. coli* SQR is an Asp. At the position corresponding to the fourth Cys of the [4Fe–4S] cluster, the [3Fe–4S] cluster contains a Leu (*W. succinogenes* QFR), Ile (*E. coli* SQR), Val (*E. coli* QFR), or Ser (*B. subtilis* SQR). Whereas the introduction of a Cys into *E. coli* QFR could replace the native [3Fe–4S] by a [4Fe–4S] cluster, this was not the case for *B. subtilis* SQR.

The Integral Membrane Subunit(s) C (and D) and the Sites of Quinol Oxidation/Quinone Reduction

Type A, C, and D SQOR enzymes contain two hydrophobic polypeptides with three membrane-spanning

helices each (numbered I, II, and III and IV, V, and VI, respectively). According to an evolutionary model proposed by C. Hägerhäll and L. Hederstedt, the large single hydrophobic polypeptides of type B SQOR enzymes with five membrane-spanning helices are thought to have evolved from the fusion of the genes for the two small hydrophobic polypeptides with concomitant loss of transmembrane helix III. This view is supported by the structural superpositions previously discussed. To a varying degree, all transmembrane segments are tilted with respect to the membrane normal.

The planes of both heme molecules bound by *W. succinogenes* QFR are approximately perpendicular to the membrane surface, and their interplanar angle is 95°. The His axial ligands to the proximal heme b_P, located toward the cytoplasmic surface of the membrane, and thus toward the [3Fe–4S] cluster, are located on transmembrane helices II and V. Residues of the two other transmembrane helices I and IV interact with the propionate groups of heme b_P via hydrogen bonds and salt bridges; this underscores the structural importance of the bound heme. The axial ligands to the distal heme b_D are located on helices I and IV. The binding of the two heme *b* molecules by an integral membrane protein four-helix bundle described here is very different from that described for other diheme-binding membrane protein complexes, such as the cytochrome bc_1 complex, where only two transmembrane segments provide two axial heme *b* ligands each, and also the membrane-bound hydrogenases and formate dehydrogenases, where one transmembrane helix provides two axial His ligands and two others provide one His ligand each. One consequence of this difference is that the distance between the two heme iron centers is distinctly shorter in *W. succinogenes* QFR (15.6Å) than it is in the mitochondrial cytochrome bc_1 complex (21Å) and in *E. coli* formate dehydrogenase-N (20.5Å). The mode of heme binding for the single (proximal) heme of *E. coli* SQR is analogous to that described for heme b_P of *W. succinogenes* QFR.

The sites of quinol oxidation/quinone reduction have been localized in all three enzymes of known three-dimensional structure by a combination of X-ray crystallography, site-directed mutagenesis, functional characterization of resulting variant enzymes, and/or inhibitor-binding studies, respectively. In *E. coli* QFR, the menaquinol oxidation site is located proximally, close to the [3Fe–4S] cluster. In *E. coli* SQR, this position is occupied by the heme *b* group, but the ubiquinone reduction site is also located proximally, close to the [3Fe–4S] cluster, at an alternate position. In *W. succinogenes* QFR, the menaquinol oxidation site is located distally, close to heme b_D.

Electron and Proton Transfer

Electron Transfer

For the function of QFR, electrons have to be transferred from the quinol-oxidizing site in the membrane to the fumarate-reducing site, protruding into the cytoplasm. Conversely, for the function of SQR, electrons have to be transferred from the succinate oxidation site in subunit A to the quinone reduction site in the membrane. The linear arrangement of the prosthetic groups in the complexes shown in Figure 2B–2D therefore provides one straightforward pathway by which electrons could be transferred efficiently between the two sites of catalysis. It has been shown for other electron transfer proteins that physiological electron transfer between prosthetic groups occurs if the edge-to-edge distances relevant for electron transfer are shorter than 14Å, but does not occur if they are longer than 14Å. In all three cases, this indicates that physiological electron transfer can occur between the prosthetic groups of one heterotrimeric or heterotetrameric complex, but not between the two (*W. succinogenes* QFR) or three (*E. coli* SQR) complexes in the respective homodimer or homotrimer.

Prior to the determination of the three-dimensional structures, because of its very low midpoint potential ($E_m < -250$ mV), it had been suggested that the [4Fe–4S] cluster does not participate in electron transfer. However, the determined low potential may be an artifact due to anti-cooperative electrostatic interactions between the redox centers. The position of the [4Fe–4S] cluster as revealed in the structures is highly suggestive of its direct role in electron transfer between the [3Fe–4S] cluster and the [2Fe–2S] cluster. Despite this major thermodynamically unfavorable step, the calculated rate of electron transfer is on a microsecond scale, demonstrating that this barrier can easily be overcome by thermal activation as long as the electron transfer chain components are sufficiently close to promote intrinsically rapid electron tunneling.

The positioning of the heme in *E. coli* SQR is puzzling because it does not seem to be required for electron transfer between the catalytic sites. A possible explanation for this also explains why SQR is favored over QFR in *E. coli* when oxygen is present. Under aerobic conditions, reduced *E. coli* QFR produces large amounts of reactive oxygen species (ROS), including superoxide radical (O_2^-) and hydrogen peroxide (H_2O_2), which has been suggested to be caused by electron accumulation around the FAD. In sharp contrast, *E. coli* SQR reacts poorly with molecular oxygen, producing modest amounts of O_2^- and no H_2O_2. On the basis of their crystal structure, Yankovskaya *et al.* (2003) argued that the heme group

in SQR provides an electron sink when the quinone site is not occupied, thus preventing buildup of electrons around the FAD and subsequent ROS generation. However, this electron-sink mechanism is predicted to be less effective for mitochondrial SQRs because heme *b* has a lower redox potential than in *E. coli* SQR.

Electron-Coupled Proton Transfer

In addition to the transfer of electrons, two protons are bound at the site of reduction and two protons are liberated at the site of oxidation [see Eqs. (1) and (2)]. An overview of the current status of discussion of electron and proton transfer in succinate:quinone oxidoreductases is shown in Figure 4A–4D. In mitochondrial complex II and other C-type enzymes such as SQR from *P. denitrificans* and *E. coli*, electron transfer from succinate to ubiquinone does not lead to the generation of a transmembrane electrochemical potential, Δp, since the protons released by succinate oxidation are on the same side of the membrane as those consumed by quinone reduction (Figure 4A). Similarly, in *E. coli* QFR, the protons released by proximal quinol oxidation are balanced by the protons consumed by fumarate reduction (Figure 4B). Succinate oxidation by menaquinone, an endergonic reaction under standard conditions, is catalyzed by a B-type SQOR in gram-positive bacteria, e.g., *B. subtilis*. There is experimental evidence indicating that the menaquinone reduction site in *B. subtilis* SQR is close to the heme b_D in a position analogous to the menaquinol oxidation site of *W. succinogenes* QFR. This arrangement of the catalytic sites of succinate oxidation and menaquinone reduction would allow succinate oxidation by menaquinone in *B. subtilis* to be driven by the electrochemical proton potential (Figure 4C), and there is indeed experimental evidence that this is the case. This reaction is analogous to that suggested by the arrangement of the catalytic sites for *W. succinogenes* QFR, but in the opposite direction. Experimental results do indicate that *B. subtilis* SQR generates a proton potential when functioning as a QFR. However, the experimental results on intact bacteria, with inverted vesicles or liposomes containing *W. succinogenes* QFR, indicate that the oxidation of menaquinol by fumarate as catalyzed by *W. succinogenes* QFR is an electroneutral process. In order to reconcile these experimental findings with the arrangement of the catalytic sites in the structure, it has been proposed that transmembrane electron transfer in dihemic QFRs is tightly coupled to the compensatory, parallel transfer of protons across the membrane, thus balancing the protons released to the periplasm upon menaquinol oxidation and the protons bound from the cytoplasm upon fumarate reduction (Figure 4D). A key residue in this proposed proton transfer pathway is a Glu residue located in the middle of the membrane that is conserved only in dihemic menaquinol:fumarate reductases, but not in dihemic succinate:menaquinone reductases. The first experimental results supporting this E-pathway hypothesis have recently been obtained.

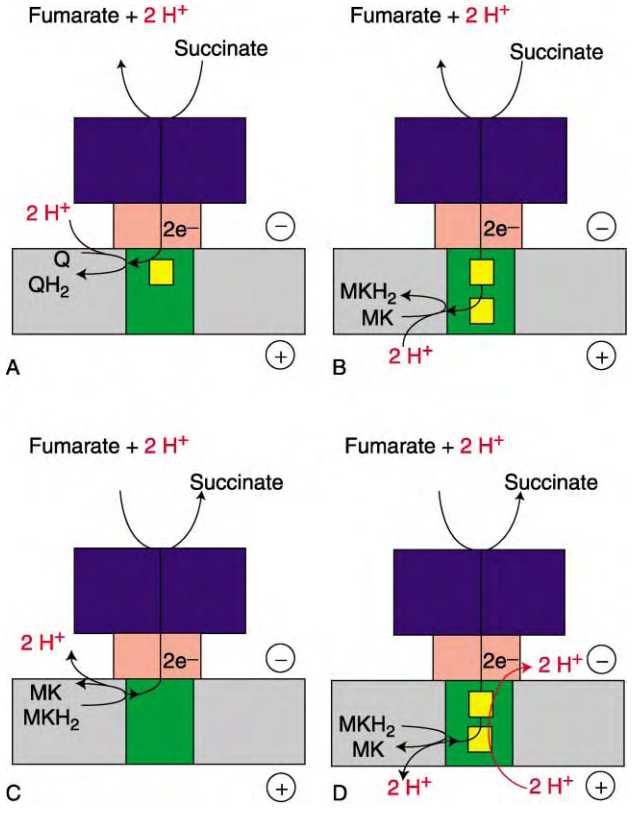

FIGURE 4 The coupling of electron and proton flow in succinate: quinone oxidoreductases in aerobic (A, B) and anaerobic respiration (A, C), respectively. Positive and negative sides of the membrane are as described for Figure 2 (A and B). Electroneutral reactions as catalyzed by C-type SQR enzymes (A) and D-type *E. coli* QFR (C). (B) Utilization of a transmembrane electrochemical potential Δp as possibly catalyzed by A-type and B-type enzymes. (D) Electroneutral fumarate reduction by B-type QFR enzymes with a proposed compensatory E-pathway.

C. Roy D. Lancaster is a Group Leader in the Department of Molecular Membrane Biology at the Max Planck Institute of Biophysics. He teaches biochemistry and biophysical chemistry at J.W. Goethe University, Frankfurt am Main. His principle research interests are in the structure and mechanism of action of membrane protein complexes. He holds an M.Sc. degree from McMaster University and a Dr. phil. nat. degree from J.W. Goethe University. His postdoctoral training was at the Max Planck Institute of Biophysics. He has determined the highest resolution structure to date of a succinate:quinone oxidoreductase and has authored and edited key texts in the field.

Respiratory Chain Complex IV

Hartmut Michel
Max Planck Institute of Biophysics, Frankfurt, Germany

Located within the inner membranes of mitochondria, or within the cytoplasmic membranes of aerobic bacteria, complex IV is the terminal enzyme of aerobic respiratory chains. It belongs to the superfamily of heme/copper containing terminal oxidases and catalyzes the reduction of oxygen to water. Typical representatives of this enzyme superfamily, as those found in mitochondria, use reduced cytochrome *c* as electron donor and are therefore also called cytochrome *c* oxidases. Cytochrome *c* provides its electrons from the outer side of the membrane, whereas the protons required for water formation access the active site from the inner ("matrix") side of mitochondria or from the cytoplasm of bacteria. As a result of the different spatial origin of the electrons and protons consumed in the reaction, four elementary charges per oxygen molecule reduced are translocated across the inner mitochondrial (or bacterial) membrane. In addition, four protons are transported ("pumped") from the mitochondrial matrix (or bacterial cytoplasm, respectively) to the outside of mitochondria or bacteria. Therefore the reaction can be written as

$$4e^- + O_2 + 8H_i^+ \rightarrow 2H_2O + 4H_o^+,$$

where H_i^+ stands for protons originating from the matrix (cytoplasmic) space and H_o^+ for protons released at the external side.

The proton transport produces a transmembrane electrochemical proton potential that drives the synthesis of adenosine-5′-triphosphate ("ATP") from adenosine-5′-diphosphate ("ADP") and inorganic phosphate through another membrane-spanning complex, the ATP synthase, which is also called complex V of the respiratory chain.

Background

Aerobic, oxygen-consuming respiration is the major means of producing energy in animals, fungi, many yeasts and bacteria. Oxygen itself is a side product of the oxygenic photosynthesis occuring in plants, algae, and cyanobacteria. These organisms produce reduced coenzymes (NADPH, quinols) and ATP in the course of the photosynthetic light reaction. NADPH is used to fix carbon dioxide and to synthesize carbohydrates and other organic compounds during the photosynthetic dark reactions. This organic matter is consumed by heterotrophic organisms. NADH and quinols are formed during the degradation of foodstuff and oxidized in the respiratory chain. In the typical mitochondrial respiratory chain (Figure 1) NADH is oxidized by complex I (NADH dehydrogenase). The electrons are transferred onto ubiquinone, the ubiquinol formed is oxidized by complex III (cytochrome bc_1 complex, also called ubiquinol-cytochrome *c* oxidoreductase) which reduces cytochrome *c*. This electron carrier is oxidized again by complex IV (cytochrome *c* oxidase). The latter uses the electrons to reduce oxygen and to form water, thus closing the cycle. Complex II (succinate dehydrogenase) constitutes a parallel entry into the respiratory chain and is also part of the citric acid cycle.

The respiratory chains from aerobic bacteria contain many more membrane-protein complexes and are often branched. They may contain up to four different terminal oxidases reacting with molecular oxygen. The electron donating substrates for the individual terminal oxidases may be cytochromes of the *c* type, various quinols, or even high-potential iron sulfur proteins. Most of them belong to the family of heme/copper containing terminal oxidases. The exception is cytochrome *bd*, which is a ubiquinol oxidase and not related to the heme/copper containing terminal oxidases. Cytochromes *bd* do not pump protons, however, electrons and protons, as in the heme/copper containing oxidases, enter the active site of this enzyme from opposite sides of the membrane leading to a net translocation of four charges per oxygen molecule consumed.

Astonishingly, the superfamily of the heme/copper containing terminal oxidases appears to be rather old. Family members are found in bacteria, as well as in archaea. The splitting into these lineages during evolution predates the conversion of the atmosphere from a reducing one to an oxidizing one, which dates back to ~2 billion years, when cyanobacteria developed the water-splitting, oxygen-releasing photosystem II. It turned out that the nitric oxide reductase (nitrogen monoxide reductase, NO reductase) is closely related to the heme/copper containing terminal oxidases. An iron atom in the NO reductases replaces a copper atom

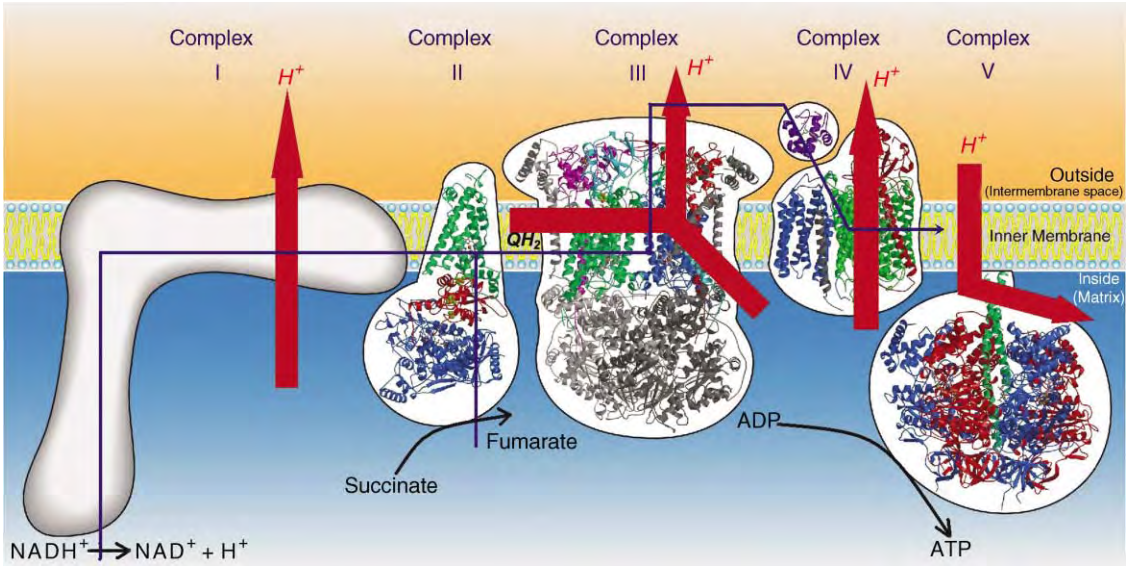

FIGURE 1 The mitochondrial respiratory chain. The five complexes of the respiratory chain are presented with their known structures in a functional context. The atomic structure of complex I or NADH dehydrogenase (left) is not known, but its shape has been determined by electron microscopy. It reduces ubiquinone to ubiquinol and pumps protons. Complex II (succinate dehydrogenase) is represented by a chain model. It also produces ubiquinol (QH_2). Ubiquinol is oxidized by complex III (cytochrome bc_1 complex). The cytochrome bc_1 complex releases protons at the outside and uses a quinone cycle to translocate additional protons across the membrane. The cytochrome bc_1 complex from yeast is shown. It reduces cytochrome *c*, which is oxidized by cytochrome *c* oxidase. The bacterial cytochrome *c* oxidase from *Paracoccus denitrificans* is shown. Cytochrome *c* oxidase pumps protons. The pumped protons flow back via the membrane part of complex V (ATP synthase). The backflow leads to a rotation of a subunit in the extramembraneous part of the ATP synthase, which is coupled to the synthesis of ATP. Proton flows are indicated by the red arrows. Figure drawn by P. Lastrico and E. Olkhova.

which is a part of the active site in the heme/copper containing terminal oxidases. NO reductases appear to be unable to pump protons. The original task of both the heme/copper containing terminal oxidases (which are OO reductases) and the NO reductases might have been detoxification. Molecular oxygen, being toxic for the organisms living under the reducing atmosphere, might have been created by photolysis of water by ultraviolet light and had to be destroyed.

Prosthetic Groups

The heme/copper containing terminal oxidases minimally contain two heme groups and one copper atom as prosthetic groups. One of the heme groups is a high-spin heme. A copper atom, called Cu_B, is found in ~5Å distance. Cu_B and the high-spin heme form the so-called binuclear center. During turnover, molecular oxygen is bound to the central iron atom of the high-spin heme between the heme and Cu_B and reduced there during the catalytic cycle of the enzyme. The second heme is a low-spin heme and acts as an intermediate electron carrier.

The optical absorbance spectra have been the signature for the cytochrome *c* oxidases. In the mitochondrial cytochrome *c* oxidases both hemes are of the A type (see Figure 2), which give rise to characteristic absorbance maxima at around 600 nm. The high-spin heme of the active site is called heme a_3, the low spin one heme *a*. The term cytochrome aa_3 was used for the terminal oxidase of mitochondria. In many bacteria, the low-spin heme is a heme B, giving rise to a terminal oxidase of the ba_3 type. One ubiquinol oxidase of *Escherichia coli* contains heme O as the high-spin heme, therefore it is also called cytochrome *bo* or bo_3.

Cytochrome *c* oxidases contain another copper center, which is called Cu_A. It is actually formed by two copper atoms, which share one electron upon reduction. During turnover of the enzyme, Cu_A receives the electron from cytochrome *c* and transfers it to the low-spin heme. Ubiquinol oxidases do not possess this Cu_A center. Several terminal oxidases also contain a covalently bound cytochrome *c*. Depending on the nature of the other hemes these enzymes are called caa_3, or *cbo*, or cbb_3 oxidases. The terminal oxidases of the cbb_3-type operate at rather low-oxygen concentrations and, for example, are required for the nitrogen fixation in *Rhizobia* in order to keep the oxygen levels very low.

Cytochrome *c* oxidases also contain a magnesium or manganese atom close to the periplasmic (intermembrane) face of the enzyme. It is missing in the ubiquinol

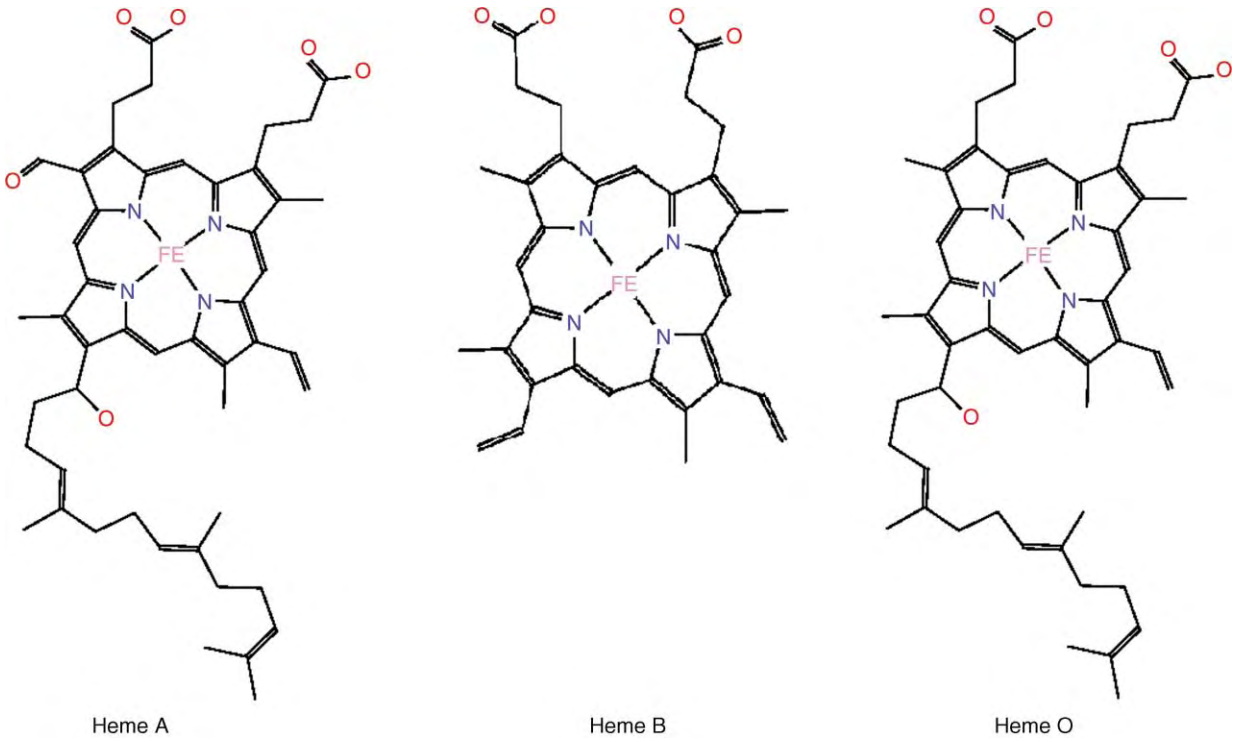

FIGURE 2 Chemical structures of the noncovalently bound hemes found in terminal oxidases. The structures of heme A, heme B, and heme O (from left to right) are shown.

oxidases and does not appear to be involved in electron transfer.

Protein Composition

The mitochondrial cytochrome *c* oxidases possess a core consisting of three protein subunits. These subunits are encoded by the mitochondrial genome. Subunit I is the largest subunit and possesses between 500 and 600 amino acid residues. It binds heme *a* as well as the heme a_3-Cu_B binuclear center and is the major catalytic subunit. Subunit II provides the binding site for the Cu_A-center and is anchored to the membrane by two N-terminal membrane-spanning helices. Subunit III possesses seven membrane-spanning helices but no prosthetic groups. Its function is unknown; it is not required for the catalytic activity. If its gene is deleted in bacteria, an active two-subunit enzyme is still found, albeit at a reduced level. If subunit III is removed the enzyme becomes rather unstable under turnover conditions.

The mitochondrial cytochrome *c* oxidases contain up to eight additional smaller subunits, which are encoded by the nuclear genome. For some of the subunits, organ specific subtypes exist; for example, there are liver and heart types of the so-called subunit VIa in the mammalian cytochrome *c* oxidase. It has been suggested that the presence of the liver or heart type determines the efficiency of proton pumping, and that only two protons per oxygen molecule are pumped by cytochrome *c* oxidase in liver, but four in heart. Subunit VIa also seems to be responsible for the dimer formation of cytochrome *c* oxidase from bovine heart mitochondria.

The bacterial cytochrome *c* oxidases of known structure contain one additional small protein subunit, called subunit IV. It has no counterpart in the mitochondrial enzyme and its function is not known.

X-Ray Crystal Structures of Cytochrome *c* Oxidases and Other Terminal Oxidases

Protein Structure

Until now atomic structures, determined by X-ray crystallography, have been presented for the cytochrome *c* oxidases from the soil bacterium *Paracoccus denitrificans*, from the purple photosynthetic bacterium *Rhodobacter sphaeroides* and from bovine heart mitochondria. These are rather typical closely related enzymes. Both *Paracoccus* and *Rhodobacter* are grouped within the α-proteobacteria, and the symbiotic ancestor of the mitochondria belonged to this group. In addition, the structure of the aberrant ba_3 type cytochrome *c* oxidase (e.g., it does not possess a

homologue of subunit III) from the bacterium *Thermus thermophilus*, and that of the ubiquinol oxidase (cytochrome bo_3) from *E. coli* have been determined.

In the cytochrome *c* oxidases the subunits I, II, and III form the core, which, viewed parallel to the membrane, has a trapezoidal shape, when seen from above it looks oval. The length of the trapezoid is about 90Å, its height 55Å. It comprises 21 membrane-spanning helical segments. The globular polar domain of subunit II is attached to the narrow, periplasmic (intermembrane, respectively) side of the trapezoid (see Figures 1 and 3). Subunit I contains twelve membrane-spanning helices which are arranged in a threefold symmetric manner. In this kind of arrangement three "pores" are formed. One contains the heme *a* with two histidine residues as axial iron ligands, another heme a_3 with one axial histidine ligand and Cu_B, and the third one is blocked by aromatic residues. Subunit II contains two N-terminal membrane-anchoring transmembrane helices. The globular domain contains a ten-stranded β-barrel similar to the copper proteins plastocyanin and azurin. The copper-binding site is in the same position, but to subunit II two copper atoms instead of one are bound. Subunit III possesses seven transmembrane helices. They form two bundles, one of five, the other of two transmembrane helices. Between them a V-shaped cleft exists, which is partially filled by lipid molecules. In the cleft at the center of the membrane, an entrance to a hydrophobic channel can be seen which leads to the active site. It has been proposed that this channel is a diffusion channel for oxygen because it leads to the active site, and because the solubility of oxygen in the hydrophobic center of the membrane is considerably higher than in the aqueous phase. Subunit III of the ubiquinol oxidase (cytochrome bo_3) from *E. coli* consists of five transmembrane helices only. The loss is compensated by the addition of two transmembrane helices to the twelve of subunit I.

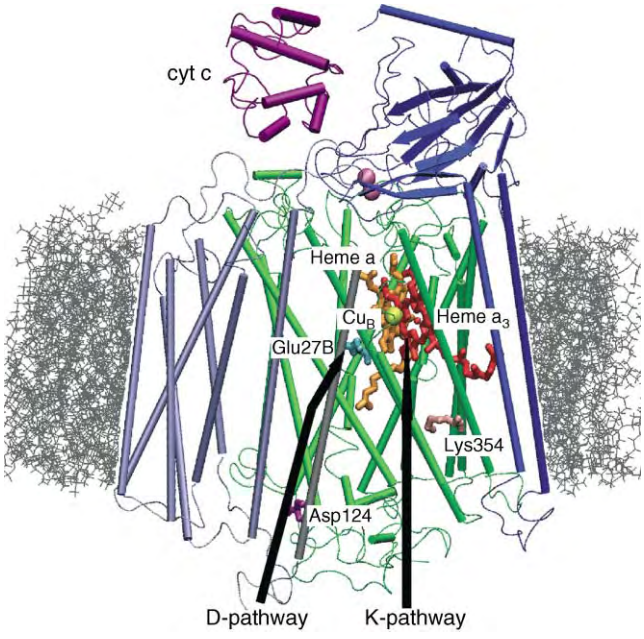

FIGURE 3 Cytochrome *c* oxidase in a bilayer membrane. The four subunits containing cytochrome *c* oxidase from *Paracoccus denitrificans* is shown together with its substrate cytochrome *c* (purple, top). Helices are represented as columns, β-strands as ribbons with arrows. Green: subunit I; dark blue: subunit II; iceblue: subunit III; gray: subunit IV; heme *a* is shown in orange, heme a_3 in red, Cu_B in yellow, and Cu_A in mauve. The lipid bilayer is represented in gray as atomic model. Figure prepared by E. Olkhova using the program vmd.

Arrangement of the Prosthetic Groups

Cu_A receives an electron from cytochrome *c* at the periplasmic (intermembrane) surface of the membrane. Tryptophan 121 (*Paracoccus* numbering) appears to play an important role in the electron transfer. From Cu_A the electron is transferred to heme *a*, the distance of the lower Cu-atom to the iron atom of heme *a* is ~20Å. Heme a_3 lies in the membrane in the same height, so that electron transfer from heme *a* to heme a_3 occurs parallel to the membrane. The center-to-center distance of both hemes is 13–14Å. The propionate side chains of both heme groups are oriented towards the external (periplasmic or intermembrane) side. Their charges are partially compensated by the formation of ion pairs with two arginine residues.

Cu_B is ~5Å away from the heme a_3 iron, so that a very rapid electron transfer between heme a_3 and Cu_B has to be expected. It is a general problem in cytochrome *c* oxidase research that Cu_B is silent and there is no spectroscopic technique available which allows determining the redox state of Cu_B. Cu_B possesses three histidine ligands. One of them is covalently linked to a nearby tyrosine. The existence of a covalent histidine-tyrosine cross-link was unknown prior to the X-ray crystallographic structure determinations.

Proton Transfer Pathways

The structural knowledge combined with the results of previous site-directed mutagenesis experiments lead to the identification of two proton transfer pathways. One, called the K-pathway because of the existence of an essential lysine residue as a component of this pathway, leads straight from the cytoplasmic (matrix) surface into the binuclear site. The cross-linked tyrosine is a part of it. Mutation of the essential lysine residue to other residues prevents the initial reductions of the binuclear site during the catalytic cycle.

A second proton transfer pathway has been called the D-pathway because an aspartic residue at the protein surface is a part of it. A change of this aspartate residue to an asparagine still allows a (reduced) turnover of the enzyme, but proton pumping is abolished. The D-pathway is wider than the K-pathway, and many water molecules are involved. It leads straight up first, then changes direction at a water filled cavity, which leads to a glutamate residue (E278 in *Paracoccus* numbering). The further pathway is unclear. There must be a possibility for proton transfer to the active site, because the reaction cycle can be started from an artificially fully reduced enzyme in K-pathway mutants, proceeds quite normally and water is formed in the active site. Proton transfer using a temporarily established chain of water molecules is a possibility. Alternatively, pumped protons can be transferred to the heme propionates and stored there in some parts of the catalytic cycle.

The existence of a third pathway, called H-pathway, has been suggested for the bovine heart mitochondrial cytochrome *c* oxidase. However, there is no evidence for it on the basis of mutagenesis experiments in bacterial enzymes and the proposal has met with a lot of skepticism.

The Catalytic Cycle and Proton Pumping

The catalytic cycle starts with a fully oxidized enzyme (O-state). All four prosthetic groups (Cu_A, heme *a*, heme a_3 and Cu_B) are oxidized. In cytochrome *c* oxidases an electron is first transferred from cytochrome *c* to Cu_A, and then to heme *a* with a time constant of 20–50 μs. The published values for the electron transfer to heme a_3 from heme *a*, vary greatly and most likely this electron transfer requires proton uptake via the K-pathway first. Most likely in this E-state, the single electron equilibrates over all prosthetic groups. A second electron has to be provided by cytochrome *c*. When the binuclear site is doubly reduced, an oxygen molecule can be bound to the iron atom of heme a_3, thus the oxygenated form, called compound A, corresponding, for example, to oxygenated myoglobin, is formed. This reacts to an intermediate state called P, which is characterized by an absorption maximum at 607 nm. P stands for peroxy because the original (incorrect) belief was that this form contains a peroxide dianion. After the input of a third electron into the enzyme a state absorbing visible light at 580 nm is formed. This was believed to be the oxoferryl state and called F. After the fourth reduction step the iron-bound oxygen atom was thought to be converted to a second water molecule under consumption of two protons and the O-state is formed again. Such a simple catalytic cycle is presented in Figure 4A.

In recent years much of the accepted knowledge had to be revised. First, it is clear now that there are two P- and F-states each, one each in the two-electron reduced enzyme, and one each in the three-electron reduced enzyme. It cannot be excluded that all of them are part of the catalytic cycle (Figure 4). Second, it has been convincingly demonstrated by resonance Raman spectroscopy and chemical experiments that in the P-state the O=O double bond is already broken and that an oxoferryl state already exists. This finding causes the problem that four electrons are required to split the O=O double bond, but only three (two from the Fe^{II} to Fe^{IV} transition upon formation of the oxoferryl state, and one from Cu_B) are available from the prosthetic group. Although definite proof could not be presented yet, it is the general belief that the fourth electron (and a proton) is provided by the cross-linked tyrosine, which becomes a neutral tyrosine radical. The existence of the cross-link which most likely is a side product formed by a tyrosine radical in one of the first turnovers, has to be considered as a hint for the occurrence of a tyrosine radical. Also most likely, a hydroxide as a Cu_B-ligand is generated, and may cause the difference of the optical absorbance spectra between the P- and the F-states. The F-state in the three-electron reduced enzyme is most likely to contain water instead of the hydroxide, and the tyrosine radical has become a neutral tyrosine.

The question, which of the electron transfer steps are coupled to proton pumping, is currently a matter of intense debate. The already generally accepted proposal that only the P to F-, and F to O-transitions are linked to proton pumping with two protons pumped each, could not be maintained. There is good evidence that one proton is pumped upon the input of the second electron into the oxidized enzyme in the absence of oxygen, and it has also been proposed that under turnover conditions already the first reduction step is connected to proton pumping. For a final answer, further experiments are required. It is a general problem in cytochrome *c* oxidase research that many kinetic experiments are started from a fully reduced enzyme (all four prosthetic groups are artificially reduced). However, this state is not part of the catalytic cycle and the value of the conclusions drawn is limited.

As long as it is unknown, when proton pumping occurs in the catalytic cycle, it is very difficult to find out the mechanism of proton pumping. A rather general mechanism of proton pumping, that has found many supporters, is based on the charge-compensation principle. This principle states that each electron transfer into the membrane to heme *a* is

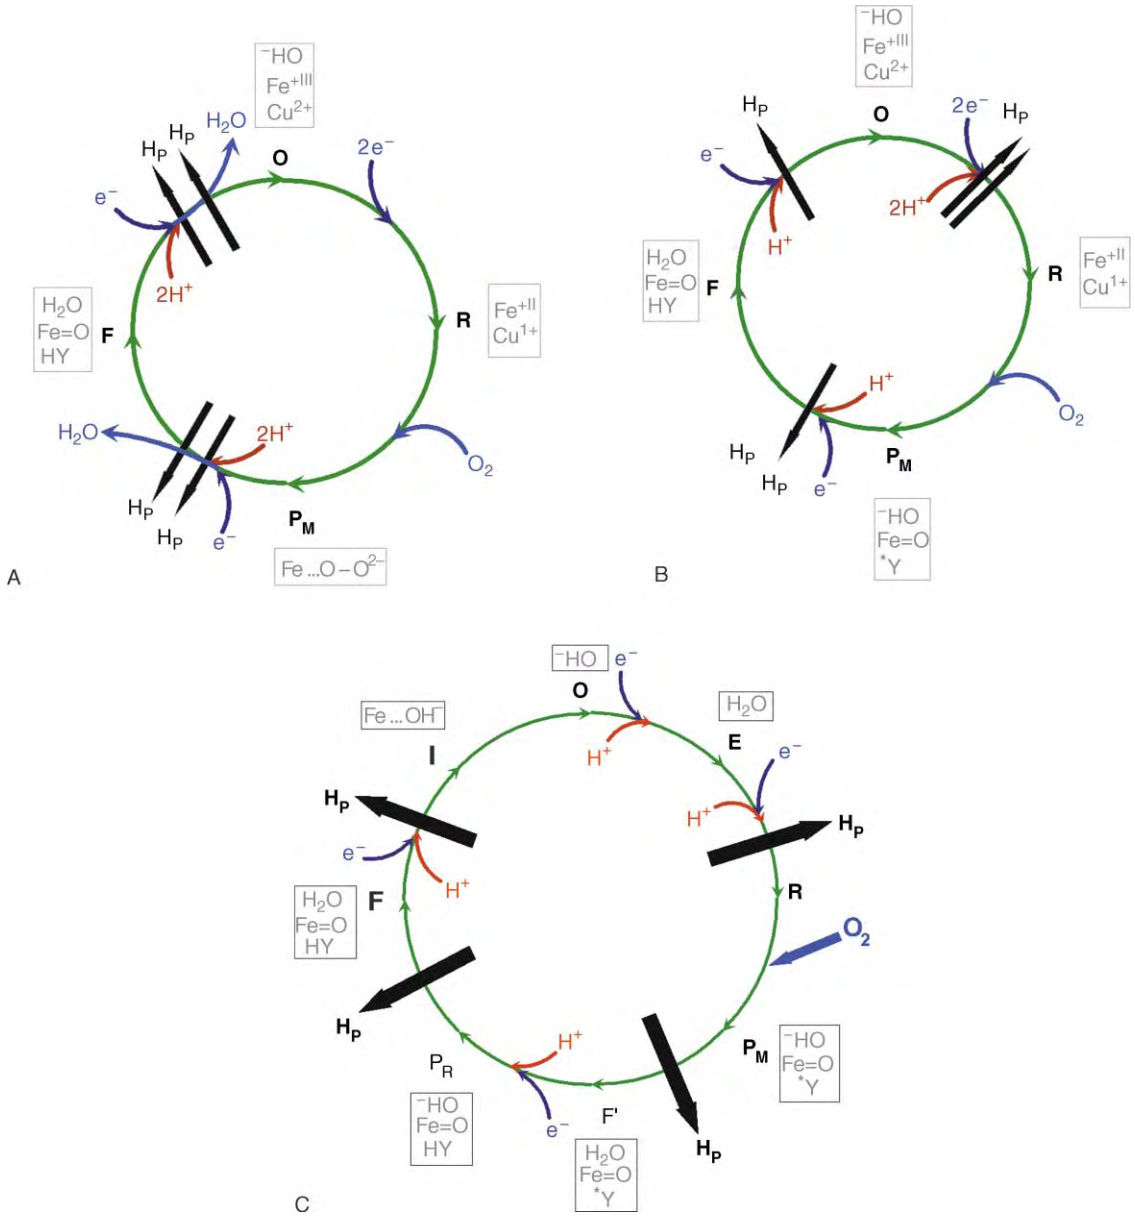

FIGURE 4 Catalytic cycles of cytochrome *c* oxidase. Classical, now obsolete cycle with only four states. The P-state erroneously has a peroxide anion bound to the heme a_3-iron; two protons are pumped during the P to F-, and during the F to O transitions under consumption of two protons each. It is clear now, that only one proton is consumed during each transition. (A) Adaptation of the classical cycle to recent findings. Two protons are taken up already during the initial two-electron reduction of the enzyme, and two protons are pumped in this phase (under turnover conditions). The P_M-state contains a oxoferryl-iron, a tyrosine radical and a hydroxide in the binuclear center, only one proton is pumped during the P to F-, and during the F to O transitions. (B) A recent cycle with two P and two F-states. The protonations of the hydroxides in the binuclear sites of the P-states leads to proton pumping, each electron uptake is accompanied by a charge compensating proton uptake. Tyrosine radicals are present in the two-electron reduced states, tyrosines in the three-electron reduced states. One proton is pumped during the second reduction step, which could now be experimentally demonstrated. One electron is pumped during the F to O-transition as a result of the protonation of the oxo-group at the heme a_3 iron. (C)

charge-compensated by uptake of one proton from the opposite side of the membrane and not consumed in water formation. This proton is supposed to be electrostatically repelled and thus pumped by those protons, which are later taken up and consumed in water formation. The mechanism requires storage of the charge-compensating protons in a way that they cannot be used for water formation.

It is evident that still many experiments are required before the mechanism of proton pumping by cytochrome *c* oxidases can be considered to be known.

Biography

Hartmut Michel is a Director at the Max Planck Institute of Biophysics and Head of the Department of Molecular Membrane Biology in Frankfurt am Main, Germany. He received a Diploma (equivalent to M.Sc.) in Biochemistry at the University of Tübingen and a Dr. rer. nat degree from the University of Würzburg. His principal research interest is to understand the mechanism of action of selected membrane–protein complexes based on accurately known structures. The focus of his current research lies on the complexes of the respiratory chain and on G protein-coupled receptors. Dr. Michel received the Nobel prize in chemistry in 1988 "for the determination of the three-dimensional structure of a photosynthetic reaction center." This was the first structure determination of a membrane protein or of a membrane–protein complex.

Respiratory Processes in Anoxygenic and Oxygenic Phototrophs

Roberto Borghese and Davide Zannoni
University of Bologna, Bologna, Italy

Phototrophic microrganisms include "*anoxygenic phototrophs,*" which are bacteria capable of growing photosynthetically with no oxygen generation, and *Cyanobacteria* which are "*oxygenic phototrophs*" because their photosynthetic apparatus generates oxygen. Several genera of anoxygenic phototrophs are capable of obtaining energy also from *aerobic* and *anaerobic respiration* in darkness; conversely, only a few filamentous cyanobacteria can grow in the dark on glucose or other sugars using the organic material as both carbon and energy source. The latter observation suggests that besides the bioenergetic aspect, respiration in cyanobacteria plays other roles such as to control the redox balance or to act as a scavenger for O_2 during nitrogen fixation. Facultative phototrophs (capable of both respiration and photosynthesis) contain a photosynthetic apparatus whose synthesis is repressed by oxygen; an exception to this rule is the group of aerobic-anoxygenic phototrophs, mainly marine microorganisms, requiring the presence of oxygen to synthesize their photosynthetic apparatus.

Anoxygenic Phototrophs

On a phylogenetic basis (16S rRNA analyses) phototrophic bacteria and their relatives are grouped in a class, the Proteobacteria, which is formed by several subclasses, named α, β, γ, δ, and ε. Facultative photosynthetic bacteria belong to α and β subclasses, e.g., genera *Rhodobacter*, *Rhodospirillum*, *Rhodocyclus*, *Rubrivivax*, and *Erytrobacter.*

Metabolic Aspects of Facultative Anoxygenic Bacteria

Facultative phototrophs are probably the most metabolically flexible organisms of the microbial world. Species such as *Rhodobacter* (*Rba.*) *capsulatus* and *Rba. sphaeroides* can grow by aerobic respiration and photosynthesis using either organic or inorganic substrates but also by anaerobic respiration with trimethylamine-N-oxide (TMAO) or dimethyl sulfoxide (DMSO) as electron acceptors. Further, some strains of the species *Rhodopseudomonas* (*Rps.*) *palustris*, *Roseobacter* (*Rsb.*) *denitrificans* and *Rba. sphaeroides* can reduce nitrate (NO_3^-) into dinitrogen (N_2) via nitrite (NO_2^-), and, in some cases, also nitric oxide (NO) and nitrous oxide (N_2O). These energy generating processes are catalyzed by oxido-reduction protein complexes forming composite electron transport chains. Apparently not all the above summarized metabolic options are activated or can be available simultaneously in a single species; however, cells of *Rba. capsulatus* or *Rba. sphaeroides* grown photosynthetically in the presence of low oxygen tension ($<1\%$) contain both photosynthetic and respiratory apparatuses.

Electron Transport Chains

Respiration in facultative phototrophs involves numerous redox carriers, namely: (1) transmembrane protein complexes such as NADH- and succinate-quinone oxidoreductases (NQR and SQR, respectively), cytochrome (cyt) bc_1 or hydroquinone-cytochrome *c* oxidoreductase (QCR), quinol oxidase(s) (QOX), and cyt cbb_3 and/or aa_3 oxidases (COX); (2) electron and/or proton carriers such as ubiquinones (UQ), cyt c_2, HiPIP, and cyt c_y; (3) enzymes of the periplasmic space such as NO_3^-, NO_2^-, N_2O, and DMSO reductases. With O_2 as final electron acceptor, the NQR, QCR, and COX enzymes constitute three main coupling sites where the potential energy between the initial donor and the final acceptor molecules is released in small steps, that are controlled by the differences between the redox midpoint potentials (E_m) of the redox couples involved, and efficiently coupled to the generation of an electrochemical proton gradient ($\Delta\mu_{H+}$). Photosynthesis converts the radiant energy into chemical energy at the level of the photochemical reaction center (RC). This transmembrane protein complex generates a charge separation that is followed by a cyclic electron transfer involving quinone molecules (UQ-10), cyt bc_1 complex, and soluble cyt c_2 in addition to the membrane-bound cyt c_y, in the case of *Rba. capsulatus*. Under dark aerobic

Black arrows indicate the influx of reducing equivalents and the efflux of electrons leading to the membrane-bound oxidases. Dashed black arrows indicate output of electrons involved in anaerobic respiration. Gray-colored redox components and arrows are those specifically involved in photocyclic electron transfer while those shaded off are shared by photosynthesis and respiration. RC, photochemical reaction center; *hν*, radiant energy; C_2, soluble cyt c_2; C_y, membrane-attached cyt c_y; QOX1, functional ubiquinol oxidase (*qxtAB* operon); QOX2, not functional ubiquinol oxidase (*qoxBA* operon).

conditions, facultative phototrophs use a respiratory chain, closely related to that present in mitochondria. The last step of O_2 reduction into H_2O is catalyzed by two oxidases (not always present in a single species): a cyt *c* oxidase (of cbb_3 and/or aa_3 type), inhibited by μM cyanide, and a quinol oxidase (of *bo* type), inhibited by mM cyanide, branching the electron flow at the level of the UQ-10 pool. Figure 1 shows a block scheme of the different electron transport pathways operating in *Rhodobacter sphaeroides*.

Interaction between the Diverse Electron Transport Chains

The interaction between the different bioenergetic chains of photosynthetic bacteria occurs by two nonexclusive mechanisms, namely: (1) an indirect mechanism, exerted by the proton motive force (PMF) as a "back pressure" on the rate of electron transport catalyzed by redox complexes, and (2) a direct mechanism of interaction between electron carriers, e.g., UQ-10 or cyt c_2, that are engaged in multiple bioenergetic processes. In this way, the activity of a given bioenergetic chain would affect the redox state of the components in common and, consequently, the functioning of the other chains.

Respiratory and photosynthetic apparatuses are localized in different parts of the internal bacterial membrane (CM); this implies the diffusion of some electron carriers such as UQ, in the lipid phase, or cyt c_2, in the periplasmic space. However, the diffusion of these elements does not occur on the entire internal membrane; thus, the different redox chains are not necessarily in thermodynamic equilibrium. For example, two functional pools of soluble cyt c_2 exist in *Rba. sphaeroides* and *Rba. capsulatus*. Further, the membrane-bound cyt c_y is a direct electron donor to the cbb_3-type oxidase of *Rba. capsulatus* or to the cbb_3/aa_3 type oxidases of *Rba. sphaeroides*. Consequently, the redox chain containing cyt c_y must be organized in *supramolecular* complexes and operate independently of the redox state of the other respiratory pathways.

Genetic Regulation of Respiration and Photosynthesis in Facultative Phototrophs

Oxygen is the key factor in the coordinated regulation of respiratory and photosynthetic activities since it participates, directly or indirectly, in determining the levels of expression of all components involved in these processes (Figure 2). The main regulatory element in *Rba. capsulatus* is the RegA/RegB couple (PrrA/PrrB in *Rba. sphaeroides*), which is able to sense the change in O_2 partial pressure in the environment, and to transform this information into a regulatory response. Within this couple, RegA is the effector component while RegB is the sensor partner. This sensor-effector couple functions according to a widespread regulatory model in which the sensor protein (RegB) detects changes in the environment, in this case variations in O_2 tension, and modifies the effector protein (RegA) by phosphorylating it. Depending on its phosphorylated or dephosphorylated status, the effector can regulate the expression of

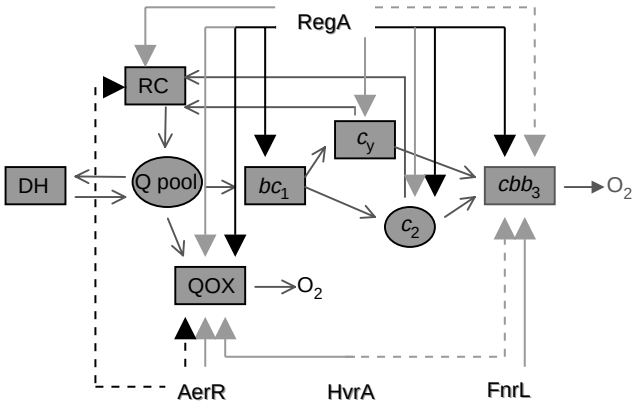

FIGURE 2 Genetic regulatory network of respiratory and photosynthetic activity in *Rhodobacter capsulatus*. Black and gray arrows indicate regulation under aerobic and anaerobic conditions, respectively. Straight lines are for positive regulation (induction), dotted lines are for negative regulation (repression). Genetic regulators are written in black while respiratory/photosynthetic components, connected by thin arrows, symbolising electron flow, are in dark gray. DH, NADH dehydrogenase; RC, photosynthetic reaction center; Q pool, ubiquinone-10 pool; bc_1, transmembrane cyt bc_1 complex; c_y, membrane-anchored cyt c_y; c_2, periplasmic (soluble) cyt c_2; cbb_3, membrane-bound cyt *c* oxidase; QOX, membrane-bound quinol oxidase. See text for further details.

a number of genes. RegA/RegB is a general aerobic/anaerobic regulatory couple that influences the expression of many processes in addition to respiration and photosynthesis: N_2 fixation, CO_2 fixation, and H_2-ase activity. The electron transport chain (ETC) genes that have been shown to be regulated by RegA/RegB are the ones coding for COX and QOX, which are specific for the respiratory chain, and those coding for the *bc*1 complex, cyt c_2 and cyt c_y which participate in both respiration and photosynthesis (Figure 2). RegA/RegB also regulate the level of the RC. Other regulatory elements that participate in the regulation of respiratory ETC components are AerR, that operates in the presence, as well as in the absence, of O_2; HvrA and FnrL are anaerobic regulators only (Figure 2). Although the interaction of all the aforementioned regulatory elements is quite complex, it allows the fine tuning and controlled interplay of respiratory and photosynthetic activities.

Oxygenic Phototrophs

Cyanobacteria are capable of oxygenic photosynthesis, differing in that from anoxygenic phototrophs. Cyanobacteria form one of the major phila of *Bacteria* and they were most likely the first oxygen-evolving organisms on Earth changing the atmosphere from anoxic to oxic. Oxygenic phototrophs are grouped into several morphological groups; however, most of the available biochemical and genetic data concern mainly unicellular genera such as *Synechococcus* and *Synechocystis*.

Respiration is by definition a membrane-bound process; in this respect, cyanobacteria contain three different types of membranes: (1) the outer membrane, typical of Gram negatives, which has no specific role in respiration; (2) the cytoplasmic membrane (CM); and (3) the intracytoplasmic membranes (ICMs) or thylakoids. Both CM and ICM contain respiratory redox complexes; electron microscopy also indicates that CM and ICM might be connected, at least in *Synechococcus* sp. strain PCC 6301, although a correct picture of the membrane arrangement *in vivo* is lacking at present.

Electron Transport Pathways in Oxygenic Phototrophs

Respiratory and photosynthetic electron transports are intimately connected in two distinct bioenergetically active membranes, ICM and CM. All photosynthetic electron transport is located in the ICM, where photosynthesis and respiration share components (Figure 3). In addition, ample experimental evidences indicate the presence of respiratory chain(s) in the CM. Cyanobacterial respiratory terminal oxidases (RTOs) have no direct function in photosynthesis and therefore can be considered the key enzymes of respiration. All cyanobacteria (investigated so far) contain several respiratory branches ending in different RTOs but their actual location in the membrane cell (ICM, CM, or both) is far from being assessed. The best-characterized species is *Synechocystis* sp. strain PC 6803, for which the complete genomic sequence is available. Three sets of genes for RTOs were found, the well-characterized aa_3-type cyt *c* oxidase (COX, encoded by *coxBAC*), a related set of genes also belonging to the heme-copper oxidase superfamily, termed alternate RTO (ARTO; encoded by *ctaCII-ctaDIIEII*), and two genes (*cydAB*) encoding a putative cyt *bd*-type quinol oxidase (Cyd).

The CM forms the inner boundary of the periplasmic space and is known to contain proteins typically associated with respiratory electron transport, such as NAD(P)H dehydrogenase, cyt b_6/f (homologous of the bc_1 complex), and terminal oxidases (presumably, ARTO). Two types of NAD(P)H dehydrogenase have been found. One is a NADPH-type I dehydrogenase (NDH-1), that is encoded by *ndh* genes, which consists of about 12 subunits and contributes to a proton gradient ($\Delta\mu_{H+}$) across the membrane. The second type of dehydrogenase is a NADH-type II dehydrogenase (NDH-2) consisting of a single subunit and probably not contributing to energy transduction.

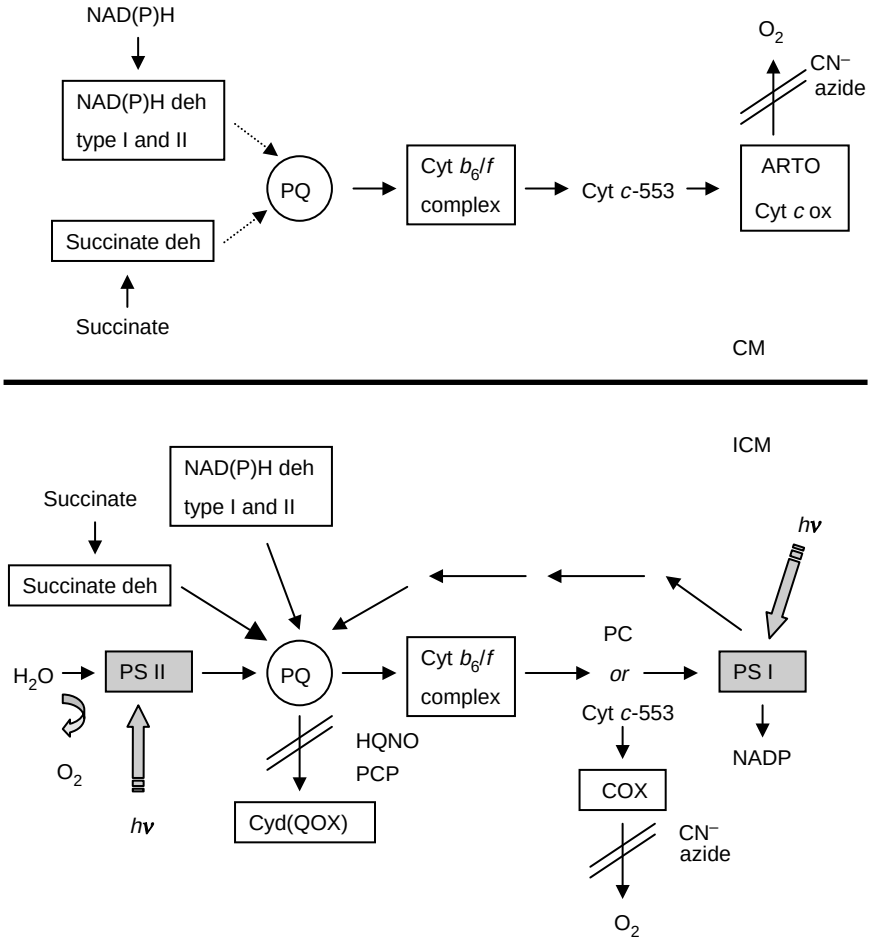

FIGURE 3 Working model of photosynthetic and respiratory electron transport chains in *Synechocystis* sp. strain PCC 6803 in CM and ICM. Membrane-bound redox complexes are indicated as rectangular boxes. Dotted arrows (CM redox chain) symbolize the lack of evidence for electron flow while the thickness of arrows (ICM redox chain) symbolize their relative activities. HQNO, 2-heptyl-4-hydroxy-quinoline-N-oxide; PCP, pentachlorophenol; CN^-, cyanide anion; PC, plastocyanin; PQ, plastoquinone pool; *hν*, radiant energy; see text for further details.

In *Synechocystis* sp. strain PCC 6803, three genes coding for NDH-2 (*ndbA,B,C*) are found.

Three intermingling pathways are dominant in *Synechocystis* sp. strain PCC 6803 thylakoids (ICM), namely: (1) a linear electron transport from H_2O to NADPH, catalyzed by photosystems I and II (PSI/PSII), (2) a respiratory transport from NAD(P)H and succinate to both COX and QOX, and (3) a cyclic electron flow around PSI, i.e. electrons at the acceptor side of PSI returning to the PQ pool (Figure 3). However, as generally seen in facultative anoxygenic phototrophs, electrons can move from one pathway to another at the level of the PQ pool, b_6/f complex, and/or soluble carriers such as plastocyanin (PC) or cyt *c*-553 (Figure 3). For example, in the absence of PSI, reducing equivalents generated by PSII are fed into COX, while in darkness, respiratory electrons are used to reduce the acceptor side of PSII if terminal oxidases are blocked. Results with mutants of *Synechocystis* sp. strain PCC 683 impaired in several combinations of respiratory and photosynthetic redox complexes indicate that succinate dehydrogenase (SDH) is the main electron transfer pathway into the PQ pool and that type I and II NAD(P)H dehydrogenases might simply operate as regulators of NADP and NAD reduction levels. This indicates that respiration in cyanobacteria plays an important role in the control of the intracellular redox balance.

In general, the genes for components of the respiratory chain(s) are present in only one copy per chromosome even in those species having two respiratory chains (Figure 3). How one gene directs its gene product into two different membranes (CM and ICM) is an intriguing yet unanswered question. Further, the amounts of several components of the respiratory chain(s) are regulated by external factors such as the concentration of Cu^{2+} for synthesis of cyt *c*-553 and plastocyanin or the ionic strength for cyt aa_3-type oxidase synthesis. Unfortunately, the mechanisms of gene regulation are largely unknown at present and they will be important topics for future studies in respiration of oxygenic phototrophs.

Biography

Davide Zannoni is Professor of General Microbiology in the Department of Biology at the University of Bologna, Italy. His main research interests are in the broad field of microbial physiology and biochemistry of facultative phototrophic and aerobic bacteria. He holds a degree in biology from the University of Bologna and received postdoctoral training at the St. Louis University School of Medicine. He carried out pioneering studies on bioenergetics of bacterial respiration and interaction between photosynthetic and respiratory redox complexes in facultative phototrophs.

Roberto Borghese is Research Associate and Lecturer of General Microbiology in the Department of Biology at the University of Bologna, Italy. He holds a degree in biology from the University of Bologna and a Ph.D. from the University of Missouri – Columbia. His main research interest is in genetics of anoxygenic photosynthetic bacteria.

Retinoblastoma Protein (pRB)

Nicholas Dyson and Maxim Frolov
Massachusetts General Hospital Cancer Center, Boston, Massachusetts, USA

The retinoblastoma protein (pRB) is the product of the retinoblastoma tumor susceptibility gene (*RB1*). The gene takes its name from the discovery that mutation of both copies of *RB1* is the critical rate-limiting event in the development of retinoblastoma, a rare form of cancer that affects very young children. Mutation of *RB1* is also found in a variety of cancers and pRB is thought to be functionally inactivated in most tumor cells. pRB is a nuclear protein, present in most cell types, that functions as a general negative regulator of cell proliferation. It is a member of a family of proteins (the pRB family) that have overlapping functions and are regulated by cyclin-dependent kinases. pRB is generally thought to function by controlling gene expression, and its best known target is the E2F transcription factor.

The pRB Family of Proteins

pRB-related proteins are conserved in plants and animals. Mammalian cells contain three pRB-family members (pRB, p107, and p130) that share a similar domain structure and a low, but significant, degree of primary sequence homology. All three proteins contain a conserved pocket domain that provides binding sites for E2F proteins, and complexes that repress transcription. In addition pRB, p107, and p130 contain many sites for phosphorylation by cyclin-dependent kinases (cdks). p130 is most highly expressed in differentiated cells, whereas p107 is highly expressed in populations of proliferating cells.

Although pRB, p107, and p130 are currently studied for their roles in the control of cell proliferation, they were first discovered as proteins that associate with the viral oncoprotein Adenovirus E1A. The binding sites for pRB, p107, and p130 map to the regions of E1A that are needed for its oncogenic properties. Similar sequences are also present in the E7 proteins of human papilloma viruses and large T antigens of several polyoma viruses. In each case, genetic studies show that the ability of the viral proteins to bind to pRB/p107/130 allows them to interfere with control of cell proliferation. The viruses are thought to use these interactions to create a cellular environment that is favorable for viral replication.

The RB Tumor Suppressor

The *RB1* gene was the first tumor suppressor gene to be identified and it is often described as a prototype for this class of cancer-related genes. Unlike oncogenes, whose activation promotes tumorigenesis, it is the inactivation of tumor suppressor genes that is linked to the development of cancer.

Individuals inheriting a mutant allele of *RB1* are very highly predisposed to develop retinoblastoma within the first two years of life. Patients, successfully treated for the eye cancer, often develop osteosarcoma in later life. Inactivation of *RB1* appears to be essential for the development of both familial and sporadic retinoblastoma, and also occurs in many osteosarcomas. *RB1* mutation is common in small cell lung cancers and has also been found in other tumors including bladder, prostate, and breast carcinomas. Although *RB1* is mutated in only a subset of tumors, it is thought that pRB is functionally compromised in most tumor cells. pRB is broadly expressed and thought to control the proliferation of most cell types. Precisely why people who inherit a mutant allele of *RB1* are only predisposed to certain types of cancer is still largely unclear. Studies with mice suggest that variations in the extent of functional overlap between pRB and other pRB family members may be important. Animals carrying a mutant allele of the murine *Rb* gene do not develop retinoblastoma but develop pituitary and thyroid tumors instead. However, the combined mutation of *Rb* and the related *p107* gene allows tumors to develop in the retina. This suggests that p107 is able to compensate for the absence of pRB in the developing mouse retina, and it may do so in other cell types.

In addition to its role in E2F regulation, which occurs in many diverse cell types, pRB also interacts with cell-type specific factors. These additional functions may explain why the inactivation of pRB has a greater effect on some cell types than others. For example, pRB interacts with the osteoblast transcription factor CBFA1 to promote the expression of bone specific genes. This role, particularly when combined with its functions in E2F regulation, may explain why pRB is important for suppression of osteosarcoma.

The Cellular Function of pRB

pRB function is often viewed through the prism of the cellular changes that occur when pRB is removed. pRB-deficient cells are smaller than wild-type cells and have defective cell cycle control. In tissue culture assays *Rb-/-* cells are generally less responsive to signals that cause wild-type cells to stop proliferating, and they are more readily driven from quiescence into the cell cycle. *Rb-/-* cells fail to arrest in G1, or S-phase, in response to DNA damage, and they show a reduced sensitivity to $p16^{INK4}$-induced cell cycle arrest and ras-induced senescence. Studies in primary cultures of mouse embryonic fibroblasts show that *Rb-/-* cells are genetically unstable and prone to polyploidy and aneuploidy.

Rb-deficient mice die fairly early in development (day 13–15 of embryogenesis) and display elevated levels of apoptosis, inappropriate cell proliferation, and developmental defects in several tissues. Studies of the murine pRB-family have revealed an extensive degree of redundancy and compensation between family members. Each of the pRB family members has been inactivated in the mouse by homologous recombination. Animals lacking two pRB family members are more severely affected than the single knockouts, and the inactivation of all three family members renders cells unresponsive to most types of G1 control. Triple knockout cells differentiate poorly, are readily immortalized, and easily transformed.

Remarkably and unexpectedly, the early lethality of *Rb-/-* animals has recently been shown to be an indirect consequence of a placental defect. When pRB is expressed specifically in the placenta, the rescue of placental function allows *Rb*-mutant embryos to survive close to birth. Although these mutant animals have defects in cell cycle control, and in skeletal muscle development, the development of these animals is surprisingly normal. Experiments in tissue culture using cells derived from the knockout animals have shown that the sudden removal of pRB causes more severe cell cycle control defects than those seen in cells derived from *Rb-/-* animals. This difference is due, at least in part, to an up-regulation of p107 that occurs in the sustained absence of pRB and appears to allow p107 to compensate for the loss of pRB function.

Regulation of pRB Activity

pRB is a long-lived protein (half-life > 16 h) and its activity is controlled by phosphorylation. When normal cells proliferate, pRB is inactivated by cdks, the kinases that drive progression through the phases of the cell division cycle. When cells cease to proliferate, the loss of cdk activity allows pRB to accumulate in its active form. Inactivation of pRB is not achieved by the phosphorylation of a single site but by the accumulation of phosphorylated residues at multiple sites that are scattered throughout the protein. A cluster of phosphorylation sites is found in the C-terminal fragments of pRB, p107, and p130 and the accumulation of negative charge in this domain is believed to drive a large conformation shift.

As quiescent cells enter the cell cycle pRB is sequentially phosphorylated by a series of cyclin-dependent kinases. Cyclin D/cdk4 is believed to be the first kinase to act on pRB with cyclin E/cdk2, and perhaps cyclin A-dependent kinases completing the process. Phosphorylation of pRB causes it to migrate slowly on SDS-PAGE gels. This mobility shift is often used as an indicator of pRB activity, but it is an unreliable measure; pRB inactivation appears to involve the cumulative effects of multiple phosphorylation events, and some modifications have no effects on the migration of the protein, whereas changes at others sites have a major effect.

Microinjection experiments on cultures of synchronized cells revealed that the ability of pRB to prevent cells from entering S-phase is restricted to a window within G1 phase of the cell cycle. Once cells progressed beyond a point in G1, ~ 2–4 h prior to S-phase, the introduction of pRB had no effect. The loss of a pRB-induced arrest correlates with the accumulation of cdk activity, and corresponds approximately to the "restriction point," a point in G1 where cells become irreversibly committed to progress through a complete cell cycle.

pRB that has been phosphorylated by cdks *in vitro* is unable to arrest cells in G1. *In vivo*, pRB is abruptly dephosphorylated at metaphase of mitosis and, presumably, reactivated. Phosphorylation is not the only type of posttranslational modification of pRB. Recent studies have shown that pRB is also acetylated on lysine residues but the functional significance of pRB aceylation is not well established at present.

The Rb Pathway

It has been proposed that pRB is a component of a critical regulatory pathway that is functionally inactivated in most tumor cells. This pathway comprises pRB, cyclin D/cdk4 (the kinase that phosphorylates pRB in G1), and $p16^{INK4}$ (a cdk inhibitor that antagonizes cyclin D/cdk4 activity and is induced in response to certain cellular stresses). Molecular studies have shown that the overexpression of cyclinD/cdk4 phosphorylates pRB and prevents it from arresting the cell cycle. In addition, cells lacking pRB are largely insensitive to $p16^{INK4}$-induced cell cycle arrest.

The $p16^{INK4}$/cyclin D/cdk4/pRB pathway is disrupted in a variety of ways in tumor cells. Retinoblastoma cells, for example, contain mutations in *RB1*. Many cervical cancers, on the other hand, express HPV E7 proteins that bind and inactivate all three of the pRB family members. Other cells contain lesions that elevate the activity of the cyclin D/cdk4 kinase (overexpression of cyclin D1, loss of the $p16^{INK4}$ cdk inhibitor, or mutations of cdk4 that are resistant to $p16^{INK4}$). Although most tumor cells contain one of these changes, these lesions primarily occur in a mutually exclusive manner. This may mean that there is no further selection for changes in this group of genes once the $p16^{INK4}$/cyclin D/cdk4/pRB pathway is disrupted. However, it is also true that several types of tumors are associated with specific types of mutations (e.g., pRB mutations are the only types of lesions in this pathway found in retinoblastoma, while most breast cancers contain elevated levels of cyclin D1), hence the relative importance of individual components of the pathway varies greatly between cell types.

Molecular Functions of pRB

Over 120 proteins have been reported to associate with pRB and many of these have been proposed to contribute to its tumor-suppressing properties. Most of these pRB-associated proteins are transcription factors and, although the list is diverse, in general pRB has been proposed to inhibit the activity of factors that are needed for cell proliferation, but to augment the activity of factors that promote cell differentiation.

The best-characterized property of pRB is its ability to repress E2F-dependent transcription. The E2F transcription factor allows the periodic expression of many proliferation-related genes to be tightly coupled with cell cycle position. E2F controls the expression of an extensive network of genes that includes essential components of the DNA synthesis machinery, and proteins needed for cell cycle progression, Mitosis, checkpoint responses, as well as regulators of apoptosis. pRB blocks cell proliferation, at least in part, by blocking the expression of E2F-regulated genes.

E2F complexes act as strong repressors of transcription in quiescent cells and during G1 phase of the cell cycle. As cells progress towards S-phase, these repressor complexes are disrupted and replaced by E2F activator complexes in a cdk-regulated process. All three pRB-family members associate with E2F proteins. In wild type cells, p107 and p130 associate primarily with E2F4 and E2F5 and are components of E2F repressor complexes. In these complexes the pRB-family members act as adapter proteins: binding to E2F with one surface, and to chromatin remodeling proteins through a second binding site (the LXCXE-binding cleft). In doing so, they allow a variety of enzymatic activities to be recruited to E2F regulated promoters. In a similar way, pRB also interacts with E2F4 and has the potential to recruit repressor complexes to DNA. In addition, pRB has the important ability to regulate E2F1, E2F2, and E2F3, the activator forms of E2F. pRB binds to an element that is buried within the transcriptional activation domain of the E2Fs, preventing them from activating transcription. Biochemical studies have also shown that pRB that is recruited to DNA by its association with E2F is also able to prevent adjacent DNA-bound transcription factors from interacting with the basal transcription machinery.

Chromatin immuno-precipitation experiments have given a detailed picture of the sequential binding of E2F and pRB-family members to E2F-regulated promoters during cell cycle progression. Surprisingly, p107 and p130 are the pRB-family members that are most easily detected at most E2F targets in proliferating cells. While some studies have found pRB at E2F-regulated promoters in cultures of proliferating cells, others have shown that pRB is most clearly recruited to E2F targets in response to specific signals, such as p16-induced cell cycle arrest, or ras-induced senescence. Under these circumstances pRB is thought to recruit histone deacetylase and/or histone methylase activities to DNA. These complexes repress transcription through modification of histone tails, changing the local chromatin structure to a form that is non-conducive to gene expression.

Genetic interactions between *Rb* and *E2F* genes have been demonstrated in multiple experimental systems and in species as diverse as mice and fruit flies. However, precisely how much of pRB's functions in development and tumor suppression are mediated through its interaction with E2F is uncertain. In addition to the many transcription factors that can bind to pRB, pRB has also been reported to relocalize to origins of replication following DNA damage and to interact with a diverse collection of chromatin-associated complexes. Further studies are needed to demonstrate the functional significance of almost all of pRB's proposed binding partners.

Glossary

apoptosis Programmed cell death.

cell cycle The complete sequence of events needed for the production of a new daughter cell. A mitotic cell cycle has two major landmarks, S-phase and Mitosis, which are separated by two gap phases, G1 (the period before DNA synthesis) and G2 (the period between the S and M-phases).

cell proliferation The overall increase in cell number that occurs when the rate of cell division is greater than the rate of cell death.

compensation A change in function that allows one type of gene product to perform a function that is normally carried out by another type of gene product.

redundancy The situation that occurs when two or more genes have a similar function and either gene is sufficient for a biological process.

Retinoic acid receptors (RARs) are nuclear transcription factors that, once activated by retinoic acid (RA), regulate the expression of RA target genes, leading to changes in cell differentiation, cell proliferation, and apoptosis. The discovery of the first RAR in 1987 defined for the first time the mechanism of action of vitamin A outside of the visual cycle. Three RAR subtypes have been identified in the vertebrate genome and have been named RARα, RARβ, and RARγ.

RA and RA Signaling

Retinoic acid (RA) is a signaling molecule derived from vitamin A (retinol) that is essential for normal embryonic development and health in the adult. RA is produced in a two-step enzymatic process involving the alcohol dehydrogenase-mediated conversion of retinol to retinaldehyde and, in a subsequent retinaldehyde dehydrogenase-catalyzed step, to RA. RA signaling is mediated by retinoic acid receptors (RARs).

RARs belong to the superfamily of nuclear receptors and bear conserved structural similarities to other members of this family, including estrogen and androgen receptors, glucocorticoid receptor, thyroid hormone receptor, and vitamin D receptor. In general, members of this family can be distinguished by the linear arrangement of six more or less conserved functional domains labeled A through F. Key functional domains of RARs include the RA-binding domain, the DNA-binding domain, and two separate transcription activation domains (see Figure 1). While the DNA- and RA-binding domains of the RARs are similar between subtypes, the transcription activation domains vary considerably, possibly reflecting target gene-specific interactions. Several regions within RAR domains mediate specific interactions with retinoid-x-receptor subtypes (RXRα, RXRβ, or RXRγ), forming an obligatory heterodimeric partnership required for activation of RA target genes. RAR/RXR heterodimers bind to specific DNA elements called retinoic acid response elements (RAREs) usually found in the promoters of such genes. The unique expression patterns of each RAR subtype in the embryo and the adult also support the specific functional role that each of the RARs fulfills. Murine knockout studies have revealed that although there is functional redundancy between RARs, each receptor is essential for normal physiology.

RAR Structure and Function

RARs share structural similarities with other members of the nuclear receptor family. The key functional domains of RARs include the RA-binding domain, the DNA-binding domain, transcriptional activation domains, and amino acid sequence motifs that are necessary for interactions between RARs and other transcription factors, including RXRs. RARs form heterodimeric complexes with RXRs in order to regulate gene expression.

DNA-Binding Domain

The hallmark of all nuclear receptors is the DNA-binding domain (domain C), which comprises a highly conserved, 66–68 amino acid stretch encoding two zinc-binding fingers labeled C1 and C2. The RARs' DNA-binding domain is 66 amino acids in length, and its structure has been determined by X-ray crystallographic studies. The two zinc fingers fold into a globular domain such that residues of the first zinc-binding finger (C1) make specific contacts with DNA through interactions between three conserved amino acid residues (P-box) with specific base residues in the major groove of the DNA double helix. The second zinc finger (C2) is more basic in nature, making contacts with the negatively charged phosphate backbone of DNA. This helps to stabilize the interaction between RARs and the DNA motifs to which they bind, RAREs. RARs do not bind to RAREs independently but rather as a heterodimeric complex formed between an RAR and an RXR. Residues in C2 are critical for heterodimer formation.

Retinoic Acid-Binding Domain

The retinoic acid-binding domain (domain E) fulfills several important functions, including, of course, retinoic acid binding, transcription activation, and nuclear localization. The RA-binding domain binds

FIGURE 1 Domain structure of RARs. All RARs and RXRs have domain structures similar to other members of the nuclear receptor family. Domains A–F are shown. DNA-binding domain (C) and ligand-binding domain (E) are highly conserved. Transcription activation functions are found in E (AF-2) and A (AF-1) domains.

both *all-trans* and 9-*cis* isomers of RA with high affinity. In contrast, the ligand-binding domain of RXRs bind only the 9-*cis* RA isomer. These ligand-binding domains possess a series of 12 α-helical structures (H1–H12) that fold together to form the ligand-binding pocket. H12 contains the transcription activation domain AF-2. From X-ray crystallographic studies, it has been proposed that conformational changes occurring with the binding of RA alter the position of H12 and thus the ability of the AF-2 to interact with transcription factors that repress or activate gene transcription. In the "mouse-trap" model of ligand activation, H12 is extended into the solvent in the absence of RA but snaps shut once ligand enters the RA-binding pocket. These dynamic conformational reconfigurations result in differential interactions with cofactors that functionally link the receptor complex with the transcription initiation complex.

Other Functional Regions of RARs

The N terminus of RARs, comprising domains A and B, contains another region important for transcriptional activation. Interestingly, differential splicing/alternate promoter usage can give rise to multiple A domains for each subtype. This multiplicity of RAR isoforms and their potential to form partnerships with RXR subtypes creates, at least conceptually, a remarkable number of combinatorial possibilities that may each have subtly different yet important contributions to RA target gene regulation. Domain D, or the hinge region, has been described as a tether that connects DNA and ligand-binding functions. This domain also appears to posses a nuclear localization motif required to sequester receptors in the nucleus. Unlike steroid hormone receptors, which reside in the cell cytoplasm bound to heat-shock proteins that are released to the nucleus upon ligand binding, RARs and RXRs are complexed with DNA in their unliganded state. The role of the F-domain located at the extreme C terminus of RAR is not known.

Retinoic Acid Response Elements

RAREs are DNA motifs to which RAR/RXR heterodimers can bind with high affinity. In most cases, these motifs comprise a direct repeat of the half-site consensus, PuGGTCA, separated by five base pairs; however, other configurations are also possible. These elements can be found in variations of number and orientation from within a few base pairs of transcription initiation sites to several thousand base pairs (usually upstream). These elements concentrate RAR/RXR heterodimers, which are normally in very low abundance, near transcription complexes.

RA Transcriptional Activation

RARs act as biosensors to detect RA in the local environment. The binding affinity of these receptors for RA is on the order of 10–30 nM. Once RAR-expressing cells are exposed to RA, changes in the pattern of gene transcription will occur. The role of transcription activators is to increase the efficiency of RNA polymerase II binding to the promoter and engage the successful transcription of a gene – and in the case of RARs, to do so only in the presence of RA. In unliganded form, the RAR/RXR heterodimer, when bound to an RARE on a target gene, can act to repress transcription (Figure 2). This complex recruits a specific type of transcription factor called a corepressor. The first such nuclear receptor corepressor found to interact with unliganded RAR was N-CoR/SMRT. The presence of RA causes allosteric modulation of the ligand-binding domain, shifting the cofactor binding preference from corepressor to coactivator. Thus, release of N-CoR/SMRT by RA results in the complex having increased affinity for coactivators such as p140 and p160. Many coregulators that interact with RAR/RXRs and that also have other chromatin-remodeling functions, such as histone-deacetylase activity, kinase activity, or methylase activity, have been isolated. In addition to chromatin-remodeling functions, some of these cofactors correspond to factors critical for establishing a stable transcription initiation complex. The net effect of these interactions is increased or decreased transcription of target genes, depending on the promoter sequence, the local concentrations of factors binding to the promoter, and whether other signaling pathways are regulating the activities of any of these factors. In this way, RA signal is processed in a manner that integrates the activities of many pathways of a given cell type.

Retinoic Acid Receptor Function

Each of the murine RAR and RXR subtypes has been knocked out by homologous recombination in order to determine their functions during embryonic development and in the adult. Although there are multiple receptor isoforms, there are distinct roles for each defined by spatiotemporal distribution and

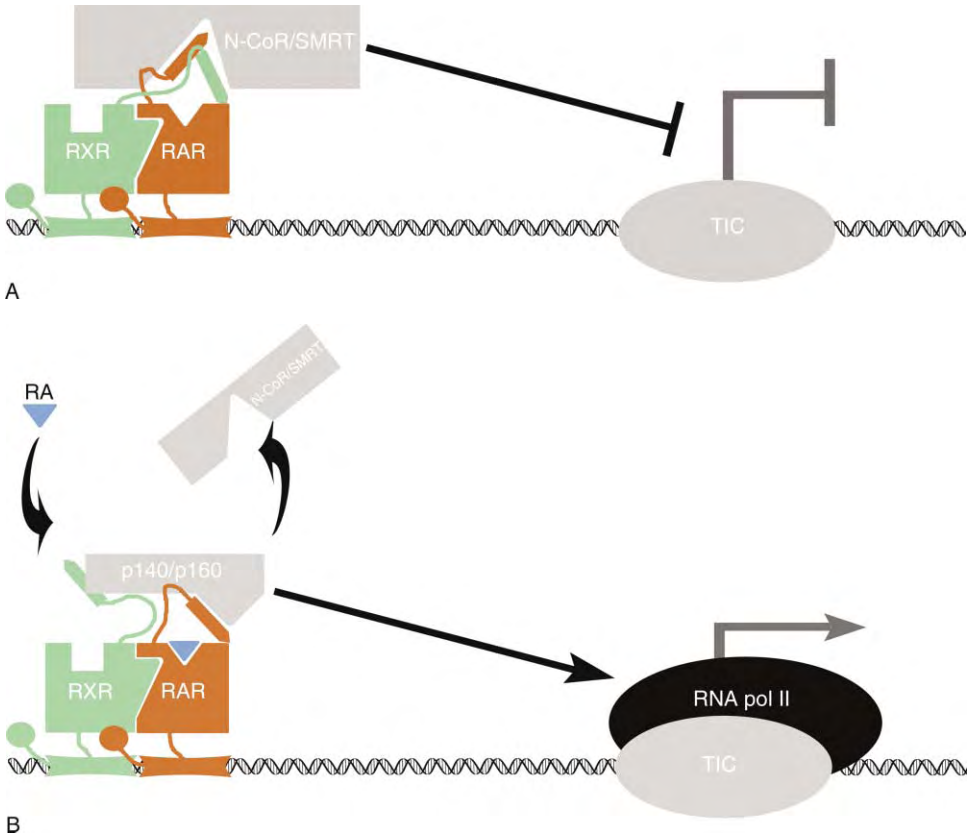

FIGURE 2 The RAR/RXR complex regulates transcription. (A) Transcriptional repression occurs when unliganded RAR/RXR heterodimer binds to an RARE in the promoter region upstream of the transcription start site of an RA-responsive gene. Unliganded receptors bind to corepressor factors such as N-CoR/SMRT that act to limit the function of the transcription initiation complex (TIC) through reorganization of chromatin structure. (B) Binding of RA ligand to the RXR/RAR complex induces a conformational change in the ligand-binding domain of RAR, causing the release of N-CoR/SMRT and allowing the recruitment of transcriptional coactivators such as the p160 complex. This coactivator complex promotes the binding of transcription accessory factors essential for the efficient engagement of RNA pol II activity.

promoter-specific activities. Throughout the murine life cycle, RARα is ubiquitously expressed and may play a role in some general housekeeping functions. In contrast, RARβ transcript distribution indicates that this receptor may be involved in ontogenesis of the central nervous system during development and differentiation of epithelia in the adult. Similarly, the expression patterns of RARγ are spatiotemporally regulated, suggesting that this receptor is involved in embryonic tail bud development, craniofacial morphogenesis, chondrogenesis, and maintenance of squamous epithelia. Among RXRs, RXRα is ubiquitously expressed, whereas RXRβ and RXRγ are more restricted during embryogenesis.

Gene knockout studies confirmed distinct roles for each RAR and RXR subtype and also revealed a high level of functional redundancy. Whereas the RARα- and RARβ-null mutants display some of the postnatal defects observed in vitamin A-deficient (VAD) mice (poor viability, growth deficiency, and male sterility), most of the RAR- or RXR-null single mutants exhibit only subtle or, in some cases, undetectable developmental abnormalities. In contrast, RAR double mutants exhibit reduced viability and recapitulate most symptoms of VAD.

RXR$\beta^{-/-}$RXR$\gamma^{-/-}$RXR$\alpha^{+/-}$ triple-mutant mice exhibit marked growth deficiency but, surprisingly, display no obvious congenital or postnatal abnormalities. However, mutation of both RXRα alleles is lethal. Therefore, RXRα may carry out most of the vital developmental and postnatal functions of the RXRs.

Biography

Martin Petkovich is a Professor of Biochemistry and Pathology in the Cancer Research Institute at Queen's University in Kingston, Ontario. His research interests include molecular genetics of retinoid signaling and metabolism in embryonic development and pattern formation. He discovered the first nuclear receptor for retinoic acid and has also identified key enzymes involved in regulating RA levels in tissue.

Reverse Transcriptase and Retroviral Replication

Laura Tarrago-Litvak, Marie-Line Andréola and Simon Litvak
Réplication et Expression des Génomes Eucaryotes et Rétroviraux (REGER), Bordeaux, France

Since its discovery, reverse transcriptase (RT) has been associated with retroviruses. In the following years this RNA-dependent DNA polymerase was found in eukaryotes, prokaryotes, retrotransposons, hepadnaviruses, retrons, and even humans. The role of RT in all retroviruses is to synthesize double-stranded DNA copying the retrovirus single-stranded RNA genome. This DNA is then integrated into the host cell's chromosomes as a provirus. Transcription then leads to copies of the viral RNA genome, from which the virus's own proteins and enzymes are formed. New viral particles then bud from the membrane of the cell. Thus, reverse transcriptase is essential for viral replication.

RT performs a remarkable feat, reversing the normal flow of genetic information. The polymerases synthesizing DNA and RNA in cells are very accurate and make very few mistakes. This is essential because they are the caretakers of our genetic information, and mistakes may be passed on to the offspring. RT, on the contrary, makes mistakes very often by incorporating a non-complementary nucleotide. One might think that this would cause severe problems to the virus. But, in fact, this high error rate turns out to be an advantage for the virus. The errors allow the retrovirus to mutate rapidly in order to fit new conditions and escape, for instance, the immunological response of the host or the effect of therapeutic agents.

Discovery of Reverse Transcriptase

The publication of the presence of reverse transcriptase (RT) in retroviruses in 1970 by the groups of Howard Temin and David Baltimore in the same issue of *Nature* must be considered as a landmark in the story of biological sciences in the second half of the twentieth century. The presence of a DNA polymerase able to copy RNA into DNA (contrary to all the enzymes of this family described before which copy a DNA template into DNA), violated the so-called central dogma of molecular biology which stated that genetic information always flowed from DNA to RNA to protein. It is of interest to point out that while the laboratory of Baltimore came to this conclusion by searching for the mechanisms used by polymerases, involved in the replication of different viruses, the findings of Temin's group came as a strong support of his earlier experiments, which showed that the replication of retroviruses was sensitive to inhibitors of DNA-dependent polymerases. Since the early 1960s Temin had proposed the idea, widely rejected at that time, that the replication of RNA oncoviruses, as they were called, had to go via a DNA intermediate that may be integrated in the host genome. Years later, after the discovery of RT, the finding in 1983 that the cause of AIDS was a retrovirus, the human immunodeficiency virus type 1 (HIV-1), and the consequent emotion provoked by the AIDS pandemics led to an explosive burst of research on this virus. It can be considered that very few organisms have provided so much information on their structure and function in such limited time as in the case of HIV-1. Most of the information on retroviral replication since the early 1980s has come from the work on this human retrovirus.

Retrovirus Genome

All retroviral genomes consist of two identical molecules of RNA, which are single-stranded, (+) sense and have a 5′-end cap and a 3′-end pol (A) as in the case of eukaryotic messenger RNAs (mRNAs). Retroviral genomes vary in size from 8 to 11 kb. Some distinctive features of the retrovirus genomes concern the fact that they are the only RNA viruses which are not only truly diploid but also whose genome is produced by the cellular transcriptional machinery, without the involvement of a viral-encoded polymerase (Figure 1). Moreover, they are the only (+) sense RNA viruses whose genome does not serve directly as mRNA immediately after infection. The two RNA genomic molecules are physically linked as a dimer by hydrogen bonds. In addition, another nucleic acid is present in all viral particles, a specific transfer RNA (tRNA) required for the initiation of replication. Most, if not all, DNA polymerases require a primer carrying

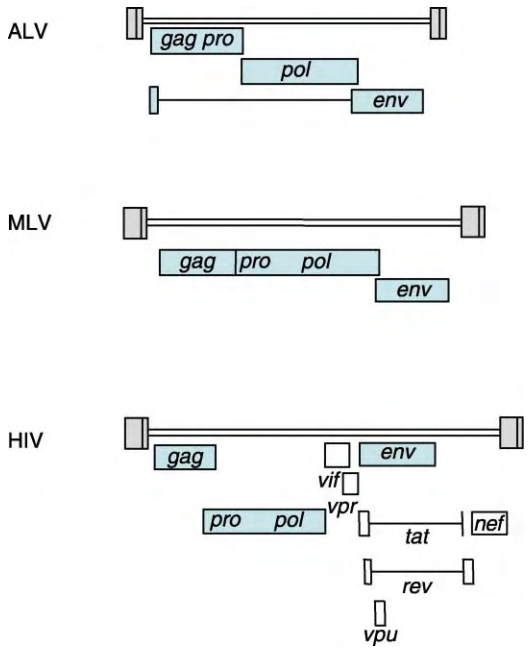

FIGURE 1 Genetic organization of prototypic retroviruses. An open rectangle indicates the open reading frame for the gene marked. Gag, pol, and env, common to all retroviruses, are shown in blue. *Gag*: encodes a polyprotein (Gag), whose cleavage products are the major structural proteins (matrix [MA], capsid [CA], and nucleocapsid [NC]) of the virus core; *pro*: encodes part of a polyprotein (Gag-Pro, or Gag-Pro-Pol), whose cleavage products include protease (PR); *pol*: encodes part of a polyprotein (Gag-Pro-Pol), whose cleavage products include reverse transcriptase (RT) and integrase (IN); *env*: encodes a polyprotein (Env), whose cleavage products SU (surface) and TM (transmembrane) are the structural proteins of the viral envelope; *tat*: an accessory gene encoding for a low-molecular-weight protein (trans activator) that activates transcription by binding to TAR; *rev*: an accessory gene encoding a protein that regulates splicing and RNA transport; *nef*: an accessory gene encoding a protein that reduces the level of CD4 on the cell surface, and also stimulates some infected cells to divide; *vpu*: an accessory gene encoding a protein (viral protein u) that triggers CD4 degradation. Enhances virion release; *vif*: an accessory gene encoding a protein (virion infectivity factor) that affects infectivity of viral particles; *vpr*: an accessory gene encoding a protein (viral protein r) that causes infected cells to arrest in G_2 and may also promote transport of the preintegration complex into the nucleus after reverse transcription. Horizontal lines indicate that this segment is spliced out. ALV: avian leukemia virus; MLV: murine leukemia virus; HIV: human immunodeficiency virus.

a free 3′-end OH from where DNA synthesis is initiated. In the case of retroviruses, this primer is a cellular tRNA, which is able to anneal partially to a region near the 5′-end of the RNA viral genome, the "primer-binding site" (PBS). Examination of the sequences of several retroviruses has shown that the PBS is complementary to the 3′-end of a given tRNA: $tRNA^{Trp}$ in avian retroviruses, $tRNA^{Pro}$ in murine viruses and $tRNA^{Lys3}$ in HIV-1. The mechanism involved in the selection of a specific tRNA is not fully understood. While the role of the viral genome has been ruled out, early results with avian retroviruses suggested that RT was involved in tRNA packaging. Very recent work seems to indicate that in the case of HIV-1, the lysine aminoacyl-tRNA synthetase may encapsidate the cognate tRNA primer in the retroviral particle. The small basic nucleocapsid (NC) protein encoded in the C-terminal region of the *gag* gene seems to play an important role in the annealing of primer tRNA to the PBS region, thus allowing the initiation of retroviral replication. The gene order in all retroviruses is invariant: 5′-gag-pol-env-3′. However, some complex retrovirus, like HIV-1, encode several other small regulatory proteins.

Activities Associated with the Reverse Transcriptase

With the exception of some murine retroviral polymerases, most RTs are heterodimeric enzymes. The retroviral-encoded protease cleaves a polyprotein precursor leading to an RT subunit that is further cleaved by the same protease (Figure 2). Thus, RTs are formed by two subunits where the smallest one carries the same sequence as the largest. Retroviral DNA synthesis is

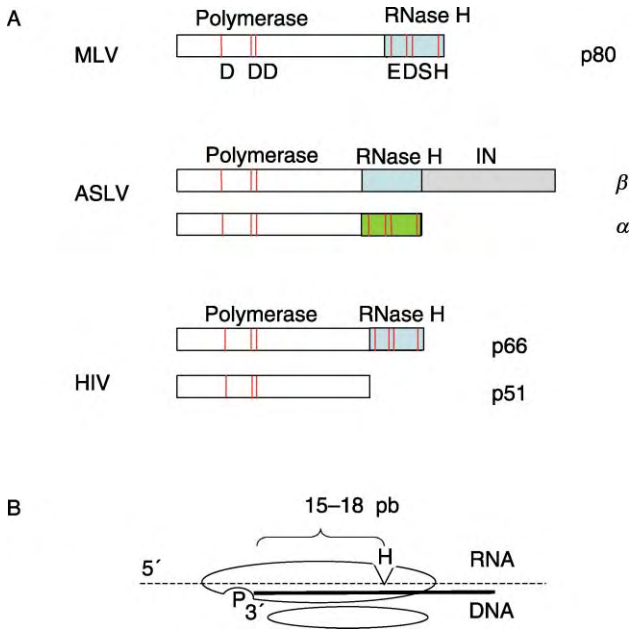

FIGURE 2 (A). Subunit structure of various retroviral RT. The MLV RT is a monomer. The ASLV RT is a heterodimer, the cleavage at the RT-IN boundary is incomplete. In HIV, the IN is produced as a separate protein. Vertical lanes show the positions of the active site residues in the polymerase and RNase H domains. (B). Mode of HIV-1 RT positioning for synthesis and RNase H cleavage. The 3′-end of the DNA directs RT positioning for optimal RNase H cleavage.

absolutely dependent on the two enzymatic activities associated with RT: a DNA polymerase that can use either RNA or DNA as a template, and a nuclease, named ribonuclease H (RNase H), that is specific for the RNA strand of RNA·DNA hybrids. All of the enzymatic functions required to complete the series of steps involved in the generation of a retroviral DNA can be attributed to either the DNA polymerase or the RNase H of RT as described below. However, it cannot be ruled out that certain viral proteins, such as the nucleocapsid protein, may increase the efficiency of reverse transcription.

Reverse transcription of the retroviral genome depends on the coordination of the polymerase and RNase H activities of RT. The spatial arrangement between the two active sites of the enzyme (corresponding to ~15–18 bases in the template) contributes to the coordination of these two activities. While the 3′-OH of the primer strand is positioned close to the RT amino acid residues important in the DNA polymerase active site, the template strand is positioned close to RT residues important for RNase H activity.

Biochemistry of Reverse Transcriptase

Mechanism of Action

The study of the mechanism of the RNA- and DNA-dependent DNA polymerase activity has led to a model involving a two-step binding mechanism. DNA polymerization catalyzed by RT is a multistep reaction, requiring the binding of the primer·template duplex and a deoxynucleoside triphosphate (dNTP) to RT prior to deoxy-nucleoside-5′-monophosphate addition to the 3′ end of the primer. Kinetic experiments have established the order of binding of the substrates. The primer·template duplex binds prior to binding of the deoxynucleoside triphosphate substrate to form the catalytically competent ternary complex. The rate-limiting step for nucleotide incorporation prior to dissociation of the enzyme is a conformational change. Following pyrophosphate liberation, the elongated product is released. Small changes in the rates and equilibrium constants have been observed for RNA- versus DNA-dependent DNA synthesis. All these mechanisms have been derived from pre-steady-state or steady-state kinetic assays using short primer·templates and do not always reflect the true nature of reverse transcription, although they are necessary in determining the kinetics and affinity of substrate binding to RT (Figure 3).

Processivity

The elongation phase of DNA synthesis by DNA polymerases may be processive or distributive. A processive DNA polymerase is able to synthesize long DNA stretches without dissociation of the enzyme from the primer·template duplex, while a distributive polymerase dissociates easily after incorporation of few nucleotides. Reverse transcriptase is considered to be poorly processive as compared with replicative DNA polymerases. However, a higher processivity of RT may be observed when copying specific regions of the viral genome or in the presence of some viral proteins.

Fidelity

All RTs show poor fidelity when compared to host DNA polymerases in *in vitro* systems. The lack of a proofreading function as well as the enzyme ability to extend mismatched primer termini probably explains much of this high error rate. The tendency of RT to switch templates, paired with its ability to extend mismatches by incorporating "wrong" nucleotides may be a significant source of replication errors. The error rates of various RTs estimated in different types of assays can be significantly affected by altering the parameters of the reaction. The error rate is quite dependent on sequence context and "hot spots," where errors occur frequently, and may differ according to the particular RT used in the assay. In addition, error rates may be different on RNA and DNA templates. As a consequence, it is not possible to define the error rate as a single number. These studies, taken together, do suggest that the overall error rate is high: about one per genome in a reverse transcription cycle. Cellular factors may alter error rates and some studies suggest that somewhat lower error rates occur *in vivo*. However, the *in vitro* data lead to the generally accepted impression that the average retroviral DNA genome differs from its parent by at least one mutation, and have provided the evidence for the existence of retroviral "quasi-species."

Replication Errors *in Vivo* and the Emergence of Antiviral Resistance

The rates at which mutations accumulate in retroviral and host genomes are very different since the viral genomes are found to evolve at rates perhaps a million-fold higher than the genomes of their hosts. The lack of RT fidelity and the accumulation of nonlethal mutations are closely related to the emergence of resistance towards antiviral therapeutic agents. This effect is especially dramatic in the case of HIV-1, the causal agent of AIDS. After short spans of treatment, viral quasi-species appear with mutations in the viral target proteins (the most used targets against HIV-1 are RT and protease). The introduction of the so-called combination therapy against AIDS has greatly improved the possibility to keep the seropositive patients for several years with a low or undetectable viral charge. The combination of several anti-proteases and anti-RTs makes it possible that if a given mutation leads to the apparition of resistance against a specific drug, the other antivirals are still effective, giving time to replace the one to which the target enzyme has become resistant.

Inhibitors of Reverse Transcriptase

Emphasis in the search of RT inhibitors has been obviously focused on the HIV-1 enzyme but some of the inhibitors developed against this agent may be useful in arresting retroviruses involved in other pathologies. Inhibitors of HIV-1 RT were the first therapeutic agents described against AIDS. The protease inhibitors appeared later, and currently inactivating agents against several viral targets (viral entry, integrase, etc.) are actively being studied. As mentioned elsewhere in this article the combined use of anti-proteases and anti-RTs has led to a great improvement in the control of HIV-1 proliferation in AIDS patients. Two main families of HIV-1 RT inhibitors are used against AIDS, the nucleoside analogue inhibitors of RT (NRTI) and the non-nucleoside inhibitors of RT (NNRTI). The first one is recognized and incorporated by RT in the newly synthesized DNA but as they lack or have a modified group in the 3′ position of the ribose they cannot be linked to the following dNTP precursor and thus they act as chain terminators. To be active *in vivo* the putative NRTI, which are active against all retroviral RTs, must be triphosphorylated by cellular kinases. The first NRTI described was azidothymidine or zidovudine but currently more than a dozen of these inhibitors have been approved by the US FDA and are used in clinics. The second family, the NNRTIs, is specific of the HIV-1 RT since they inhibit the viral polymerase after binding to a hydrophobic region of this enzyme. They do not have a typical nucleoside structure but belong to a variety of different chemical families of compounds and in contrast to NRTIs they do not need to be metabolized inside the cell to display their antiviral effect.

Recombination

Since retroviruses ordinarily carry two identical or nearly identical RNAs, the genetic consequences of using only one RNA versus portions of both of the RNAs to template DNA synthesis are usually the same. However, under certain conditions, two genetically distinct RNAs can be encapsidated. Portions of each template can be used to generate a single DNA, producing a recombinant. Recombination does occur in virions produced by a single cell that has been co-infected by two different viruses demonstrating that recombination requires co-packaging of two viral genomes into the same particle. During reverse transcription in such heterozygous virion particles, the DNA product can be generated containing portions of each of the two genomic sequences in one molecule.

The Role of RT in Reverse Transcription

Reverse transcription catalyzed by RT begins when the viral particle enters the cytoplasm of a target cell. DNA synthesis using the RNA retroviral genome as template takes place in the cytoplasm leading to a linear double-stranded DNA (dsDNA), co-linear with the viral RNA template, the proviral DNA. However, proviral DNA contains terminal duplications known as the long terminal repeats (LTRs) that are not present in viral RNA (Figure 4).

The following scheme is widely accepted to reflect the process of retroviral DNA synthesis catalyzed by RT:

1. Minus-strand DNA synthesis starts from the 3′ end of a tRNA partially annealed to the primer-binding site (PBS) in genomic RNA. Minus-strand DNA synthesis proceeds until the 5′-end of genomic RNA is reached, generating a short DNA intermediate termed minus-strand strong-stop DNA (−sssDNA). Since the PBS is near the 5′end of viral RNA, the length of this strong-stop DNA is ~100–150 nucleotides.
2. Following RNase H-mediated degradation of the RNA strand of the RNA·(−sssDNA) duplex, the first strand transfer involves the annealing of the −sssDNA to the 3′-end of a viral genomic RNA. This transfer is allowed by the presence of identical sequences known as the repeated (R) sequences, present at the 5′- and 3′-ends of the RNA genome. The 3′-end of (−sssDNA) is copied from the R sequences at the 5′-end of the viral genome and therefore contains sequences

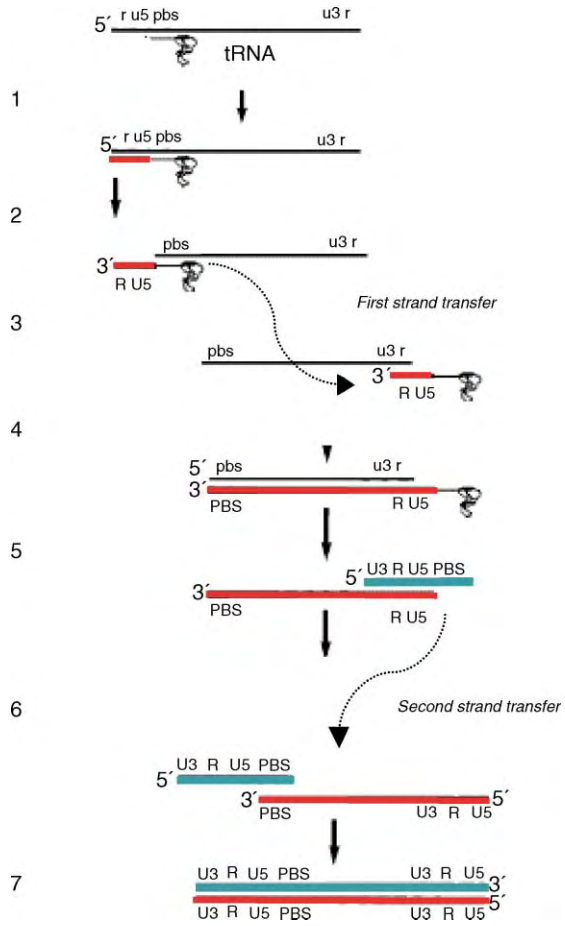

FIGURE 4 Process of reverse transcription. Thick lane, DNA; thin lane, RNA.

complementary to R. After the RNA template has been removed, the (− sssDNA) can anneal to the R sequences at the 3′-end of the RNA genome. The annealing reaction related to the first strand transfer, appears to be facilitated by the NC protein.

3. Once the (− sssDNA) has been transferred to the 3′ R region on viral RNA, minus-strand DNA synthesis may start again, followed by RNase H digestion of the template strand.

4. RNase H degradation is not complete since some hybrid regions seem to be more resistant to the nuclease. The RNA genome contains a short polypurine tract (PPT) that is relatively resistant to RNase H degradation. A defined RNA segment derived from the PPT primes plus-strand DNA synthesis. Plus-strand synthesis is halted after a portion of the primer tRNA is reverse-transcribed, leading to a DNA called plus-strand strong-stop DNA (+sssDNA). Some retroviruses generate more than one plus-strand primers from the RNA genome.

5. RNase H removes the primer tRNA, exposing sequences in (+sssDNA) that are complementary to sequences at or near the 3′ end of plus-strand DNA.

6. Annealing of the complementary PBS segments in (+sssDNA) and minus-strand DNA constitutes the second strand transfer.

7. Plus- and minus-strand syntheses are then completed, with the plus and minus strands of DNA each serving as a template for the other strand.

Integration and Retroviral Replication

As proposed by Temin since the early 1960s, retrovirus replication is performed via a DNA intermediate, the proviral DNA is synthesized by the RT in the cytoplasm. Integrase (IN), the third retroviral encoded enzyme in addition to RT and protease, is involved in the integration of the proviral DNA in the nuclear DNA of the infected cell. Integration is a crucial step in viral replication since retroviral DNA molecules are not ordinarily able to replicate autonomously and they depend on integration for stable maintenance in dividing cells. Once integrated the proviral DNA is recognized by the host-cell enzymatic machinery for efficient transcription of viral DNA into new copies of the viral genome and mRNAs that encode viral proteins. Moreover, integration also stabilizes the viral DNA against degradation and allows its genetic transfer as an integral element of the host genome.

Role of Reverse Transcriptase in Modern Biology

It is now well known that RT is present not only in animal retroviruses but also plays a crucial role in DNA replication of prokaryotic and eukaryotic cells, in the replication of some plant and animal DNA viruses, as well as in the function of several classes of transposable elements. As mentioned in the remarkable book *Retroviruses* "it should be remembered that RT has had a critical role in the development of modern biology. The ability to convert RNA into DNA has been as important to molecular biologists as it has been to retrovirologists. It is worth taking a moment to reflect on how much more difficult it would have been to solve the puzzles posed by the organization and expression of genes in higher eukaryotes if RT did not exist."

Glossary

cap The structure at the 5′-end of eukaryotic mRNA introduced after transcription. It results from adding a methylated G to the terminal base of the mRNA.

DNA polymerase An enzyme that systhesizes a daughter strand of DNA under direction from a DNA or an RNA template.

hot spot A site at which the frequency of mutation (or recombination) is increased significantly.

LTR An abbreviation for long-terminal repeat, a sequence directly repeated at both ends of a retroviral DNA.

primer A short sequence (often of RNA) that provides a free 3′-OH end at which a DNA polymerase starts synthesis of a deoxyribonucleotide chain.

retrovirus An RNA virus that propagates *via* conversion into duplex DNA.

template A polynucleotide which furnishes the instructions for the sequence of nucleotides to be added to the primer strand during DNA polymerization.

Biography

Laura Tarrago-Litvak was born in Santiago, Chile. She did her university undergraduate studies at the University of Chile and obtained her Ph.D. at the University of Bordeaux, France. Her current research interest is in the field of retroviruses, mainly in two retroviral enzymes, reverse transcriptase and integrase.

Marie-Line Andréola was born in Sainte-Foy-la-Grande, France. She did her university undergraduate studies and obtained her Ph.D. at the University of Bordeaux, France. Her current research interest is in the field of retroviruses, focused on the mechanism of action and search of inhibitors of two retroviral enzymes, reverse transcriptase (RNase H activity) and integrase.

Simon Litvak was born in Valparaiso, Chile. He did his university undergraduate studies at the University of Chile at Santiago and obtained his Ph.D. at the University of Paris, France. He is affiliated to the CNRS as Principal Investigator and is currently the Director of the REGER Laboratory (UMR-5097. CNRS – University of Bordeaux 2) and former Director of the Institut Federatif des Recherches "Pathologies Infectieuses et cancers," Bordeaux, France. His current research interest is in the field of retroviruses. Research in his group is focused on the mechanism of action of two key HIV-1 enzymes: reverse transcriptase and integrase. He has also contributed in the search for specific inhibitors of HIV-1 RT and IN (small ligands and oligonucleotides).

Rho GTPases and Actin Cytoskeleton Dynamics

Priam Villalonga and Anne J. Ridley
Ludwig Institute for Cancer Research and University College London, UK

The dynamic regulation of the actin cytoskeleton plays a crucial role in the control of cell shape and movement, and therefore has a profound impact on the biology of multicellular organisms. Accordingly, actin cytoskeleton regulators modulate a broad array of cellular processes such as cell migration, tissue morphogenesis, inflammation, vesicular trafficking, secretion, and cancer cell invasion and metastasis, just to name a few of them. Members of the Rho family of small GTPases have emerged as major regulators of the actin cytoskeleton in all eukaryotic cells. Like other small GTPases, these proteins are molecular switches that are exquisitely regulated by several positive and negative regulators that can either "switch" them on or off. Once activated, they bind to and activate a number of downstream effectors, most of them directly implicated in the regulation of actin-related biochemical events (e.g., actin polymerization). This enables Rho GTPases to act as key players in processes that require the dynamic regulation of the actin cytoskeleton.

Rho GTPase Family: Overview and Regulation

Rho GTPases constitute a separate family within the larger Ras superfamily of small GTPases. In mammalian cells, the prototypical Rho family members are RhoA, Rac1, and Cdc42, which have been the most extensively characterized. However, there are many other members in this family including Rho, Rac, and Cdc42 isoforms and several other proteins that are more or less related to these three in terms of sequence homology, thereby defining subfamilies within the Rho family (Figure 1). Some Rho family members show a tissue-specific pattern of expression, although most of them are expressed in the vast majority of mammalian cells, localizing to different cellular membranes as a consequence of lipid modifications at their carboxy termini. Like other GTPases, Rho proteins bind to guanine nucleotides and, except for members of the Rnd subfamily, cycle between an active GTP-bound state and an inactive GDP-bound state. Three different types of regulators can modulate the activation levels of these GTPases: guanine-nucleotide-exchange factors (GEFs), GTPase-activating proteins (GAPs), and guanine-nucleotide-dissociation inhibitors (GDIs), as illustrated in Figure 2.

Guanine-Nucleotide-Exchange Factors

GEFs promote the release and exchange of bound nucleotides on the GTPase, effectively leading to an increase in the number of GTP-bound molecules due to the higher intracellular concentration of GTP. GEFs are, therefore, positive regulators of Rho GTPases that promote their activation. In mammalian cells, a large number of GEFs have been described, all sharing a highly conserved exchange factor domain termed Dbl-homology (DH), named after the first GEF identified, Dbl. They also have other conserved domains such as the phospholipid-binding domain PH (Pleckstrin homology), involved in the localization of GEFs in the vicinity of the GTPases on membranes, providing a mechanism for GEF regulation. In addition to their regulation by phospholipid binding, GEFs can be regulated by binding to other proteins or by phosphorylation. Rho GEFs exhibit different degrees of specificity *in vitro* towards Rho GTPases, but it still has not been clearly established which GEFs regulate each of the Rho GTPase members *in vivo*.

GTPase-Activating Proteins

GAPs act by binding to the GTPase and enhancing hydrolysis of GTP, an otherwise slow and inefficient process, and by promoting the conversion of GTP to GDP they are negative regulators of Rho GTPases. Rho GAPs share in common a 140 amino acid domain, termed the RhoGAP domain, that confers GAP activity. However, they are usually large

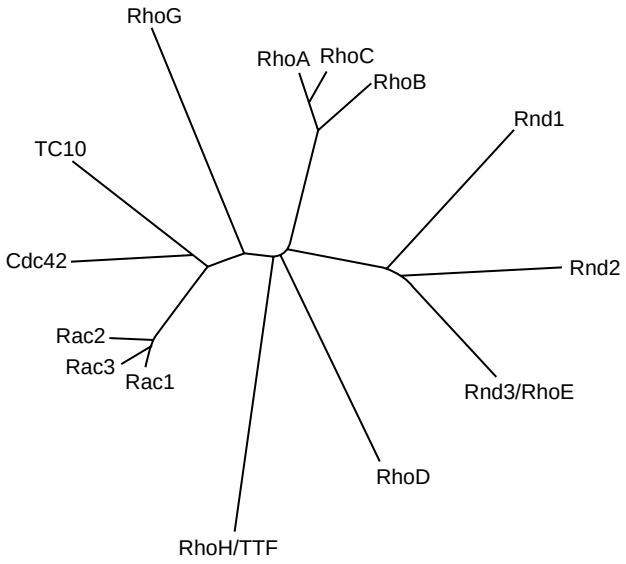

FIGURE 1 Phylogenetic tree of the Rho GTPase family. Rho GTPase family members can be grouped into subfamilies according to their sequence similarity.

proteins containing other domains involved in signaling and lipid and protein binding. Although these domains are thought to influence GAP function in cells, very little is known concerning how these proteins are regulated *in vivo*, although it has been reported that some of them can be regulated by tyrosine phosphorylation.

Guanine-Nucleotide-Dissociation Inhibitors

GDIs bind to Rho GTPases in the cytosol and prevent their interaction with the membranes, and with both GEFs and GAPs. For these reasons they are considered to be negative regulators of Rho GTPases that sequester them in an inactive form in the cytoplasm. Signals that activate Rho GTPases will disrupt the GTPase/GDI complex and localize the GTPase to membranes. It has been reported that GDIs can be phosphorylated by protein kinase C, leading to their dissociation from GTPases and consequently to GTPase activation. There are three RhoGDIs in mammalian cells that show differences in their pattern of expression, activity, and specificity.

Rho GTPase Family Activity: Downstream Targets

Rho GTPases exert their function by binding to and modulating the activity of an array of downstream effectors. Here the manner in which Rho GTPases activate some of their most relevant targets in terms of actin cytoskeleton control will be described (Table 1).

Rho Effectors

The archetypical responses elicited by Rho activation in cells are the assembly of bundles of filamentous actin

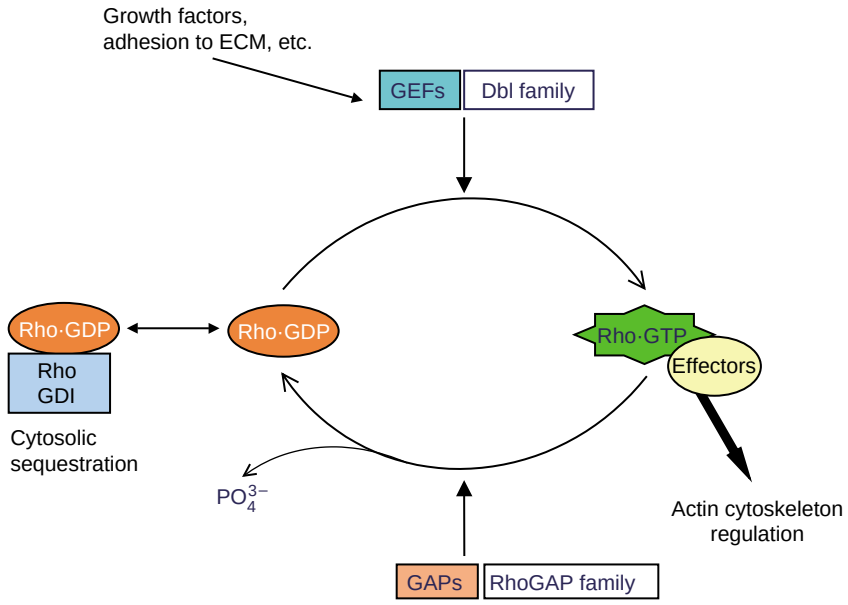

FIGURE 2 Rho GTPase regulation. Rho GTPases cycle between a GDP-bound, inactive state, and a GTP-bound active state. When GDP-bound, Rho GTPases can bind to RhoGDIs and remain sequestered in the cytoplasm. Extracellular signals induce the exchange of GDP for GTP, which is regulated by GEFs, thereby activating Rho GTPases and localizing them on membranes. In their GTP-bound form, Rho GTPases interact with their downstream effectors and regulate the actin cytoskeleton. Inactivation is achieved through GTP hydrolysis, which is often promoted by GAP binding to Rho GTPases.

TABLE 1

Rho GTPase, Downstream Effectors, and their Functions

Rho GTPase	Downstream effectors	Function in cell biology
RhoA, B, C	ROCK I, II	Actomyosin contractility: Stress fiber and focal adhesion formation. Tail retraction and new focal adhesion formation in cell migration
	mDia	Actin filament formation
Rac1, 2, 3	IRSp53	Actin polymerization, through WAVE activation, and Lamellipodia formation. Driving force in cell migration
	PAK1, 2, 3	Actin polymerization through LIMK-induced cofilin inhibition
Cdc42	WASP/N-WASP	Actin polymerization and filopodia formation. Sensor role in cell migration
Rnd1, 2, 3/RhoE	Unknown (RhoE binds to ROCK I)	Antagonizing RhoA effects: Disassembly of actin stress fibers and focal adhesions
RhoH/TTF	Unknown	Antagonizes some aspects of RhoA signaling in lymphocytes
TC10	WASP	Actin polymerization, filopodia formation

and myosin, termed stress fibers, and the formation of multimolecular complexes at the end of those fibers at sites of integrin-mediated cell adhesion, termed focal adhesions. Both effects can be largely attributed to one Rho effector, the serine/threonine kinase, Rho-kinase (ROCK). Rho-GTP binding to ROCK unfolds and relieves its kinase domain from an otherwise closed, autoinhibited, conformation. The two isoforms of ROCK phosphorylate a number of proteins involved in regulating the actin cytoskeleton, including the myosin-binding subunit of myosin light-chain phosphatase, thereby inhibiting its phosphatase activity and enhancing myosin light-chain phosphorylation and actomyosin-based contractility. Other Rho effectors contribute to Rho-mediated actin cytoskeleton regulation, such as mDia, which binds to the actin-binding protein profilin and stimulates actin filament formation.

Cdc42 Effectors

Activation of Cdc42 in most cells promotes the formation of filopodia, spike-like membrane protrusions induced by actin polymerization in parallel bundles. As with Rac-induced lamellipodia, these structures are associated with the leading edge of migrating cells. A clear model has emerged in which a Cdc42 effector, WASP (Wiskott Aldrich syndrome protein), directly controls actin polymerization to extend filopodia in response to extracellular signals. The hematopoietic-specific WASP or its widely expressed isoform, N-WASP, induce *de novo* actin polymerization through their binding to the Arp2/3 (actin-related protein) complex. Binding of active Cdc42 to WASP changes its conformation, relieving it from an autoinhibited state and exposing a previously masked domain, the VCA domain (verprolin-homology, cofilin-homology and acidic region). Once exposed, this domain binds to G-actin through the V-domain and to the Arp2/3 complex through the CA-domain, strongly activating Arp2/3 complex-induced actin nucleation and polymerization. WASP also binds to the actin-binding protein profilin, which further enhances WASP-mediated actin filament formation through its ATP/ADP exchange activity towards actin. Activation of WASP family proteins by Rho GTPases, such as WASP activation by Cdc42, is a typical example of downstream effector activation by binding to active GTPases (Figure 3).

Rac Effectors

In most mammalian cells, activation of Rac induces lamellipodia and membrane ruffles, both being plasma membrane protrusions that extend over the substratum or upwards, respectively. These protrusions are driven by a branching network of actively polymerizing actin filaments, and are usually found at the leading edge of migrating cells. The Rac effector pathway that leads most directly to actin polymerization involves WAVE proteins (wasp/verprolin homologous protein). WAVEs are members of the WASP family that are crucial mediators of actin polymerization mediated by the Arp2/3 complex. WAVE1 and WAVE2 have been shown to be activated downstream of Rac, although Rac does not bind directly WAVEs and the mechanism of activation is different to Cdc42 stimulation of WASP, but with similar consequences: activation of Arp2/3 complex-mediated actin polymerization (see Figure 3). Other Rac effectors also contribute to actin polymerization and to extension of lamellipodia and membrane ruffles. For example, PAKs (p21-activated

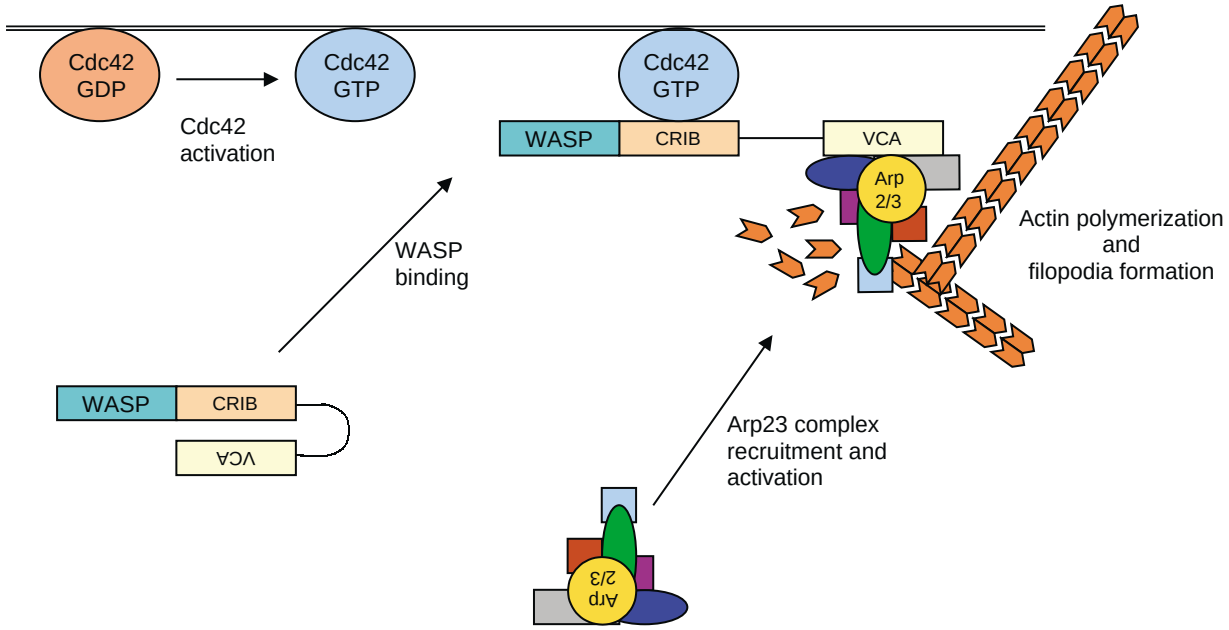

FIGURE 3 Model of effector activation by Rho GTPases: Cdc42-induced WASP activation promotes filopodia. When Cdc42 is inactive, WASP is in an auto-inhibited conformation. Upon Cdc42 activation, inactive WASP binds to Cdc42-GTP through its CRIB domain, relieving its inhibitory conformation and exposing its VCA domain. The VCA domain is now available to recruit and activate the Arp2/3 complex, stimulating actin polymerization and formation of filopodia.

kinases) are a family of kinases that can be activated by Rac and Cdc42 and contribute to actin reorganization, for instance through phosphorylation of LIM kinase, which phosphorylates and inhibits the actin-depolymerizing protein cofilin, and thus promotes actin polymerization.

Other Members

Although RhoA, Rac1, and Cdc42 are the most-extensively studied members of the Rho family, evidence is now accumulating that they are not alone in their regulatory roles on the actin cytoskeleton. First of all, it is not yet clear what the specific roles are of closely related isoforms of these proteins such as RhoB or Rac2, and other less-characterized members of the family are only starting to be investigated. The Rnd proteins are an exciting new subfamily that have been shown to be unusual examples of GTP-binding proteins as they do not cycle between an active GTP-bound state and an inactive GDP-bound state. Among these proteins, Rnd1 and Rnd3/RhoE have been shown to antagonize RhoA in its effects on the actin cytoskeleton, promoting stress fiber and focal adhesion disassembly in several different types of mammalian cells. Similarly to Rnd proteins, RhoH/TTF seems to antagonize some of the RhoA GTPase functions, but it is only expressed in hematopoietic cells. Other members have more similar effects to those of the prototypical Rho GTPases: RhoG signals in parallel to Rac and Cdc42, whereas TC10 is more related to Cdc42 and induces filopodia.

Rho GTPase Family: Functions in Cell Biology

The ability to regulate the actin cytoskeleton dynamically enables Rho GTPases to be involved in many cellular processes, the most obvious of them being cell migration. However, there are many other processes that require Rho GTPases, such as secretion, endocytosis, and cell proliferation.

Cell Migration

Cell movement requires an orchestrated spatio-temporal regulation of the actin cytoskeleton, which involves coordinated activation of several members of the Rho GTPase family. Rac isoforms are important to induce actin polymerization in the leading edge of the cell, in the form of lamellipodia and membrane ruffles, pushing forward the plasma membrane and generating the driving force for cell motility. Cdc42 has shown to be essential for directionality, for instance in macrophage chemotaxis, through the formation of filopodia that are believed to sense the extracellular environment. Rho, in turn, contributes to cell motility by providing actomyosin-based contractility necessary for cell body contraction and tail retraction. Rac activity is also crucial to form adhesions as cells move forward and interact with new extracellular matrix. In addition, Rho GTPases affect microtubule dynamics, which is also important for cell migration. Although the principal

roles of Rho GTPases in cell migration have been already established, there are important differences in the role that these proteins have in different cell types, such as epithelial cells versus macrophages. Furthermore, it is not yet fully understood how these proteins and their effectors are spatially and temporally regulated, and how such an exquisite level of coordination in their functions is achieved in cell migration.

Secretion and Endocytosis

Vesicle trafficking requires both the actin cytoskeleton and the microtubule network, and Rho GTPases have been shown to affect different aspects of vesicle trafficking. Activation of Rho, Rac, and Cdc42 enhance secretion in mast cells, and conversely, their inhibition reduces secretion induced by different agents in these cells. Although it has been established that secretion is accompanied by Rho GTPase-dependent actin reorganization, it is not clear how each Rho GTPase specifically contributes to this process. Rho GTPases have also been shown to modulate endocytosis, and interestingly, two less-studied Rho family members, RhoB and RhoD, have been found to localize to endosomes, and RhoD has been shown to modulate endosome dynamics, fuelling the concept that these proteins may play an important role in endocytosis.

Proliferation and Transformation

Both Rho and Rac isoforms have been shown to be necessary for cell proliferation. Although Rho effectors are important for the actin ring contraction that drives cytokinesis, it is in the G_1 phase of the cell cycle where Rho GTPase function seems to be essential in cell cycle progression. Activation of both Rho and Rac have been linked to the activation of cyclin-dependent kinases through the expression of D-type cyclins and the inhibition of the expression of cyclin-dependent kinase inhibitors, such as $p21^{cip1}$ and $p27^{kip1}$. However, the downstream effectors that lie between Rho GTPases and cell cycle regulators remain completely unknown. Interestingly, Rho GTPases also contribute to cell transformation. Active mutants of Rho, Rac, and Cdc42 all have positive effects on cell transformation and anchorage-independent growth, although they are not considered to be true oncogenes when compared to mutant forms of Ras or Src, for example. However, their biological effects on cell proliferation and actin cytoskeleton place them as potentially important mediators of neoplastic transformation. For instance, their crucial role in cell motility has been shown to influence the loss of epithelial polarity and invasiveness of cancer cells.

Glossary

cell transformation A complex alteration of cellular behavior that is characteristic of cancer cells. It involves a reduction in the dependence on soluble mitogens and anchorage to the extracellular matrix in order for the cells to proliferate, together with loss of the ability to respond to growth-inhibitory signals both from the extracellular environment or arising from intracellular checkpoint controls.

cytoskeleton Filaments consisting of protein polymers that are responsible for giving the cell mechanical strength, controlling its shape and driving cell movement. Three types of filaments are found in animal cells: actin filaments, microtubules, and intermediate filaments.

leading edge The front of an actively migrating cell, which generally displays a fan-shaped meshwork of actin filaments that push forward the plasma membrane as they polymerize and grow.

small GTPases Monomeric GTP-binding proteins, as opposed to the transmembrane receptor-coupled family of heterotrimeric G proteins, that bind guanine nucleotides and have different conformations when bound to GTP or GDP. This enables them to act as molecular switches and transiently activate several effector proteins.

Biography

Priam Villalonga completed his M.Sc. in Pharmacy (Biochemistry) in the University of Barcelona, and then obtained his Ph.D. working on Ras signaling and cell cycle in the School of Medicine in Barcelona. He is now a postdoctoral fellow working on RhoE and its role in cell proliferation and transformation in Anne Ridley's laboratory in the Ludwig Institute for Cancer Research in London.

Anne Ridley studied biochemistry in Cambridge, then carried out her Ph.D. research in London, studying the role of Ras in cell transformation. She worked as a postdoctoral fellow in Cambridge, Massachusetts and then in London, investigating the functions of Rho and Rac proteins. She is now a Laboratory Leader at the Ludwig Institute for Cancer Research, studying the molecular basis for eukaryotic cell migration, concentrating on intracellular signaling processes involving the Rho family of GTPases.

Ribosome Assembly

John L. Woolford
Carnegie Mellon University, Pittsburgh, Pennsylvania, USA

The assembly of ribosomal proteins with rRNAs to form ribosomes is a major metabolic pathway in cells. Because ribosomes are central to the growth and proliferation of cells, many cellular functions have evolved to ensure a steady and regulated supply of ribosomes. Ribosomes consist of two ribonucleoprotein particles that catalyze protein synthesis through translation of the genetic code in mRNA. This is an essential step in the expression of genes in all organisms. The smaller (30S to 40S) subunit of the ribosome serves as a platform to bring together messenger RNA, aminoacylated transfer RNAs, and translation factors. The larger (50S to 60S) ribosomal subunit provides peptidyl transferase activity to catalyze peptide bond formation in nascent polypeptides.

Introduction

The 30S ribosomal subunit of prokaryotes and archaea contains ~20 different proteins (depending on the species), and a 16S ribosomal RNA (rRNA), while the 50S ribosomal subunit contains 30–40 proteins, a 5S rRNA, and a 23S rRNA. Eukaryote ribosomes are more complex. The 40S subunit contains ~32 proteins and the 18S rRNA, while the 60S subunit contains ~47 proteins and the 5S, 5.8S, and 25S (or 28S in metazoans) rRNAs. The structure and function of these ancient multimolecular machines have been explored in great detail. Each ribosomal subunit contains an intricate structural core of RNA decorated on its surface with the ribosomal proteins. A significant fraction of the nucleotides in the RNA contact ribosomal proteins or base pair with other sequences in the RNA.

How these multiple, dynamic protein–RNA, RNA–RNA, and protein–protein interactions are established and rearranged during the assembly of ribosomes is a central question in ribosome biology. In eukaryotes, ribosome assembly occurs primarily in the nucleolus, a subcompartment of the nucleus where the rDNA genes are actively transcribed. There are several major steps in ribosome assembly: synthesis, modification, and nucleolytic processing of the pre-rRNAs, ordered assembly of ribosomal proteins with the pre-rRNAs, and in eukaryotes, release of the nascent ribonucleoprotein particles from the nucleolus to the nucleoplasm, and subsequent export to the cytoplasm, where the mature ribosomes catalyze protein synthesis.

Model Systems

Much has been learned about ribosome biogenesis from studies of bacterial ribosome assembly *in vitro* and from analysis of yeast ribosome synthesis *in vivo*. Analysis of the nucleotide sequence of genomes from prokaryotic and eukaryotic model organisms demonstrates that ribosomes and the RNAs, and proteins necessary for their production are highly conserved. Thus, the principles and mechanisms of ribosome assembly learned from bacteria and yeast will be applicable to other organisms.

Assembly of Bacterial Ribosomes *in vitro*

Functional bacterial 30S and 50S ribosomal subunits can be reconstituted *in vitro* from rRNA plus each of the ribosomal proteins. These studies provide useful paradigms to understand the mechanism of assembly of ribosomes *in vivo*. For example, reconstitution studies defined an "assembly map" for the order of association of each ribosomal protein with rRNA (Figure 1). Ribosomal proteins can be divided into three obligatory binding classes. Primary binding proteins associate directly with the rRNA, often requiring or inducing changes in the conformation of the RNA. Secondary binding ribosomal proteins bind only after a primary protein has assembled and create a binding site for the next protein. Tertiary proteins assemble upon association of the primary and secondary proteins, to complete the pathway of assembly. Despite its hierarchical, interdependent nature, ribosome assembly is not completely cooperative. Three nucleation sites assemble independently to form three structurally separate domains of the 30S subunit: the body, platform, and head. The body assembles around the 5′ structural domain of 16S rRNA, the platform with the central domain, and the head around the 3′ major domain of

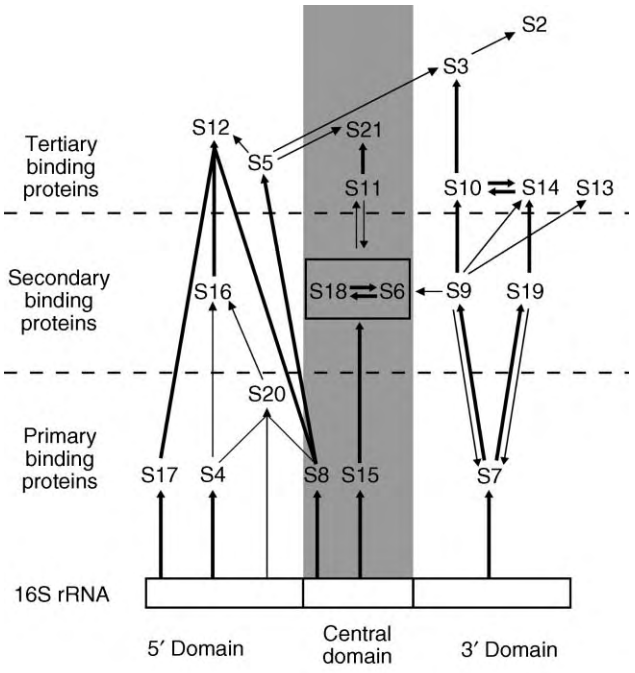

FIGURE 1 Assembly map for reconstitution of *E. coli* 30S ribosomal subunits from 16S rRNA and 20 ribosomal proteins. Each of the three structural domains of the 16S rRNA independently assembles with a subset of ribosomal proteins in a defined order. Primary ribosomal proteins bind first, then secondary proteins, and finally tertiary proteins. The thick or thin arrows represent the relative strength of binding or the relative facilitating effect on binding of one protein to another protein or to RNA.

16S rRNA (Figure 1). Each domain can be independently reconstituted *in vitro*. Formation of the central platform nicely illustrates details of assembly. First, the primary protein S15 binds to a particular conformer of the junction of rRNA helices 20, 21, and 22. Binding is stabilized by additional contacts between S15 and a tetraloop at the end of helix 23a, and by an interhelical RNA–RNA base pairing. The latter is required for binding of secondary proteins S6 and S18, which first form a heterodimer. Their association with the growing platform may establish a conformation of helix 23b, required for assembly of the tertiary binding protein S11. Bound S11 is further stabilized through interactions with S18.

Self-assembly of 30S ribosomal subunits *in vitro* suggests that extrinsic factors are not required to build a ribosome. However, several other results indicate otherwise. First, *in vitro* assembly is temperature dependent. At low temperatures, 16S rRNA binds to a subset of ribosomal proteins to form a 21S–26S assembly intermediate. Subsequent heating is required for conformational rearrangements to create an activated intermediate that can bind the remaining ribosomal proteins. The requirement for this heat-sensitive step can be circumvented by addition of the DnaK, DnaJ, and GrpE proteins plus ATP. This molecular chaperone system may recognize exposed hydrophobic surfaces of incompletely folded proteins or RNA in the assembling ribosome and either prevents misfolding and aggregation into nonproductive intermediates or promotes productive conformational changes. Second, a number of bacterial mutants have been identified that are deficient in production of ribosomes. Such mutants, including a *DnaK* mutant of *E. coli*, may be defective in assembly due to loss of function of a *trans*-acting assembly factor. As described below, a large number of *bona fide trans*-acting factors involved in ribosome biogenesis have been identified in eukaryotes.

Eukaryotic Ribosome Biogenesis *in vivo*

Synthesis, Modification, and Processing of rRNA

The 18S, 5.8S, and 25S/28S eukaryotic rRNAs are derived from a single 35S (47S in metazoans) transcript synthesized by RNA polymerase I (Figure 2). The 5S rRNA is transcribed from separate genes by RNA polymerase III. The genes for rRNA are tandemly repeated (100 to 10,000 copies – depending on the organism) at one or a few chromosomal loci. In yeast and a few other eukaryotes, the 5S and 35S genes are interspersed, comprising one repeat unit, although in most organisms the two classes of genes (5S and 35S/47S) are unlinked. The high copy number of these genes enables cells to produce large quantities of ribosomes when necessary, e.g., ~40 ribosomes per second in rapidly dividing yeast cells.

Immediately following transcription, the 35S pre-rRNA is covalently modified. In yeast cells, rRNA undergoes 2′-O-ribose methylation at 55 positions, pseudouridylation (rotation of a uridine) at 45 positions, and methylation of 12 bases. The sites of modification are located within conserved, functionally important domains of the mature rRNA. Although base methylations are catalyzed by individual proteins, most of the modification sites are identified and modified by a large collection of small nucleolar RNAs (snoRNAs). Each snoRNA contains sequences complementary to one of the modified rRNA sequences and thus functions as a "modification guide" to identify a potential target. The snoRNAs are associated with a small set of proteins, in small nucleolar ribonucleoprotein particles (snoRNPs). One class of snoRNP proteins is associated with the "C + D" class of snoRNAs responsible for methylation, and a different set of snoRNP proteins is present in the "H + ACA" snoRNPs catalyzing pseudouridylation.

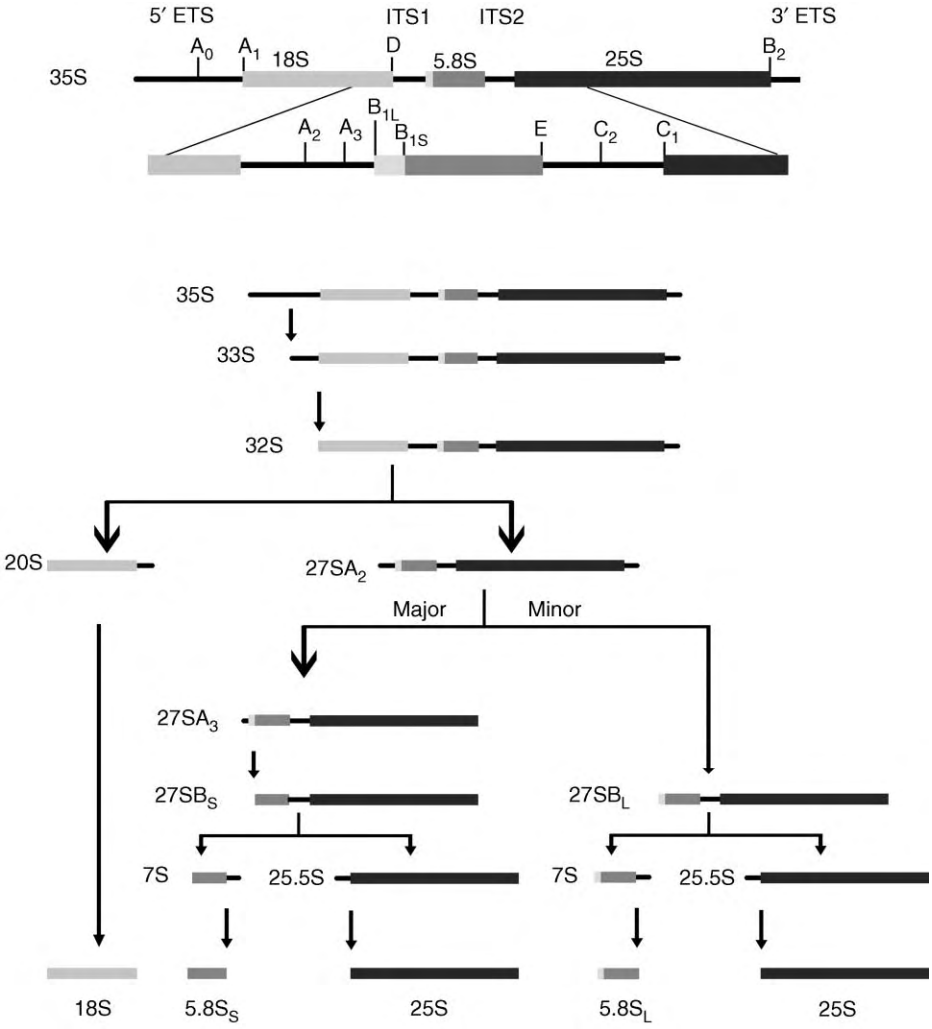

FIGURE 2 (A) Structure of the 35S pre-rRNA primary transcript. The external and internal transcribed spacers are indicated by thin lines, and the mature rRNA sequences by thick lines. Locations of the known processing sites are indicated. (B) Pathway of processing of 35S pre-rRNA to produce the mature 18S, 5.8S, and 25S rRNAs. Each pre-rRNA processing intermediate in the pathway is shown. The ordered set of processing steps is indicated.

Among these snoRNP proteins are the potential rRNA 2′-O-methyl transferase Nop1p and the putative pseudouridine synthase Cbf5p. Although snoRNPs associate with nascent rRNA, modification does not occur until transcription is completed. It is not clear what triggers these modifications, or how the snoRNPs are released from the assembly complex. Also, the function of the modifications is not known.

Eukaryotic rRNA precursors contain two internal transcribed spacers, ITS1 and ITS2 separating the 18S, 5.8S, and 25S/28S rRNA sequences, respectively. Additionally, there are 5′ and 3′ external transcribed spacers, 5′ETS and 3′ETS flanking the mature rRNA sequences (Figure 2). The predicted secondary structures of the mature rRNAs are highly conserved, although their lengths vary slightly among species. However, these features are somewhat less conserved for the transcribed spacer RNAs. The spacers are removed from the 35S–47S primary transcript to produce the three mature rRNAs by a series of conserved endonucleolytic and exonucleolytic processing steps (Figure 2). The secondary structures of the excised spacers are important for their removal. The pathways of rRNA processing appear to be quite similar among the best-studied eukaryotes – yeast, *Drosophila*, Xenopus, mouse, rat, and humans. However, certain ambiguities still exist concerning the precise locations of processing sites and whether sites are generated exo- or endonucleolytically (or by a combination).

In yeast, the first detectable precursor is the 35S pre-rRNA, which has already undergone cleavage by the Rnt1p endonuclease near the 5′ end of the 3′ ETS. The 5′ ETS of 35S pre-rRNA is then removed by rapid sequential endonucleolytic cleavages at the A_0 and A_1

sites to generate the 33S and 32S intermediates. The biosynthetic pathway then bifurcates upon cleavage at the A_2 site to generate the 20S and $27SA_2$ pre-rRNAs. The remainder of ITS1 is removed from the 20S pre-rRNA by processing at site D to generate the mature 18S rRNA. The $27SA_2$ pre-rRNA undergoes a more complex series of processing reactions to produce mature 5.8S and 25S rRNAs. The majority of $27SA_2$ is cleaved at site A_3 by the endonuclease activity of the MRP RNP, immediately followed by $5' \rightarrow 3'$ exonucleolytic trimming of $27SA_3$ to the B_{1S} site by Rat1p or Xrn1p exonucleases to generate $27SB_{1S}$. Alternatively, a small fraction of $27SA_2$ is processed to $27SB_{1L}$, by a mechanism yet to be determined. The two 27SB pre-rRNAs are endonucleolytically cleaved at the C_2 and perhaps C_2' sites, to create the 7S and 25.5S pre-rRNAs. The $3'$ end of 7S is removed by the exosome complex of $3' \rightarrow 5'$ exonucleases to generate the $5.8S_L$ and $5.8S_S$ rRNAs. The $5'$ end of the 25.5S pre-rRNA undergoes rapid $5' \rightarrow 3'$ trimming to the C_1 site by the Rat1p or Xrn1p exonucleases, generating mature 25S rRNA.

Endonucleolytic cleavage at the A_0, A_1, and A_2 sites requires the U3, U14, snR10, and snR30 snoRNPs as well as several individual proteins. Cleavage at A_0 requires base pairing between the U3 snoRNA and sequences in the $5'$ ETS ~140 nucleotides, $5'$ of the A_0 site. Likewise, base pairing between U14 snoRNA and rRNA is necessary for U14 function. The exact roles of these molecules are not known; no endonucleases have been identified that cleave the A_0, A_1, and A_2 sites. The interdependence observed for these three processing reactions may reflect a complex series of rearrangements of the architecture of the processing rRNA, mediated by the snoRNPs and protein factors.

Ribosome Assembly

Initial studies revealed a crude outline of the assembly pathway. 35S pre-rRNA is present in a 90S rRNP that is converted to 43S and 66S rRNP assembly intermediates. These precursor particles are then converted to the mature 40S and 60S ribosomal subunits, respectively (Figure 3). The 43S assembly intermediate contains the 20S pre-rRNA. There are at least six 66S assembly intermediates containing the $27SA_2$, $27SA_3$, $27SB_{1L}$, $27SB_{1S}$, 25.5S + 7S, and 25S + 5.8S rRNAs, respectively. Each of these rRNPs contains a subset of the ribosomal proteins found in mature subunits, plus a number of nonribosomal proteins not present in mature functioning ribosomes. More than 150 such *trans*-acting factors required for assembly of ribosomes have been identified in yeast, using genetic screens or selections to identify mutants defective in ribosome biogenesis or using proteomic approaches to purify and characterize assembly intermediates. Recently, metazoan counterparts of most of these proteins have been identified by mass spectrometry of proteins from purified nucleoli.

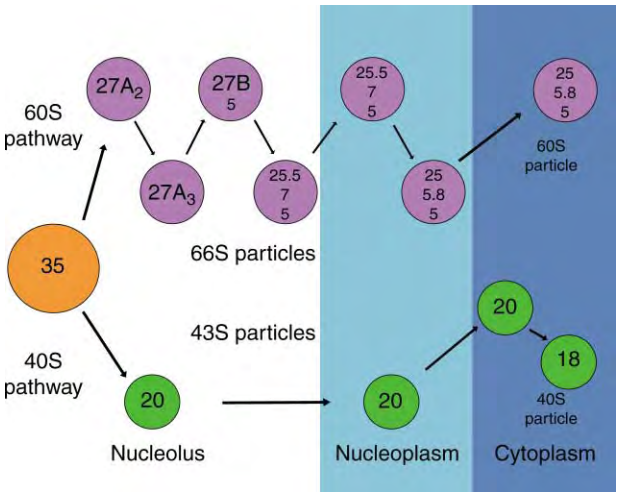

FIGURE 3 Pathway of ribosome assembly. The earliest ribosome precursor particle is the 90S rRNP, which is converted to 43S and 66S rRNP assembly intermediates. Each 66S rRNP intermediate contains a unique successive pre-rRNA processing intermediate. Most steps in assembly occur in the nucleolus. However, the 43S rRNP undergoes final maturation in the cytoplasm, and the 66S rRNP undergoes late maturation steps in the nucleoplasm and the cytoplasm. The pre-rRNA intermediates present within each rRNP are indicated.

The earliest defined step in ribosome assembly is association of the U3 snoRNP with the $5'$ ETS of the nascent 35S pre-rRNA. Electron microscopy of chromatin spreads reveals "terminal knobs" present near the $5'$ ends of nascent rRNA, which contain the U3 snoRNP. During or immediately after completion of transcription, 20–30 nonribosomal proteins plus the U14, snR10, and snR30 snoRNPs also associate with the 35S pre-rRNA. At the same time, a large number of ribosomal proteins destined for the 40S subunit, as well as a few destined for the 60S subunit, assemble into the nascent rRNP. Thus, upon termination of its transcription, the 35S rRNA is packaged into a rapidly changing, short-lived, and heterogeneous collection of RNPs ~90S in size. Cleavage at the A_0, A_1, and A_2 sites occurs within these rRNPs.

The 43S and 66S rRNPs are generated from the 90S rRNP by cleavage of the A_2 site. All but seven of the nonribosomal molecules present in the 90S rRNP are absent from the 43S rRNP or 66S rRNPs. The 43S pre-rRNP travels rapidly from the nucleolus through the nucleoplasm to the cytoplasm, where it undergoes final steps in maturation, including cleavage of 20S pre-rRNA at site D, to form the functional 40S subunit. Several of the ribosomal and nonribosomal proteins present in the 43S rRNP are required for this step, which is likely to involve the reconfiguration of the 20S pre-rRNA and the 43S rRNP into conformations favoring cleavage.

Late assembling ribosomal proteins associate with the 43S rRNP in the nucleoplasm and in the cytoplasm.

While most of the nonribosomal proteins necessary for production of 40S ribosomal subunits assemble with the 35S pre-rRNA in 90S rRNPs, only a few factors involved in 60S subunit biogenesis have been found in association with 35S pre-rRNA. The mechanism of transition from the 90S rRNPs to 66S rRNPs is less clear than that for the 43S rRNP. The first defined 66S rRNP contains $27SA_3$ pre-rRNA and several dozen nonribosomal proteins necessary for 60S subunit production. It is not clear whether these 60S assembly factors associate weakly with the 90S rRNP and therefore cannot be detected in the purified particle, or else assemble into early 66S complexes during or immediately after processing at the A_2 site.

What functions must occur to produce mature ribosomal subunits from the precursor particles and what kinds of molecules carry out these functions? Clues come not only from the paradigms of bacterial ribosome assembly *in vitro*, but also from functions suggested by the amino acid sequence motifs within the nonribosomal proteins implicated in assembly. For example, a number of nonribosomal proteins necessary for ribosome assembly contain RNA-binding motifs. Such proteins may function as RNA chaperones to help fold the pre-rRNA or to prevent misfolding. In addition to nucleases that catalyze rRNA processing, ribosome biogenesis requires cofactors necessary to remodel the rRNA and rRNPs into configurations necessary for the processing. Dynamic rearrangement of the nascent RNPs most likely also creates binding sites for the many ribosomal proteins (and nonribosomal proteins) added to the growing subunit. Such rearrangements must also enable dissociation of processing or assembly factors. Seventeen putative RNA-dependent helicases/ATPases, six potential GTPases, and an AAA-type ATPase are involved in production of ribosomal subunits. These RNA helicases are thought to catalyze winding or unwinding of RNA helices as well as rearrangement of protein conformations in the rRNP. As observed for the prototype GTPase translation factor G, the nucleotidases may also reconfigure the RNP. In addition, they have been hypothesized to serve as checkpoint or quality control factors, for successfully monitoring assembly of functional ribosomal precursors. The assembly factors Rlp7, Rlp24, and Mrt4p are ribosome-like proteins, close relatives of the ribosomal proteins, Rpl7, Rpl24, and RpP0, respectively. They may function as "stunt-doubles" to form or maintain a potential ribosomal protein assembly site. Alternatively, the exchange of such an Rlp protein with the corresponding ribosomal protein may provide another "structural proofreading" function in the assembly pathway. A number of potential scaffolding proteins are present in assembly intermediates; they may function as platforms for assembly of multimolecule-subassembly complexes. Several proteins associated with 90S, 66S, and 43S rRNPs are implicated in triggering release of 43S and 66S rRNPs from the nucleolus to the nucleoplasm. It is not known whether these proteins help make subunits competent for nucleolar exit by (1) serving as receptors or tags to "mark" subunits for exit, (2) reconfiguring the nascent subunits to expose such a tag, or (3) helping overcome mechanisms of retention in the nucleolus or nucleoplasm. Nuclear export of pre-60S RNPs involves binding of ribosomal protein rpL10 to the adaptor protein Nmd3p. Nmd3p binds to the export receptor Xpo1p/Crm1p which links ribosomes to Ran GTP and nuclear pore proteins. Likewise, 43S rRNPs require Ran GTP for export to the cytoplasm.

Integration of Ribosome Biogenesis with Cell Growth and Proliferation

Regulation of the biogenesis and function of ribosomes appears to play a critical role in mechanisms that couple cell growth and cell proliferation. However, few details are clear for how this occurs. A number of proteins necessary for ribosome assembly are also involved in cell growth and proliferation. These include not only nonribosomal proteins, but also ribosomal proteins. For example, several of the ribosome assembly factors interact with the origin recognition complex (ORC) and are required for DNA replication. Some are required for exit from Go and entry into the cell cycle, or for progression through other steps of the cell cycle. A recent screen for yeast mutants with abnormally small or large cell volumes identified 15 proteins, previously implicated in ribosome biogenesis. It will be of great interest to learn whether and how these molecules help couple growth and proliferation.

Another important question remaining to be explored is how ribosome synthesis is coupled with cell cycle progression. Cyclin-dependent kinases are thought to govern formation and maintenance of the nucleolus during the cell cycle. A number of protein phosphatases and protein kinases are localized to the nucleolus or copurify with ribosome assembly factors, but their functions in ribosome biogenesis remain to be explored.

Glossary

nucleolus Nuclear subcompartment of eukaryotic cells defined by the location of actively transcribing rDNA genes. Most, but not all steps of ribosome assembly occur in the nucleolus.

pre-rRNA rRNA primary transcript or processing intermediate; precursor to mature rRNA.

ribosomal protein Protein stably associated with mature, functional ribosomes.

rRNA RNA molecule present in mature, functional ribosomes.

rRNP Ribosomal ribonucleoprotein particle; ribosome assembly intermediate containing pre-rRNAs, ribosomal proteins, and nonribosomal proteins involved in assembly.

Biography

John Woolford is a Professor of Biological Sciences at Carnegie Mellon University in Pittsburgh, Pennsylvania. His principal research interests are in the regulation of expression of ribosomal protein genes and the mechanism of ribosome assembly. He holds a Ph.D. in biochemistry from Duke University and was a postdoctoral fellow at Brandeis University. His laboratory has made several important contributions towards the understanding of coordinate expression of ribosomal protein genes, and was one of the first groups to purify and characterize intermediates in the assembly of eukaryotic ribosomes.

Ribosome Structure

Brian T. Wimberly
Rib-X Pharmaceuticals, Inc., New Haven, Connecticut, USA

The ribosome is the large and complex polymerase responsible for translation, the synthesis of protein according to genetic instructions encoded in a mRNA template. Ribosomes make proteins by joining amino acids delivered by its substrates, the aminoacyl tRNAs. The most important activities of the ribosome are accurate substrate selection, catalysis of peptide bond formation, and movement of the substrate–template complex through the ribosome. Understanding and exploiting these activities will require determination of three-dimensional structures of this universal and uniquely complex macromolecular machine in its many different functional states.

Ribosome Function

Overview

In all organisms, template-directed protein synthesis is performed by the ribosome. The ribosome translates genetic information contained within its template, messenger RNA (mRNA), by joining amino acids carried by its substrate, transfer RNA (tRNA). The mRNA template is a linear sequence of non-overlapping three-nucleotide codons, each of which codes for a single amino acid to be added to the protein chain. There are 20 different tRNA substrates, one for each kind of amino acid. Each is a fairly large, L-shaped macromolecule with functionally important ends. One end, the 3′ CCA terminus, is the site of covalent attachment of the amino acid, while the other end features a three-nucleotide anticodon that forms base-pairing interactions with a complementary mRNA codon while in the ribosome. As the base-paired tRNA–mRNA complex passes through the ribosome, each tRNA adds its amino acid to the growing peptide chain. After passing through the ribosome, tRNAs dissociate from the mRNA template, since their triplet base-pairing interaction is only marginally stable.

The chemistry of peptide bond formation originally suggested that the ribosome should contain binding sites for mRNA and two tRNAs. In fact, the ribosome contains three distinct binding sites for substrate tRNAs, as well as a path for mRNA (Figure 1A). The three tRNA-binding sites are named after the distinguishing amino acid or peptide group attached to their resident tRNAs. The A site binds an incoming aminoacyl tRNA, which carries a single amino acid, the next to be added to the growing peptide chain. The P site contains the peptidyl tRNA, to which the nascent peptide chain is covalently attached. The E site contains an "empty" or exiting tRNA, which has already donated its amino acid to the growing chain and is therefore deacylated (not esterified by an amino acid or peptide). As translation proceeds, the tRNA–mRNA complex moves in concert through the ribosome, from right to left, while the growing peptide chain exits the ribosome through a separate tunnel.

Fundamental Activities of the Ribosome

All of the most important ribosomal functions are exemplified during the elongation cycle of translation. At the beginning of the cycle, a candidate aminoacyl tRNA binds to the A site. The ribosome then determines whether the candidate tRNA is a correct (or cognate) tRNA, or one of the more numerous incorrect (noncognate) tRNAs. This gate-keeping function, known as decoding, is crucial for maintaining the accuracy of translation. Decoding is a multistep process that requires testing the fit of the aminoacyl tRNA in the A site. Although not all of the details are known, it is clear that decoding depends on the ribosome's ability to monitor both the geometry and the affinity of the three base-pairing interactions between the aminoacyl tRNA anticodon and the A-site mRNA codon.

Once an incoming aminoacyl tRNA has been accepted in the A site, its amino acid must be added to the peptide chain attached to the P-site tRNA. Catalysis of the formation of the new peptide bond, known as peptidyl transfer, is the second fundamental ribosomal activity. The reaction occurs when the α-amino group of the A site amino acid attacks the C-terminal carbonyl of the growing peptide (Figure 1B). This results in the transient attachment of the now slightly longer peptide chain to the tRNA in the A site and the transient presence of a deacylated tRNA in the P site. Subsequent movement of the tRNA–mRNA complex relative to the

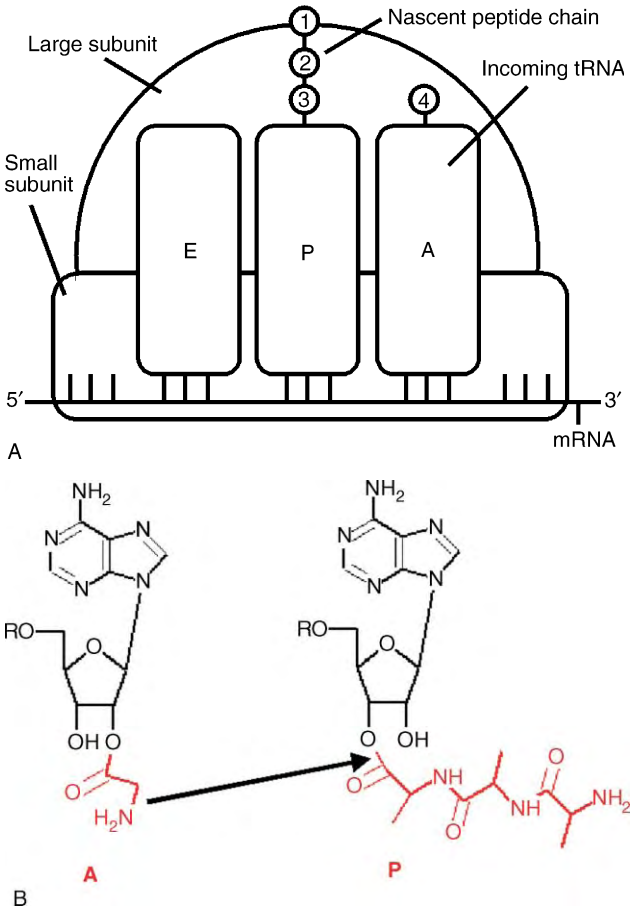

FIGURE 1 (A) Schematic view of a translating ribosome. Three amino acids (circles numbered 1–3) have already been joined to form the nascent peptide chain, whose C-terminal end is covalently attached to the tRNA (center rectangle) in the P site. The N-terminal end of the peptide is traversing a tunnel in the large ribosomal subunit. The next amino acid to be added (circle 4) is attached to an aminoacyl tRNA (right rectangle), which has just bound the ribosomal A site. A deacylated tRNA (left rectangle) is in the E site and will soon exit the ribosome. Vertical triplet bars represent codons in the mRNA, which base-pair to complementary anticodons in the tRNAs. The tRNA–mRNA complex moves through the ribosome from right to left, with each tRNA donating its covalently attached amino acid to the growing peptide chain as it passes through the peptidyltransferase site. See text for further details. (B) The chemistry of peptide bond formation. The 3′-terminal aminoacylated adenosine of an incoming aminoacyl tRNA in the A site (left) and the 3′-terminal peptidyl adenosine of the P-site tRNA (right) are shown at the moment of peptide bond formation. The peptidyl and aminoacyl moieties are highlighted in red. The N terminus of the A-site amino acid attacks the esterified C-terminal end of the peptidyl moiety. This reaction results in addition of a new amino acid to the peptide chain and transient attachment of the chain to the tRNA in the A site.

ribosome (from right to left in Figure 1A) restores a peptidyl tRNA in the P site and places a deacylated tRNA in the E site. This movement, known as translocation, is a third crucial ribosomal activity. The mechanism of translocation is still not well understood. It is thought to proceed in at least two steps, with movement of the tRNA CCA ends preceding movement of the anticodon ends. Because the tRNA substrates are so large, translocation requires large tRNA displacements of tens of Angstroms. Thus the ribosome is not only an enzyme; it is also a molecular machine.

The need for translocation also highlights an additional requirement seemingly at odds with the need for ligand movement. During translocation, the ribosome must prevent slippage of the tRNA substrates relative to the mRNA template. In other words, the reading frame must be maintained. Such a slippage, known as a frameshift event, results in the synthesis of an incorrect and usually prematurely terminated protein, which is usually detrimental to the organism. Because translocation must involve releasing and reforming of ribosome–ligand contacts, whereas maintaining the reading frame requires keeping such contacts, the structural basis of translocation is of particular interest.

This simplified summary of elongation neglects the important contributions of the nonribosomal protein elongation factors, which vastly accelerate translation rates and are essential for translation *in vivo*. Moreover, like other polymerization processes, translation also has distinct initiation and termination phases, each of which normally requires nonribosomal initiation and termination factors. Nevertheless, the fundamental ribosomal functions – decoding, peptidyltransferase, translocation, and maintenance of the reading frame – have been shown to be intrinsic to the ribosome itself.

Ribosome Structure

Distinguishing Structural Features of the Ribosome

Ribosomes have functions more complex than virtually any other enzyme, so it is not surprising that ribosomes have a unique and complex structure. The ribosome's most striking and distinguishing structural feature is its great size. The simplest ribosomes from bacteria have a mass of some 2.5 million Da, which is many times larger than a typical monomeric enzyme that catalyzes a reaction between small-molecule substrates. However, because the ribosomal substrates are themselves macromolecules – tRNAs have a mass of 25 kDa and measure some 75Å end to end – the size of the ribosome is, in fact, in normal proportion to the size of its substrates. When one considers that the ribosome must accommodate not one but three substrate tRNAs, as well as the mRNA template and large-scale movements of all of these ligands, the ribosome begins to look like a marvel of structural efficiency.

A second distinguishing feature of the ribosome is its unusual and complex composition. All ribosomes

consist of an RNA core and a large number of small proteins. Bacterial ribosomes, for example, are about two-thirds RNA by mass and contain approximately 50 different proteins, while ribosomes from eukaryotic organisms contain relatively more protein. It does not appear to be an accident that the ribosome is an RNA-based enzyme, whereas most other enzymes are made entirely of protein. After all, if proteins were made by a hypothetical ribosome composed entirely of protein, then it would be hard to imagine how this protein-only ribosome could have evolved. An RNA-based ribosome solves this "chicken-and-egg" problem, and jibes well with speculations about an "RNA world" preceding the existence of large proteins and DNA.

Subunit Organization and Nomenclature

All ribosomes consist of two loosely associated subunits of unequal size. In the well-studied bacterial ribosome, the larger subunit is denoted 50S, the smaller subunit 30S, and the entire ribosome 70S, according to their rates of sedimentation during ultracentrifugation. The bacterial small subunit RNA is the 16S RNA of approximately 1500 nucleotides, while the large subunit contains two RNAs, the 23S RNA (about 2900 residues) and the 5S RNA (about 120 residues). All eukaryotic cells contain both cytoplasmic and mitochondrial ribosomes; plants also have chloroplast ribosomes. The mitochondrial and chloroplast ribosomes are very similar to the bacterial ribosome, although the mitochondrial ribosome has a much smaller RNA component and an expanded number of proteins. The eukaryotic cytosolic ribosome is denoted 80S, with a 60S large subunit and a 40S small subunit. The RNA of the 40S subunit is the 18S RNA, and the large subunit RNAs are denoted 5S, 28S, and 5.8S (the last two of which are homologous to the bacterial 23S RNA). In all ribosomes, the large subunit interacts with the CCA end of the tRNAs and contains the active site that catalyzes peptide bond formation (the peptidyltransferase center). The small subunit binds the anticodon end of the tRNAs, both monitoring (during decoding) and maintaining (during translocation) the tRNA–mRNA base-pairing interactions. The ribosomal proteins are numbered and assigned to a subunit using a prefix of S (small) or L (large), so that individual proteins are denoted S1, S2, …, S21, L1, L2, and so forth.

Struggling with Ribosome Structure

The great size and complex composition of ribosomes have been enormous barriers to efforts to determine the structural basis of ribosome function. The ribosome is of an inconvenient size for structural biology: it has been until very recently too large for X-ray crystallography, but also rather too small for traditional electron microscopy (EM) methods. EM played a crucial role in the discovery and early structural characterization of ribosomes. However, negatively stained EM images were of very low resolution, allowing identification of only the largest structural features. During the 1970s and 1980s, many ingenious new genetic, biochemical, and biophysical methods were developed to probe ribosome structure, and an enormous amount of data was obtained. Combination of these data with EM-derived structures allowed the low-resolution assignment of a variety of functional sites. A complementary "divide and conquer" strategy to determine high-resolution structures of ribosomal fragments began to bear fruit in the 1980s and early 1990s, when a number of X-ray and NMR-derived structures of individual ribosomal proteins and ribosomal RNA fragments began to appear. Such data provided valuable insights into ribosome function and were useful guides for the design of new experiments, but it was not clear how such methods could ever result in a complete structure of a subunit, let alone the entire ribosome, at a resolution that would reveal the chemical basis of protein synthesis. However, in the mid-1990s, new techniques combining EM with single particle reconstruction revealed higher resolution images, including the first direct visualization of tRNAs and elongation factors bound between the ribosomal subunits. Ultimately, however, these new EM methods did not win the race to the long-sought goal of high resolution. In 2000, the first near-atomic resolution structures of ribosomal subunits were determined by X-ray crystallography methods, and in 2001 a medium-resolution crystal structure of the bacterial 70S ribosome was determined.

Why do we need to know the structure of the ribosome at high resolution? One motivation is the desire to determine the fundamental physical mechanisms of translation. Understanding exactly how ribosomes work will enrich and advance understanding of other aspects of biology in ways that are difficult to predict. Because the ribosome has many distinct functional states, a complete understanding of translational mechanisms will require many different structures – in other words, a "movie" of translation. Moreover, these structures must be of atomic or near-atomic resolution in order to identify the substrate–ribosome interactions that suggest mechanisms, and to direct additional experiments (for example, site-directed mutagenesis) to test these mechanistic hypotheses. The other reason to determine high-resolution ribosome structures is the more practical need to exploit fundamental knowledge

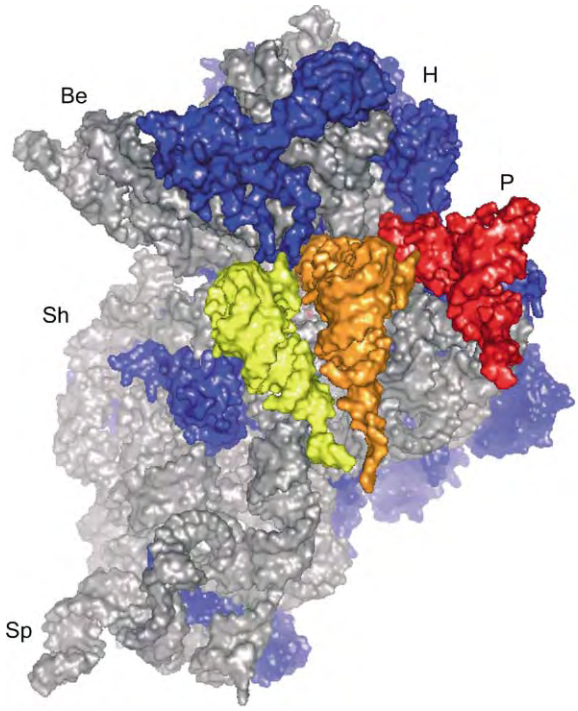

FIGURE 2 The high-resolution structure of the bacterial small ribosomal subunit, as determined by X-ray crystallography. The view is from the large subunit. Ribosomal RNA is gray, and ribosomal proteins are blue. Landmark features previously known from lower resolution methods are labeled: H (the head domain), Be (the beak), P (the platform), Sh (the shoulder), and Sp (the spur). The A-site (yellow), P-site (orange), and E-site (red) substrate tRNAs are also shown, in positions determined from the crystal structure of the entire bacterial 70S ribosome. The mRNA template (not visible in this view) is buried in the neck region, a crevice between the head, shoulder, and platform. Note the proximity of the CCA ends of the A- and P-site tRNA substrates (foreground), as required for peptide bond formation.

of biological mechanisms. Because the ribosome is the target of many clinically useful antibiotics, high-resolution ribosome structures will have a very practical use: structure-based design of improved new antibiotics that overcome the increasingly serious problem of antibiotic resistance mutations. It is also possible that a detailed structural understanding of human translation could be used to treat diseases caused by defects in normal human translation.

General Features of Ribosomal Architecture Revealed from the Subunit Structures

After more than 40 years of only low-resolution ribosome structures, the crystal structures of the large and small subunits, reported within a few months of each other in 2000, suddenly revealed almost all of the details of ribosomal architecture, as well as many fundamental new insights into the structural basis for translation mechanisms. Both its overall architecture and the composition of its functional centers reveal the ribosome to be essentially an RNA-based machine. The overall shape of both subunits is determined by the RNA component: only one of the landmark features visible at low resolution (the L7/L12 stalk) is composed only of protein (Figures 2 and 3). Moreover, the overall distribution of the proteins is not uniform: the proteins are concentrated on the back and sides of the subunits, away from the most functionally important regions at the subunit interface. The protein component is also concentrated on the surface, rather than buried in the middle of the subunits; the ribosome thus literally has an RNA core. Many of the proteins contain both a globular component on the periphery of the subunits, and one or more narrow extended peptide "tails" that penetrate deeply into crevices of the RNA core. Many of the proteins are found to interact with RNA multistem junctions and tight bends in the RNA, which suggests particular functional roles in subunit assembly. In the case of the 30S subunit, there are extensive biochemical data on the mechanisms of assembly, and an analysis of the crystal structure is in good overall agreement with these data. The subunit crystal structures have provided an enormous boost to the understanding of RNA–protein interactions, since relatively few

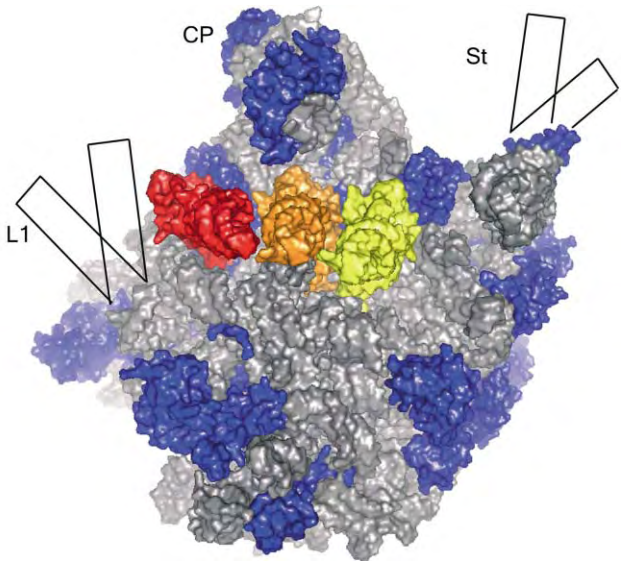

FIGURE 3 The high-resolution structure of the large ribosomal subunit from *Haloarcula marismortui*, as determined by X-ray crystallography. The view is from the small subunit, and the color scheme is as in Figure 2. The central protuberance (CP), a landmark feature previously known from lower resolution methods, is labeled. Two additional landmark features (the L1 arm and the L7/L12 stalk) are partially disordered in the crystal structure; their approximate locations and range of motions are schematically indicated. Substrate tRNAs are also shown, in positions determined from the crystal structure of the entire bacterial ribosome.

structures of RNA–protein complexes were available prior to 2000. Even less was known about RNA tertiary structure, and the subunit structures have revealed several new principles of RNA higher order structure. A common strategy for packing RNA helices makes use of patches of adenine residues, whose bases and 2′ OH moieties pack favorably against the minor groove of another RNA helix. Four different classes of this A-minor motif were defined, some of which had been previously observed in other structures. Another common RNA structural motif is the kink-turn, a tight bend that is often stabilized, although in various ways, by a bound protein. There is also a special role for G-U pairs in mediating some helix–helix packings. Analysis of the structures is continuing, and may lead to improvements in the prediction of RNA tertiary structure. The resolution of the *Haloarcula marismortui* 50S structure – at 2.4Å, significantly higher than any of the other subunit structures, and much higher than that of the 70S structures – allows reliable identification of metal ions and water molecules, which play important roles in stabilizing RNA structure. The relatively high resolution also allows the finer details of the conformation of RNA and protein to be determined. The *H. marismortui* 50S structure therefore serves as the "gold standard" for ongoing efforts to mine the recently vastly expanded RNA structure database.

There is one difference between the large-scale architectures of the 30S and 50S subunits that is probably functionally important. Whereas the secondary structure domains of the 23S rRNA interact closely to form a single, nearly hemispherical mass, the 16S rRNA secondary structure domains are for the most part independent globular entities – i.e., true three-dimensional domains – that have relatively few interactions with each other. One domain of the 16S rRNA constitutes the head, another the platform, and another the bulk of the body (Figure 2). This architecture suggests that independent movement of one or more of the domains (e.g., the head or platform domains, as has been observed in cryo-EM work) may be functionally important. For example, several groups had previously suggested that rotation of the head may accompany translocation; this hypothesis now seems probable.

High-Resolution Structure of the Small Subunit

The crystal structure of the 30S subunit from the thermophilic bacterium *Thermus thermophilus* has been determined at 3Å resolution (Figure 2). The refined structure includes virtually all of the 16S rRNA and almost all of the small subunit proteins, except for protein S1, which can be considered an initiation factor. The structure was determined in the absence of any explicitly added tRNA or mRNA ligands. However, the relatively high affinity of the 30S subunit for an RNA stem-loop in its P site resulted in a crystal packing arrangement that provides a high-resolution model for how the P-site tRNA and mRNA interact with the P site of 30S subunit. Helix 6, which constitutes the spur feature, was found to pack into the P site of a neighboring 30S subunit in a manner that mimics how the P-site tRNA anticodon stem-loop would bind. In addition, the hairpin loop of this helix was found to base-pair with a segment of single-stranded RNA – a mimic of the P-site mRNA. For several reasons, this model is only approximate, but it is nevertheless in good agreement with the lower resolution view of tRNA/mRNA–30S interactions seen in the 70S crystal structures from Noller and co-workers (see later discussion).

The 30S subunit plays a crucial role in decoding, by directly monitoring base-pairing interactions between the tRNA anticodon and the mRNA codon in the A site. The role of 30S in decoding has been investigated by determining several crystal structures with a cognate, near-cognate, or noncognate tRNA oligonucleotide analogues bound to the 30S subunit. In the presence of a cognate A-site tRNA anticodon stem-loop, several conformational changes occur in the 16S rRNA. First, Gua-530 and Ade-1492/Ade-1493 (*Escherichia coli* numbering) swing out and dock into the minor groove of the A-site codon-anticodon minihelix. Together with other conserved elements of the head (helix 34) and body (the 530 loop) previously implicated in decoding, these mobile 16S rRNA residues directly sense the "correctness" of the codon–anticodon interaction. Second, in the presence of a cognate tRNA substrate there is a more global conformational change, movement of the head and shoulder elements, resulting in a tightened grip on the A-site tRNA–mRNA helix. This larger scale conformational change from an open to a closed form has been proposed to be the signal for GTP hydrolysis by EF-Tu, the elongation factor that delivers the incoming candidate tRNAs to the A site.

Interestingly, binding of error-inducing antibiotics of the aminoglycoside family induces some of these conformational changes, such as the swinging out of A1492-3. These aminoglycosides were thus proposed to induce miscoding by stabilizing a conformation very similar to the "closed" form adopted during normal translation. Structures of the *Thermus thermophilus* 30S subunit bound to many other antibiotics (streptomycin, spectinomycin, tetracycline, hygromycin B, pactamycin, edeine) and two different initiation factors (IF-1 and IF-3) have also been reported.

High-Resolution Structures of the 50S Subunit

The structure of the 50S subunit from the halophilic archaeon *H. marismortui* was determined by Moore, Steitz, and co-workers. Despite the presence of many RNA insertions and an expanded protein repertoire, this archaeal 50S subunit is sufficiently similar to the *E. coli* subunit to allow exploitation of the vast literature describing the bacterial subunit. The 50S subunit features several protuberances, two of which are particularly disordered in the crystal structure (Figure 3). Both features are known to be functionally important. The L1 arm is thought to play a role in release of the E-site tRNA from the ribosome, while the L7/L12 stalk plays an important but poorly understood role in stimulating the GTPase activity of the elongation factors. A better understanding of how the 50S subunit interacts with these factors will come from studies on whole ribosomes. The 50S structure is more useful in understanding the nature of the peptidyl transferase activity. There is no protein at all within 18Å of the peptidyl transferase site, which was localized crystallographically by soaking in a transition-state analogue: definitive proof at last that the ribosome is an RNA enzyme, or ribozyme. This structural work and supporting biochemical data were also used to propose a mechanism for peptidyltransferase activity, with a catalytic role for nucleotide Ade-2486 (Ade-2451 in the *E. coli* numbering). However, subsequent genetic and biochemical experiments cast doubt on the proposed role of Ade-2486 as a general acid or base. More work is needed to nail down the details of the peptidyl transferase mechanism.

In 2001, a structure of the 50S subunit from the bacterium *Deinococcus radiodurans* was reported by Yonath, Franceschi, and co-workers at lower resolution. Most of the structural results are in good agreement with the *H. marismortui* structure. Interestingly, however, there are significant differences in the positioning of the L1 arm and in the conformation of RNA residues surrounding the peptidyltransferase center. The *D. radiodurans* 50S subunit structure has also been solved in the presence of five different antibiotics, four macrolides and chloramphenicol, at reported resolutions of 3.1–3.5Å. Structures of the *H. marismortui* 50S subunit bound to a variety of different antibiotics have also been reported. Such high-resolution structures of 50S–antibiotic complexes will be of great utility in the rational design of improved antibacterial drugs.

Medium-Resolution Structure of the 70S Ribosome

Structures of the *T. thermophilus* 70S ribosome with tRNA and mRNA ligands were reported by Noller, Cate, Yusupov, and colleagues in 2001, at resolutions as high as 5.5Å. This apparently rather modest resolution is in fact a phenomenal achievement, given the even greater biochemical and crystallographic difficulties of the 70S system. At this resolution, it is possible to trace RNA (but not protein) chains, albeit with errors in registry, if there are additional data to constrain the chain tracing. Once available, the high-resolution 30S structures were used to correct errors in the registry of the 16S rRNA trace and as a source for the structures of the small subunit proteins. Similarly, the high-resolution *H. marismortui* 50S structure was also invaluable for interpretation of the electron density for the large subunit in the 70S maps, although the many differences between the archaeal and eubacterial 50S subunits limited the extent to which the *T. thermophilus* 50S proteins could be built. The 70S crystal structures are largely complementary to the higher resolution subunit structures described previously. The 70S system is clearly more relevant for an understanding of the structure of the entire ribosome; thus, the 70S structures can be used to confirm the relevance of certain aspects of the higher resolution subunit structures. On the other hand, the 70S structures suffer from a lack of resolution. Thus, the high-resolution structures are of crucial importance in maximizing the utility of the 70S structures.

Comparison of the high-resolution subunit crystal structures with their structures in the context of the 70S particle reveals many small but significant differences, many of which can be ascribed to the effects of crystal packing in the "naked" high-resolution subunit structures. Some of the functionally important protein and RNA features that protrude from the 50S subunit, and that were partly disordered in one or both of the 50S structures, are found to be well ordered in the 70S structure by virtue of their interactions with the 30S subunit or tRNA ligands. Indeed, the most exciting aspects of the 70S structure are the identification of the 30S–50S contacts and the ribosome–tRNA contacts. The core of the 30S–50S contact region consists of RNA–RNA contacts, with a more peripheral ring of RNA–protein and protein–protein contacts. As with the overall architecture of each subunit, this RNA-based manner of subunit association once again emphasizes the overriding functional importance of the RNA component. Analysis of the tRNA–ribosome interactions is equally fascinating. The three tRNA substrates are intimately cradled by intersubunit bridges in the intersubunit space (Figure 4), in such a way that relative movement of the subunits, as seen in cryo-EM experiments, could effect translocation of the tRNAs.

Clearly, a more complete understanding of translational mechanisms will require more, and higher resolution, structures of distinct functional states of the

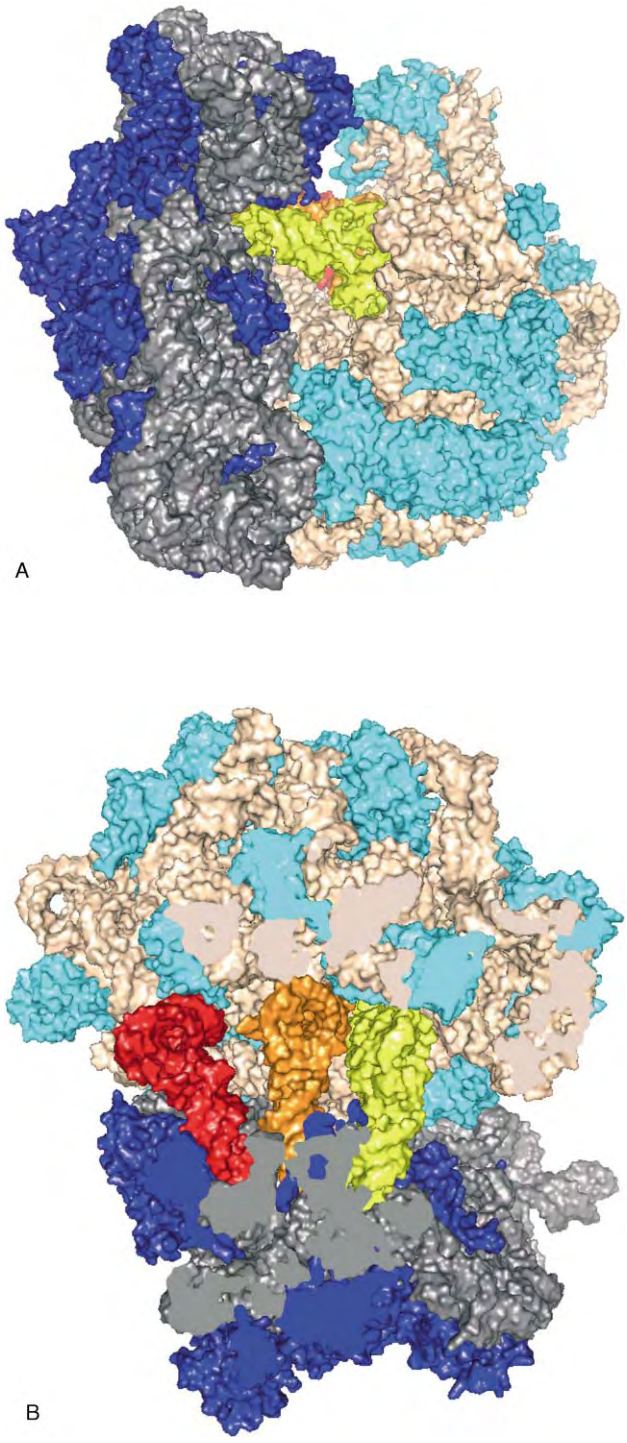

FIGURE 4 (A) The medium-resolution structure of the entire ribosome, as determined by X-ray crystallography. The view is from the A-site side, with the small subunit on the left and the large subunit on the right. For clarity, the small subunit RNA is gray, the small subunit proteins are blue, the large subunit RNA is salmon, and the large subunit proteins are light blue. The tRNAs (colored as in Figure 2) bind between the 50S and 30S subunits, with the tRNA anticodons base-paired with mRNA (not visible here), and the aminoacyl ends of the A- and P-site tRNAs are located in the peptidyltransferase site on the 50S subunit. (B) Cutaway view of the substrate tRNAs in the ribosome, with the color scheme as in A.

ribosome. Both X-ray crystallography and cryoelectron microscopy will be used toward these ends. Equally importantly, the structures now available are being used to design new genetic, biochemical, and kinetic experiments. Thus, this burst of structural information is by no means the end of the story; it is instead a new beginning.

Glossary

A site The ribosomal binding site for the incoming aminoacyl tRNA, whose covalently bound amino acid will be the next addition to the growing peptide chain.

decoding The multistep process in which the ribosome decides whether an incoming tRNA carrying the next amino acid to be added is correct or incorrect. If incorrect, the tRNA is rejected.

E site The ribosomal binding site for the exiting tRNA, which has already donated its amino acid to the peptide chain.

messenger RNA (mRNA) A transient RNA copy of the DNA instructions coding for the protein to be synthesized, hence the genetic template for protein synthesis on the ribosome.

peptidyltransfer The chemical reaction between the free amino group of an amino acid and the esterified carboxy terminus of a peptide, which results in the formation of a new peptide bond. The RNA-based ribosomal activity that catalyzes this reaction is referred to as peptidyltransferase.

P site The ribosomal binding site for the peptidyl tRNA, which is covalently attached to the growing peptide.

ribosome The macromolecular complex of several large RNAs and about 50 small proteins that performs translation.

translation The synthesis of protein, as determined by a messenger RNA template; it is catalyzed by ribosomes and ribosome-associated proteins, such as the initiation, elongation, and termination factors.

transfer RNA (tRNA) The substrate for the ribosome. One end of the L-shaped tRNA base pairs with mRNA, which allows ribosomal decoding, while the other end bears a covalently attached amino acid, which is added to the growing protein in the ribosome.

translocation The movement of tRNAs and associated mRNA through the ribosome, from A site to P site, and from P site to E site.

BIOGRAPHY

Brian T. Wimberly is Associate Director of Structure-Based Drug Design at Rib-X Pharmaceuticals, where he leads the X-ray crystallography part of the effort to discover new antibiotics active against bacterial ribosomes. He holds a Ph.D. from the University of California at Berkeley. During his postdoctoral training with Venki Ramakrishnan, he played a leading role in the determination of the high-resolution crystal structure of the bacterial 30S ribosomal subunit.

Ribozyme Mechanisms

John Hsieh and Carol A. Fierke
University of Michigan, Ann Arbor, Michigan, USA

RNA-catalyzed reactions are ubiquitous and important in many processes. RNA enzymes, or ribozymes, enhance chemical reaction rates using a variety of catalytic strategies, similar to those used by protein enzymes, to stabilize the transition state of the reaction. RNA and protein enzymes both use acid–base groups and metal ions to activate nucleophiles and to stabilize developing charge in the leaving group. Although limited by the ranges of functional groups and naturally occurring structure motifs, RNA enzymes can function as well as protein enzymes. The catalytic mechanisms of several well-characterized RNA enzymes, including ribonuclease P, *Tetrahymena* group I self-splicing intron and hammerhead ribozyme are discussed in detail.

Introduction

A class of naturally occurring RNA molecules, called ribozymes, enhance the speed and specificity of biologically important phosphodiester bond cleavage and peptide bond synthesis reactions, with rates that are increased by many orders of magnitude. Ribozymes have been discovered in all types of organisms from viruses to humans. Additionally, many new ribozymes that catalyze a broad range of chemical reactions have been identified in laboratory experiments called *in vitro* selection experiments. These observations have given credibility to the hypothesis of an ancient RNA World, where RNA initially served both as the genetic material and the principal cellular catalyst. During evolution, the catalytic functions of many RNA molecules were taken over by proteins. The remaining ribozymes catalyze essential biological reactions and often form complexes with proteins.

Today, many important biological processes in organisms from bacteria to humans are still carried out by RNA–protein (ribonucleoprotein, or RNP) complexes (Table I). These complexes vary greatly in size and function. For example, more than 40 protein and several RNA components are present in the ribosome, the protein synthesis machinery. Recently, the RNA components in the ribosome have been proposed to be the site responsible for catalytic activity. The spliceosome, which catalyzes the removal of noncoding sequences (introns) from pre-messenger RNA (pre-mRNA), consists of 30–100 proteins and several RNA species. Additionally, in most eukaryotes, the ends of chromosomes (the telomeres) are replicated by an enzyme called telomerase, in which an RNA subunit acts as a template, and a protein subunit catalyzes the synthesis of telomeric DNA. These examples demonstrate the importance of RNA catalysts in biology.

To understand the chemical repertoire and limitations of RNA-catalyzed reactions, this review will focus on several topics: the chemical structure of RNA, the folding of RNA molecules, and examples of the mechanism of specific ribozyme-catalyzed reactions.

Chemical Structure of RNA

Similar to DNA, RNA is made of repeating units of ribonucleotides. Each ribonucleotide consists of a five-carbon sugar in ring form (the ribose), a phosphate group, and a nitrogenous base (a pyrimidine or a purine). The same two purines, adenine (A) and guanine (G), are found in RNA and DNA. The two pyrimidines found in RNA are cytosine (C) and uracil (U); in DNA, thymine is incorporated instead of uracil. The polymer is formed by linking the monomer units via a phosphodiester bond between the 3′-hydroxyl group on one ribose unit and the 5′-phosphate group on its neighbor. Hence, the RNA polymer exhibits 5′ to 3′ directionality. The 2′-hydroxyl group on the ribose moiety of the ribonucleotide can react with the adjacent 3′-phosphodiester group to cleave the RNA polymer. This reaction is accelerated by the interaction of metal ions with the 2′-hydroxyl. The reactivity of the 2′-hydroxyl group is important for the activity of many catalytic RNAs but this moiety also makes RNA less stable in solution than DNA, which lacks a 2′-hydroxyl group.

Similar to DNA, the nucleotide bases of RNA can interact with complementary bases by hydrogen bonds. However, base pairing in RNA does not strictly obey the Watson–Crick base-pairing scheme observed in DNA, where A/T and G/C pairing occurs through hydrogen

TABLE I

Naturally Occurring Ribozymes

Ribozyme	Catalytic function	Biological function
Ribosome	Peptide bond formation	Protein synthesis
Ribonuclease P	Phosphodiester bond hydrolysis	Maturation of transfer RNA
Spliceosome Self-splicing group I and group II introns	Phosphodiester bond hydrolysis and ligation	Remove introns from precursor messenger RNA
Hairpin ribozyme Hammerhead HDV *Neurospora* Varkud Satellite	Phosphodiester bond hydrolysis	RNA virus replication pathway

bonding. In addition, since single-stranded RNA is more flexible than DNA, complementary RNA strands or different regions of the same strand can base-pair to form complex secondary and tertiary structures. This process is called RNA folding, and the stable compact structure of an RNA polymer is often referred to as its native structure. Because of the high density of negative charges when the RNA strands are brought into proximity with each other, the folding of RNA is accompanied by the binding of positively charged cations to prevent charge repulsion between the backbone phosphate ions. Therefore, RNA folding can be stimulated by the presence of cations (monovalent or divalent) as well as interactions with basic proteins. In many cases, divalent cations such as magnesium are strictly required for RNA to fold into a functional conformation; in a few cases, monovalent cations, such as potassium and ammonium ions, may make important contributions.

Catalytic Requirements of RNA and Protein Enzymes

In many aspects, protein and RNA enzymes face the same main challenge in catalysis: stabilizing the most unstable species formed during the chemical reaction, called the transition state. Like protein enzymes, RNA catalysis requires the formation of a specific tertiary structure and is sensitive to mutations in the RNA. Under optimized conditions, ribozymes can be as efficient as protein enzymes. For example, the hepatitis delta virus (HDV) ribozyme carries out phosphodiester bond cleavage ($10^2 - 10^4\ s^{-1}$) as fast as the protein enzyme RNase A ($1.4 \times 10^3\ s^{-1}$) at room temperature. However, catalysis by RNA enzymes differs from protein enzymes in several ways. First, since RNA contains only four unique nucleotide bases while proteins are composed of 20 different amino acids, RNA lacks the diverse functional groups characteristic of protein enzymes. This fact potentially limits the range of mechanisms that can be catalyzed by RNA. Nonetheless, small RNAs that can catalyze diverse chemical reactions have been selected in the laboratory from large pools of RNA molecules, in experiments termed *in vitro* selection. Second, the amino acid side chains are mainly located on the outside of protein secondary structures (α-helices or β-sheets) where they can form tertiary and quaternary contacts, while the chemical groups of the RNA bases are largely on the interior of base-paired duplexes. The third way that RNA and protein enzymes differ is that the proteins fold around a central hydrophobic core, whereas RNA usually folds by the packing of domains around a central conserved region. The high density of negative charges and the flexibility of the phosphate backbone of RNA could prevent RNA from forming stable active-site pockets. These differences affect how RNA and protein enzymes function.

The lack of diverse functional groups in RNA molecules and the propensity for RNA to bind metal ions led to the early hypotheses that all ribozymes require bound divalent metal ions to catalyze chemical reactions. However, small ribozymes, such as the hairpin and hammerhead ribozymes, can both fold and catalyze phosphodiester bond cleavage in the presence of monovalent ions (i.e., Na^+, Li^+, and NH_4^+) without any divalent cations. These small enzymes perform site-specific strand scission reactions using base-pairing and other interactions to align the cleavage site to the ribozyme active site. Current data indicate that cleavage reactions catalyzed by RNA enzymes use diverse mechanisms.

The examples of RNA enzymes described below are those whose catalytic mechanisms are among the best characterized. There are still many RNA reactions in which the catalytic mechanisms have not yet been elucidated.

Metalloribozymes

Ribonuclease P

Ribonuclease P (RNase P) catalyzes site-specific hydrolysis of precursor tRNA substrates to produce 5′-phosphate and 3′-hydroxyl end groups. This reaction is essential for the formation of mature tRNA required for protein translation. In bacteria, RNase P consists of one catalytically active RNA and one protein subunit. RNase P enzymes in eukaryotes contain multiple protein subunits. The bacterial RNA component alone is capable of catalyzing the cleavage of multiple substrate tRNAs in the presence of high salt. The protein

component is required for cleavage by RNase P *in vivo* and increases the catalytic efficiency *in vitro*. Evidence that RNase P is a metalloenzyme comes from several experimental observations. First, catalytic activity is observed only in the presence of divalent cations such as Mg^{2+} or Mn^{2+}, even though the RNA component forms a native-like structure in the absence of divalent cations. Second, the substitution of phosphate oxygen atoms with sulfur atoms at the phosphodiester bond that is cleaved in precursor tRNA leads to a significant decrease in catalytic activity in the presence of Mg^{2+}, which prefers to coordinate oxygen atoms. The decrease in the catalytic activity is less in the presence of Mn^{2+} or Cd^{2+} which can more readily coordinate the sulfur atom, suggesting that a metal ion may directly coordinate to the phosphate oxygen to enhance catalysis. These observations have led to a model for the RNase P catalyzed cleavage reaction (Figure 1A). In this model, a hydroxide ion, or metal-coordinated hydroxide, attacks the phosphate atom at the same time as the phosphate–oxygen bond begins to break. In the transition state, the phosphate atom has trigonal-bipyramidal geometry. This model is very similar to the catalytic mechanism of phosphoryl transfer reactions catalyzed by many protein enzymes. The essential metal ion(s) have been proposed to play multiple roles, including activation of the water nucleophile and stabilization of the developing negative charge in the transition state. The exact position and function of the catalytic metal ions in this reaction have not been completely elucidated.

Self-Splicing Introns

Introns are small segments of noncoding RNA that are interspersed among the regions of mRNA that code for protein. Prior to translation, these segments must be removed to form a mature mRNA. Certain intron sequences contain a common secondary structure core and use a common mechanism to catalyze excision of the RNA, termed self-splicing. This self-splicing reaction is a two-step transesterification reaction. In group I introns, self-splicing is initiated by nucleophilic attack of an exogenous molecule of guanosine. In a second type of reaction used by group II introns, the 2′-hydroxyl group of a specific adenosine within the intron acts as the nucleophile. Metal ions, Mg^{2+} and/or Mn^{2+}, are essential for the self-splicing reaction catalyzed by group I and II introns. A recent model for the transition state of the group I intron from *Tetrahymena*, based on kinetic assays of metal-dependent activity in introns containing single sulfur atom substitutions, suggests that up to three metal ions are catalytically important. In addition to promoting the formation of the correct active site structure, the catalytically important metal ions are proposed to correctly position the substrates with respect to the catalytic groups, activate the nucleophilic attack by deprotonating the 2′ hydroxyl group of the guanosine, and stabilize the developing negative charge in the transition state (Figure 1C).

Small Ribozymes that do not Require Divalent Metals

A number of small, virally encoded ribozymes have been identified, including the hammerhead, the hairpin, the HDV, and the *Neurospora* Varkud satellite (VS) ribozymes. These ribozymes are distinguished from each other by different secondary and tertiary structures. However, they all catalyze the nucleophilic attack of a 2′-hydroxyl on the neighboring 3′ phosphate to form a 2′–3′ cyclic phosphate (Figure 1B). Since this is not an irreversible reaction, these ribozymes are also observed to catalyze religation. This class of ribozymes retains significant catalytic activity with high concentrations of monovalent cations and no divalent cations, suggesting a mechanism that is different than that used by RNase P and self-splicing introns. In these ribozymes, the phosphoryl transfer reaction is proposed to be catalyzed by a general acid–base mechanism, similar to reactions catalyzed by protein RNases. The 2′-hydroxyl adjacent to the scissile phosphate is activated for nucleophilic attack by abstraction of a proton by a basic group. Concurrently, a proton is donated to stabilize the developing negative charge on the leaving group oxygen (Figure 1B).

Acid–base chemistry was not initially considered for RNA-catalyzed reactions, since there are no functional groups in ribonucleotides that can be protonated near neutral pH. In RNA, the pK_a values of the ring nitrogens of adenine and cytosine are between 3.5 and 4.1. However, in the folded RNA, the environment around the ionizing group can significantly alter the pK_a of a group. The first evidence of acid–base catalysis was observed in the HDV ribozyme when the catalytic activity of a mutant ribozyme could be partially rescued by the addition of exogenous imidazole, proposed to function as a general acid–base catalyst. A similar function has been proposed for a conserved and catalytically important guanosine of the hairpin ribozyme based on its proximity to the 2′ hydroxyl group near the scissile phosphodiester bond in the active site, as observed in the X-ray crystallographic studies. Therefore, general acid–base catalysis may be a common mechanism for RNA-mediated reactions. However, it is difficult to test this mechanism unambiguously since chemical modification or mutations of the nucleotides may perturb both chemical interactions and the structure of the RNA.

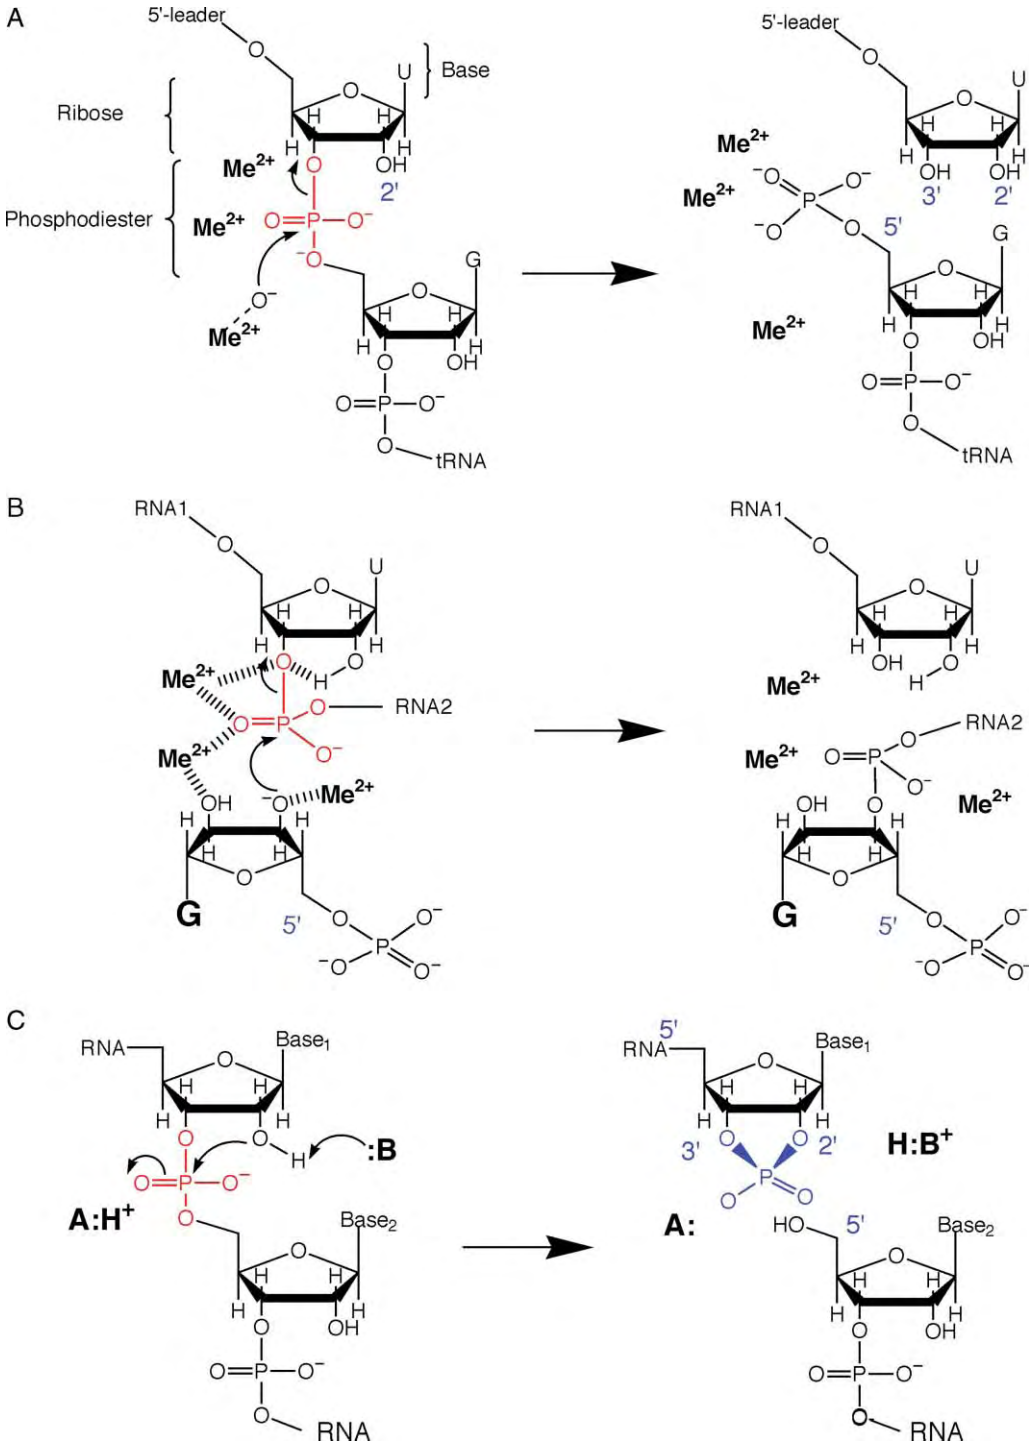

FIGURE 1 Models for ribozyme-catalyzed reactions. The phosphodiester bond is colored red. (A) Metal-mediated reaction catalyzed by RNase P. As many as four metal ions (Me) are proposed to enhance this reaction. One of the products has a 3′ hydroxyl group and the mature tRNA product contains a 5′ phosphate group. (B) General acid–base mechanism proposed for the reaction catalyzed by hammerhead or HDV ribozyme. The 2′-hydroxyl adjacent to the scissile phosphodiester is activated by a base (:B) for nucleophilic attack. Concurrently, a proton is donated to stabilize the developing negative charge on the leaving group oxygen. Note that one of the products is a 2′–3′ cyclic phosphate (in blue), and the other, a 5′ hydroxyl group. (C) Proposed metal-catalyzed mechanism for RNA cleavage catalyzed by the *Tetrahymena* group I intron.

Summary

RNA-catalyzed reactions are ubiquitous and important in many processes. Due to the limited range of functional groups and naturally occurring structure motifs, it is surprising that RNA enzymes can function as well as protein enzymes. The general catalytic strategies used by both biological catalysts appear to be similar; RNA and protein enzymes both use acid-base groups and metal ions to activate nucleophiles and to stabilize developing charge on the leaving group. Both types of enzymes use a variety of strategies to stabilize the transition state and thereby enhance the reaction rate.

Biography

John (Chang-tai) Hsieh holds a Ph.D. from Washington University in Saint Louis, and is a postdoctoral research fellow at the University of Michigan. His research interests have been in the catalytic properties of enzymes in nucleic acid metabolisms. With Dr. Fierke, his research focuses on the elucidation of the kinetic properties of the ribonuclease P.

Carol Ann Fierke received her Ph.D. from Brandeis University and was an NIH postdoctoral fellow at the Pennsylvania State University. She was appointed as an Assistant Professor of Biochemistry at Duke University Medical Center and was promoted to associate professor. She then moved to the University of Michigan, where she is appointed as the Jerome and Isabella Karle Collegiate Professor of Chemistry and Professor of Biological Chemistry. Her research focuses on mechanisms of biological catalysis in metalloenzymes and ribozymes.

Ribozyme Structural Elements: Group I Introns

Barbara L. Golden
Purdue University, West Lafayette, Indiana, USA

Many eukaryotic genes are interrupted by segments of DNA called intervening sequences or introns. These introns are transcribed into RNA along with the coding segments of gene, called exons. In most cases, the introns are removed from the RNA by a cellular apparatus called the spliceosome. In the presence of biologically relevant concentrations of magnesium and guanosine nucleoside, some introns, called group I introns, are capable of self-splicing: excising themselves from the flanking RNA, and religating the RNA exons to form a functional RNA. Group I introns are the relics of selfish genetic elements that carried with them genes encoding enzymes capable of integrating the entire genetic element into cellular DNA. The self-splicing activity of the RNA transcript allowed the element to have minimal impact upon the host gene. Group I introns are found within a diverse variety of genes including those encoding the energy transducing machinery in mitochondria, ribosomal RNAs, tRNAs, and phage genes. By appropriate engineering, a group I intron can be converted into a multiple turnover RNA enzyme, or ribozyme, capable of cleaving single-stranded RNA substrates. The catalytic activity of these molecules depends on accurate folding into a three-dimensional structure that precisely positions both functional groups on the RNA and divalent metal ions to catalyze a specific phosphotransesterification reaction.

The Self-Splicing Reaction

The self-splicing reaction of group I introns is accomplished by two sequential phosphotransesterification reactions (Figure 1A). In the first step of splicing, a guanosine nucleoside substrate (guanosine, GMP, GDP, or GTP) is bound by the intron and positioned for nucleophilic attack at the 5′ splice site. The 3′-OH of the guanosine attacks at the phosphorus of the 5′ splice site and displaces the 3′-OH of the 5′ exon. This reaction results in release of the 5′ exon, and covalent attachment of the guanosine molecule to the intron. In the second step of splicing (Figure 1A), a conserved guanosine at the 3′ end of the intron (called ωG) is positioned by the intron in a manner similar to binding of the exogenous guanosine substrate in the first step of splicing. In a reaction chemically analogous to the reverse of the first step of splicing, the 3′-OH of the 5′ exon displaces the 3′-OH of ωG from the phosphate at the 3′ splice site. Ligation of the 5′- and 3′ exons, and release of the intron results.

Secondary Structure

Structured RNAs, such as tRNAs, ribosomal RNAs, and ribozymes do not have extended linear structures; they are folded. While not completely double-stranded-like genomic DNA, they have short base-paired regions formed from self-complementary sequences within the primary structure of the RNA. Group I introns have a conserved secondary structure consisting of a series of double-stranded regions labeled P1–P9 (Figure 2). These helical regions are linked by "single-stranded," or joining, stretches of RNA labeled for the two helices that they connect (e.g., J8/7) and are capped by loops designated with an "L." While most joining and loop regions are not involved in forming Watson–Crick base pairs, they usually form well-defined structures, including base pairs. These helices, loops, and joining nucleotides are organized into three domains designated P1–P2, P3–P9, and P4–P6 (Figure 2).

The P1–P2 domain, or substrate domain, spans the 5′ end of the molecule and contains the 5′ splice site, which is located within the short helix P1. The final nucleotide in the 5′ exon is a uridine, which is base-paired to guanosine on the complementary RNA strand of the intron, forming a G·U wobble base pair. The P3–P9 domain immediately follows the P1–P2 domain in the primary structure of the intron. This domain contains the helix P7 that binds to an exogenous guanosine substrate in the first step of splicing, and to ωG in the second step of splicing. The P3–P9 domain also contains a single-stranded stretch of 5–6 nucleotides called J8/7 that is involved in binding and positioning the P1 helix, and thereby the 5′ splice site. The P3–P9 domain is interrupted by the P4–P6 domain. The P4–P6 domain folds together with the P3–P9 domain, to comprise most, if not all, of the catalytic core of the intron.

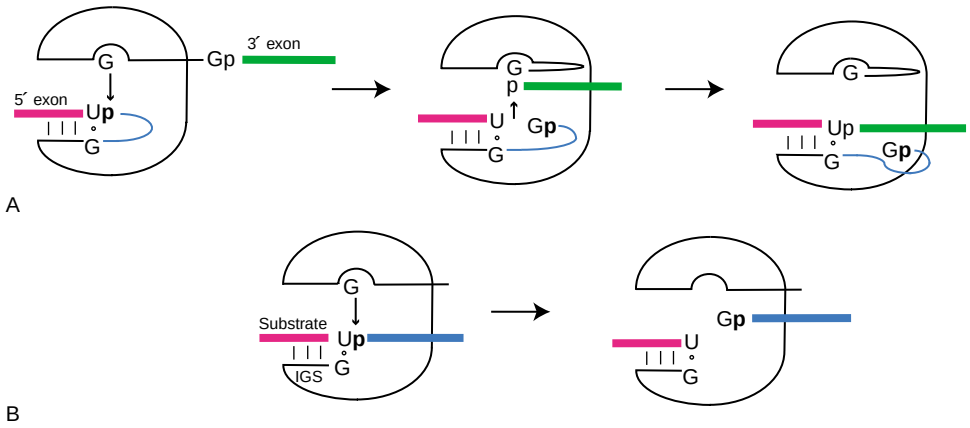

FIGURE 1 Reactions of group I intron RNAs. A. The self-spicing reaction is initiated by binding of a guanosine nucleoside. The 3′-OH of the nucleoside is activated for attack at the 5′ exon–intron junction. In the first step of splicing the guanosine becomes covalently attached to the intron, and the 5′ exon (pink) is cleaved from the intron (blue). In the second step of splicing, the 3′-OH of the 5′ exon attacks at the junction of the intron and the 3′ exon (green). This reaction links the 5′ and 3′ exons and releases the intron. B. The intron can be converted into a ribozyme capable of cleaving an RNA substrate using a guanosine nucleoside. The substrate RNA, like the 5′ exon in the self-splicing molecule, can base-pair to the 5′ end of the ribozyme that is called the IGS (G = guanosine, GMP, GDP, or GTP).

This domain also participates in splice-site recognition by binding the guanosine within the G·U wobble base pair at the 5′ splice site.

Tertiary Structure

The secondary structures in the intron fold in a magnesium-dependent manner to form a compact tertiary structure much like a globular protein enzyme (Figure 3). Formation of the folded structure is absolutely dependent on divalent metal ions, usually Mg (II), which serve to stabilize the structure by neutralizing the negative charges of the phosphate groups on the RNA backbone and by organizing the RNA into specific structures required for proper folding. In crystal structures of group I intron domains, magnesium ions are seen bound within the major groove, mediating the close approach of RNA helices, and stabilizing unusual conformations that allow the formation of intramolecular RNA–RNA contacts. Folding of the RNA creates binding sites for the P1 helix and the guanosine nucleotide cofactor described below.

The tertiary structure of group I introns has been investigated from two opposite directions. Fragments of group I introns have been crystallized to generate models of the three-dimensional structure. These studies have provided high-resolution structural information for one of the domains, medium-resolution structural information for a second domain, and no structural information for the third domain. Complementary work has been performed to elucidate contacts between individual atoms within the ribozyme as it approaches the transition state. These data can be put together to help elucidate the structural basis for group I intron catalysis.

The crystal structure of the P4–P6 domain of a group I intron reveals many of the strategies used by RNAs to form tertiary structures. Perfectly double-stranded helical RNAs do not tend to form stable tertiary structures. The structural information encoded by the RNA sequence is sequestered within the base pairs of a perfect helix, and the exposed, accessible surface is limited to the backbone and the shallow minor groove.

To facilitate tertiary structure formation, "flaws" in the helices are often present, containing base pairs other than the standard Watson–Crick A–U and G–C base pairs. These can readily form in between helices and, when present, they distort the major and minor grooves of the double-stranded helix to create distinct shapes and to expose hydrogen-bonding groups on the bases. This forms complementary surfaces that allow RNA domains to pack together. Loops, particularly four nucleotide sequences called tetraloops, which cap helices can also form distinct structures that mediate long-range tertiary interactions. These interactions are further stabilized by hydrogen bonds that can form between the 2′-OH groups of the ribose backbone. These tertiary structures are termed "ribose zippers."

Substrate Recognition

Group I introns have binding sites for two substrates: a guanosine nucleophile and a short duplex containing a G·U wobble base pair.

The Guanosine-Binding Site

The guanosine cofactor (in the ribozyme reaction and in the first step of splicing) and ωG (in the second step of

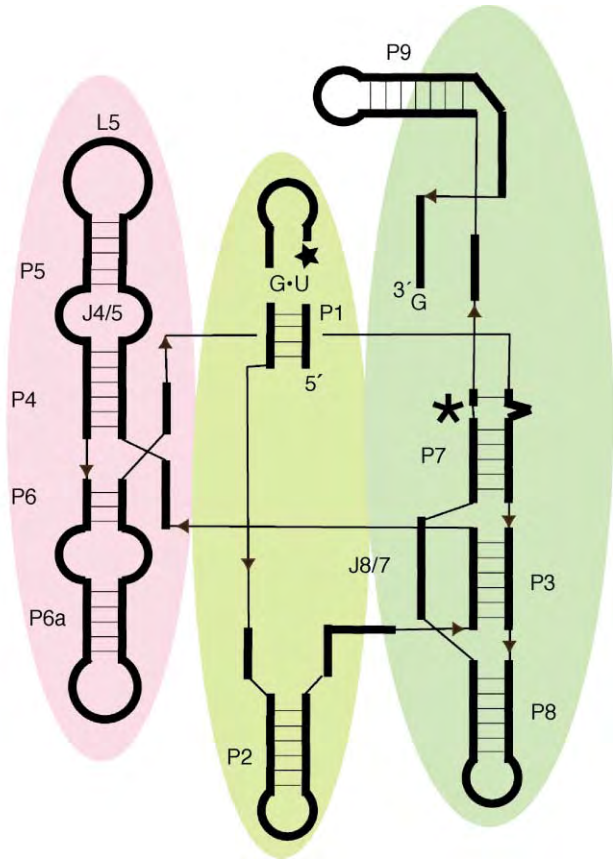

FIGURE 2 Secondary structure of a group I intron. The sequence of a group I intron folds into a secondary structure containing a series of base-paired regions called P1–P9. These short duplexes are linked by "single-stranded" nucleotides designated "J" and capped with loop sequences designated "L." These secondary structural elements are organized into three domains termed P1–P2, P3–P9, and P4–P6 that are shaded yellow, green, and pink, respectively. The P1 helix is formed by base pairing between the 5′ end of the ribozyme and the 5′ intron. Folding of the ribozyme brings the 5′ splice site (★) and the guanosine substrate binding site (∗) into proximity.

splicing) are recognized by a single guanosine-binding site located in the major groove of helix P7, a distorted double helix with a narrowed major groove. A G–C base pair near the "top" of the P7 helix provides significant specificity for the guanosine base. Recognition of the guanosine base can largely be described as a base triple. Additional orientation of the ribose group of the guanosine comes from magnesium ions bound at the intron's active site (Figure 4).

Helix P1 and 5′ Splice-Site Recognition

The 5′ splice site is recognized in the context of a short double-stranded region called P1. In self-splicing introns, helix P1 is formed by intramolecular base pairing between the 5′ exon and a complementary sequence near the 5′ end of the intron, creating a stem-loop structure (Figure 2). The helix is 3–6 bp in length, depending on the specific intron, and the final base pair is a G·U wobble pair composed of the last nucleotide in the 5′ exon, and a guanosine near the 5′ end of the intron. G·U wobble pairs, like A–U base pairs, contain two hydrogen bonds between the two bases (Figure 4), but the geometry of the pair is slightly altered compared to a Watson–Crick base pair: the guanosine base is pushed slightly into the minor groove and the uridine base is pushed slightly into the major groove. This base pair can be readily incorporated into an RNA double helix and is about as stable as an A–U base pair.

The intron may be converted into a ribozyme by splitting the P1 helix into two molecules (Figure 1). The first strand is formed from the very 5′ end of the ribozyme and is called an internal guide sequence (labeled IGS in Figure 1). The second strand serves as

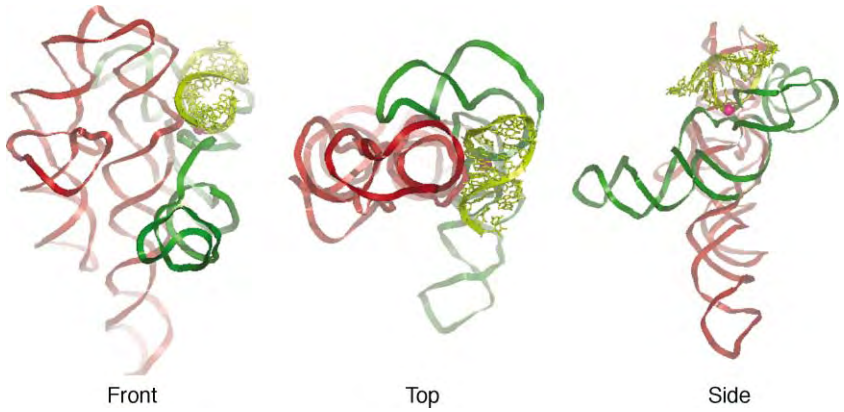

FIGURE 3 The three domains of a group I intron packed closely together to create an active site made of RNA. The model consists of the crystal structure an RNA spanning the P4–P6 (red) and P3–P9 (green) domains of a group I intron from *Tetrahymena* ribosomal RNA. Docked into the active site is a model of helix P1 that contains the 5′ splice site helix (yellow). The phosphorus atom at the 5′ splice site is drawn as a magenta sphere. The P1 helix is bound and positioned by cooperative action of the P4–P6 and P3–P9 domains.

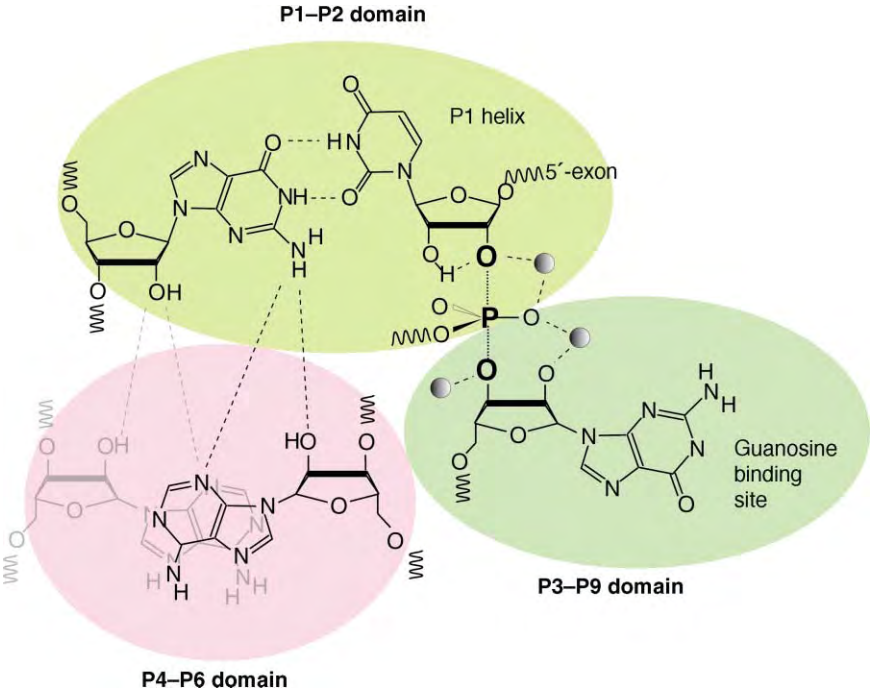

FIGURE 4 Interactions between the three domains in the transition state. Near the transition state for the ribozyme reaction, the bond between the 5′ exon and the intron is partially broken and the bond between the guanosine substrate and the intron is partially formed. Three magnesium ions help orient the substrates and stabilize the transition state, facilitating catalysis. The G·U wobble at the 5′ splice site is shaded yellow. The guanosine bound in the guanosine-binding site is shaded green. Adenosines within the P4–P6 domain involved in positioning the G·U wobble are shaded pink. Magnesium ions that participate in catalysis are drawn as spheres. Hydrogen bonds and metal interactions are indicated by dashed lines, and partial bonds are indicated by dotted lines.

a substrate for the ribozyme. It is complementary to the first strand, maintains the G·U wobble base pair, and extends for at least one nucleotide beyond the cleavage or splice site.

P1, whether composed of a hairpin in the self-splicing intron or composed of an intermolecular duplex in a ribozyme form, docks into the active site of the ribozyme. Docking is stabilized by interactions between the single-stranded region J8/7 and the minor groove of P1. These contacts are primarily hydrogen bonds to the ribose backbone and, therefore, are sequence independent. Except for the G·U wobble base pair, identity of base pairs within the P1 helix is not critical for recognition. Thus, by appropriate variation of the nucleotides in the IGS, almost any RNA substrate containing a uridine can be recognized and cleaved by a group I ribozyme.

The guanosine of the G·U wobble base pair is recognized by the J4/5 region of the P4–P6 domain. The J4/5 region contains tandem A·A non-Watson–Crick base pairs that interact with the exocyclic amine and the 2′-OH of the guanosine in the wobble pair (Figure 4). With the ribozyme "pinched" down upon the guanosine in the wobble pair, the phosphate that follows the uridine is placed in an optimal position to interact with the guanosine nucleophile and the intron's active site. The requirement for a G·U instead of a G–C Watson–Crick base pair at this position can be attributed to two characteristics of this special base pair. First, the exocyclic amine of the guanosine is displaced into the minor groove, allowing it to hydrogen bond to the J4/5 region. The exocyclic amine of a guanosine within a G–C base pair is involved in hydrogen bonding to the cytosine and is, therefore, sterically occluded from this interaction. Second, if the guanosine base in a G·U base pair is superposed on the guanosine G–C base pair, the position of the pyrimidine (U or C), and therefore the phosphate at the 3′ position, is quite different in the two structures. Displacement of the uridine towards the major groove as occurs in a wobble base pair is required to place the phosphate at the 5′ splice site into the active site of the intron.

In summary, group I introns may be thought of as RNA restriction endonucleases, capable of recognizing double-stranded RNA and specific for cleavage at G·U wobble base pairs. The catalytic activity of group I introns is dependent on proper folding of the RNA into a stable three-dimensional structure containing three domains. The three domains act cooperatively to position the 3′-OH of the guanosine nucleophile, the 5′ splice-site phosphate, and at least three magnesium

ions bound in the heart of the ribozyme (Figure 4), and thereby promote catalysis.

Ribozyme Structural Elements: Hairpin Ribozyme

Adrian R. Ferré-D'Amaré
Fred Hutchinson Cancer Research Center, Seattle, Washington, USA

The hairpin ribozyme is an RNA that catalyzes sequence-specific cleavage and ligation of the phosphate backbone of its RNA substrate. Two short irregular double helices, stems A and B, dock to form the active RNA. The scissile phosphate is in stem A. The reaction catalyzed by this RNA requires that the reactive groups adopt an in-line conformation. Prior to docking, the conformation of stem A is such that the reaction cannot take place. Docking of stems A and B results in a dramatic rearrangement that produces a reactive, in-line substrate conformation. Comparison of structures of the hairpin ribozyme in complex with a noncleavable substrate mimic, a transition-state mimic, and the cleavage products shows that the ribozyme has an active site with a rigid arrangement of purine bases that make more hydrogen bonds to the transition state than to the precursor or products, thus lowering the activation energy of the reaction. Because RNAs have less chemical diversity than proteins, catalytic strategies such as precise reactive group orientation and transition state stabilization are important for ribozyme function.

Biological Context

Four RNAs that catalyze RNA cleavage and ligation through transesterification have been identified from natural sources: the hammerhead, hairpin, hepatitis delta virus (HDV), and Varkud satellite (VS) ribozymes. In nature, all four function in the life cycle of satellite RNAs of viruses, or a replication intermediate of a plasmid (VS). In all cases, the ribozyme domain is part of a larger circular RNA that is replicated through a rolling-circle mechanism by host RNA polymerases. The linear concatamers produced by rolling-circle replication self-cleave into unit-length RNA molecules. These can then be ligated (either by the RNA itself or by a different catalyst) into circles. These circles, which are complementary in sequence to the infecting circular RNA, undergo an equivalent replication/self-cleavage/ligation cycle to produce copies of the original RNA.

The domain responsible for cleavage and ligation of the minus strand of the satellite of tobacco ringspot virus (-sTRSV) was mapped by deletion analysis. When synthesized *in vitro*, this RNA domain can act as a multiple turnover catalyst. This is the hairpin ribozyme. Because of its small size (constructs less than 60 nucleotides in length are active *in vitro*) the hairpin ribozyme has been amenable to extensive genetic, biochemical, and structural analysis, and constitutes one of the paradigms of catalytic RNA.

Primary and Secondary Structures

The minimal sequence elements required for hairpin ribozyme activity *in vitro* are contained in two helical segments, stems A and B (Figure 1). Each stem comprises a central portion of conserved nucleotides that engage in nonstandard base pairing or are unpaired (these are referred to as loops A and B in the older literature), flanked on both sides by canonical Watson-Crick base-paired duplexes. As long as base pairing is maintained, the sequences of these flanking duplexes can be varied arbitrarily.

One of the strands of stem A is the substrate RNA. As indicated in Figure 1, the cleavage site can be preceded by any nucleotide (position − 1), but must be followed (position + 1) by a G residue. Three other residues on the substrate strand are conserved at positions − 2, +2, and + 3. As long as these four nucleotides are present in the correct order in a substrate, a hairpin ribozyme can be engineered to cleave it by making the sequence of the Watson–Crick segments of the other strand of stem A complementary to the sequence of the target RNA.

Tertiary Structure

Stems A and B can be synthesized as separate molecules, and mixed to reconstitute activity in the test tube. The two stems associate with modest affinity to form the active species. In the biological RNA, stems A and B are connected to each other as part of a four-helix junction. The four-helix junction increases the

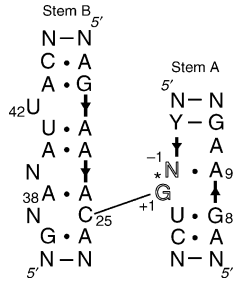

FIGURE 1 Schematic secondary structure of the core of the hairpin ribozyme. Two irregular double helices, stems A and B, dock to form the active ribozyme. One of the strands of stem A is the substrate, and carries the scissile phosphate (* , flanked by the two nucleotides shown in outline letters). Nucleotides whose identity is essential to function are identified in single letter code (A, C, G, U), those that can be varied freely without compromising activity, as N. Y denotes either pyrimidine. Thin lines denote Watson–Crick pairs, black circles, noncanonical pairs. Numbering is according to convention. Note the interhelical Watson–Crick base pair between G + 1 (in the substrate strand of stem A) and C25 (stem B).

local concentration of stems A and B and places the two stems in the optimal orientation relative to each other. Constructs that incorporate the junction are much more active *in vitro* than the two isolated stems, or even the two stems connected by a flexible linker. Four-helix junction constructs of the hairpin ribozyme bind two equivalents of divalent metal ions with high affinity and, upon metal ion binding, undergo a conformation rearrangement at the junction that brings the conserved, noncanonical segments of stems A and B into close spatial proximity.

The three-dimensional structure of a four-helix junction form of the hairpin ribozyme was determined by X-ray crystallography. Stems A and B were revealed to be highly irregular (with stem B particularly overwound), and to associate through their minor groove faces (Figure 2). The interhelical interface buries $\sim 1600 Å^2$ of solvent accessible surface area, implying that considerable binding energy is available from docking of the stems. The scissile phosphate lies at the interface of the two stems, surrounded by the purine bases of residues 8, 9, 10, and 38. These four nucleotides are all highly conserved (Figure 1) and have been shown by mutagenesis experiments to be essential for catalysis.

The structures of the isolated stems A and B were determined by nuclear magnetic resonance spectroscopy. Comparison of their free and docked structures shows that both stems undergo dramatic conformation rearrangements upon association. Only two out of nine noncanonical base pairs that constitute the core of the docked ribozyme are present in the free stems. Of particular importance is the extrusion of the base of G + 1 from the stem-A helical stack upon assembly of the ribozyme. As can be seen in Figure 2B, this base forms part of an interhelical pair in the docked

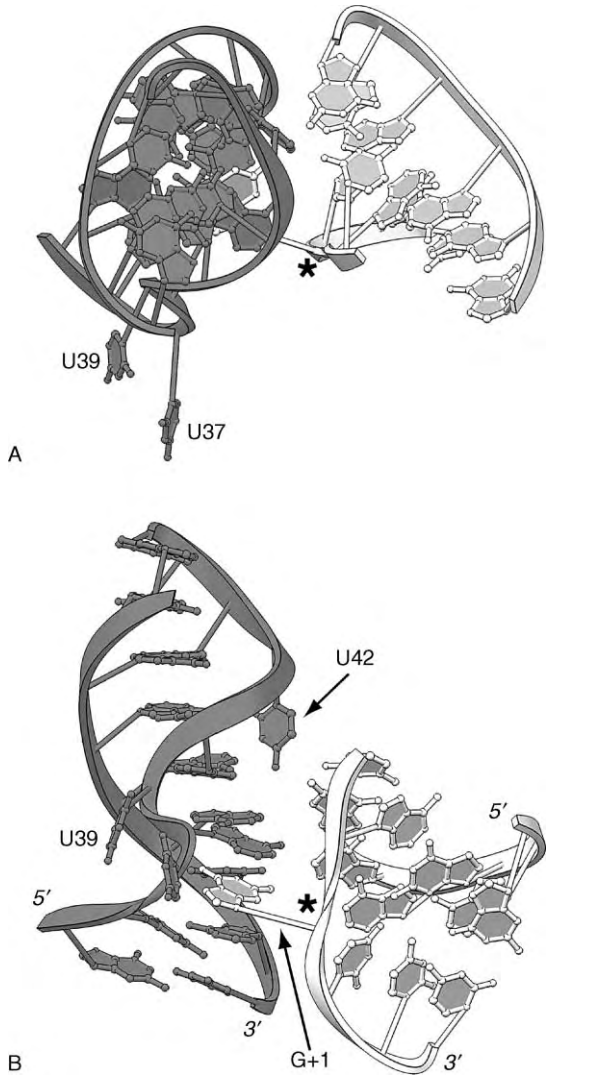

FIGURE 2 Simplified representation of the three-dimensional structure of the hairpin ribozyme. The RNA backbone is depicted as a ribbon; nucleotide bases are shown in ball-and-stick representation. Stem A is in white; stem B in dark gray. The position of the scissile phosphate is indicated byasterisk. Panel A is a view orthogonal to panel B. The scissile phosphate is buried in the interface of the two irregular helices.

ribozyme. G + 1 forms a Watson–Crick pair with C25 (from stem B; see also Figure 1).

The S_N2 (bimolecular nucleophilic substitution) reaction catalyzed by the hairpin ribozyme requires that the 2′-OH nucleophile and the 5′-oxo leaving groups be aligned with the phosphorus of the scissile phosphate. Prior to docking, the conformation of stem A is such that the reaction cannot take place. Extrusion of G + 1 from stem A concomitant with docking results in a reactive, in-line substrate conformation. The ribozyme uses the energy resulting from formation of the interhelical interface to properly orient its substrate.

Catalytic Mechanism

Although divalent metal ions are essential for activity of the hairpin ribozyme, biochemical and structural studies have shown that these ions play a structural role, rather than acting as cofactors in the active site. The hairpin ribozyme is active in a variety of divalent cations. The ribozyme is also active when the divalent cations are replaced by the complex ion cobalt (III) hexammine. The amine ligands that coordinate the cobalt in this complex do not exchange with solvent ions. While cobalt hexammine mimics hydrated magnesium ion (with its six water ligands), it is incapable of making direct metal to RNA interactions (inner sphere coordination), or to bind water and activate it to act as a base. Full activity of the hairpin ribozyme in cobalt hexammine implies that the RNA does not need to make direct coordination with its bound metal ions, nor does it use the cations as cofactors for generating hydroxyl ions. The crystal structure of the docked hairpin ribozyme shows the locations of several bound metal ions. These are in the narrow major groove of stem B, not in the wide minor groove where the active site lies.

Crystal structures have been determined of the hairpin ribozyme in complex with a noncleavable substrate mimic, a transition-state mimic (Figure 3), and the cleavage products. Comparison of these structures shows that the ribozyme has an active site with a rigid arrangement of purine bases that make more hydrogen bonds to the transition state than to the precursor or products, thus lowering the activation energy of the reaction. Although this has not been demonstrated directly, it appears that the pK_a of one of the active site adenosines (A38, Figure 3) is shifted towards neutral pH, resulting in protonation of its N1 imino nitrogen. The positive charge thus acquired by this active-site adenosine may also aid in catalysis.

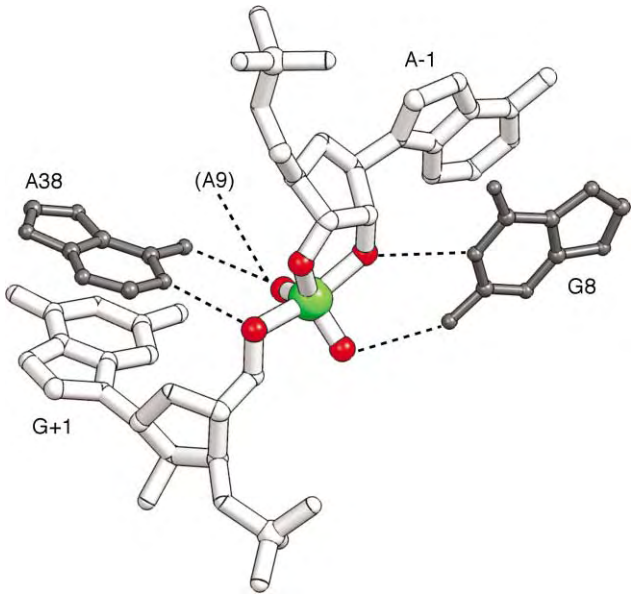

FIGURE 3 Structure of the active site of a transition-state mimic complex of the hairpin ribozyme. Vanadate (vanadium coordinated to five oxygens, three of which are provided by the RNA) mimics the trigonal bipyramidal coordination geometry of the scissile phosphate, which is pentavalent in the transition state. The vanadium atom is colored green, and the five oxygen atoms to which it coordinates are red.

Comparison with Other Ribozymes

Whereas protein enzymes can use 20 chemically varied amino acids to construct their active sites, ribozymes are limited to four nucleotides with limited functional group diversity. Studies on the group I intron, the first catalytic RNA discovered, demonstrated that this ribozyme overcomes the chemical limitations of RNA by recruiting multiple divalent cations into its active site. The group I intron uses these to orient reactive moieties, to activate water (to generate basic hydroxyl ions), and as sources of positive charge to stabilize negatively charged transition states. Early work on ribozymes assumed that RNA catalysts would always use cations as active-site cofactors.

We now know that ribozyme mechanisms can be more varied. Although isolated nucleotides do not have functional groups with near-physiologic pK_a, intricately folded RNA structures are capable of perturbing the acidities of purine and pyrimidine bases. For instance, the HDV ribozyme uses a cytosine whose pK_a is shifted from 4.2 to ~7 as a general acid catalyst (analogous to His119 in RNase A, a protein enzyme that catalyzes the same transesterification reaction as the hairpin ribozyme; see Figure 4). The hairpin ribozyme demonstrates

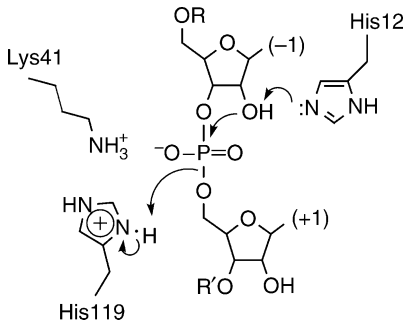

FIGURE 4 Catalytic mechanism of ribonuclease A. Histidine is particularly well suited to act as a general acid–base catalyst because its p*Ka* is close to physiologic pH. In RNase A, histidines 12 and 119 act as general base and acid, deprotonating the nucleophile and protonating the leaving group of the transesterification, respectively. Deprotonation of the 2′-OH makes it a better nucleophile, and protonation of the 5′-oxo leaving group lowers the energy of the product state. Lysine 41 (which has a positively charged side chain at physiologic pH) counteracts the increased negative charge at the scissile phosphate during the transition state, and thus helps lower the activation energy of the reaction.

another way in which a catalytic RNA can achieve catalysis: selective hydrogen bonding to one state of the reaction. Nucleotide bases are well suited for hydrogen bonding, and the ribozyme provides a rigid structure to orient them precisely. It appears that the ribosome also achieves catalyses (protein synthesis in this case) by precise orientation of functional groups, rather than general acid-base catalysis.

His principal research interests are in RNA catalysis and RNA–protein interactions. He received his Ph.D. from the Rockefeller University, and was a postdoctoral fellow at Yale University. He has developed procedures that facilitate the crystallization of RNA, and his laboratory was the first to obtain crystallographic "snapshots" of a catalytic RNA as it carries out its reaction.

Ribozymes and Evolution

Niles Lehman
Portland State University, Portland, Oregon, USA

Ribozymes, also known as ribonucleic acid (RNA) enzymes, have been known since the early 1980s when it was first discovered that RNA could catalyze chemical reactions. Previously it had been thought that all enzymes were proteins, but it is now clear that RNA-directed catalysis plays many important cellular functions, and that numerous ribozymes can be found in organisms spanning the tree of life. Notably, for example, we now realize that the catalytic core of the ribosome itself, the cellular machinery for protein synthesis, consists of RNA such that peptide-bond formation is catalyzed by ribosomal RNA. These findings suggest strongly that RNA, or some RNA-like molecule, was an integral piece of the earliest biochemical processes to evolve on the Earth. In 1986 Walter Gilbert coined the phrase "RNA World" to invoke a time during the coalescence of life when RNA was responsible for most if not all of the genetic transformations of the planet's first organisms. Ribozymes have thus played an important role in biological evolution and have recently been used to perform evolution experiments in the laboratory.

RNA

RNA is a polymer of ribonucleotides. RNA differs from DNA in three basic respects. First, RNA employs uracil as a nitrogenous base, in place of the thymine used in DNA. Second, RNA nucleotides possess a hydroxyl group at the 2′ position, while DNA is deoxygenated at that position to a proton. And third, RNA is more often found single stranded than DNA, which is typically completely base paired into a double helix. All three of these features help engender RNA with catalytic capabilities, although they also tend to make RNA chains less chemically stable than DNA. From an informational point of view, both DNA and RNA have the capability to store and transmit biological information through complementary base paring: C with G, and T(U) with A.

Catalytic RNA

RNA as an Enzyme

Enzymes are molecules that can catalyze a chemical reaction by lowering the activation energy needed to transit from reactants to products. Proteins, built up from amino acids of twenty or more varieties, are well known to perform catalysis in biological systems. RNA is built up from only four nucleotide varieties but still can perform catalysis. Similar to protein-directed catalysis, the basis for this is the acquisition of a three-dimensional structure that contains a catalytic pocket. Many ribozymes can speed up the rate of reaction 10^3- to 10^{11}-fold over the corresponding uncatalyzed rate, and can behave as true enzymes by "turning over," catalyzing more than one reaction event.

Chemistry

In the catalytic pocket, RNA usually relies on metal-ion coordination and one or more chemical strategies to accomplish catalysis. In some cases, the 2-hydroxy group itself can serve as a nucleophile to attack a chemical bond in the substrate molecule. In other cases, the chemical moieties on the nitrogenous bases (adenine, guanine, uracil, or cytosine) can act as acids or bases to stimulate a reaction. For example, it is now thought that peptide-bond formation in the heart of the ribosome is promoted by some type of interaction between amino acids and a phylogenetically invariant adenosine residue in the ribosomal RNA. In most cases, RNA must bind divalent metals such as magnesium to help properly position the substrate molecules in order to stabilize the transition state.

Classes of Natural Ribozymes

Since 1982, several types of naturally occurring ribozymes have been discovered (Figure 1). With the notable exception of the ribosome, these ribozymes are generally limited in their capacity to making and/or breaking phosphoester bonds that hold nucleic acids together. In addition to the list below, RNA plays an important role in the catalytic events promoted by ribonucleoproteins such as telomerases, spliceosomes, and editosomes. Other natural ribozyme will undoubtedly be discovered in the near future.

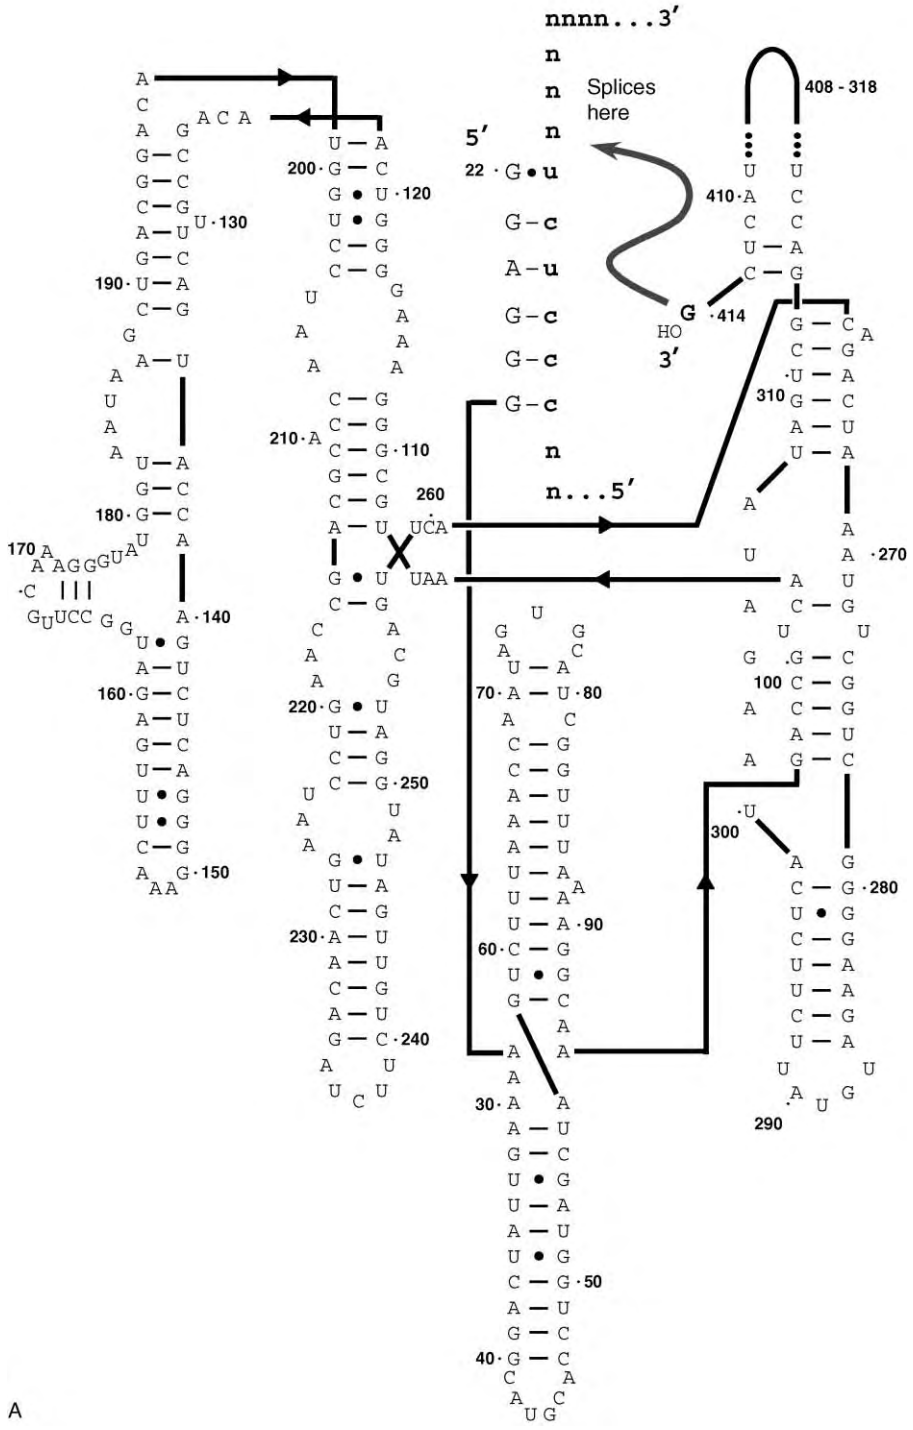

FIGURE 1 Some known ribozymes. (A) The group I intron from the ciliate *Tetrahymena thermophila*. Shown is the shortened version of the natural rRNA intron; this 414 nucleotide ribozyme binds a complementary RNA substrate (lower case letters) via complementary base pairing and catalyzes phosphoester bond cleavage and ligation reactions at the site indicated by the arrow. (B) One possible hammerhead ribozyme. This ribozyme self-cleaves at the site indicated by the arrow.

Group I and Group II Introns

These are large (>200 nucleotides) self-splicing introns: rRNA or tRNA introns that excise themselves from nascent RNA transcripts via ribozyme activity.

RNase P

RNase P is a large ribozyme that allows maturation of nascent tRNA transcripts and a few other small RNAs by removing the 5′-leader portion of those transcripts.

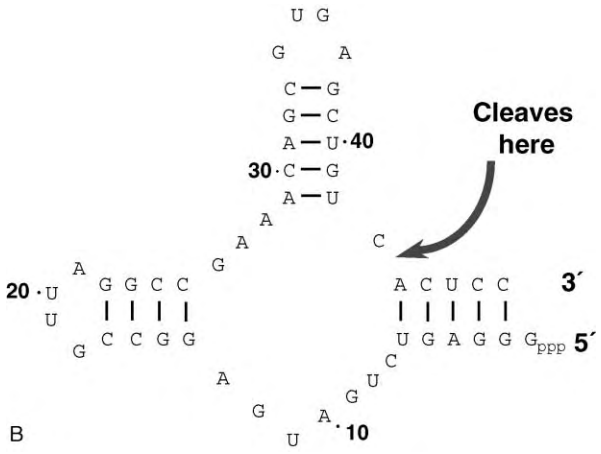

FIGURE 1 (*continued*)

Hammerhead

These small ribozymes, of which there are many throughout nature, possess three base-paired stems and catalyze self cleavage of a RNA phosphodiester bond.

Hairpin

Like the hammerheads, hairpin ribozymes, originally found in a tobacco RNA virus, self-cleave an RNA bond, but unlike the hammerheads, consist of four stems in two general domains.

Hepatitis Delta Virus

The HDV ribozyme is another viral-derived small ribozyme that catalyzes RNA bond cleavage, but it is slightly more complex, having a "pseudoknot" folded structure.

VS

The VS motif is another small self-cleaving ribozyme, found first in a satellite plasmid of *Neurospora* mitochondria. This ribozyme, as is the case for all RNA enzymes, can also catalyze the reverse reaction, which here would be ligation of two RNA strands.

Unnatural Ribozymes

Using the techniques of SELEX, *in vitro* selection, and *in vitro* evolution, many novel catalytic RNA sequences have been discovered (Figure 2), many of which promote chemistries not yet seen in natural ribozymes. The existence of these ribozymes demonstrates not only that RNA has a wide repertoire of catalytic capabilities, but that evolutionary forces are quite adept at molding RNA-based catalysis.

Ligase Ribozymes

Isolated from random pools of RNA sequences, the ligase ribozymes were one of the first type of unnatural ribozymes to be fashioned. These RNAs catalyze phosphoester-bond formation between themselves and an exogenous oligoribonucleotide. Several classes of ligase ribozymes exist, with differing RNA folds. Ligases catalyze bond formation by a chemistry that is distinct from that of known natural ribozymes, but which is remarkably similar to the chemistry used by the protein enzyme RNA polymerase. In fact some ligases can be engineered to behave as rudimentary RNA polymerases.

Diels-Alderase Ribozymes

To move from phosphoester chemistry to carbon–carbon bond chemistry, it was necessary to derivatize one of the four bases, uridine, with a pyridyl moiety. This allowed the selection *in vitro* of a Cu^{2+}-dependent ribozyme that could catalyze a Diels-Alder cycloaddition reaction.

Three- and Two-Base Ribozymes

Recently ribozymes have been selected that use only three (i.e., A, G, and U) nucleotides to perform catalysis. Also, if only U and 2,6-diaminopurine are available, a 2-base ligase ribozyme can be constructed through *in vitro* evolution.

Other Unnatural Ribozymes

Many other unnatural ribozymes exist and more are being constructed. These ribozymes can catalyze amide bond formation, N-alkylation, porphyrin metallation, thioester bond formation, and a host of other chemical reactions.

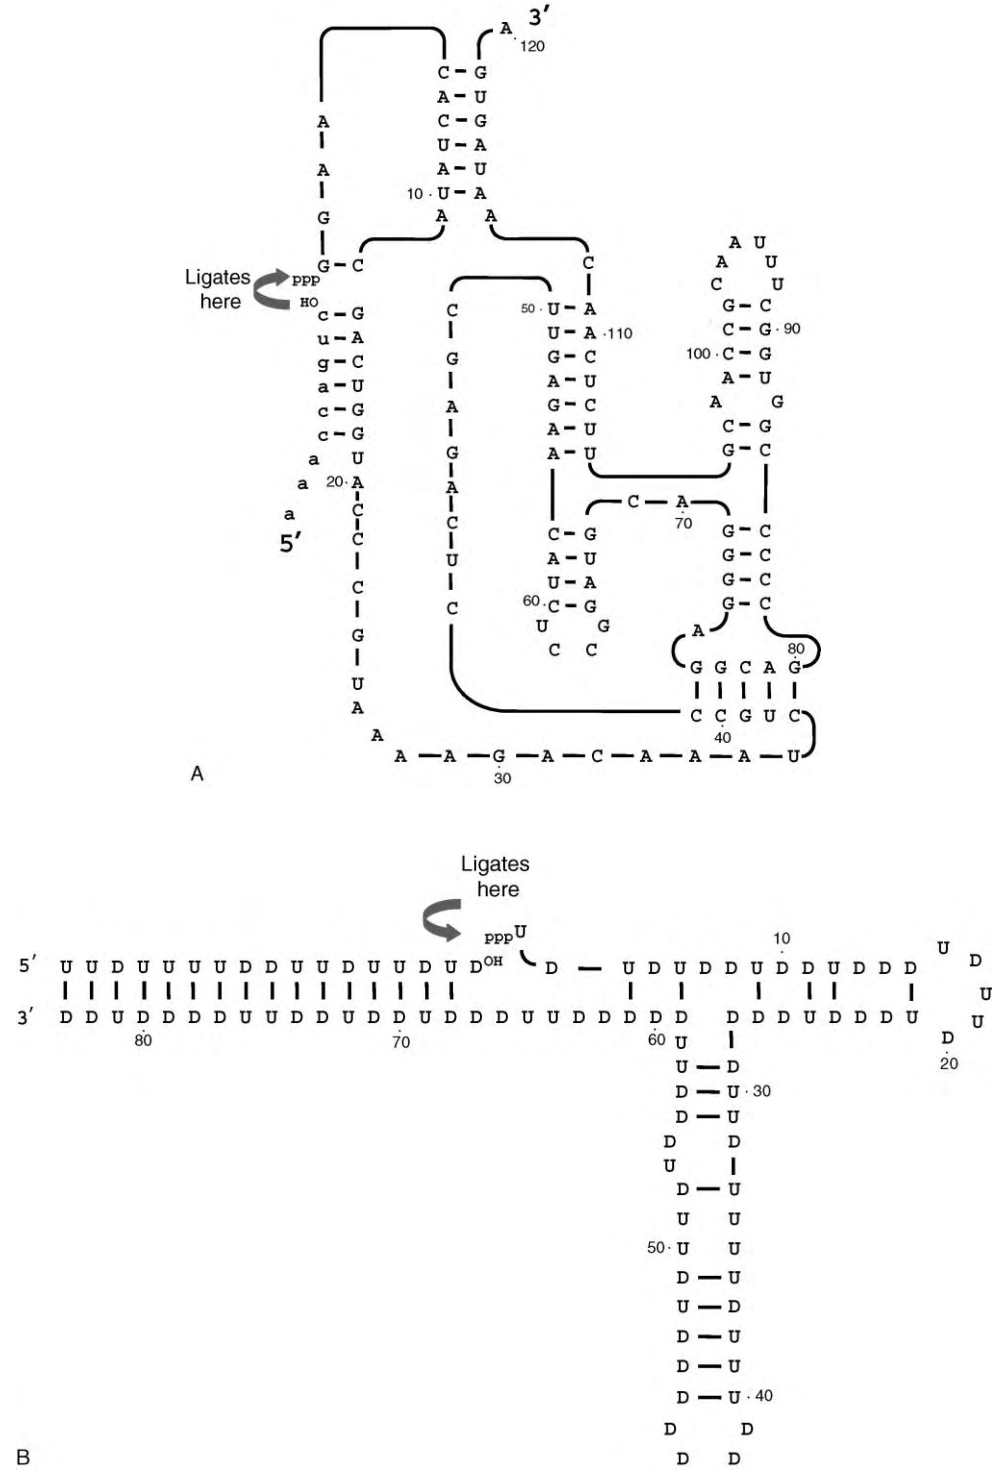

FIGURE 2 Some known unnatural ribozymes. (A) The b1-207 ligase ribozyme selected *in vitro* from a random pool of RNA sequences. This ribozyme binds a complementary RNA substrate (lower case letters) via complementary base pairing and catalyzes a ligation to form a new phosphoester bond. (B) A ligase ribozyme evolved *in vitro* to function with only two nucleotides: D = 2,6-diaminopurine and U = uridine.

Phylogenetic Distribution of Ribozymes

Judging from the phylogenetic distribution of natural ribozymes (Figure 3) and from the central nature of the reactions that they catalyze, it is clear that catalytic RNA was likely present in the last common universal ancestor (LUCA) of contemporary life. Group I ribozymes for example, are present in eukaryotes (e.g., the ciliated protozoan *Tetrahymena*) and in eubacteria, including some bacteria thought to occupy basal lineages in the tree of life (e.g., the hyperthermophilic bacterium *Thermatoga*). Ribozymes are wide spread in RNA viruses, group II introns have been recently isolated from deep-sea hydrothermal vent bacteria, and small ribozymes have been isolated from genomes in organelles such as mitochondria and chloroplasts. Also, the RNase P ribozyme is present in a variety of archaeal species.

RNA and the Origins of Life

In addition to the inference that ribozymes were a feature in the LUCA, there is much evidence and corresponding speculation that RNA, in particular catalytic RNA, was critical in the earliest life forms on the Earth. RNA, or an RNA-like molecule, could even have been the basis for the origins of life itself. Initially this postulate was based on the observation that RNA was the only known polymer to possess simultaneously a genotype and a phenotype. Subsequently, more direct evidence of the antiquity of RNA has come to light. These data include the realization that, the ribosome is a ribozyme, RNA can catalyze a diverse array of reactions, a ligase-derived RNA can catalyze rudimentary RNA polymerization, RNA can catalyze recombination, and, importantly, populations of RNA can evolve in a test tube and respond to environmental pressures in manners quite analogous to natural populations of organisms. Moreover, much is now known about plausible abiotic synthetic routes to RNA precursors such as purines, pyrimidines, carbohydrates, and phosphorylated compounds. For example, cationic clays such as montmorillonite can promote the polymerization of RNA-like monomers into RNA chains of 50 or more nucleotides in length.

In vitro Evolution of RNA

SELEX

Systematic evolution of ligands by exponential enrichment (SELEX) is a powerful method to isolate RNA sequences that bind to particular substrates without necessarily reacting with them. Random pools of RNA, typically 40–100 nucleotides in length, are created such that billions of possible sequences are represented. These pools are challenged to bind a target substrate, such as a

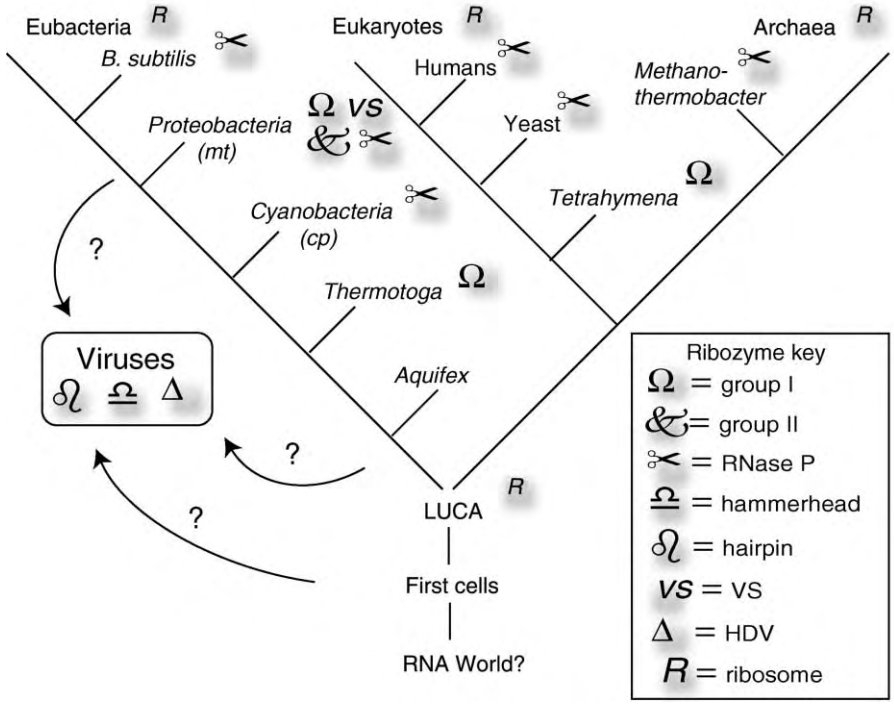

FIGURE 3 Distribution of ribozymes in the tree of life. The examples shown here are not exhaustive; branch lengths are not indicative of extinction events or amount of evolutionary change. Mitochondria (mt) and chloroplasts (cp) are included with their bacterial precursors.

particular protein or small molecule such as an amino acid, and the successful binders are separated from the failures and amplified. Repetition of this process 5–10 times often generates a small subset of RNA sequences, called aptamers that have a high-binding affinity toward the substrate.

Selection *in vitro*

Selection *in vitro* (in a test tube) follows the same basic strategy as SELEX, only RNAs are isolated that catalyze a target chemical reaction (Figure 4). These RNAs must bind one or more substrates and then promote a reaction in such a way that the RNA is modified or "tagged" for amplification. In this technique, the initial pool can either be a set of random RNA sequences, or a set of mutants based on a particular known wild-type sequence.

Evolution *in vitro*

Evolution *in vitro* follows the strategy of selection *in vitro* except that in each round, mutations are deliberately introduced into the RNA population to provide additional variation on which natural selection can operate (Figure 4). The mutation can come from error-prone protein polymerase enzymes, from mutagenic PCR, or from sexual PCR. Evolution *in vitro* can in principle be carried out for an indefinite number of rounds, but in principle convergence on a particular catalytic solution, if one exists, typically occurs after 10–20 rounds and will occur in general accordance to the principles of population genetics.

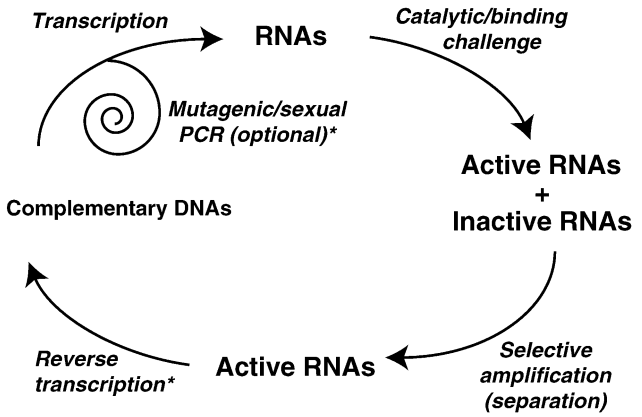

FIGURE 4 *In vitro* selection/evolution. A pool of RNA molecules, partially or completely randomized in nucleotide sequence, is challenged to perform a novel binding and/or catalytic event. As a result of successfully performing that event, RNA molecules become physically tagged in such a manner that they can be separated from unsuccessful RNA molecules. The successful RNAs then get converted to a corresponding DNA sequence through reverse transcription and back into RNA by forward transcription. A complete cycle is called a round, or a generation, and may or may not include mutagenic steps (indicated by asterisks) to introduce an evolutionary element into the process.

Continuous Evolution *in vitro*

The most recent modification of these RNA evolution techniques is to mimic a prebiological milieu in which all the components of evolution – the RNA, the nucleotides, the salts, the oligonucleotides, and the protein enzymes, if any – are simultaneously present in a single test tube. In this fashion several rounds of evolution occur autonomously before equilibrium is reached. Serial dilution and fresh additions of reagents can result in the extremely rapid evolution of RNA populations.

He is an associate editor of the *Journal of Molecular Evolution*, and his laboratory has pioneered the studies on RNA-directed recombination of RNA.

RNA Editing

Charles E. Samuel
University of California, Santa Barbara, California, USA

RNA editing is the posttranscriptional modification of an RNA nucleotide sequence at one or more positions. There are two general types of RNA editing, viz., substitution editing and insertion/deletion editing. RNA editing of either type leads to the formation of transcripts whose sequence differs from that found in the genome. Such RNA sequence differences between mature transcript and encoding genome represent a form of genetic recoding. The sequence changes generated by RNA editing are different from those arising from 5′-capping, 3′-polyadenylation, and splicing, processing events that also may occur as part of mRNA biogenesis. RNA editing is widely observed in eukaryotic organisms and their viruses. Editing, like splicing, represents a form of processing that has the capacity to amplify genetic diversity and product function by altering the information transfer process at the posttranscriptional level of gene expression.

Discovery of RNA Editing

RNA editing was discovered in a unicellular protozoan. The frameshifted cytochrome oxidase *coxII* transcript of trypanosome mitochondria was found to contain four inserted uridines that were not encoded by the genomic DNA. Then editing by nucleotide substitution was found in two mammalian RNAs. The apolipoprotein B (apoB) mRNA in mouse intestine had a translation stop codon at a position in the mature mRNA, where the genomic DNA specified the amino acid glutamine, and the glutamate-gated ion channel (GluR-B) mRNA in mouse brain had the amino acid arginine in place of the genome-encoded glutamine at the same position. Several biochemical mechanisms account for the RNA editing identified in mRNA transcripts. These include A-to-I substitution editing; C-to-U substitution editing; U insertion/deletion editing; C insertion editing; and G insertion editing. In addition, 2′-O-methyl ribose nucleotide modification and uridine to pseudouridine conversion represent editing events mediated by complexes of small nucleolar RNA (snoRNA) cofactor guides and associated proteins that modify ribosomal RNAs and other RNAs. This article will focus on A-to-I and C-to-U RNA editing that occur by selective RNA-specific deamination reactions that lead to nucleotide substitutions. Genetic recoding by such substitution editing can create gene products with altered sequence and hence altered function.

Adenosine-to-Inosine Substitution RNA Editing

RNA Substrates that Undergo A-to-I Editing

RNA editing by adenosine (A) to inosine (I) substitution is catalyzed by C6-adenosine deaminases that act on double-stranded RNA substrates (Figure 1A). A-to-I editing occurs in several eukaryotes including *Caenorhabditis* (nematode worm), *Drosophila* (fruit fly), and *Xenopus* (frog) in addition to mammals and their viruses. Among mammalian RNAs, transcripts encoding glutamate-receptor (GluR) channels of the α-amino-3-hydroxy-5-methyl-isoxaole-4-propionate (AMPA) and kainate GluR receptor subtypes represent one of the best-understood cases of A-to-I editing. This is illustrated by the AMPA receptor subunit B (GluR-B), one of four GluR subunits. Exon 11 possesses a genome-encoded glutamine (Q) codon (CAG) in unedited GluR-B transcripts. This exon codes for a hydrophobic domain (TM2) that loops into the cytoplasmic membrane. The edited GluR-B mRNA possesses an arginine (R) codon (C*I*G) at the same codon position, because I is recognized as G by decoding ribosomes during the translational process. Editing at this site, known as the Q/R site, occurs almost completely in the brain of adult rodents. Q/R editing of GluR-B affects channel subunit assembly in a manner that results in reduced permeability to Ca^{++} ions. A second A-to-I editing site in GluR RNA, termed the R/G site, involves the conversion of a genome-encoded arginine (R) codon (*A*GA) to a glycine (G) codon (*I*GA) in exon 13 of edited GluR-B, -C, and -D subunit transcripts. Editing at the R/G site controls the kinetic properties of AMPA receptor channels and leads to faster recovery rates from receptor desensitization.

Editing of GluR-B occurs at the pre-mRNA level within the nucleus, prior to splicing. RNA elements

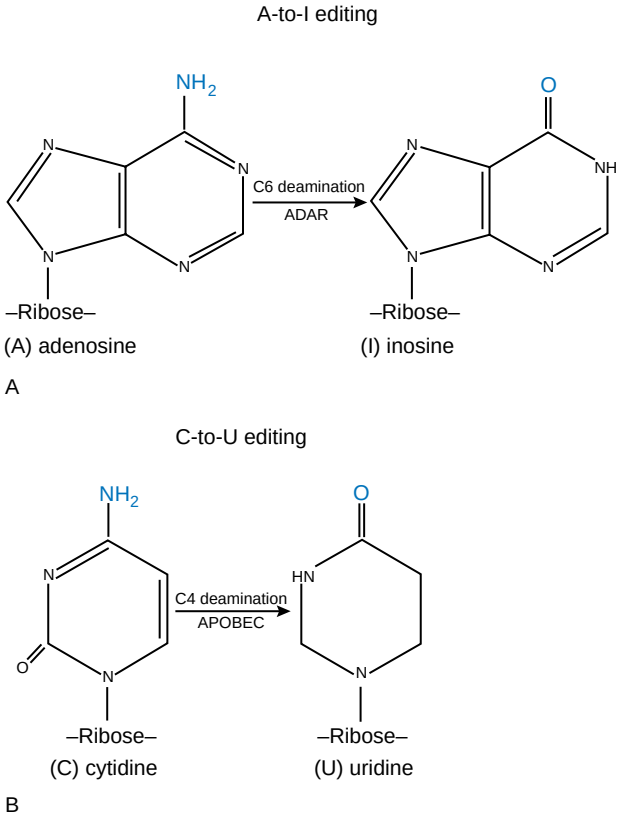

FIGURE 1 Substitution RNA editing by hydrolytic deamination. (A) A-to-I RNA editing involves the C6 deamination of adenosine to generate inosine catalyzed by ADAR enzymes. (B) C-to-U RNA editing involves the C4 deamination of cytidine to generate uridine catalyzed by APOBEC enzymes.

dictate the specificity of editing at the Q/R and R/G sites. The elements consist of unique *cis*-acting complementary inverted repeat sequences that are present in the intron adjacent to the exon possessing the edited adenosine. For the Q/R site in exon 11, the inverted repeat in intron 11 is predicted to form an imperfect duplex structure spanning the edited "A" at the Q/R site. A similar duplex RNA structure also exists within exon 13 containing the R/G site and the proximal portion of the adjacent intron 13. These exon–intron double-stranded RNA structures are absolutely essential for efficient editing at the Q/R and R/G sites of GluR-B.

The serotonin (5-hydroxytryptamine)-2C receptor (5-HT_{2c}R) provides another example of a neurotransmitter receptor whereby A-to-I editing of the pre-mRNA prior to splicing leads to amino acid substitutions in the encoded protein that alter activity. In the case of rat 5-HT_{2c}R pre-mRNA, four selective A-to-I editing sites denoted A, B, C, and D have been identified in exon 3 that specify three amino acid substitutions. The 5-HT_{2c}R genomic sequence specifies the sequence …AUA CGU AAU CCU AUU… that encodes …*ile*-arg-*asn*-pro-*ile*… in the unedited RNA. Editing of the four sites leads to the sequence …IUI CGU AIU CCU IUU… in fully edited RNA that encodes …*val*-arg-*ser*-pro-*val*… The three amino acid substitutions created by A-to-I editing of 5-HT_{2c}R transcripts occur in the putative intracellular loop II of the receptor and they cause an ~tenfold reduction in G protein-mediated signaling. Here again, the selective editing of 5-HT_{2c}R pre-mRNAs is dictated by imperfect inverted repeat sequence that forms an RNA duplex between the 3′-end of exon 3 spanning the four editing sites and the 5′-end of the adjacent intron-3.

One of the challenges of A-to-I editing is to identify additional substrates. The GluR-B and 5-HT_{2c}R substrates in rodents and humans were identified serendipitously. In *Drosophila*, a comparative genomics approach has identified 16 new targets for A-to-I editing; all were voltage-gated ion channels, ligand-gated ion channels, or part of the synaptic release machinery.

Adenosine Deaminases that Act on RNA

A-to-I editing events of substrates such as GluR-B and 5-HT_{2c}R are catalyzed by a multigene family of enzymes known as ADARs, *a*denosine *dea*minases that act on *R*NA. Two mammalian genes are known to encode catalytically active deaminases, *ADAR1* and *ADAR2*, that efficiently deaminate both synthetic and naturally occurring double-stranded RNA substrates (Figure 2). The ADAR1 and ADAR2 enzymes show different activities for the different sites in the GluR-B and 5-HT_{2c}R transcript RNAs. The ADAR2 deaminase efficiently edits the Q/R site of GluR-B, but the ADAR1 enzyme possesses little editing activity at Q/R. Both ADAR1 and ADAR2, however, are capable of editing the R/G site of GluR-B. For 5-HT_{2c}R, ADAR1 very efficiently edits the A site but is inactive for the D site, whereas ADAR2 efficiently edits the D site. ADAR1 and ADAR2 possess multiple copies of a canonical double-stranded RNA-binding motif (R, dsRBM) that are located in the central region of the protein. The interferon inducible form of ADAR1 possesses, in addition to the R motifs, two copies of a Z-DNA-binding motif (Zα and Zβ) in the N-terminal region of the protein. The dsRNA- and Z-DNA-binding motifs of ADAR1 are distinct from the deaminase catalytic domain located in C-terminal region of the ADAR proteins (Figure 2). The dsRNA-binding motifs are presumed to play a role in the binding of substrate RNAs, but it is also possible that they too play a role in regulation of enzymatic activity. For example, adenovirus VA_I RNA, a small and highly structured viral gene product transcribed by cellular RNA polIII, efficiently antagonizes ADAR deaminase activity.

The expression of ADAR enzymes in cells is a complex process. For example, in the case of the

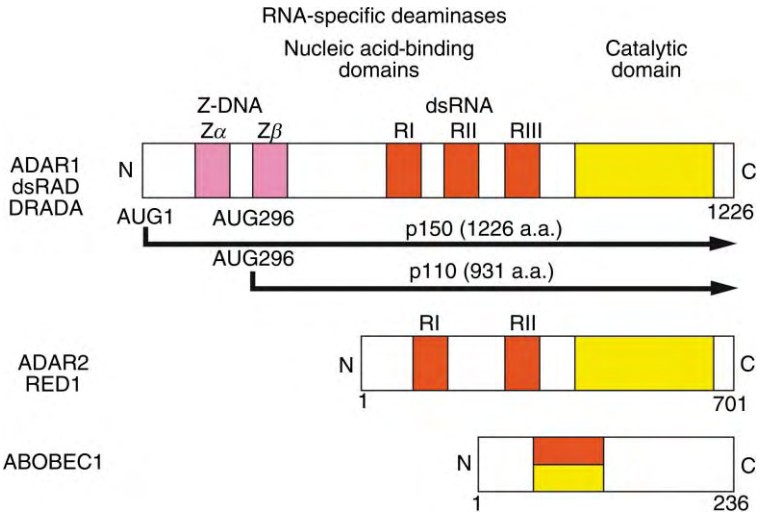

FIGURE 2 Schematic structure of mammalian RNA-specific deaminases. ADAR1 and ADAR2 possess double-stranded RNA-binding (R) motifs (red) and Z-DNA-binding motifs (pink). The RNA-binding motif of APOBEC1 overlaps with the catalytic domain. The catalytic domains of ADAR and APOBEC are shown in yellow. Two size forms of ADAR1 are expressed, the larger p150 interferon inducible form and the smaller constitutive p110 form. ADAR2 and APOBEC1 are not known to be regulated by cytokines or growth factors.

human *ADAR1* gene, alternative promoters including one inducible by interferons together with alternative exon 1 splicing give rise to two differently sized enzyme isoforms, p150 and p110 (Figure 2). The interferon inducible form of ADAR1, p150, is found in both the cytoplasm and nucleus of cells. The constitutive p110 form, which lacks the N-terminal 295 amino acids that includes the Zα-binding motif, is found predominantly if not exclusively in the nucleus. Additional ADAR protein multiplicity is achieved by alternative splicing involving downstream exons, both in the case of ADAR1 and ADAR2. The physiological significance of the splice variants of ADAR is not known; one possibility may relate to the substrate selectivity of the enzymes.

Cytidine-to-Uridine Substitution RNA Editing

RNA Substrates that Undergo C-to-U Editing

Cytidine (C) to uridine (U) substitutional RNA editing is catalyzed by C4-cytidine deaminases that act on single-stranded RNA substrates (Figure 1B). C-to-U editing has been characterized in both plants and mammals. One of the best-understood examples is the mammalian mRNA transcript that encodes apolipoprotein B (apoB) that functions in lipid metabolism. There are two forms of apoB. The larger form (apoB100) is synthesized in the liver and assembled into lipoprotein particles that are secreted into the bloodstream. The carboxyl terminal region of apoB100 interacts with the low-density lipoprotein receptor to remove LDL from circulation. Editing of apoB mRNA by deamination of a single cytidine changes a genome-encoded glutamine codon (*CAA*) to a translation termination codon (*UAA*). This C-to-U editing happens in the small intestine but not the liver. ApoB RNA editing causes the synthesis of a truncated intestinal lipoprotein known as apoB48 that lacks the C-terminal region of apoB100, but otherwise is identical to the N-terminal 48% of apoB100. While apoB100 is associated with LDL protein particles, apoB48 is associated with chylomicron and lacks receptor-binding activity.

Editosome Complex

C-to-U editing of apoB mRNA occurs in the nucleus and is selective for spliced transcripts rather than pre-mRNAs. Deamination is mediated by a multiprotein complex as illustrated by the schematic diagram shown as Figure 3. This complex, called an editosome, includes a protein that possesses catalytic activity (*Apo*lipoprotein *B E*diting Catalytic subunit 1, APOBEC-1) together with one or more associated proteins that include an *a*pobec-1 *c*ompetence *f*actor (ACF), which possesses RNA-binding activity. Unlike the ADARs, APOBEC does not possess a separate canonical RNA-binding motif, but rather RNA-binding activity overlaps with the catalytic domain residues (Figure 2). A tripartite RNA motif that includes efficiency elements, spacer, and a mooring sequence surrounds the edited nucleotide C6666 of apoB mRNA and appears sufficient to confer the required specificity in the C-to-U editing reaction. ACF protein binds apoB RNA selectively at the region of the editing site and interacts with APOBEC-1 deaminase to mediate C-to-U editing activity. Multiple

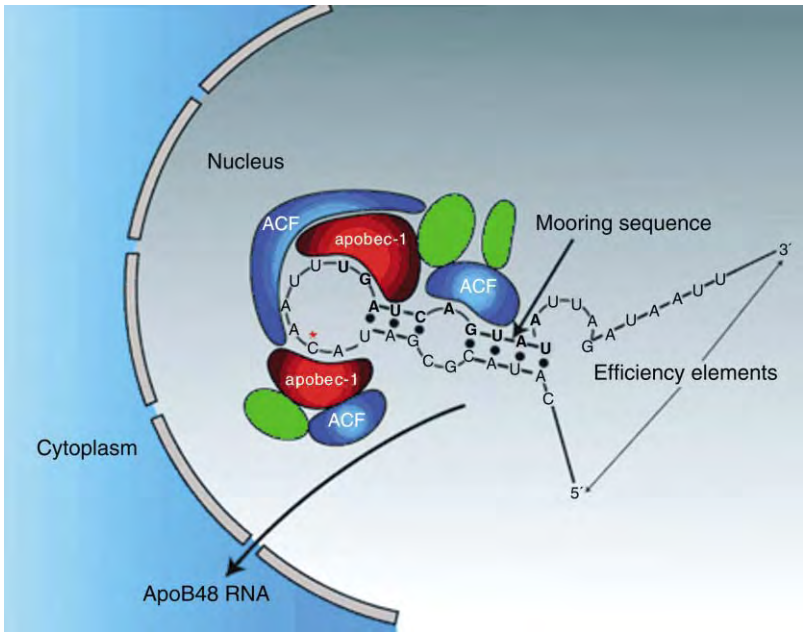

FIGURE 3 Model for C-to-U editing of apolipoprotein B mRNA. The schematic representation shows the APOBEC-1 enzyme (red) and ACF competence factor (blue) binding to the apoB RNA both 5′ and 3′ to the edited C. Additional proteins (green) may modulate assembly of the editosome complex. The mooring sequence is shown in bold font. (Reprinted from Blanc, V., and Davidson, N. O. (2003). C-to-U RNA editing: Mechanisms leading to genetic diversity. *J. Biol. Chem.* **278**, 1395–1398, with permission of the American Society for Biochemistry & Molecular Biology.)

splice variants of the ACF protein are found in different human tissues, but their functional significance remains unknown. Likewise, several homologues of the APOBEC-1 catalytic deaminase have been identified including ARCD1/APOBEC-2, AID, and phorbolin/ARCD2-7/APOBEC-3A to G. The target substrates and physiologic roles of the many APOBEC homologue proteins in RNA editing are not yet well defined.

The existence of multiple APOBEC-1 homologues and ACF variants points to the existence of primary substrates beyond apoB mRNA that may undergo C-to-U editing. One candidate for site-specific cytidine deamination is the cellular mRNA for the neurofibromatosis type 1 (NF1) protein encoded by NF1 tumor suppressor gene. This protein, neurofibromin, functions as a Ras-GTPase-activating protein (GAP). Site-specific deamination of a cytidine (nucleotide C3916) in NF1 mRNA converts a genome coded arginine codon (*C*GA) to a translation termination codon (*U*GA). The shortened NF1 open reading frame that results from this C-to-U editing has been observed in neuronal tissue from NF1 patients and is predicted to give rise to a truncated neurofibromin protein product deficient in GAP activity.

Substitution Editing of Viral RNAs

RNA editing may play a significant role in viral pathogenesis and affect the host response to viral infection. A number of viral RNAs, including those of avian leukosis virus (ALV), hepatitis delta virus (HDV), measles virus, parainfluenza virus 3, polyoma virus, respiratory syncytial virus, and vesicular stomatitis virus, all show codon changes under certain infection conditions that are consistent with A-to-I editing. The best-characterized viral RNA substrate is that of HDV. Both ADAR1 and ADAR2 convert an amber translation stop codon (UAG) to a tryptophan codon (UIG) in HDV antigenomic RNA. This editing allows for the synthesis of two delta virus antigen forms, a short form used in viral replication and a long form necessary for assembly of viral particles. A viral RNA candidate for A-to-I editing is that of measles virus (MV), where viral RNAs isolated from brains of persistently infected subacute sclerosing panencephalitis (SSPE) patients, possess multiple sequence differences from the viral RNA genome that correspond to A-to-G and U-to-C substitution mutations. Because MV, a negative-strand RNA virus, replicates in the cytoplasm, it is presumed that ADAR1 is the responsible enzyme. The DNA virus vaccinia that also replicates in the cytoplasm of cells encodes a protein product (E3L) that efficiently antagonizes ADAR1 deaminase activity, and mutations in E3L are known to affect viral pathogenesis in the mouse model.

Finally, C-to-U RNA editing like A-to-I editing may play a role in the interactions between viral pathogens and their hosts. Among the homologues of APOBEC-1, the APOBEC-3G gene product has been shown to possess broad anti-retroviral activity. The antiviral effects of APOBEC-3G appear to result from the generation of biased G to A hypermutations that impair

virus replication in a manner that, in the case of human immunodeficiency virus, is modulated by an accessory protein of the virus known as Vif.

Editing by Nucleotide Insertion/Deletion

A second general type of RNA editing, in addition to base substitution editing, is nucleotide insertion/deletion editing. Among the best-characterized examples of insertion/deletion editing is that of U-insertion and U-deletion. Uridine insertion/deletion editing occurs by an enzymatic cleavage-ligation mechanism. The specificity of U-insertion/deletion editing is determined by RNA–RNA base pairing between a complementary guide RNA (gRNA) and the target RNA (mRNA) substrate. The base-paired RNA complex serves to position the enzymatic machinery at the site of U insertion or deletion, thereby "guiding" the modification process. Much has been learned from the trypanosome mitochondrial system about the features and requirements of the complimentary gRNAs that act in trans to target enzyme complexes to the mRNA site of uridine insertion/deletion editing. The enzymatic cleavage-ligation mechanism of U insertion/deletion editing involves hybridization of gRNA to mRNA to form a gRNA:mRNA anchor duplex, after which the mRNA is specifically cleaved by a gRNA-dependent ribonuclease at the site of the gRNA:mRNA mismatch. For U-insertion editing, a 3′-terminal uridylyl transferase (TUTase) then adds U's to the 3′-end of the 5′-fragment guided by base pairing with the gRNA, followed by ligation of the two fragments by an RNA ligase. For U-deletion editing, a U-specific 3′-5′ exonuclease removes the bulged U residues, followed by ligation of the two RNA fragments. Finally, in addition to U-insertion editing as exemplified by the cytochrome oxidase mRNA in trypanosome mitochondria, C-insertion editing and G-insertion editing also are known to occur as illustrated by Physarum mitochondria and by negative-strand RNA viruses, respectively. In the case of paramyxoviruses such as Sendai virus, G-nucleotide insertion occurs during the RNA transcription process to generate edited P/C mRNA that includes nontemplated Gs.

Roles of RNA Editing

Altering the information transfer process at the post-transcriptional level of gene expression by RNA editing represents an important strategy for amplifying genetic diversity and modifying the functions of products encoded by an organism's genome. Some of the mechanistic roles that substitution editing through A-to-I and C-to-U deamination play, or are anticipated to play, in biological processes are summarized in Figure 4. These biochemical mechanisms include effects of editing on mRNA translation, pre-mRNA splicing, RNA degradation, RNA replication, and RNA structure that result from nucleotide substitution via deamination or nucleotide insertions. Site-specific editing may change the coding potential of mRNA transcripts, leading to proteins with altered function due to amino acid substitutions following A-to-I editing. This is exemplified

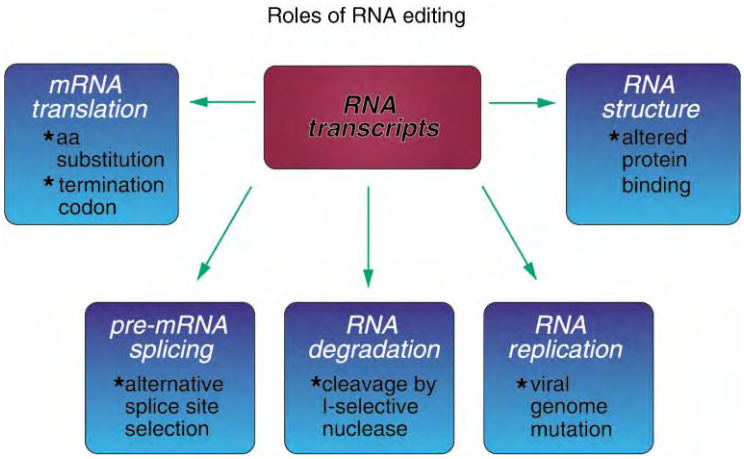

FIGURE 4 Established and potential roles of RNA editing by deamination. Edited RNA transcripts (A-to-I; C-to-U) possess different sequences than their unedited transcript counterparts, and hence may display different functional activities than that shown by the unedited transcripts. Editing may alter processes including mRNA translation, by changing codons and hence coding potential; editing may alter pre-mRNA splicing patterns by changing splice site-recognition sequences; editing may affect RNA degradation by modifying RNA sequences involved in nuclease recognition; editing may affect viral RNA genome stability by changing template and hence product sequences during RNA replication; and, editing potentially may affect RNA structure-dependent activities that entail binding of RNA by proteins. (Reprinted from Samuel, C. E. (2003). RNA editing minireview prologue. *J. Biol. Chem.* **278**, 1389–1390, with permission of the American Society for Biochemistry & Molecular Biology.)

by the GluR-B and serotonin-2c receptor proteins. Introduction or removal of translation termination codons may also occur, as exemplified by apoB and NF1 mRNAs where C-to-U editing generates UAA and UGA translation termination codons respectively, and HDV RNA where A-to-I editing converts an amber UAG stop to a tryptophan codon. ADAR2 edits its own transcript, to create an alternative splice acceptor site; and, a novel ribonuclease selective for inosine-containing RNAs has been described, consistent with the notion that A-to-I edited transcripts may be degraded preferentially relative to the unedited transcripts. For viral RNAs, deaminations in either the plus- or minus-strand RNA could lead to mutations in the encapsidated viral genome sequence. Finally, sequence changes resulting from editing may subsequently affect RNA structure and function, including protein–RNA interactions (Figure 4).

Biography

Charles Samuel is the C. A. Storke II Professor and Chair of the Department of Molecular, Cellular, and Developmental Biology at the University of California, Santa Barbara. His research concerns the mechanisms of interferon action, including the modification of RNA by editing. He holds a Ph.D. in biochemistry from the University of California, Berkeley, was a Damon Runyon Scholar at Duke University Medical School, and has authored more than 150 research publications in the fields of virology and biochemistry.

RNA Polymerase I and RNA Polymerase III in Eukaryotes

Robert J. White
University of Glasgow, Glasgow, UK

RNA polymerases are the enzymes responsible for synthesizing RNA, in a process called transcription. They use DNA as a template, and the RNA they produce carries a faithful copy of the genetic information contained in the template. Whereas bacteria use a single RNA polymerase to transcribe all their genes, the nuclei of eukaryotes contain three. Each is responsible for transcribing a unique set of essential genes. RNA polymerase I synthesizes most of the rRNA, RNA polymerase II synthesizes the protein-encoding mRNA and most snRNA, while RNA polymerase III synthesizes a variety of small untranslated RNAs, including tRNA and 5S rRNA. An additional RNA polymerase is present in mitochondria, which carry a small DNA molecule of their own. This division of labor could have become necessary as genomic complexity increased during evolution. In actively growing cells, RNA polymerase I can be responsible for ~70% of all nuclear transcription, whereas RNA polymerases II and III contribute ~20% and 10%, respectively.

Genes Transcribed by RNA Polymerases I and III

Despite its very high activity, RNA polymerase I only transcribes a single type of gene, which encodes the large rRNA precursor molecule. This precursor is then processed into the mature 5.8S, 18S, and 28S rRNA components of ribosomes. A single molecule of each of these rRNAs, along with a 5S rRNA molecule and ~85 proteins, is incorporated into each ribosome. The pre-rRNA is encoded by multiple gene copies, the number of which varies between different organisms; mammals have ~150–200 copies arranged in tandem head-to-tail arrays.

The genes transcribed by RNA polymerase III are invariably very short, rarely exceeding 300 bp in length. Many of their products have essential functions, such as the 5S rRNA and tRNAs (required for protein synthesis), 7SL RNA (involved in intracellular trafficking of proteins as part of the signal recognition particle), and the U6, MRP, and H1 RNAs (involved in the processing of mRNA, rRNA, and tRNA, respectively). Mammalian genomes also contain large numbers of short interspersed repeats (SINEs) that are transcribed by RNA polymerase III, such as the Alu family in man. In addition, certain viruses carry genes that are transcribed by RNA polymerase III, such as the VA genes of adenovirus and the EBER genes of Epstein–Barr Virus. The products of these viral genes can subvert the translational machinery of an infected cell, diverting it towards the more effective production of viral proteins.

Nucleoli

Within the nucleus, the most obvious landmarks under a light microscope are nucleoli, because of their high density. These form around the actively transcribed rRNA gene repeats and contain closely packed molecules of transcribing RNA polymerase I, each with a nascent pre-rRNA attached. Furthermore, ribosomal proteins assemble on the nascent transcript whilst it is being made. Although nucleoli have the appearance of organelles, they are in fact dynamic structures without membranes that disappear when transcription stops (e.g., during the general suppression of gene expression that accompanies mitosis). Transferring rRNA genes to a novel chromosomal location can result in the appearance of an ectopic nucleolus. When cells become very old, their nucleoli fragment; it has been suggested that nucleolar degeneration may be an important aspect of cellular aging.

The RNA Polymerase Molecules

RNA polymerases I, II, and III are large and complex proteins, consisting of 14, 12, and 17 subunits, respectively. Five of these subunits are shared, and a further two are found in RNA polymerases I and III, but not in RNA polymerase II. The two largest subunits of each enzyme are unique, but share substantial homology with each other and also with bacterial RNA polymerases;

they fold together to provide the catalytic site of the enzyme. Besides these, RNA polymerases I, II, and III each have an additional set of unique subunits. Although most of the subunits are required for cell viability, their precise roles remain poorly characterized.

The RNA Polymerase I and III Transcription Apparatus

Despite their complexity, the nuclear RNA polymerases require considerable assistance to locate their genetic templates. Sets of transcription factor proteins assemble at promoter DNA sequences near the initiation sites of genes and then serve as molecular beacons which recruit the appropriate RNA polymerase.

For the large rRNA genes, promoter recognition is achieved by the homodimeric factor UBF that binds across the promoter region upstream of the transcription start site. UBF bends the DNA and wraps it around itself to create a three-dimensional nucleoprotein structure that is recognized by SL1, the factor responsible for polymerase recruitment. RNA polymerase I is pre-assembled with a polypeptide called Rrn3 that serves as an essential bridge between the polymerase and SL1 (Figure 1A). Several additional transcription factors are also associated with RNA polymerase I and are recruited with it in a concerted manner. Although these principles apply to mammals and frogs, the machinery required for rRNA synthesis is rather different in yeast. Indeed, the RNA polymerase I transcription apparatus is much less well conserved through evolution than those of RNA polymerases II or III; whereas human proteins can transcribe a yeast tRNA gene, they will not even recognize the large rRNA genes from mouse.

In the case of RNA polymerase III, two key transcription factors, TFIIIB and TFIIIC, play central roles in both yeast and man (Figure 1B). The former is responsible for recruiting RNA polymerase III and positioning it over the transcription initiation site; it also helps separate the two strands of the DNA helix, thereby facilitating the start of RNA synthesis. However, TFIIIB is unable to recognize the DNA sequences of most RNA polymerase III promoters, but must be brought into position through protein-protein interactions with DNA-bound TFIIIC. An unusual feature of this system is that the promoter sequences recognized by TFIIIC are located downstream of the transcription start site, within the transcribed region. Although in most cases TFIIIC binds directly to DNA, this is not possible for the 5S rRNA genes which have a distinct promoter arrangement. In these cases, an additional polypeptide, TFIIIA, binds along the DNA and provides a protein scaffold to which TFIIIC binds (Figure 1C). TFIIIA contains nine tandem copies of the zinc finger DNA-binding domain. Indeed, it was the

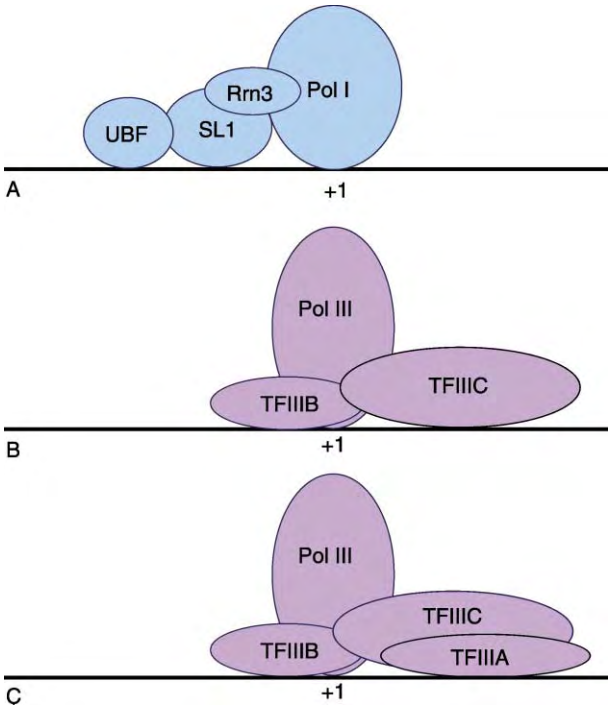

FIGURE 1 Simplified model of the transcription complexes used by RNA polymerases I and III. (A) UBF and SL1 assemble at the promoters of large rRNA genes and then recruit a preassembled complex containing Rrn3 and RNA polymerase I (Pol I), as well as additional factors not shown. (B) TFIIIC binds directly to the promoters of most genes transcribed by RNA polymerase III, e.g., tRNA genes. TFIIIB is recruited by protein/protein interactions with TFIIIC and then serves to bring RNA polymerase III (Pol III) to the transcriptional start site. (C) Similar events occur at 5S rRNA genes, but these are initiated by TFIIIA, which binds promoter DNA and provides a scaffold for TFIIIC assembly. + 1 denotes where transcription initiates.

founder member of the zinc finger family, the largest group of transcription factors in organisms ranging from yeast to man (~900 members in humans).

Alu Genes and Retrotransposition

The human genome carries over a million copies of the Alu gene, which provides ~10% of our total DNA. Despite their abundance, only small numbers of Alu genes are actually transcribed, the remainder being silenced through epigenetic mechanisms, including methylation and incorporation into repressive chromatin. SINEs propagate by retrotransposition, in which their RNA transcripts are copied into DNA and then inserted into novel genomic sites. These insertions occur preferentially into areas of active transcription, perhaps because of their more open and accessible chromatin structure. This increases the danger that integrating SINEs will disrupt genes at the recipient loci, thereby having a mutagenic effect. Indeed, cases of haemophilia,

neurofibromatosis, and breast cancer are believed to have arisen in this way. It is estimated that Alu insertions account for ~0.1% of all human genetic disorders. In contrast, retrotransposition is much more active in mice, where it may contribute ~10% of mutations.

RNA Polymerases I and III and Tumor Suppression

The RNA polymerase I and III transcription systems are both targeted directly by two key tumor suppressor products, p53 and RB. Both these proteins bind to TFIIIB and block its interactions with TFIIIC and RNA polymerase III, thereby repressing transcription. RB also binds to UBF to inhibit synthesis of large rRNA, whereas p53 inactivates SL1. The ability of RB and p53 to suppress the output of RNA polymerases I and III may contribute to their capacity to restrain cell growth. RB has been described as a gatekeeper that only allows cells to grow and proliferate when conditions are propitious. Inherited mutations in RB can cause the paediatric eye cancer retinoblastoma. Indeed, it is widely believed that RB function must be compromised in some way before any tumor can develop. The most commonly mutated gene in human cancer is p53, which is famous as "the guardian of the genome." If a cell's DNA gets damaged, for example, through exposure of skin to excessive doses of UV light, p53 gets activated and triggers a protective response; this can involve halting growth and cell cycle progression until the damage has been mended or, under extreme circumstances, apoptotic death. These responses ensure that DNA carrying potentially harmful mutations are not passed on to further generations of cells.

Links between Human Disease and RNA Polymerases I and III

RNA polymerases I and III together may contribute ~80% of nuclear transcription and provide ~95% of the total RNA in cells. This very high level of production is necessary to make the several million new ribosomes that are needed per generation to maintain protein synthetic capability. Because they are such major determinants of biosynthetic capacity, the activities of RNA polymerases I and III are closely linked to the rate of cellular growth. In hyperproliferative diseases such as cancer, there is generally an elevated rate of transcription by these polymerases. Indeed, pathologists use enlarged nucleoli (a sign of accelerated rRNA synthesis) as a diagnostic indicator of tumor formation. To a large degree, the elevated activity of RNA polymerases I and III in cancer cells is likely to reflect the inactivation of p53 and/or RB; since these tumor suppressors play a major role in restraining transcription by RNA polymerases I and III in healthy cells, their inactivation during cancer development will remove a major restraining influence and allow deregulated gene expression. These effects must be extremely widespread, since p53 is mutated in ~50% of human tumors and RB function may be compromised in all forms of malignancy. In addition to their release from these transcriptional repressors, the output of RNA polymerases I and III is also increased in some cancers through the action of certain oncogenic proteins. An example is c-Myc, which is deregulated in many tumor types and is believed to contribute to one in seven US cancer deaths. TFIIIB is bound and activated by c-Myc, leading to elevated rates of RNA polymerase III transcription. Certain types of cancer also produce abnormally high levels of the transcription factors used by RNA polymerases I and III. For example, UBF is frequently overexpressed in hepatocellular carcinomas, whereas TFIIIC is unusually abundant in ovarian tumors.

Epstein–Barr Virus is associated with gastric and nasopharyngeal carcinomas, Burkitt's lymphoma, Hodgkin's disease, and AIDS-associated lymphoma. Its most highly expressed gene products are the EBER RNAs, which are synthesized by RNA polymerase III. The presence of these transcripts is used diagnostically as a test for Epstein–Barr Virus. Indeed, very few other viral genes are expressed in Burkitt's lymphomas. Recent studies have shown that the EBER1 transcript can be sufficient for oncogenic transformation, a remarkable fact since it is only 167 nucleotides long. This provides the first reported example of an untranslated RNA that can transform cells.

An inherited-developmental disorder has been shown to result from mutations in the MRP gene that is transcribed by RNA polymerase III to produce a short RNA that is required for mitochondrial replication and for the processing of large rRNA. Families afflicted with this condition suffer from cartilage–hair-hypoplasia, a complex syndrome involving short stature (adult heights of 104-149 cm), abnormal cartilage, and hypoplastic hair, sometimes with a compromised immune system. This disorder is especially common amongst the Old Order Amish of Pennsylvania.

Biography

Robert J. White is Professor of Gene Transcription at the Institute of Biomedical and Life Sciences at the University of Glasgow, UK. His principal research interests concern transcription by RNA polymerases I and III, and how this is regulated in health and disease. Most noted for his work on RNA polymerase III and cancer, he was chosen by the European Association for Cancer Research as the Young Cancer Researcher of 2003.

RNA Polymerase II and Basal Transcription Factors in Eukaryotes

Joan Weliky Conaway and Ronald C. Conaway
Stowers Institute for Medical Research, Kansas City, Missouri, USA

In eukaryotes from yeast to man, synthesis of messenger RNA is catalyzed by the 12 subunit enzyme RNA polymerase II, with the assistance of a set of five basal transcription factors designated TFIIB, TFIID, TFIIE, TFIIF, and TFIIH. The basal transcription factors function together to promote proper binding of RNA polymerase II to the promoter-regulatory regions of genes and synthesis of the first few phosphodiester bonds of new transcripts.

Structure and Catalytic Activity of RNA Polymerase II

RNA polymerase II (pol II) is a DNA-dependent RNA polymerase that is responsible for transcription of protein-coding genes in the nucleus of eukaryotic cells. Pol II transcription results in synthesis of an RNA copy of the protein-coding DNA strand of genes. This primary RNA transcript is referred to as pre-mRNA and is subsequently spliced and polyadenylated to form mature mRNA, which can then be exported to the cytoplasm to direct translation of its protein products by the ribosomes. Pol II is capable of initiating transcription in a promoter-independent fashion on single-stranded DNA templates and of elongating transcripts on single- or double-stranded DNA templates without assistance from auxillary transcription factors. To initiate transcription from the promoters of protein-coding genes, however, pol II requires the assistance of a set of auxillary transcription factors referred to as the "basal" factors.

Pol II carries out initiation and synthesis of pre-mRNA by catalyzing DNA template-directed addition of single nucleotides to the 3′-end of growing transcripts. Pol II accomplishes this by catalyzing formation of phosphodiester bonds between the 3′-nucleotide of the transcript and incoming ribonucleoside triphosphates specified by the DNA. Phosphodiester bonds are formed by nucleophilic attack of the 3′-hydroxyl of the transcript on the α-phosphorus of the incoming ribonucleoside triphosphate, with the release of pyrophosphate. A remarkable feature of transcribing pol II is the enormous stability of the pol II–DNA–RNA ternary elongation complex, which can synthesize transcripts as long as the two-million-nucleotide *dystrophin* pre-mRNA without dissociating from the DNA.

Pol II is a multisubunit enzyme composed of ~12 subunits designated Rpb1–Rpb12, with sizes ranging from ~220 to ~10 kDa, respectively. Pol II is highly evolutionarily conserved from yeast to man. High-resolution X-ray crystal structures of free and transcribing *Saccharomyces cerevisiae* pol II have revealed that the two largest pol II Rpb1 and Rpb2 subunits associate with one another to form the core of the enzyme, with the remaining pol II subunits positioned on the outer surface of the Rpb1–Rpb2 core. The pol II catalytic site is contained within a positively charged cleft formed at the Rpb1–Rpb2 interface. The cleft extends from the enzyme's outer surface to the catalytic Mg^{2+} ion buried deep in the enzyme. The cleft is of sufficient size to accommodate as many as 20 bp of DNA. The catalytic Mg^{2+} ion participates directly in formation of phosphodiester bonds, most likely by coordinating the phosphates of the incoming ribonucleoside triphosphate in preparation for nucleophilic attack by the oxygen of the 3′-hydroxyl of the nascent transcript.

The X-ray crystal structure of the transcribing pol II–DNA–RNA ternary complex has revealed features of the complex that provide insights into the mechanism of pol II transcription. Approximately nine nucleotides of RNA at the 3′-end of the nascent pre-mRNA transcript are base-paired to the DNA in a DNA–RNA hybrid that holds the transcript's 3′-hydroxyl properly positioned with respect to the catalytic Mg^{2+} ion. Approximately 4 bp of DNA ahead of the 3′-end of the nascent transcript are unwound, providing the incoming ribonucleoside triphosphates with access to the single-stranded DNA template to ensure proper base-pairing with the template. The pre-mRNA is physically separated from the DNA–RNA hybrid ~10 nucleotides upstream of the transcript's 3′-end and exits the pol II catalytic site through a discrete RNA-binding groove in the enzyme. Finally, a large ~50 kDa clamp comprising portions

of the Rpb1, Rpb2, and Rpb3 subunits closes tightly around the DNA–RNA hybrid, providing a molecular explanation for the great stability and high processivity of the pol II–DNA–RNA ternary elongation complex.

Mechanism of Transcription Initiation by RNA Polymerase II

Synthesis of eukaryotic pre-mRNA by pol II requires that the enzyme finds and binds selectively to promoters located upstream of the protein-coding genes they control and, in most cases, buried amid thousands of base pairs of DNA separating adjacent genes on the chromosomes. Unlike most bacterial RNA polymerases, which are capable of recognizing and binding their promoters and initiating transcription pol II requires a minimum set of five basal transcription factors designated as TFIIB, TFIID, TFIIE, TFIIF, and TFIIH, which are necessary to direct selective binding of the enzyme to its promoters and to support transcription initiation. Like pol II, the basal factors exhibit a high degree of evolutionary conservation from yeast to man. The basal factors assemble with pol II at promoters into a stable preinitiation complex that can initiate transcription when provided with an ATP or dATP cofactor and the ribonucleoside triphosphates needed for RNA synthesis.

Pol II Promoters

Pol II promoters vary considerably from gene to gene and can include as little as a few hundred to many thousands of base pairs of DNA located upstream and even within or downstream of the genes they control. All pol II promoters include a "core" element, which surrounds the transcriptional start site and is sufficient to direct synthesis of accurately initiated transcripts. Core promoters include some combination of three types of promoter element: (1) an ~7 bp, degenerate motif called the TATA box, which is found from ~24 to ~30 bp upstream of the transcriptional start site and has the consensus sequence TATAAAA, (2) an initiator element (Inr), which surrounds the transcriptional start site and has the consensus sequence Y_{4-5}CANTY_{4-5} (where Y is a pyrimidine, and N can be any of the four bases A, C, G, or T), and (3) a 5 bp downstream promoter element or DPE, which is positioned at residues 28–32 bp downstream of the conserved A residue within the Inr. The consensus sequence for the *Drosophila melanogaster* DPE, which has been most thoroughly studied, is (A/G)G(A/T)Y(G/A/C).

In metazoans, a recognizable TATA element is found in a little less than half of the promoters examined, while Inr elements are included in ~70% of promoters. Some promoters have both a TATA element and an Inr, and others have only one or the other of these elements. DPEs are most commonly found in promoters that lack TATA boxes. Unlike the TATA or Inr elements, DPEs cannot function independently of other core promoter elements, but must be precisely positioned downstream of an Inr.

In addition to a core promoter, pol II promoters include additional DNA sequence motifs that serve as binding sites for one or more of the large number of DNA-binding transcriptional regulatory proteins that control the frequency of pol II transcription initiation from the core promoter. Among these DNA motifs are upstream promoter elements (UPEs), enhancers, and silencers. UPEs are typically clustered a few hundred base pairs upstream of the core promoter. Enhancers and silencers can be located thousands of base pairs upstream or downstream of the core promoter. Estimates suggest that as many as 10 000 human genes encode UPE, enhancer, and silencer DNA-binding proteins that function alone and in combination to fine tune the levels of pol II transcription of eukaryotic protein-coding genes.

Roles of the Basal Factors in Transcription Initiation by Pol II

Transcription initiation by pol II is a multistep process that begins with assembly of the enzyme with the basal factors at the core promoter to form a stable preinitiation complex and culminates with ATP (dATP)-dependent unwinding of core promoter DNA at the transcriptional start site, synthesis of the first few phosphodiester bonds of the nascent transcript, and escape of polymerase from the promoter. In the first step, the basal factor TFIID binds to the core promoter to form the nucleoprotein recognition site for pol II on the DNA. TFIID is a multisubunit protein composed of the TATA-box binding protein (TBP) and as many as 13 additional proteins designated TBP-associated factors (TAFs). The TBP subunit of TFIID binds directly to the TATA box and is capable of recognizing and binding stably to TATA boxes not only with the consensus TATAAA sequence, but also with a large number of divergent TATA-box sequences. The TFIID subunit TAF2 can bind in a sequence-specific manner to the Inr element surrounding the transcriptional start site. Although it is not yet clear how the DPE is recognized, some evidence suggests that the TFIID subunits TAF6 and TAF9 are located close to the DPE and may make sequence-specific contacts with it.

Once TFIID has bound the core promoter, the basal factor TFIIB recruits pol II to the TFIID–core promoter complex through specific protein–protein interactions with both the TBP subunit of TFIID and pol II. TFIIB is a small, modular protein of ~30 kDa with distinct

protein–protein interaction domains capable of interacting independently with TBP and pol II. Once pol II and TFIIB have bound to the TFIID–core promoter complex, TFIIF can enter the preinitiation complex. TFIIF is a two-subunit protein that strongly stabilizes binding of pol II to the core promoter. TFIIF is also required for stepwise entry of TFIIE and TFIIH into the pol II complex to form the fully assembled preinitiation complex. TFIIE is a two-subunit protein, and TFIIH is a nine-subunit protein possessing both DNA helicase and protein kinase activities. As a component of the preinitiation complex, the TFIIH DNA helicase catalyzes ATP(dATP)-dependent unwinding of core promoter DNA at the transcriptional start site to provide pol II access to a short stretch of single-stranded DNA to allow initiation of pre-mRNA synthesis.

Biography

Joan Weliky Conaway and Ronald C. Conaway are investigators at the Stowers Institute for Medical Research in Kansas City, Missouri. Research in their laboratory is aimed at contributing to an understanding of the molecular mechanisms that control the synthesis of eukaryotic messenger RNA. They hold Ph.D.s from the Stanford University School of Medicine.

RNA Polymerase II Elongation Control in Eukaryotes

David H. Price
University of Iowa, Iowa City, Iowa, USA

During the 1990s, it became clear that the elongation properties of RNA polymerase II are regulated and the factors responsible play a critical role in controlling gene expression in eukaryotic cells. One set of factors helps RNA polymerase II to negotiate pause and arrest sequences in the template and to maintain an elongation rate of 1000–1500 nucleotides per minute. The initiation factor TFIIF reduces RNA polymerase II pause times and stimulates the rate of elongation. The elongation factor S-II or (TFIIS) rescues polymerase molecules that are blocked from further elongation at arrest sites. Another set of factors is responsible for an elongation control process that regulates the fraction of initiated polymerases that enter productive elongation to generate mRNAs. Negative transcription elongation factors (N-TEFs), such as DSIF and NELF, slow the rate of elongation and restrict the polymerase to promoter proximal sequences. The positive transcription elongation factor, P-TEFb, overcomes the effect of the negative factors and allows the production of full length transcripts. The function of P-TEFb is regulated through interactions with many other transcription factors and the amount of active P-TEFb in the cell is precisely regulated through a reversible inhibition by the small cellular RNA, 7SK.

Historical Perspective

It has been clear for some time that much of the regulation of prokaryotic gene expression is accomplished by controlling the elongation potential of RNA polymerase, but only recently has it become apparent that eukaryotic gene expression is similarly regulated. Early work in John Lis's lab showed that there was an RNA polymerase II molecule engaged in transcription of the major *Drosophila* heat shock gene, HSP70, under conditions where no full length mRNAs were being produced. Only after heat shock were the polymerases allowed to continue elongation and produce mRNAs. Similarly, regulated premature termination of transcription was seen on a number of viral genes, most notably from HIV, as well as on cellular genes, including oncogenes such as c-myc and c-fos. In the early 1990s *in vitro* systems were beginning to reproduce the elongation control process and ultimately these systems allowed the identification and purification of some of the specific factors involved. The current model of RNA polymerase II elongation control has the look and feel of models of prokaryotic antitermination, but there are important differences in mechanistic details.

Positive and Negative Elongation Factors

Elongation Maintenance Factors

During transcription, RNA polymerase II is aided by specific factors as it encounters numerous blocks to elongation inherent in a template sequence. During normal transcription *in vivo*, each nucleotide addition to an RNA chain requires ~50 ms on average. However, *in vitro* RNA polymerase II may pause for seconds or minutes at specific sites in the absence of any accessory factors. TFIIF, a factor required for RNA polymerase II initiation, can also decrease the time that the polymerase spends at pause sites. This has the effect of increasing the overall elongation rate because, for the most part, the elongation rate is determined by how long the polymerase stops at the strongest pause sites. It has been hypothesized that the mechanism utilized by TFIIF involves an interaction-induced change in the polymerase from the paused conformation to the elongation competent form. Other factors that belong in this same class are ELL and elongin, but TFIIF has the most dramatic elongation stimulatory activity. The elongation factor S-II functions by a completely different mechanism. At some sites a fraction of RNA polymerase II molecules fall into an arrested conformation from which they cannot escape unaided. At these sites the 3′ end of the nascent transcript is removed from the active site of the polymerase as the polymerase "backslides" along the template while maintaining an RNA:DNA hybrid. When this happens, the polymerase may remain engaged for hours or days without extending the transcript. S-II stimulates an intrinsic ribonuclease activity of the

polymerase that removes the unpaired 3′ end of the transcript and puts the new 3′ end in register with the active site of the polymerase. This reactivates elongation and the polymerase has a second chance to pass the arrest site. Eventually, all polymerases can pass the arrest site although many may require several rounds of S-II-mediated transcript cleavage. Through the combined function of both classes of factors, the elongation rate of RNA polymerase II is maintained between 1000 and 1500 nucleotides per minute.

Elongation Control

In addition to the factors that maintain efficient elongation, there is another set of factors responsible for regulating the efficiency of initiated polymerases to reach the 3′ end of genes. This process has been termed RNA polymerase II elongation control and is best viewed as an obligatory event mediated by the default action of negative factors, N-TEFs, and the regulated action of a positive factor, P-TEFb (Figure 1). The process was demonstrated *in vitro* by first showing that the transcription inhibitor 5,6-dichlororibofuranosyl benzamidizole (DRB) could block the production of long, but not short transcripts. Elongation control was further characterized by the separation of N-TEFs, which direct polymerases to generate only short promoter proximal transcripts, from a positive factor, ultimately identified as P-TEFb, which reverses the action of the N-TEFs. A combination of the action of the N-TEFs and the activity of transcription termination factor 2 (TTF2) results in a process called abortive elongation characterized by the premature termination of transcripts before the mature 3′ end of the gene is reached. P-TEFb plays a key role in that it is responsible for the transition into productive elongation. Stated in another way, the ability to produce mRNAs is directly linked to the activity of P-TEFb. Elongation control machinery exists in all eukaryotic species that have been examined and the current evidence suggests that P-TEFb is required for transcription of most genes.

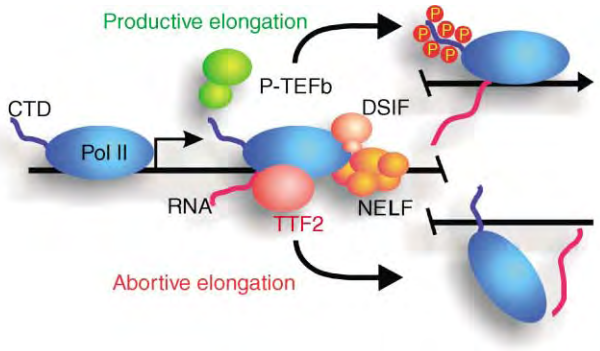

FIGURE 1 RNA polymerase II elongation control. After initiation pol II enters abortive elongation by default because of the action of N-TEFs, such as DSIF and NELF. Phosphorylation of the CTD of the large subunit of RNA polymerase II by P-TEFb causes the transition into productive elongation. If P-TEFb does not act, transcription is prematurely terminated by TTF2.

N-TEFs and Termination Factors

The evidence gathered so far points to the existence of two factors (DSIF and NELF) that play a negative role in elongation control. DSIF, the DRB sensitivity-inducing factor, was discovered as a protein required for DRB sensitive transcription *in vitro*. It is comprised of two subunits with strong sequence similarity to the yeast proteins SPT4 and SPT5. DSIF has almost no function on RNA polymerase II alone. The negative elongation factor (NELF) also has no effect on RNA polymerase II alone, but the combination of NELF and DSIF is able to slow the elongation rate and cause the polymerase to reside longer at pause sites. In this way, NELF and DSIF act in exactly the opposite way as TFIIF, which reduces pause time. NELF is comprised of four subunits, including a putative RNA-binding protein called RD. A defined elongation control system comprised of isolated RNA polymerase II elongation complexes (NELF, DSIF, and P-TEFb) displays many of the properties of elongation control seen when transcription is carried out in nuclear extract. DSIF is involved in controlling transcription from the HSP70 locus in *Drosophila*, but the generality of its function has not been demonstrated. Although removal of DSIF in *C. elegans* using RNAi techniques relieved most of the requirements of P-TEFb at a heat shock locus, similar results were not found in expression of several other genes. These facts along with the fact that homologues of NELF subunits have not been identified in many organisms suggest that other negative factors, which operate at a wide variety of genes, remain to be discovered.

So far only one transcription termination factor, TTF2 (formerly and uninformatively called factor 2), has been identified. It is a member of the SWI2/SNF2 family of proteins that are generally involved in disrupting protein nucleic acid interactions. It binds to both single- and double-strand DNA and has a strong dsDNA-dependent ATPase activity that is required for termination activity. The termination activity of TTF2 is inhibited by TFIIF, and while the mechanism of this inhibition is unknown, it provides a possible method to control the activity of TTF2 during transcription. The role of TTF2 seems to operate outside of the elongation control process in that its negative effect is not directly reversed by P-TEFb. However, a role for the factor in abortive elongation (premature termination) or in normal termination associated with mature 3′ end formation has not been ruled out.

P-TEFb

Subunits and Activity

P-TEFb is a cyclin-dependent kinase comprised of Cdk9 and one of several cyclin subunits. Three genes in humans – T1, T2, and K – encode cyclin subunits that can associate with and activate Cdk9. Two cyclin T genes have been found in *C. elegans*, but only one in *Drosophila*. Supporting a broad role in gene expression, knockout of Cdk9 in *C. elegans* causes loss of gene expression and death at the same early stage as knockout of one of the subunits of RNA polymerase II. The same lethal phenotype is observed when both cyclin T's are knocked out. The carboxyl terminal domain (CTD) of the large subunit of RNA polymerase II is phosphorylated by P-TEFb and this domain has been shown to be required for the function of P-TEFb in the transition into productive elongation. The CTD is comprised of multiple repeats of the heptapeptide YSPTSPS, and P-TEFb predominately phosphorylates the second serine. P-TEFb had been shown to have broad substrate specificity *in vitro* and will phosphorylate the large subunit of both DSIF and TFIIF. Although the CTD is phosphorylated by P-TEFb and is required for the function of P-TEFb in transcription, there may be other important functional phosphorylation targets. The effect of DRB on transcription is explained by the fact that it inhibits the kinase activity of P-TEFb. All P-TEFb inhibitors reduce the production of mRNAs *in vivo* and are lethal at high concentrations. Flavopiridol, the most potent P-TEFb inhibitor found, is in clinical trials against cancer.

Recruitment of P-TEFb

P-TEFb interacts in a functional way with a number of important transcription factors. Cyclin T1 interacts with the HIV transactivator Tat, and P-TEFb containing cyclin T1 can be recruited to elongation complexes on the HIV template through the interaction of Tat and cyclin T1 with a stem loop structure that forms in the nascent HIV transcript called TAR. This recruitment of P-TEFb activates transcription of the HIV genome. A cellular factor, CIITA, which is involved in activating transcription of the MHC class II genes, has also been shown to function through interaction with P-TEFb. That interaction is blocked in the presence of Tat suggesting that the binding site is similar for the viral and cellular protein and providing a mechanism for inhibition of MHC class II gene expression during HIV infection. Other transcription factors and enhancer binding proteins – including NFκB, c-myc, MCEF, and the androgen receptor – have been demonstrated to various degrees to have functional interactions with P-TEFb.

Recruitment of P-TEFb through artificial targeting to promoter DNA or to nascent RNA has revealed several important aspects of its function. First, when a protein is expressed in which Cdk9 or cyclin T1 or T2 is tethered to the DNA-binding domain of a yeast protein (Gal4) and the binding sites for that protein are placed close to a human promoter, transcription is stimulated from that promoter. Besides the core promoter elements, SP1 binding sites are also required to see an effect of the recruited P-TEFb in this system. This is consistent with the model for P-TEFb function because P-TEFb only affects polymerases that have already initiated and SP1 increases the initiation efficiency. Expression of Cdk9, cyclin T1, T2, or K tethered to an RNA-binding domain (e.g., HIV rev) activates transcription of a gene containing the appropriate RNA element. In both tethering experiments, the untethered component of P-TEFb is also recruited due to the inherent interaction between P-TEFb subunits. Cyclin K does not work when tethered to DNA elements because it lacks a CTD present on both cyclin T1 and T2 that plays another role by interacting with the CTD of the large subunit of RNA polymerase II.

Control of P-TEFb by 7SK

Very recently, the laboratories of Olivier Bensaude and Qiang Zhou simultaneously discovered the small cellular RNA, 7SK, in association with a fraction of P-TEFb in cells. The large complex containing P-TEFb and 7SK was relatively inactive compared to the free P-TEFb (Figure 2). Addition of small amounts of compounds that inhibit elongation by RNA polymerase II causes a reduction in the large form of P-TEFb *in vivo* and a concomitant increase in the small active form. Evidently, a cell will try to compensate for reduced production of mRNAs by activating more P-TEFb. The change in large to small form of P-TEFb can occur within minutes and is reversible. The significance of the large form of P-TEFb was demonstrated using a mouse model of cardiac hypertrophy. Heart cells that were stimulated to grow in size had an increase in P-TEFb activity, but no increase in the amount of P-TEFb. It was shown that all hypertrophic signals tested caused a release of 7SK. The signal transduction pathways involved in hypertrophy of cardiac cells at least partially routes through the elongation control pathway.

Integration of Elongation Control and Gene Expression

Elongation control may play a very significant role in controlling eukaryotic gene expression. Most RNA polymerase II molecules found transcribing human genes require the prior function of P-TEFb. Recruitment

FIGURE 2 Control of P-TEFb by 7SK. The amount of P-TEFb activity in the cell can be quickly adjusted by the reversible association of 7SK RNA. The large form with 7SK bound is inactive.

of P-TEFb by transcription factors allows specific genes to be targeted, and both the targeted and the untargeted functions of P-TEFb may allow global regulation of mRNA production. Regulating the conversion of the large to small P-TEFb form by signal transduction pathways is another global means to regulate mRNA levels. Overall, the combined action of negative and then positive factors results in a kinetic delay of the progression of polymerases down the gene. This may provide a window of opportunity for RNA processing machinery to function or associate with the elongating polymerase, ensuring a truly productive elongation event resulting in a complete, functional mRNA. The human capping enzyme is functionally coupled to transcription and guanylates the nascent transcript before P-TEFb acts. However, some components of the polyadenylation and splicing machinery have been shown to associate with the phosphorylated CTD. Perhaps the processing machinery is functionally coupled to transcription through interactions provided by elongation control and scans the nascent transcript for processing sites as it is being made. Many mechanistic details of how RNA polymerase II elongation control is accomplished and the ramifications of the process on subsequent events remain to be determined.

Biography

David Price, Ph.D., is a Professor of Biochemistry at the University of Iowa. His interest is in understanding the basic mechanisms controlling eukaryotic gene expression. His laboratory focuses on postinitiation activities of RNA polymerase II, including elongation and termination, and how RNA processing and transcription are functionally coupled. The discovery of P-TEFb and its involvement in HIV in his laboratory is currently being extended by mechanistic studies concerning how HIV controls P-TEFb during infection.

RNA Polymerase II Structure in Eukaryotes

Patrick Cramer
University of Munich, Munich, Germany

RNA polymerase II (pol II) carries out transcription of protein-coding genes by catalyzing DNA-directed synthesis of messenger RNA. Detailed three-dimensional structures are now available for yeast pol II in free form, in form of a minimal elongation complex with bound nucleic acids, in an inhibited form with the bound toxin α-amanitin, and in complex with two additional subunits, Rpb4 and Rpb7. Together with functional data, these structures provide many insights into the mechanism of mRNA transcription.

Architecture

A ten-polypeptide pol II core enzyme is sufficient to elongate the RNA transcript. For transcription initiation, an additional two-subunit Rpb4/7 complex, and several general transcription factors are required. In the crystal structures of the pol II core, the two large subunits, Rpb1 and Rpb2 (Table I), form the central mass of the enzyme, and opposite sides of a positively charged "cleft" that contains the active center (Figure 1). The two large subunits are bridged on one side by a module of subunits Rpb3, Rpb10, Rpb11, and Rpb12. Around the periphery of the enzyme, Rpb5, Rpb6, and Rpb8 bind to Rpb1, and Rpb9 binds to both Rpb1 and Rpb2. The structures lack subunits Rpb4 and Rpb7, which form a stable heterodimer that can dissociate from the yeast pol II core. The structure of an archaeal Rpb4/7 counterpart revealed that Rpb7 spans the elongated heterodimer and is organized in two domains. The Rpb4 homologue forms a conserved hydrophobic interface with the Rpb7 homologue at the connection between the two Rpb7 domains. Recent structures revealed that the Rpb4/7 complex binds to the pol II core via subunit Rpb7 and that it protrudes from the pol II core surface near subunit Rpb6.

Structural Elements

The Rpb1 side of the pol II cleft is formed by a mobile clamp, whereas the Rpb2 side consists of the lobe and protrusion domains. The entrance to the cleft is formed between the upper and the lower jaw, which include subunits Rpb9 and Rpb5, respectively. The end of the cleft is blocked by a protein wall. The active center is at the floor of the cleft, between the protrusion, the wall, and the clamp. Before the active center and opposite of the wall, a long bridge helix spans the cleft. The bridge partially lines a pore in the active center, which widens toward the other side of the enzyme, creating an inverted funnel. The rim of the pore includes the highly conserved aspartate loop of Rpb1 that binds a catalytic Mg^{2+} ion, termed metal A. A second metal ion, metal B, is weakly bound next to metal A further in the pore. Both metal ions are accessible from one side.

The clamp is trapped in two different open states in the free core structures, but is rotated and closed in the structure of the pol II transcription–elongation complex that comprises template DNA and the RNA transcript. In this structure, the clamp binds the DNA template strand with three out of five switch regions. The switch regions form the base of the clamp, connecting to the remainder of pol II. Upon clamp closure, the switches change conformation or undergo folding transitions. The closed conformation of the clamp is also observed in the complete pol II that contains the Rpb4/7 complex. The Rpb4/7 complex appears to form a wedge between the clamp and subunit Rpb6, thus preventing clamp opening.

The Rpb1 polypeptide chain protrudes below the Rpb4/7 complex on the outside of pol II, and gets disordered after a few residues. These residues of Rpb1 constitute the beginning of a flexible linker that connects to the mobile C-terminal repeat domain (CTD). The CTD, a unique feature of pol II, consists of repeats of a heptapeptide with the consensus sequence Tyr-Ser-Pro-Thr-Ser-Pro-Ser. A total of 26 and 52 CTD repeats are found in yeast and human Rpb1, respectively.

initiation include promoter binding, DNA melting, and synthesis of short RNA transcripts. The transition from initiation to elongation is referred to as promoter escape, and results in a stable elongation complex that is characterized by an open DNA region, the transcription bubble. The bubble contains the DNA–RNA hybrid, a heteroduplex of eight or nine base pairs. The growing RNA 3′-end is located at the end of the hybrid that is engaged with the pol II active site. Pol II alone can maintain an open transcription bubble, translocate along the DNA template, synthesize RNA, and detect errors in the nascent RNA. For all other steps, however, pol II requires the help of additional proteins.

Several steps of the transcription cycle are accompanied by phosphorylation or dephosphorylation of the pol II CTD. During initiation, the CTD gets phosphorylated, and the CTD phosphorylation pattern changes during elongation. CTD phosphorylation patterns govern specific interaction with RNA processing factors, thereby coupling transcription to RNA processing. The CTD is flexibly linked to a region beyond the saddle, from which RNA exits, consistent with its role in coupling transcription to mRNA processing. Several kinases and at least one phosphatase control the phosphorylation state of the pol II CTD.

Initiation

To bind and melt promoter DNA, pol II assembles on DNA with the general transcription factors TFIIB,

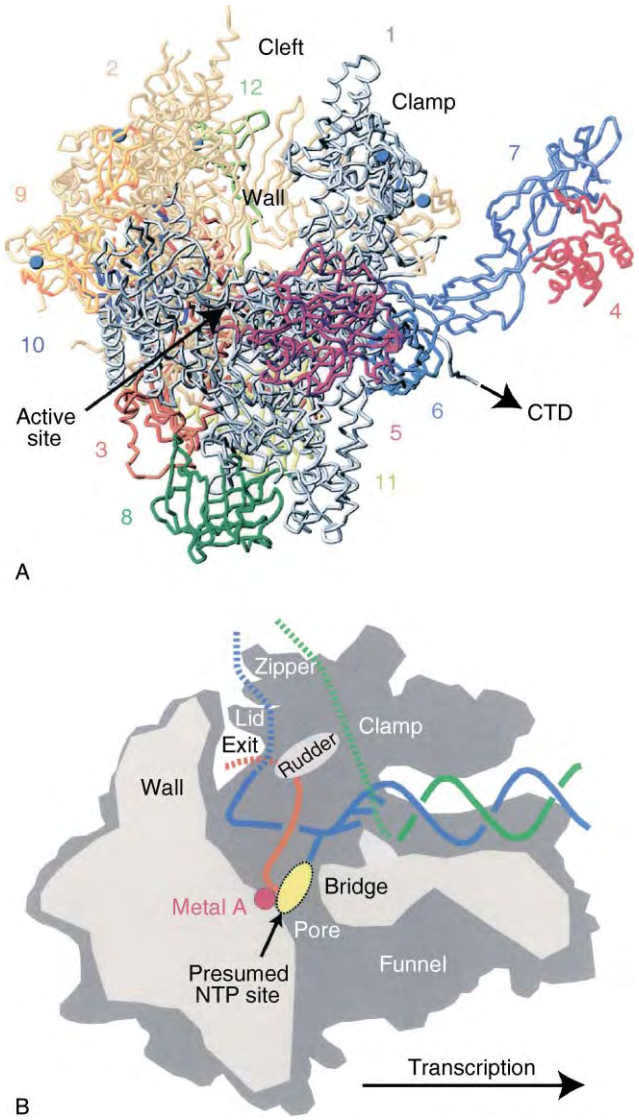

FIGURE 1 RNA polymerase II structures. (A) Ribbon model of yeast RNA polymerase II. The 12 subunits are shown in different colors. The active site metal ion A is depicted as a pink sphere. Zinc ions are shown as cyan spheres. (B) Schematic cut-away view of the pol II core elongation complex. The view is related to the one in (A) by a 90° rotation around a vertical axis. The DNA template and nontemplate strands are in blue and green, respectively, and the RNA is in red. Four of the bases in the DNA template strand are indicated as sticks protruding from the backbone. The yellow oval depicts the presumed binding site for the incoming nucleoside triphosphate substrate.

-D, -E, -F, and -H. The general factors are involved in sequence-specific promoter recognition (TFIIB, TFIID), prevention of nonspecific DNA binding (TFIIF), and DNA melting and CTD phosphorylation (TFIIE, TFIIH). RNA synthesis initiates within the bubble. The early transcribing complex is functionally unstable. Short RNAs are frequently released and pol II has to restart transcription (abortive cycling). There is a decline in abortive transcription when the RNA reaches a length of about four nucleotides, a transition

termed "escape commitment." RNA that has grown to a length of at least four nucleotides is generally not contacted by pol II anymore and is held in the elongation complex by base pairing with the DNA template strand. A second barrier in the transition from initiation to elongation has to be overcome when the RNA reaches a length of about ten nucleotides. At this length, the 5′-end of the RNA is detached from the DNA template strand, and is redirected to the pol II "saddle" and an exit tunnel. A third transition of the early elongation complex is reflected in the continued requirement for ATP and TFIIH until the RNA is about 15 nucleotides long. This transition may reflect successful positioning of all bubble-maintaining structural elements of pol II with respect to the bubble, and detachment of RNA from the pol II surface. Two possible RNA exit grooves have been suggested beyond the saddle, and binding of RNA to the saddle and to one of the exit grooves could account for an additional gain in stability of the elongation complex. Successful passage of early pol II elongation complexes through all three transitions has been referred to as "promoter clearance."

Elongation

During elongation, downstream DNA enters pol II at two mobile "jaws," and extends through the cleft toward the active site. Beyond the active site, a nine base pair DNA–RNA hybrid extends upward, toward the wall. The axes of the downstream DNA duplex and the DNA–RNA hybrid heteroduplex enclose an angle of ~90°. The growing RNA 3′-end is located above the pore, which allows entry of nucleoside triphosphate substrates from below. In the crystal structure of the pol II elongation complex, the incoming DNA duplex is mobile and badly ordered. However, three nucleotides before the active site, the DNA template strand becomes well-ordered by binding to the bridge helix and to two "switch" regions at the base of the clamp. A 90° twist between subsequent nucleotides orients a DNA base toward the active site for base pairing with an incoming nucleotide.

The property of the polymerase to stay attached to the template, even during transcription of long genes, is often referred to as processivity. The major cause of processivity is the high stability of the pol II elongation complex, caused by tight binding of the DNA–RNA hybrid. This stability can be accounted for by the highly complementary hybrid-binding site on pol II, which is partially created upon clamp closure and folding of the switches. Several pol II structural elements are predicted to maintain the hybrid and the transcription bubble during elongation, including the fork loops, the top of the wall, and three loops protruding from the edge of the clamp, called rudder, lid, and zipper.

The nucleotide addition cycle during RNA chain elongation begins with entry of the nucleoside triphosphate (NTP) substrate, maybe together with metal B, and its binding between the bridge helix and the end of the hybrid, to form a base pair with the coding DNA base. Correct orientation of the substrates and metal ions would lead to synthesis of a new phosphodiester bond and to the release of pyrophosphate, maybe together with metal B. The resulting complex adopts the pre-translocation state, which was apparently trapped in the pol II elongation complex structure, with the RNA 3′-terminal nucleotide occupying the NTP-binding site. Subsequent translocation of nucleic acids would align the new RNA 3′ end with metal A, and would free the NTP-binding site, preparing pol II for another cycle of nucleotide addition.

Specificity for synthesizing RNA rather than DNA is achieved by at least three mechanisms. First, the discriminating 2′-OH group of the incoming NTP may be hydrogen-bonded by a conserved pol II residue. Second, 2′-OH groups of the last few nucleotides that were incorporated into the growing RNA are directly hydrogen-bonded by pol II residues. Finally, the active center of pol II is complementary to the resulting DNA–RNA hybrid duplex that adopts a conformation intermediary between canonical A- and B-forms.

It is a mystery of the transcription mechanism how rapid translocation of nucleic acids can be achieved while nucleic acids are bound tightly by pol II. Hints for understanding translocation are, however, provided by the pol II structures. First, nucleic acids are only contacted via their backbones; base interactions that would impede translocation are not observed. Second, long-range electrostatic attraction of the nucleic acid backbones by positively charged protein groups in a "second shell" may enable tight binding of nucleic acids without restricting their movement. Finally, translocation may be accompanied by conformational changes in pol II that could maintain some of the protein–nucleic acid contacts during translocation. Structural comparisons suggest that one such conformational change may be bending of the bridge helix.

Pol II elongation is inhibited by the cyclic octapeptide α-amanitin, the toxin of the "death cap" mushroom. α-Amanitin does not greatly influence NTP binding, and a phosphodiester bond can still be formed when the toxin is added to an elongation complex. However, the rate of transcription is dramatically reduced. Only several nucleotides are incorporated per minute. In the structure of a pol II core–α-amanitin complex, α-amanitin binds to the bridge helix, and could restrain a possible movement of this helix, thereby blocking conformational changes that are important for translocation. However, the exact mechanism of pol II inhibition by α-amanitin is not understood.

Pol II does not move along the DNA template in a unidirectional manner, it rather oscillates between movements forward and backward ("backtracking"). During backtracking, RNA is extruded through the pol II pore into the funnel. Backtracking can lead to transcriptional pausing and arrest. Pausing is defined as a temporary block to elongation, from which pol II can escape by itself. In contrast, pol II cannot escape from arrest without the help of the transcript cleavage factor TFIIS, which stimulates a weak intrinsic nuclease activity of pol II, which cleaves RNA. Access of TFIIS to the pol II active site is apparently provided via the funnel and pore. Backtracking and TFIIS action may also underlie "proofreading" of the nascent transcript. During proofreading, a misincorporated nucleotide results in a mismatch base pair within the DNA–RNA hybrid. The induced distortion of the hybrid destabilizes the elongation complex and can lead to immediate cleavage of a mononucleotide, or it can trigger in backtracking, which results in threading of a short stretch of RNA (comprising the misincorporated nucleotide) into the pore and cleavage with the help of TFIIS. Any proofreading reaction creates a new RNA 3′-end at the active site, from which transcription can resume.

Termination

Transcription termination occurs in a reaction coupled to RNA 3′-end processing. Most eukaryotic mRNA precursors are cleaved in a site-specific manner in the 3′-untranslated region, followed by polyadenylation of the upstream cleavage product. A large number of proteins is involved in these reactions. The exact mechanism of coupling between 3′-end processing and transcription termination remains unclear. Termination is accompanied by dephosphorylation of the pol II CTD, but the precise timing of pol II dephosphorylation is also unclear. Dephosphorylation is required for the reinitiation of transcription, since pol II can only join an initiation complex in its unphosphorylated form. The CTD phosphatase Fcp1 plays a key role in pol II dephosphorylation and recycling. Fcp1 binds to pol II via Rpb4. Rpb4 apparently recruits Fcp1 to the vicinity of the CTD since the Rpb4/7 complex binds near the linker that connects the pol II core to the CTD.

Conservation

Pol II belongs to the family of cellular RNA polymerases, which also includes the two other eukaryotic RNA polymerases, pol I and pol III, and the bacterial and archaeal RNA polymerases. All three eukaryotic RNA polymerases share five common subunits (Table I). Four core subunits of pol II, Rpb1, Rpb2, Rpb3, and Rpb11, as well as subunit Rpb9, all have close homologues in pol I and pol III. Recent studies show that the Rpb4/7 complex of pol II also has structural and functional counterparts in pol I and pol III, and in the archaeal RNA polymerase. Since the 12 subunits of pol II are either identical or homologous in all three eukaryotic enzymes, the pol II structure is a good model for all eukaryotic RNA polymerases. Comparison of pol II with a bacterial RNA polymerase structure revealed that five core subunits underlie a general RNA polymerase architecture with an active center cleft. Twenty-two regions of sequence homology cluster around the active site and generally adopt the same structure in all cellular RNA polymerases. The structurally conserved core includes the functional elements of the active center, indicating that all cellular RNA polymerases share common mechanistic features. Homologues for all pol II subunits (except Rpb8) are found in archaeal RNA polymerases. Thus the overall structure of archaeal RNA polymerases is very similar to that of pol II except several external domains.

The pol II structure is strikingly different from structures of the many single subunit DNA and RNA polymerases. However, in functional complexes of these diverse enzymes, nucleic acids take a similar course through the active center. The entering DNA duplex encloses an angle of $\sim 90°$ with the exiting template–product duplex. At the location of the bend, subsequent DNA template bases are twisted. This twist aligns the coding base with the binding site for the incoming nucleoside triphosphate substrate. The nucleoside triphosphate enters through an opening that is found in all polymerases, and generally binds between an α-helix and two catalytic metal ions. The exiting template–product duplex is bound from the minor groove side in all polymerases. Conformational changes upon nucleic acid binding have been detected for several different polymerases, but the nature of this "induced fit" differs.

RNA Polymerase Reaction in Bacteria

Arkady A. Mustaev and Alexander D. Goldfarb
Public Health Research Institute, Newark, New Jersey, USA

The expression of genetic information encoded in DNA requires the production of an RNA molecule (known as transcription) using DNA as a template. The resulting RNA (the transcript) represents an exact copy of the transcribed DNA segment, or the gene. Information in RNA is encoded using a four-letter alphabet of nitrous bases, the same as in DNA, with the difference that uracil (U) is used in RNA instead of thymine (T). In addition to the copying of the DNA sequence into RNA, the transcription process involves the selection of the beginning (promoter) and the end (terminator) of each gene.

Transcription: Basic Mechanism

RNA synthesis requires base-pairing interactions between the single-stranded DNA template and ribonucleoside-5′-triphosphate (NTP) substrates. Thus, transcription involves unwinding of a small section (10–13 nucleotide residues) of the DNA double helix at which point one of the two DNA strands acts as a template for RNA synthesis. The unwound portion of DNA is called the transcription bubble; it contains a DNA–RNA hybrid of 8–9 base pairs. Each elementary step of transcription constitutes the incorporation of an NTP at the 3′ terminus of the growing RNA chain, so that the bubble propagates stepwise along the template accompanied by unwinding of the DNA duplex ahead, peeling of the transcript from the hybrid, and closing of the DNA duplex behind.

The nucleotide addition is accomplished through the formation of a phosphodiester bond and the release of pyrophosphate (PPi). It is a highly energetically favorable reaction ($\Delta G \cong 7$ kcal/mol), which is practically irreversible under physiological conditions but may be reversed *in vitro* by excess of PPi. As the result, a linear RNA polymer is built in the 5′ to 3′ direction. Selection of the substrates is achieved through hydrogen bonding between complementary bases, adenine to thymine (or uracil), and guanine to cytosine.

The enzyme that performs transcription of cellular DNA is called DNA-dependent RNA polymerases (RNAPs). The best characterized RNAP is that from the bacterium *Escherichia coli*. RNAP's catalytic core enzyme contains five subunits (α_2, β, β', and ω) and has an M_r of 390 kDa. The sixth interchangeable subunit, σ, is derived from a group of related polypeptides of different size. The σ-subunit is a specificity factor, which transiently associates with the core enzyme to form the holoenzyme that is capable of recognition of and specific binding to the promoter. The most common σ-factor in the bacterial cell is σ70. In contrast to DNA polymerase, the RNAP holoenzyme is able to initiate RNA synthesis starting from NTP and does not require a primer. Transcription is completely processive, i.e., RNAP is associated with the transcription bubble at all times in a ternary complex in which the nucleic acid scaffold slides through the protein as the bubble propagates. At the termination site, the ternary complex dissociates, the bubble collapses, and single-stranded RNA product is released.

Thus, synthesis of a particular transcript can be divided into three distinct steps: initiation, elongation, and termination, which jointly constitute the transcription cycle (Figure 1). Each step of the transcription cycle is subject to regulation either by factors external to the transcriptional apparatus or by signals encoded in the DNA sequence.

Transcription Initiation

The search for a promoter occurs through occasional collision and sliding of RNAP along DNA. Sliding greatly accelerates the search, which is concluded by establishment of specific contacts between RNAP and a promoter in a relatively unstable closed complex. In bacteria, the RNAP holoenzyme binds to the promoter region from -70 to -40 to $+30$ nucleotides relative to the transcription start site. Within the promoter, RNAP usually recognizes two relatively short sites centered around the positions -35 and -10 (Figure 2A), which are contacted by the σ-subunit. Some of the promoters contain an additional recognized sequence, the so-called UP element, which spawns the register -60 to -40 and interacts with the α-subunit of RNAP.

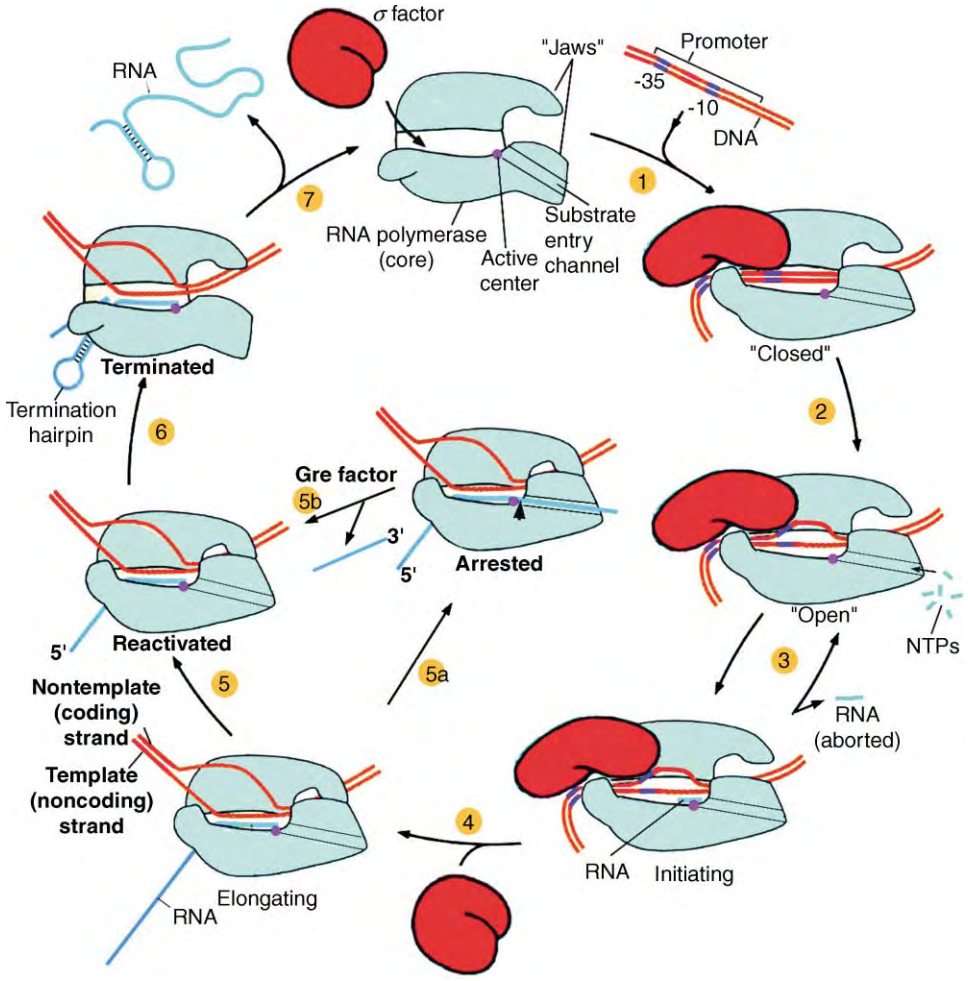

FIGURE 1 The transcription cycle. The RNAP core enzyme associates with the σ-factor and recognizes a promoter (step 1). RNAP locally melts the DNA duplex and starts RNA synthesis on the template strand of DNA (steps 2 and 3). The enzyme is still anchored to the promoter due to specific contacts with the recognition sequence, which impede the promoter escape, causing premature dissociation of short RNA products and their resynthesis in the cyclic reaction of abortive initiation. Occasionally, some RNA products that have reached a critical size (approximately 8–10 nucleotides) enter the RNA exit channel and displace the σ-factor. This leads to the stabilization of the transcription complex and relinquishing of the contacts between the σ-subunit and the promoter (step 4). The ternary elongating complex is highly processive. At certain sequences, RNAP occasionally backtracks, losing its grip on the growing RNA end, which extrudes beyond the active center, rendering the complex inactive (step 5a). The transcription factor GreB assists with cleavage of the extruded RNA, reactivating the enzyme (step 5b). Eventually, the elongating complex encounters a terminator, which causes the enzyme to stop and release the transcript due to a conformational change induced by the RNA hairpin. The RNAP core enzyme can rebind σ-factor and perform another cycle of transcription.

Even though the sequence of promoters is not strictly conserved (which accounts for variations in their efficiency), there are certain nucleotides that are found with high frequency at each position of a consensus sequence. The consensus sequences for the -35 and -10 positions are TTGACA and TATAAT, respectively. Some promoters have an extended -10 recognition region with the invariant dinucleotide TG just one nucleotide upstream of the main consensus sequence. The typical length of the nonspecific spacers between the -35 and -10 regions and from the -10 region to the first transcribed nucleotide are 17 and 7 nucleotides, respectively, with slight variations (Figure 2B).

Much of the regulation of gene expression occurs at the level of promoter recognition. Promoters can be subdivided into two groups, constitutive promoters, whose activity always remains constant, and regulated promoters, in which RNAP has to be recruited by an auxiliary protein factor or the promoter is blocked by bound repressor. For example, cAMP receptor protein activates promoters for the production of enzymes involved in the metabolism of some sugars, whereas Lac repressor blocks transcription of the genes for utilization of lactose.

After promoter recognition, the DNA double helix unwinds locally, resulting in the formation of the open

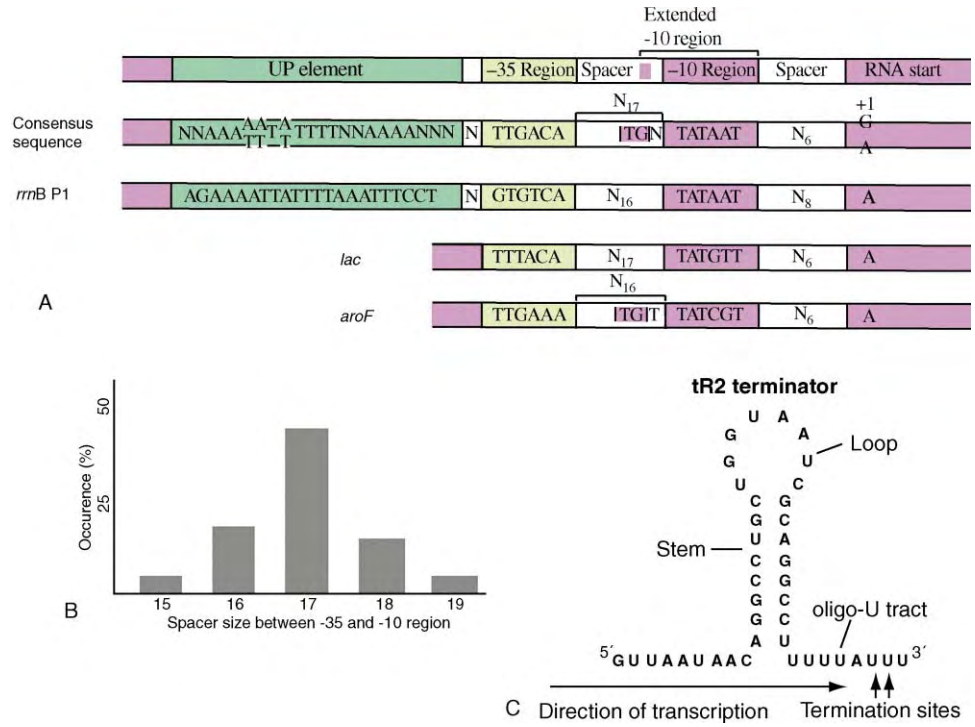

FIGURE 2 Bacterial promoters and terminators. (A) Typical promoters recognized by the RNAP holoenzyme containing σ70. Sequences of the nontemplate strand at the recognition sites are shown in the direction from 5′ to 3′. The structure of the promoters is variable, which is consistent with the wide range of their efficiency. The recognition sequences are highlighted. (B) Variation in the spacer size between the −10 and −35 regions in natural promoters. (C) The structure of a typical ρ-independent terminator. The tR2 terminator shown contains two self-complementary G-C reach regions followed by oligo-U tracts. The termination site is usually located 7–8 nucleotides downstream from the stem of the RNA hairpin.

complex (Figure 1, step 2). At this point, the active center of the RNAP enzyme can initiate synthesis. The initial short RNA molecules are poorly retained at the active center and dissociate into solution in a phenomenon called abortive synthesis (Figure 1, step 3). After each abortion cycle, the enzyme remains promoter bound, and it reinitiates and releases RNA again until it eventually escapes the promoter. This escape to the elongation phase occurs after the size of the transcript reaches 7–11 nucleotides. Transition from initiation to elongation (promoter clearance) (Figure 1, step 4) is accompanied by the relinquishing of the sequence-specific interactions between DNA and the σ-subunit complex and often by dissociation of σ. In some cases, however, the subunit remains associated with RNAP.

Transcription Elongation

Even though the ternary elongation complex (TEC) is exceptionally stable to dissociation, it is maintained only by topological contacts between protein, DNA, and RNA, which allow free sliding of the enzyme along the template. During elongation, TEC acts as a powerful motor, generating a force (25 pN) greatly exceeding that for conventional cellular motors such as kinesin and myosine. The relative force generated by RNAP is about 10^6 times greater than that generated by the space shuttle carrier.

The principal nucleic acid–protein interactions in TEC occur at three crucial operationally defined sites (Figure 3): the DNA-binding site that holds on to the downstream DNA duplex and acts as a sliding clamp, and the front and rear zip-locks at the ends of the RNA–DNA hybrid-binding site that accommodates the RNA–DNA heteroduplex (Figure 3B). The rear zip-lock ensures displacement of RNA product from the template during elongation. The front zip-lock coincides with the RNAP active center and also enables peeling of RNA from DNA upon TEC's occasional backtracking, a process in which the bubble propagates backward while extruding the 3′ terminus of RNA (Figure 1, step 5a).

In the X-ray crystal structure of TEC (Figure 3A), the DNA-binding site is seen as a deep trough formed by the β'-subunit, which is topped by a "roof" formed by a domain of the β-subunit. The RNA–DNA hybrid is enclosed in the main channel formed by the β- and β'-subunits of the enzyme, between the active center at its downstream end and the rudder loop of the β'-subunit at its upstream end, corresponding to the front and rear zip-locks, respectively. The active center, which contains

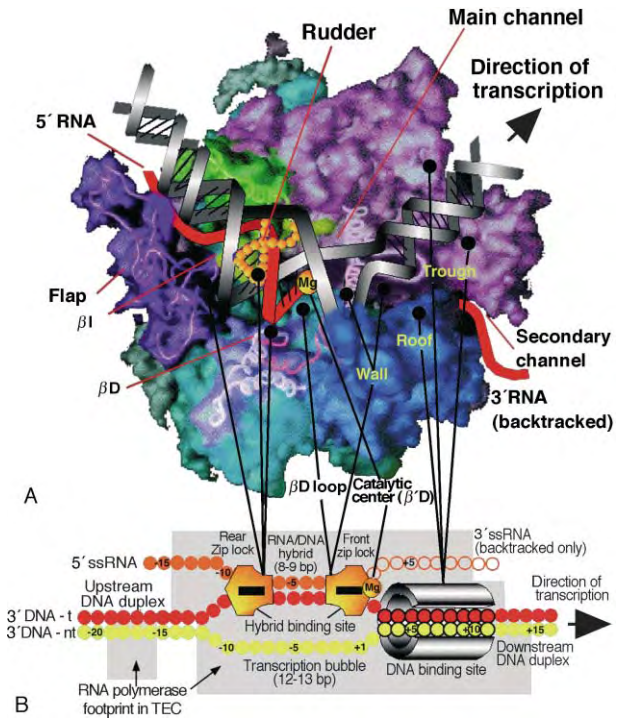

FIGURE 3 A structure–function model of the ternary elongating complex (TEC). (A) A model of TEC based on the X-ray crystal structure of RNAP. White lines show the correspondence between the operationally defined functional elements and the structural features of TEC. (B) The nucleic acid scaffold and its interactions with RNAP protein in TEC. The five elements are the upstream and downstream DNA duplexes, the 8–9 bp RNA–DNA hybrid, the single-stranded region of DNA in the transcription bubble, and the nascent single-stranded RNA upstream of the hybrid. In the "backtracked" complex, an additional segment of RNA appears downstream of the bubble. Filled circles represent the DNA (red, template strand; yellow, nontemplate strand); the DNA-binding site is represented by the sliding clamp that encloses 9 bp of the downstream DNA duplex. The hybrid-binding site that accommodates the RNA–DNA heteroduplex is flanked by the two zip-locks that hold on to the edges of heteroduplex and either zip or unzip the hybrid, maintaining its constant size during lateral movement of RNAP. The gray area shows the RNAP footprint on DNA.

the stably bound catalytic Mg^{2+} ion, marks the beginning of the secondary channel, which is used for the supply of NTP substrates and which accommodates the 3′-terminal end of single-stranded RNA upon RNAP backtracking. The secondary channel is branched from the main channel by the wall. The 5′ segment of the nascent transcript exits through the channel underneath the flap, which is a long flexible loop of the β-subunit.

The rate of RNA synthesis in elongation is sequence dependent, usually about 10 to 50 nucleotides per second, but can slow down to a full stop at points called pausing sites. One of the reasons for pausing is the energetics of base-pairing in the DNA–RNA scaffold of TEC. The energy of base-pairing is not equal for different nucleotides (ranging from 0.9 to 3.2 kcal/mol), so that TEC translocation is strongly suppressed at certain sites. In extreme cases, this causes reversible backtracking or even irreversible transcriptional arrest. The GreB protein rescues the arrested complex by stimulating RNA cleavage activity intrinsic to the RNAP active center, releasing the extruded 3′ RNA segment, and allowing RNA synthesis to continue (Figure 1, step 5b). A homologous GreA protein facilitates RNA cleavage in slightly backtracked TECs (by 1 or 2 nucleotides), thus preventing the arrest pathway.

Pausing, backtracking, and excision regulate elongation rate and serve to correct errors of elongation, which occur at a rate of one per every 10^4–10^5 nucleotides (compare with the fidelity of replication—one misincorporation per 10^7 nucleotides).

The RNA synthesis in bacteria is sensitive to inhibitors. The most important are rifampicin, streptolydigin, and microcin J-25. Rifampicin plugs the RNA exit channel in TEC, streptolydigin inhibits RNAP translocation, and microcin J-25 most likely blocks the NTP entry into the active center.

The Unified Catalytic Mechanism of RNA Synthesis and Degradation

The principal enzymatic activity of RNAP is the transfer of nucleotidyl moiety from the NTP substrate to the 3′ hydroxyl of the RNA terminus. Thus, the RNAP active center (Figure 4) *a priori* includes the binding site for the RNA terminus (i site) and the site for the NTP donor of the nucleotidyl residue (i + 1 site). The formation of the phosphodiester bond is followed by translocation of the newly formed RNA terminus from the i + 1 to the i site. The reaction and the movement are reversible: excess of PPi stimulates processive degradation of RNA (pyrophosphorolysis) with the release of 3′-terminal RNA residues in the form of NTPs. The RNAP active center can also perform hydrolysis of RNA in backtracked and arrested complexes. Central to these reactions is a symmetrical pair of Mg^{2+} ions that switch their roles in synthesis and degradation (Figure 4). One ion is retained in RNAP permanently (I) while the other is recruited for each act of catalysis (II). In polymerization reactions, it is recruited by incoming NTP (Figure 4A), whereas in cleavage reactions it is recruited by carboxylate residues of the Gre factors (Figure 4B).

Transcription Termination

Termination signals are encoded in the DNA sequence. There are two classes of termination signals in bacteria: one in which termination is assisted by a protein factor ρ, and another in which termination is ρ independent. The ρ-independent terminators (Figure 2C) contain

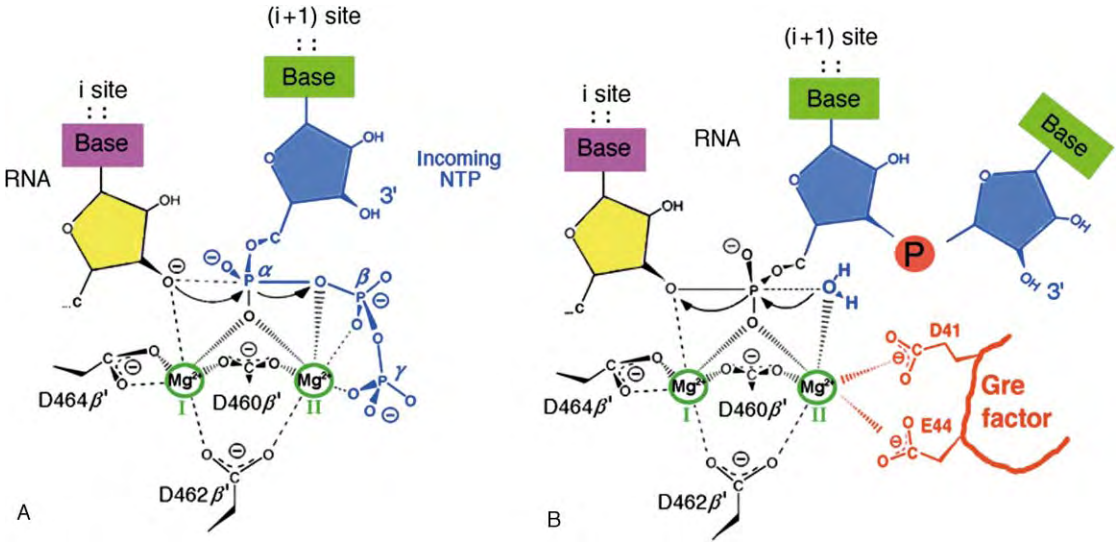

FIGURE 4 Catalytic mechanism of in RNA synthesis and degradation by RNAP. (A) The nucleotidyl transfer reaction. Two Mg^{2+} ions coordinated by three aspartate residues of the active center are enclosed in green circles. The tightly bound Mg-I activates the 3′ hydroxyl of the terminal RNA residue, promoting its attack on the α-phosphorus of the incoming NTP, and stabilizes the penta-coordinated transition state, while Mg-II facilitates the release of PPi during the phosphodiester bond formation. (B) The transcript cleavage reaction, assisted by the Gre factor. The Gre protein recruits the weakly bound Mg-II by providing residues for additional coordination. Mg-II orients and activates the attacking water molecule for hydrolytic cleavage of the phosphodiester bond. Mg-I coordinates the 3′ hydroxyl group of the RNA residue occupying the i site of the active center, making it a better leaving group. The disengaged 3′ RNA terminus is tilted to reflect the loss of base-pairing with DNA through backtracking.

short self-complementary GC-rich sequences followed by an oligo-A tract. Transcription of such sequences is accompanied by pausing of RNAP due to backtracking, which ensures the formation of a hairpin-like RNA structure (Figure 1, step 6). The RNA hairpin destroys the nucleic acid contacts in the rear zip-lock, forcing the rudder and the flap to open, which leads to collapse of the transcription bubble and disintegration of the transcription complex (Figure 1, step 7).

The ρ-dependent termination also requires pausing, but entails sequences without oligo-A tracts. The ρ protein loads onto RNA at some distance behind TEC and moves along the transcript toward RNAP, using the energy of ATP hydrolysis. Eventually, the factor bumps into the enzyme and pulls out RNA from the complex, causing the release of the transcript and dissociation of RNAP from DNA.

Biography

Arkady A. Mustaev is a Research Associate at the Public Health Research Institute in Newark, New Jersey. He holds a Ph.D. from the Novosibirsk Institute of Bioorganic Chemistry (Russia). His principal research interest is studies of the catalytic mechanism of RNA polymerase. He developed superselective affinity labeling and fast mapping of the cross-linking sites in proteins, use of which allowed the design of a high-resolution model of the transcription elongation complex.

Alex Goldfarb is a Professor at the Public Health Research Institute. He holds a Ph.D. from the Weizmann Institute of Science in Israel. His principal research interest is the molecular mechanisms of transcription.

RNA Polymerase Structure, Bacterial

Michael Anikin, Dmitri Temiakov and William T. McAllister
State University of New York, Downstate Medical Center, Brooklyn, New York, USA

The first step in gene expression, transcription of genetic information in the DNA into messenger RNA, is carried out by DNA-dependent RNA polymerase (RNAP). Understanding how this enzyme carries out RNA synthesis and responds to regulatory signals is of fundamental importance to the comprehension of gene regulation. Extensive studies over the past decade (i.e., since 1990s) have probed the nature of the machinery that carries out this process. These approaches have involved genetics (identification and characterization of the genes that encode the protein subunits of the RNAP and the transcription factors that interact with the RNAP) and biochemical approaches (such as cross-linking experiments to characterize the trajectory of the nucleic acid components within the transcription complex). More recently, structural studies using methods such as NMR, X-ray crystallography, and fluorescence resonance energy transfer (FRET) have been brought to bear in an attempt to characterize the transcription complex in greater detail. The past few years have seen unprecedented breakthroughs in our understanding of the organization and function of the transcription complex, resulting in high resolution structures that may be interpreted in light of the abundant genetic and biochemical data. An overview of our understanding of the organization of bacterial RNAPs, and the relationship of structure to the mechanism of polymerase action is provided in this article.

Organization of the Transcription Complex

In a bacterium such as *E. coli* (the paradigm for studies of bacterial RNAPs), the minimal configuration needed for transcript elongation is a "core" complex that consists of five subunits, ($\alpha_2\beta\beta'\omega$) having an aggregate molecular weight of ~400 kDa and an additional factor, σ, is required for recognition of the promoter during initiation, and other factors may regulate the ability of the polymerase to clear the promoter, enhance processivity, or modulate termination. RNAPs from eukaryotic cells also have multiple subunits, and many of these subunits are homologous to the core subunits found in the bacterial RNAP. Thus, much of the information that comes from the study of bacterial RNAPs has direct relevance to studies of RNAPs from higher organisms.

Unlike DNA polymerases (DNAPs), which extend a primer and leave the polynucleotide product in association with the template, RNAPs must displace the RNA product from the template and restore the DNA to duplex form after the passage of the enzyme. To accomplish this, the polymerase establishes a locally unwound transcription bubble of ~12–14 bp which encloses an RNA:DNA hybrid that extends ~8 bp upstream from the growing end of the RNA chain. As the polymerase moves downstream, the two DNA strands are separated at the leading edge of the bubble and reannealed at the trailing edge, where the RNA is displaced (see Figure 1).

Extensive biochemical and genetic experimentation anticipated the essential elements that are required for RNA synthesis, and a general understanding of the organization of the complex (Figure 1). A central cavity encloses the active site and the short RNA:DNA hybrid where the nascent transcript is found before its displacement from the template (T) strand of the DNA. Leading into this cavity are pores and channels for the entrance and exit of the duplex DNA, an exit channel for the RNA product, and a substrate entrance pore. Another channel is required to accommodate the locally displaced nontemplate (NT) strand of the DNA in the transcription bubble.

Structure of the Core Enzyme

For a number of reasons, RNAPs from thermophilic organisms such as *Thermus aquaticus* (*Taq*) have proven more amenable for crystallographic analysis than the *E. coli* enzyme. A high resolution structure of the *Taq* core RNAP is shown in Figure 2. The overall organization of the enzyme resembles that of a crab claw which surrounds an open cleft in which the DNA is bound. The active site (which involves coordination of two Mg^{++} ions that are essential for the phosphoryl transferase reaction) is located at the back of this cleft. Many of the features that are important for the catalytic steps and processivity described above may be visualized

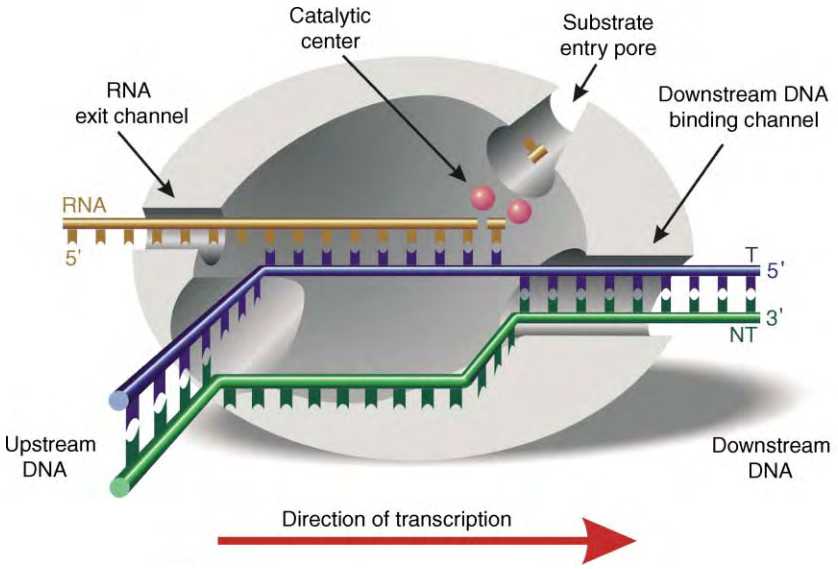

FIGURE 1 Organization of the transcription complex. The elongating RNA is found in the interior of the protein as an 8 bp RNA:DNA hybrid (RNA yellow, DNA blue). The nontemplate strand of the DNA (green) is displaced from the template strand at the leading edge of the transcription bubble and reannealed at the trailing edge. Channels that lead to the interior cavity allow for entry and exit of the duplex DNA, exit of the RNA product, and entrance of substrate. Elongation of the RNA chain occurs at the active site (catalytic center) where the phosphoryl transferase reaction is catalyzed by a pair of magnesium ions (purple spheres).

in this structure. Although the structure of an elongation complex of the bacterial RNAP in association with all of the nucleic acid components has not yet been determined, the structure of a yeast RNAP elongation complex has been solved. The organization of the eukaryotic complex is remarkably similar to that of the bacterial enzyme.

FIGURE 2 Structure of the *Taq* core enzyme. The core subunits are color coded as indicated. A magnesium ion in the active site is indicated by a purple sphere.

The bacterial RNAP structure is supported, and is made interpretable, by the results of previous biochemical and genetic experiments that identified important functional regions of the various subunits, and the nature of their interactions with nucleic acid components. In addition to the general features described in Figure 1, more details concerning the mechanism of transcription are revealed by the structure. These include upstream and downstream "zippers" for unwinding and rewinding the duplex DNA and displacing the product, and the organization of the active site. Nevertheless, more information will be required to understand other aspects of transcription, such as the mechanism of substrate selection and discrimination (ribo- versus deoxyribonucleotides), and how the movement of the RNAP along the template (translocation) is controlled.

Structure of the Holoenzyme

One of the key events during the transcription process is the transition from an unstable initiation complex to a processive elongation complex, which is accompanied by release of the promoter contacts and movement of the RNAP away from the promoter. The σ factor is intimately involved in promoter recognition and in the early stages of transcription. Association of σ with the core enzyme results in the formation of the "holoenzyme", which carries out the early stages of transcription. The structure of the holoenzyme from *Thermus thermophilus* (*Tth*) is shown in Figure 3.

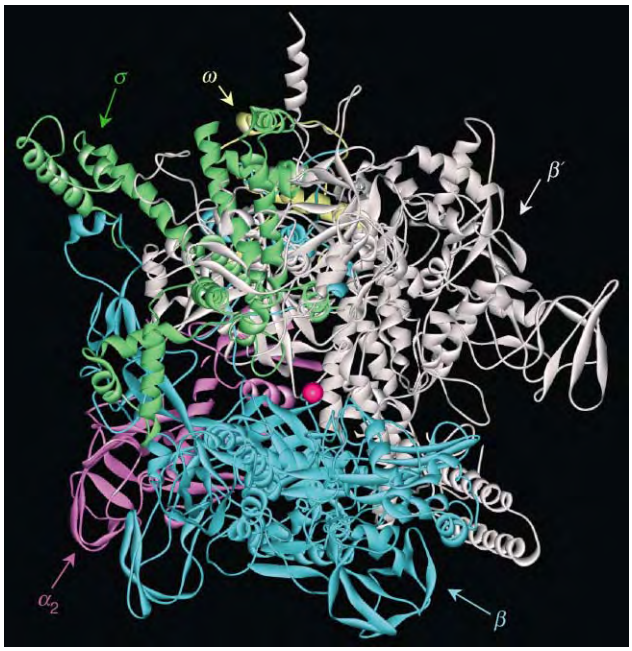

FIGURE 3 Structure of the *Tth* holoenzyme. The subunits of the core enzyme are colored as in Figure 2; (σ factor is green). The surface-exposed components are available for binding to the promoter DNA in a specific manner; a portion of σ is embedded in the hybrid binding cleft, and must be displaced during initiation.

In this structure, the regions of σ that are known to be involved in promoter recognition are displayed on the surface of the enzyme, where they would be able to interact with the upstream regions of the promoter. However, a flexible loop segment of σ is buried within the core enzyme, and occupies part of the RNA exit channel and the RNA:DNA hybrid binding cavity. This portion of σ would need to be displaced during initiation, perhaps precipitating the loss of σ that occurs during the transition to the elongation phase.

Structure of a Single Subunit Phage RNAP

Although the multisubunit RNAP described above is responsible for transcription of cellular DNA under normal growth conditions, there are occasions in which other RNAPs may also be operative within the bacterial cell. For example, certain viruses that infect bacteria encode a new RNAP that is responsible for transcription of the viral genome. The paradigm of this is the RNAP encoded by bacteriophage T7, which consists of a single subunit of ~100 kDa. Although this enzyme does not exhibit any amino acid sequence conservation with the bacterial enzymes, it is related to mitochondrial polymerases and with many organellar RNAPs from higher cells and plants (e.g., chloroplasts). It thus appears to be an evolutionarily conserved RNAP that arose at a different time from the multisubunit RNAPs. Interestingly, the phage RNAPs are also related to bacterial DNAPs and to reverse transcriptases. They are therefore members of a superfamily of nucleotide polymerases that is distinct from the multisubunit RNAPs.

Despite the differences in the sequence and detailed structure of the phage RNAP versus the bacterial RNAP, the phage RNAP nevertheless carries out all of the steps in the transcription cycle in an identical manner to the multisubunit RNAPs, including promoter recognition, elongation, and termination.

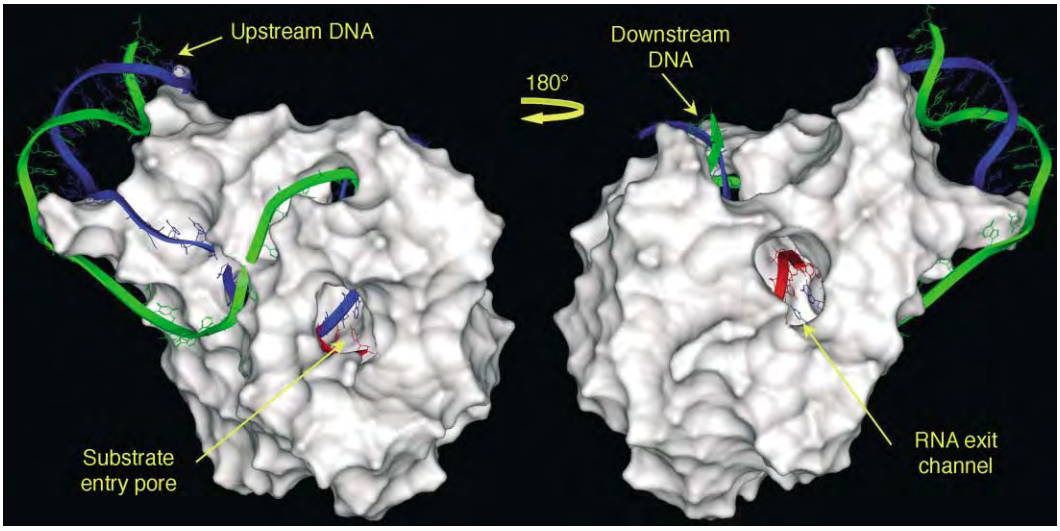

FIGURE 4 Model of a T7 RNA polymerase elongation complex just prior to promoter release. The RNAP maintains contacts with the upstream region of the promoter until it enters a fully processive elongation mode; potential interactions of the promoter with the RNAP at this stage of initiation are shown (DNA template strand, blue; nontemplate strand, green; RNA, red). The substrate entry and RNA exit channels are indicated.

Characterization of phage RNAP structures is more comprehensive than that of the bacterial RNAPs. Structures have now been solved for the free enzyme, the enzyme in association with its promoter, an early initiation complex, and elongation complexes in the presence and absence of substrate. Thus, many of the events in the overall transcription cycle have been captured in atomic detail for the phage RNAP.

The transition from an initiation complex to an elongation complex by T7 RNAP is accompanied by a massive reorganization of the amino terminal one-third of the enzyme (Figure 4). Remarkably, after the transition to an elongation complex, the overall organization of T7 RNAP resembles the organization of the bacterial RNAP, having an RNA:DNA hybrid of ~8 bps, pores for substrate entry and exit, a channel for the displaced NT strand, and regions for binding of upstream and downstream DNA. More detailed examination of the phage RNAP reveals elements that are involved in displacing the RNA product and for reannealling the T and NT strands at the upstream edge of the bubble, as well as mechanisms for substrate selection and translocation control. Due to the conservation in the overall mechanism of transcription, many of the findings from the phage RNAPs are likely to inform experimental approaches in the multisubunit RNAPs.

Future Prospects

Until the past few years, characterization of transcription complexes had relied largely upon biochemical and genetic approaches. The merger of structural methods with biochemical and genetic methods now affords the opportunity to determine the organization of the complexes at each stage of the transcription cycle with atomic resolution, and to correlate this structure with mutational and biochemical analyses.

Biography

Michael Anikin received his Ph.D. in Bioorganic Chemistry from the Moscow Institute of Fine Chemical Technology.

Dmitri Temiakov received his Ph.D. in Molecular Biology from the Institute for Genetics and Selection of Microorganisms, Moscow.

William McAllister, Professor and Chair, received his Ph.D. from the University of New Hampshire, and postdoctoral training at the University of Heidelberg.

The authors are in the Morse Institute for Molecular Genetics, Department of Microbiology and Immunology, SUNY Downstate Medical Center, Brooklyn, NY. The research interests of the laboratory focus upon the structure and function of the single subunit bacteriophage T7 RNA polymerase.

Editors-in-Chief

William J. Lennarz

State University of New York at Stony Brook, Stony Brook, New York, USA

Section: Lipids, Carbohydrates, Membranes and Membrane Proteins

WILLIAM J. LENNARZ received his B.S. in Chemistry from Pennsylvania State University and a Ph.D. in Organic Chemistry from the University of Illinois. Subsequently he carried out postdoctoral work at Harvard with Konrad Bloch on fatty acid biosynthesis. In 1962 he was appointed Assistant Professor at Johns Hopkins in the Department of Physiological Chemistry. After promotion to Associate Professor in 1967, and full Professor in 1971, he remained at Hopkins until 1983. At that time, he was appointed Robert A. Welch Professor and Chair of the Department of Biochemistry and Molecular Biology at the University of Texas Cancer Center, M.D. Anderson Hospital. In 1989 he became a Leading Professor and Chair of the Department of Biochemistry and Cell Biology at SUNY at Stony Brook. In 1990 he founded and became Director of the Institute for Cell and Developmental Biology at Stony Brook.

Dr. Lennarz has served on many national and international committees. He has served as President of the Biochemistry Chairman's Organization, President of the American Society for Biochemistry and Molecular Biology and President of the Society for Glycobiology. He was a member of the Executive Committee of the International Union of Biochemistry and Molecular Biology for almost a decade.

He has presented special lectures at the University of Notre Dame, the NIH, the University of West Virginia, Johns Hopkins University, Florida State University, the University of California at San Diego, the University of Arkansas, Indiana University and the Medical College of Virginia.

He is a member of the National Academy of Sciences. The focus of his early work was on lipids and bacterial cell surfaces. More recent efforts have been in the structure, biosynthesis and function of cell surface glycoproteins. The biosynthesis studies initially were carried out in liver and oviduct, but these efforts now are focused in yeast. The functional studies have concentrated on the role of cell surface glycoproteins in fertilization and early development in the sea urchin and, more recently, the frog. For over 30 years Dr. Lennarz' research has been supported by federal sources, primarily the National Institutes of Health. Recently he was appointed Distinguished Professor and Chair of his department.

M. Daniel Lane

The Johns Hopkins University, School of Medicine, Baltimore, Maryland, USA

Section: Metabolism, Vitamins and Hormones

M. DANIEL LANE received B.S. and M.S. degrees in 1951 and 1953 from Iowa State University and a Ph.D. in 1956 from the University of Illinois. He was a Senior Postdoctoral Fellow with Professor Feodor Lynen at the Max-Planck Institute Fur Zellchemie in Munich. Following faculty positions at Virginia Polytechnic Institute and New York University School of Medicine, he joined the faculty at the Johns Hopkins University School of Medicine in 1969 and served as DeLamar Professor and Director of the Department of Biological Chemistry from 1978 to 1997. He is presently Distinguished Service Professor at Johns Hopkins. In 2002 he received an honorary degree, Doctor of Humane Letters, from Iowa State University.

Dr. Lane was elected to membership in the National Academy of Sciences (in 1987) and was elected as a Fellow of the American Academy of Arts and Sciences (in 1982) and of the American Society of Nutritional Sciences (in 1996). He received the Mead Johnson Award from the American Society for Nutritional Sciences in 1966 for his research on biotin-dependent enzymes and in 1981, the William C. Rose Award from the American Society for Biochemistry and Molecular Biology for his work on the insulin receptor. In 1990–1991 Lane served as President of the American Society of Biochemistry and Molecular Biology. He has presented many named lectureships (including the

Feodor Lynen Lecture in Germany in 1999) and served on numerous editorial boards including the Journal of Biological Chemistry and the Annual Reviews of Biochemistry. Currently he is Associate Editor for Biochemical and Biophysical Research Communications.

Dr. Lane has published 280 research papers in major scientific journals. His early work focused on various enzymatic CO_2 fixation reactions, notably the mechanisms by which the B-vitamin, biotin, functions in enzymes to catalyze carboxylation. Dr. Lane's work on the regulation of acetyl-CoA carboxylase, the key regulatory enzyme of fatty acid synthesis, led him to his present interests which are to understand the basic mechanisms of lipogenesis, adipogenesis and the consequence of aberrations in these processes, most notably obesity. Research currently underway in his laboratory focuses on: (1) the genes that signal stem cell "commitment" to the adipocyte lineage and subsequent differentiation into adipocytes, and (2) the mechanisms by which the region of the brain, known as the hypothalamus, monitors and controls the drive to eat.

Associate Editors

Ernesto Carafoli

Università degli Studi di Padova, Padova, Italy
Section: Bioenergetics

ERNESTO CARAFOLI earned his M.D. degree at the University of Modena in Italy in 1957. After postdoctoral studies in the Laboratory of Albert L. Lehninger at Johns Hopkins University in the mid 1960s he returned to his home institution in Italy where he worked until 1973, when he was appointed Professor of Biochemistry at the Swiss Federal Institute of Technology (ETH) in Zurich. He returned to Italy in 1998 as a Professor of Biochemistry at the University of Padova, where he now also directs the newly founded Venetian Institute of Molecular Medicine (VIMM).

Dr. Carafoli became interested in calcium as a signaling agent during his post-doctoral days at Johns Hopkins. When he arrived there his main interests were in mitochondrial bioenergetics and it was thus natural for him to expand them to the newly discovered area of mitochondrial calcium transport. He was involved in most of the early discoveries in the field, and he continued to work on mitochondria and calcium after his return to Italy and until he moved to the ETH. There his interests still remained focused on calcium, but the emphasis shifted to the proteins that transport it across membranes and to those that process its signal. His favorite object of study became the calcium pumps, especially that of the plasma membrane, an enzyme which is essential to the regulation of calcium homeostasis and thus to the well being of cells. His contributions on the enzyme, especially after he purified it in 1979, have helped establishing most of its properties and have clarified important problems of mechanism, regulation and structure.

Dr. Carafoli has authored or co-authored about 450 peer-reviewed articles and reviews, and has edited or co-edited about 20 books. He has served on the Editorial or Advisory Boards of several periodicals and has organized about 30 International Workshops and Symposia. He has been featured as a plenary or honorary lecturer at numerous events ranging from specialized Workshops to International Symposia and Congresses. Dr. Carafoli's honors and awards include several international prizes and medals, memberships in several Academies, and three honorary degrees.

Don W. Cleveland

University of California, San Diego, La Jolla, CA, USA
Section: Cell Architecture and Function

DON W. CLEVELAND has been a longstanding contributor to the elucidation of regulation of assembly of mitotic spindles and chromosome movement and how errors in these contribute to the chromosome loss characteristic of human tumors. He discovered the tubulin gene families encoding the major subunits of microtubules and the first mammalian example of control of gene expression through regulated RNA instability. He identified components required for microtubule nucleation and anchoring during spindle assembly. He identified the first human centromeric protein (CENP-B). He then discovered CENP-E, the centromere-associated, microtubule-motor that he showed to be essential for chromosome attachment and for activation and silencing of the mitotic checkpoint, the cell cycle control mechanism that prevents errors of chromosome segregation in mitosis.

Dr. Cleveland has also been a leading force in dissecting the disease mechanism for major human neurodegenerative disorders. He initially purified and characterized tau, the microtubule-associated protein that assembles aberrantly in human dementias including Alzheimer's disease and Pick's disease. He established that the extreme asymmetry of neurons acquired during development is achieved with a deformable array of interlinked neurofilaments, microtubules and actin. He showed that disorganization of neurofilament arrays caused selective death of motor neurons in mice and humans. He also demonstrated that neuronal death could also arise by a toxicity of mutant superoxide dismutase unrelated to its normal activity, thereby uncovering the mechanism underlying the major genetic form of amyotrophic lateral sclerosis. He showed that this toxicity could be

sharply ameliorated by lowering the content of neurofilaments.

Dr. Cleveland is currently Head, Laboratory for Cell Biology in the Ludwig Institute for Cancer Research and Professor of Medicine, Neurosciences and Cellular and Molecular Medicine at the University of California at San Diego. He is also the Editor of the Journal of Cell Biology and Current Opinion in Cell Biology.

Jack E. Dixon

University of California, San Diego School of Medicine,
La Jolla, CA, USA
Section: Protein/Enzyme Structure, Function, and Degradation

JACK E. DIXON earned his Ph.D. in Chemistry at the University of California, Santa Barbara in 1971 and did his postdoctoral training in Biochemistry at the University of California, San Diego.

Dr. Dixon is a pioneer and leader in the structure and function of the protein tyrosine phosphatases (PTPases). He demonstrated that the unique catalytic mechanism of the PTPases proceeds via a novel cysteine-phosphate intermediate. He discovered the first dual-specificity phosphatase, which led to the identification of the cell cycle protein, $p80^{cdc25}$, as a phosphatase. He also showed that the bacteria responsible for the plague or "black death" harbor the most active PTPase ever described. He and his colleagues went on to demonstrate that this PTPase gene product is essential for the pathogenesis of the bacteria. Dr. Dixon and his colleagues determined X-ray structures for both tyrosine and dual specificity phosphatases. Dr. Dixon also found that sequences outside of the PTPase catalytic domain could function to direct the subcellular localization of the PTPases and to restrict their substrate specificity. This is now a widely acknowledged regulatory paradigm for the PTPases. Recently, his laboratory demonstrated that the tumor suppressor gene, PTEN, which shares sequence identity with the PTPases, catalyzes the dephosphorylation of a lipid second messenger, phosphatidylinositol 3,4,5-trisphosphate (PIP3). This represents the first example of a PTPase dephosphorylating a lipid second messenger. PIP3 activates the protein kinase, AKT, which plays a critical role in controlling the balance between apoptosis and cell survival. The loss of the PTEN gene elevates PIP3 levels leading to constitutive activation by AKT and oncogenesis. Recently, Dr. Dixon in collaboration with Nikola Pavletich determined the X-ray structure of PTEN. Their structure–function studies explain the PIP3 substrate specificity of PTEN and also provide a rationale for many of the mutations seen in human cancers. Earlier in his career, Dr. Dixon adopted the tools of molecular biology as they became available in the 1970s, and his laboratory was among the first to use synthetic oligonucleotides to isolate and extensively characterize cDNAs encoding peptide hormones.

Dr. Dixon is Professor of Pharmacology, Cellular and Molecular Medicine and Chemistry and Biochemistry and Dean of Scientific Affairs at the University of California, San Diego. He is a member of the National Academy of Sciences, the Institute of Medicine and the American Academy of Arts and Sciences. Dr. Dixon was the recipient of the 2003 William C. Rose Award from the American Society for Biochemistry and Molecular Biology.

John H. Exton

Howard Hughes Medical Institute, Vanderbilt University School of Medicine, Nashvillie, TN, USA
Section: Signaling

JOHN H. EXTON was born and educated in New Zealand where he received his medical training and a Ph.D. in Biochemistry from the University of Otago in 1963. He did postdoctoral work at Vanderbilt University under Charles R. Park and Earl W. Sutherland, and became an Investigator of the Howard Hughes Medical Institute in 1968 and Professor of Physiology in 1970. He is presently Professor of Molecular Physiology and Biophysics, Professor of Pharmacology and a Hughes Investigator at Vanderbilt.

Dr. Exton's research initially focused on the changes in carbohydrate metabolism in liver during diabetes and treatment with various hormones using the perfused rat liver as the experimental system. His work concentrated on gluconeogenesis and identified the enzymatic reactions that were under control by insulin, epinephrine (adrenaline), glucagon and glucocorticoids, and demonstrated the importance of cyclic AMP in the regulation of these reactions. The role played by the supply of substrates, especially of alanine, was also shown.

Dr. Exton then turned his attention to the action of epinephrine (adrenaline) and demonstrated that many of its actions were not mediated by cyclic AMP but by calcium ions. This led to study of the breakdown of inositol phospholipids by phospholipase C that underlay the increase in calcium. Later this resulted in the discovery of G_q, a novel G protein that activated phospholipase C. Further studies demonstrated that agonists caused the breakdown of another phospholipid (phosphatidylcholine) by another phospholipase (phospholipase D). Current work is focused on the physiological role of phospholipase D.

Dr. Exton has authored over 350 scientific articles and is presently an Associate Editor of the Journal of Biological Chemistry. He has served on many scientific review groups and as a reviewer for many journals. He has won numerous awards, most notably the Lilly

Award of the American Diabetes Association, Fellow of the American Association for the Advancement of Science and election to membership in the National Academy of Sciences.

Paul Modrich

Duke University Medical Center, Durham, NC, USA
Section: Molecular Biology

PAUL MODRICH is an Investigator of the Howard Hughes Medical Institute and James B. Duke Professor of Biochemistry at Duke University Medical Center. He received his undergraduate degree from M.I.T. and his Ph.D. in Biochemistry from Stanford University. His current research addresses the mechanisms of DNA repair. He has served on the editorial boards of the Journal of Biological Chemistry, Biochemistry, Proceedings of the National Academy of Sciences, and DNA Repair. His honors include election to National Academy of Sciences and the Institute of Medicine, the Pfizer Award in Enzyme Chemistry, the General Motors Mott Prize in Cancer Research, and the Pasarow Foundation Award in Cancer Research.

Preface

Biological Chemistry is defined as the chemistry of the compounds and processes that constitute living organisms. The ultimate goal, of course, is to understand and define biology at a mechanistic level. This was aptly stated in an historical treatise on the founding of the *Journal of Biological Chemistry*, where John Edsall quoted a statement in a letter from J. L. Loeb (in Berkeley), "The future of biology lies with those who attack its problems from a chemical point of view." What was an emerging field in 1900 with its origins in physiology, nutrition and chemistry has broadened and expanded to include numerous other fields including mechanistic enzymology, molecular biology, structural biology, cell biology, genomics, proteomics, bioinformatics, metabolomics and others, that were not defined as discrete fields at that time.

Modern biochemistry (biological chemistry) began with the accidental discovery by Eduard Buchner in 1897 that a cell-free yeast extract could carry out fermentation of glucose to alcohol and CO_2 *in the absence of intact cells*. He named the dissolved substance responsible for this process zymase, the substance(s) we now refer to as enzymes. Importantly, Buchner recognized the significance of his discovery. This ended the dogma of the time, perpetuated by Pasteur, the concept of *vitalism*; i.e., that fermentation (and presumably other complex biological phenomena) required the action of intact cells. Thus, serendipity and a prepared mind ushered in a new era of discovery. Now it became possible to dissect complex physiological processes and to study them with preparations free of the constraints of intact cells. Once a metabolic pathway/process was established, it became possible to purify the enzymes, cofactors and substrates involved, to reconstitute the process with purified components and to characterize the components chemically. What followed was an information explosion in the field of biochemistry and progression through a series of trends, each "in vogue" in its time. The identification of the dietary essentials, the hunt for the vitamins/cofactors, the hormones, identification of metabolic pathways and the enzymes involved, oxidative phosphorylation, protein synthesis, molecular biology—each developed as a primary focus.

The need to associate chemistry with function came early and was evident in the naming of departments and journals. Over time names changed from Agricultural Chemistry to Physiological Chemistry to Biochemistry to Biological Chemistry. An example is the Department of Biochemistry at the University of Wisconsin, which began in 1883 as the Department of Agricultural Chemistry.

Where are we headed? We have reached the point where the borders of these areas have become blurred. What constitutes cell biology, molecular biology/genetics, developmental biology, physiology, immunology—ultimately reduces to chemistry. To understand these processes we must know what the molecules are and understand how they interact, i.e. the basic chemistry. That is what this encyclopedia is about.

The breadth of content of this encyclopedia aims to cover major topics of modern biochemistry, each authored by an expert in the area. We feel that the coverage is broad and we have been inclusive in choice of topics. The encyclopedia is a reference work encompassing four volumes containing over 500 articles with more than 750 authors or coauthors. Each article/topic covers an important area of the field which reflects the point of view of the authors. Together the articles cover virtually every aspect of biology for which we have "mechanistic" information. For those who wish to probe more deeply into a topic, references to further readings are included at the end of each article. The editorial board that made decisions on coverage consists of seven members, each an expert representing a major area in the field of biochemistry. A dedicated effort was made to provide coverage that is as complete as possible. The content is presented at a level that we hope will be interpretable to interested individuals with some background in chemistry and biology. It is intended for such individuals rather than specialists with extensive scientific backgrounds in specific areas. It is aimed at the generalist as opposed to the specialist.

Finally, we would like to single out Gail Rice and Dr. Noelle Gracy for their enormous contribution in putting this encyclopedia together. They, in fact, were a driving force that brought this major work to completion.

Notes on the Subject Index

Abbreviations used in subentries without explanation:

CoA	coenzyme A
DAG	diacylglycerol
ELISA	enzyme-linked immunosorbent assay
ERK	extracellular-signal regulated kinase
GlcNAC	N-Acetylglucosamine
HPLC	high-pressure liquid chromatography
IP_3	inositol 1,4,5-triphosphate
MAP	mitogen-activated protein
MMP	matrix metalloproteinase
mtDNA	mitochondrial DNA
NADPH	nicotinamide-adenine dinucleotide phosphate
PFK-2/ FBPase-2	6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase
PI3K	phosphatidylinositol 3-kinase
PIP_2	phosphatidylinositol 4,5-bisphosphate
PIP_3	phosphatidylinositol-3,4,5-triphosphate
PPAR	peroxisome proliferator-activated receptor
RPLC	reversed-phase high-performance liquid chromatography

Volume 1

ABC Transporters, Pages 1-5, Andre Goffeau, Benoit De Hertogh and Philippe V. Baret

Abscisic Acid (ABA), Pages 6-11, Ramanjulu Sunkar and Jian-Kang Zhu

Actin Assembly/Disassembly, Pages 12-18, Henry N. Higgs

Actin-Capping and -Severing Proteins, Pages 19-26, Sankar Maiti and James R. Bamburg

Actin-Related Proteins, Pages 27-33, R. Dyche Mullins

Adenosine Receptors, Pages 34-39, Lauren J. Murphree and Joel Linden

Adenylyl Cyclases, Pages 40-45, Ronald Taussig

Adrenergic Receptors, Pages 46-50, David B. Bylund

Affinity Chromatography, Pages 51-56, Pedro Cuatrecasas and Meir Wilchek

Affinity Tags for Protein Purification, Pages 57-63, Joseph J. Falke and John A. Corbin

A-Kinase Anchoring Proteins, Pages 64-67, Lorene K. Langeberg and John D. Scott

Allosteric Regulation, Pages 68-73, Barry S. Cooperman

Alternative Splicing: Regulation of Fibroblast Growth Factor Receptor (FGFR), Pages 74-77, Mariano A. Garcia-Blanco

Alternative Splicing: Regulation of Sex Determination in Drosophila melanogaster, Pages 78-84, Jill K. M. Penn, Patricia Graham and Paul Schedl

Amine Oxidases, Pages 85-89, Giovanni Floris and Alessandro Finazzi Agro

Amino Acid Metabolism, Pages 90-95, Luc Cynober

Aminopeptidases, Pages 96-98, Ralph A. Bradshaw

Amyloid, Pages 99-104, Ronald Wetzel

Anaplerosis, Pages 105-110, Raymond R. Russell, III and Heinrich Taegtmeyer

Angiotensin Receptors, Pages 111-115, Tadashi Inagami

ara Operon, Pages 116-119, Robert F. Schleif

ARF Family, Pages 120-122, Gustavo Pacheco-Rodriguez, Joel Moss and Martha Vaughan

Aspartic Proteases, Pages 123-127, Ben M. Dunn

ATP Synthesis in Plant Mitochondria: Substrates, Inhibitors, Uncouplers, Pages 128-132, Kathleen L. Soole and R. Ian Menz

ATP Synthesis: Mitochondrial Cyanide-Resistant Terminal Oxidases, Pages 133-137, James N. Siedow

Autophagy in Fungi and Mammals, Pages 138-143, Daniel J. Klionsky and Ju Guan

B12-Containing Enzymes, Pages 145-151, Vahe Bandarian and Rowena G. Matthews

Bax and Bcl2 Cell Death Enhancers and Inhibitors, Pages 152-154, David L. Vaux

B-Cell Antigen Receptor, Pages 155-158, Thomas M. Yankee and Edward A. Clark

Bile Salts and their Metabolism, Pages 159-163, Ulrich Beuers and Thomas Pusl

Biliary Cirrhosis, Primary, Pages 164-169, Marshall M. Kaplan

Bioenergetics: General Definition of Principles, Pages 170-173, David G. Nicholls

Biotin, Pages 174-178, Steven W. Polyak and Anne Chapman-Smith

Biotinylation of Proteins, Pages 179-181, Ronald A. Kohanski

Bradykinin Receptors, Pages 182-185, Ronald M. Burch

Branched-Chain -Ketoacids, Pages 186-191, David T. Chuang

Brassinosteroids, Pages 192-197, Steven D. Clouse

Cadherin Signaling, Pages 199-204, David B. Sacks and Jonathan M. G. Higgins

Cadherin-Mediated Cell-Cell Adhesion, Pages 205-211, Frauke Drees and W. James Nelson

Calcitonin Gene-Related Peptide and Adrenomedullin Receptors, Pages 212-216, Debbie L. Hay, Alex C. Conner and David R. Poyner

Calcitonin Receptor, Pages 217-220, Samia I. Girgis, Niloufar Moradi-Bidhendi, Lucia Mancini and Iain MacIntyre

Calcium Buffering Proteins: Calbindin, Pages 221-225, Willi Hunziker and Igor Bendik

Calcium Buffering Proteins: ER Luminal Proteins, Pages 226-230, Jody Groenendyk and Marek Michalak

Calcium Oscillations, Pages 231-234, Marisa Brini

Calcium Sensing Receptor, Pages 235-240, Jacob Tfelt-Hansen and Edward M. Brown

Calcium Signaling: Calmodulin-Dependent Phosphatase, Pages 241-245, Claude Klee, Hao Ren and Shipeng Li

Calcium Signaling: Cell Cycle, Pages 246-249, Luigia Santella

Calcium Signaling: Motility (Actomyosin-Troponin System), Pages 250-255, Takeyuki Wakabayashi and Setsuro Ebashi

Calcium Signaling: NO Synthase, Pages 256-260, Zhi-Qiang Wang and Dennis J. Stuehr

Calcium Transport in Mitochondria, Pages 261-266, Rosario Rizzuto and Marisa Brini

Calcium Waves, Pages 267-269, Lionel F. Jaffe

Calcium, Biological Fitness of, Pages 270-273, Robert J. P. Williams

Calcium/Calmodulin-Dependent Protein Kinase II, Pages 274-280, Andy Hudmon and Howard Schulman

Calcium/Calmodulin-Dependent Protein Kinases, Pages 281-286, J. Robison and Roger J. Colbran

Calcium-Binding Proteins: Cytosolic (Annexins, Gelsolins, C2-Domain Proteins) , Pages 287-293, Joachim Krebs

Calcium-Modulated Proteins (EF-Hand), Pages 294-299, Robert H. Kretsinger

Calpain, Pages 300-306, Hiroyuki Sorimachi and Yasuko Ono

Carbohydrate Chains: Enzymatic and Chemical Synthesis, Pages 307-313, Thomas J. Tolbert and Chi-Huey Wong

Carnitine and -Oxidation, Pages 314-318, Janos Kerner and Charles L. Hoppel

Caspases and Cell Death, Pages 319-327, Don W. Nicholson, Pierluigi Nicotera and Gerry Melino

Cell Cycle Controls in G1 and G0, Pages 328-331, WengeShi and Steven F. Dowdy

Cell Cycle: Control of Entry and Progression Through S Phase, Pages 332-337, Susan L. Forsburg

Cell Cycle: DNA Damage Checkpoints, Pages 338-344, Jean Y. J. Wang

Cell Cycle: Mitotic Checkpoint, Pages 345-351, Tim J. Yen

Cell Death by Apoptosis and Necrosis, Pages 352-355, Pierluigi Nicotera

Cell Migration, Pages 356-361, J. Victor Small and Emmanuel Vignal

Cell-Matrix Interactions, Pages 362-366, Janet A. Askari and Martin J. Humphries

Centromeres, Pages 367-371, Beth A. Sullivan

Centrosomes and Microtubule Nucleation, Pages 372-376, Reiko Nakajima, Ming-Ying Tsai and Yixian Zheng

c-fes Proto-Oncogene, Pages 377-382, Thomas E. Smithgall and Robert I. Glazer

Chaperones for Metalloproteins, Pages 383-386, Valeria C. Culotta and Edward Luk

Chaperones, Molecular, Pages 387-392, Sue Wickner and Joel R. Hoskins

Chaperonins, Pages 393-398, Arthur L. Horwich, Wayne A. Fenton and George W. Farr

Chemiluminescence and Bioluminescence, Pages 399-404, Thomas O. Baldwin

Chemiosmotic Theory, Pages 405-412, Keith D. Garlid

Chemokine Receptors, Pages 413-418, Ann Richmond and Guo-Huang Fan

Chemolithotrophy, Pages 419-424, Alan B. Hooper

Chemotactic Peptide/Complement Receptors, Pages 425-429, Eric R. Prossnitz and Larry A. Sklar

Chlorophylls and Carotenoids, Pages 430-437, Hugo Scheer

Chloroplast Redox Poise and Signaling, Pages 438-445, John F. Allen

Chloroplasts, Pages 446-450, Nicoletta Rascio

Cholesterol Synthesis, Pages 451-455, Peter A. Edwards

Chromatin Remodeling, Pages 456-463, Eric Kallin and Yi Zhang

Chromatin: Physical Organization, Pages 464-468, Christopher L. Woodcock

Chromosome Organization and Structure, Overview, Pages 469-474, Elena Gracheva and Sarah C. R. Elgin

Coenzyme A, Pages 475-477, M. Daniel Lane

Collagenases, Pages 478-481, Kenn Holmbeck and Henning Birkedal-Hansen

Collagens, Pages 482-487, Darwin J. Prockop

Cyclic AMP Receptors of Dictyostelium, Pages 488-493, Dale Hereld and Peter N. Devreotes

Cyclic GMP Phosphodiesterases, Pages 494-500, Sharron H. Francis and Jackie D. Corbin

Cyclic Nucleotide Phosphodiesterases, Pages 501-505, Vincent C. Manganiello and Eva Degerman

Cyclic Nucleotide-Dependent Protein Kinases, Pages 506-511, Sharron H. Francis and Jackie D. Corbin

Cyclic Nucleotide-Regulated Cation Channels, Pages 512-515, Martin Biel and Franz Hofmann

Cysteine Proteases, Pages 516-520, David J. Buttle and John S. Mort

Cytochrome b6f Complex, Pages 521-527, Gunter A. Hauska and Thomas Schodl

Cytochrome bc1 Complex (Respiratory Chain Complex III), Pages 528-534, Bernard L. Trumpower

Cytochrome c, Pages 535-538, Hans Tuppy and Gunther Kreil

Cytochrome Oxidases, Bacterial, Pages 539-543, Peter Brzezinski and Pia Adelroth

Cytochrome P-450, Pages 544-549, Rita Bernhardt

Cytokines, Pages 550-555, Andrea L. Wurster and Michael J. Grusby

Cytokinesis, Pages 556-561, Masanori Mishima and Michael Glotzer

Cytokinin, Pages 562-567, Thomas Schmulling

Desmosomes and Hemidesmosomes, Pages 569-576, Rachel L. Dusek, Jonathan C. R. Jones and Kathleen J. Green

Detergent Properties, Pages 577-581, Darrell R. McCaslin

Diabetes, Pages 582-592, David W. Cooke

Diacylglycerol Kinases and Phosphatidic Acid Phosphatases, Pages 593-597, Stephen M. Prescott and Matthew K. Topham

Disulfide Bond Formation, Pages 598-602, Hiram F. Gilbert

DNA Base Excision Repair, Pages 603-608, Hilde Nilsen and Tomas Lindahl

DNA Damage: Alkylation, Pages 609-613, Anton B. Guliaev and B. Singer

DNA Glycosylases: Mechanisms, Pages 614-617, Daniel J. Krosky and James T. Stivers

DNA Helicases: Dimeric Enzyme Action, Pages 618-623, Timothy M. Lohman

DNA Helicases: HexamericEnzyme Action, Pages 624-631, Smita S. Patel

DNA Ligases: Mechanism and Functions, Pages 632-636, Alan E. Tomkinson and John B. Leppard

DNA Ligases: Structures, Pages 637-643, C. Kiong Ho, Mark Odell and Dimitar B. Nikolov

DNA Methyltransferases, Bacterial, Pages 644-651, Albert Jeltsch and Richard I. Gumport

DNA Methyltransferases, Structural Themes, Pages 652-659, Sanjay Kumar

DNA Methyltransferases: Eubacterial GATC, Pages 660-664, Martin G. Marinus

DNA Mismatch Repair and Homologous Recombination, Pages 665-670, Ivan Matic and Miroslav Radman

DNA Mismatch Repair and the DNA Damage Response, Pages 671-674, Guo-Min Li and Steven R. Presnell

DNA Mismatch Repair Defects and Cancer, Pages 675-681, Richard D. Kolodner

DNA Mismatch Repair in Bacteria, Pages 682-686, A-Lien Lu

DNA Mismatch Repair in Mammals, Pages 687-690, James T. Drummond

DNA Mismatch Repair: E. coli Vsr and Eukaryotic G-T Systems, Pages 691-693, Margaret Lieb

DNA Oxidation, Pages 694-697, Arthur P. Grollman and Dmitry O. Zharkov

DNA Photolyase, Pages 698-702, Carrie L. Partch and Aziz Sancar

DNA Polymerase, Eukaryotic α, Pages 703-707, Teresa S. -F. Wang

DNA Polymerase, Eukaryotic β, Pages 708-712, William A. Beard and Samuel H. Wilson

DNA Polymerase, Eukaryotic δ, Pages 713-715, Antero G. So and Kathleen M. Downey

DNA Polymerase, Eukaryotic ε, Pages 716-719, Yasuo Kawasaki and Akio Sugino

DNA Polymerase I, Bacterial, Pages 720-725, Catherine M. Joyce

DNA Polymerase II, Bacterial, Pages 726-728, Judith L. Campbell

DNA Polymerase III, Bacterial, Pages 729-733, Hisaji Maki

DNA Polymerases: Kinetics and Mechanism, Pages 734-739, Kenneth A. Johnson

DNA Replication Fork, Bacterial, Pages 740-744, Nancy G. Nossal

DNA Replication Fork, Eukaryotic, Pages 745-748, Lori M. Kelman, Jerard Hurwitz and Zvi Kelman

DNA Replication, Mitochondrial, Pages 749-752, David A. Clayton

DNA Replication: Eukaryotic Origins and the Origin Recognition Complex, Pages 753-760, Melvin L. DePamphilis and Cong-jun Li

DNA Replication: Initiation in Bacteria, Pages 761-766, Jon M. Kaguni

DNA Restriction and Modification: Type I Enzymes, Pages 767-771, David T. F. Dryden

DNA Restriction and Modification: Type II Enzymes, Pages 772-777, Darren M. Gowers and Stephen E. Halford

DNA Restriction and Modification: Type III Enzymes, Pages 778-781, Desirazu N. Rao and S. Srivani

DNA Secondary Structure, Pages 782-787, Albino Bacolla and Robert D. Wells

DNA Sequence Recognition by Proteins, Pages 788-793, Arabela A. Grigorescu and John M. Rosenberg

DNA Supercoiling, Pages 794-797, Tao-shih Hsieh

DNA Topoisomerases: Type I, Pages 798-805, James J. Champoux

DNA Topoisomerases: Type II, Pages 806-811, Renier Velez-Cruz and Neil Osheroff

DNA Topoisomerases: Type III-RecQ Helicase Systems, Pages 812-816, Rodney Rothstein and Erika Shor

Dopamine Receptors, Pages 817-822, Kim A. Neve

Dynactin, Pages 823-826, Trina A. Schroer

Dynein, Pages 827-831, K. Kevin Pfister

Volume 2

EF-G and EF-Tu Structures and Translation Elongation in Bacteria, Pages 1-5, Poul Nissen and Jens Nyborg

Eicosanoid Receptors, Pages 6-9, Richard M. Breyer and Matthew D. Breyer

Elastin, Pages 10-12, Judith Ann Foster

Endocannabinoids, Pages 13-15, Daniele Piomelli

Endocytosis, Pages 16-19, Julie G. Donaldson

Endoplasmic Reticulum-Associated Protein Degradation, Pages 20-23, Maurizio Molinari

Energy Transduction in Anaerobic Prokaryotes, Pages 24-30, Gottfried Unden

Enzyme Inhibitors, Pages 31-37, Vern L. Schramm

Enzyme Kinetics, Pages 38-44, Irwin H. Segel

Enzyme Reaction Mechanisms: Stereochemistry, Pages 45-50, Ming-Daw Tsai, Li Zhao and Brandon J. Lamarche

Epidermal Growth Factor Receptor Family, Pages 51-55, Denis Tvorogov and Graham Carpenter

ER/SR Calcium Pump: Function, Pages 56-60, Giuseppe Inesi

ER/SR Calcium Pump: Structure, Pages 61-65, Chikashi Toyoshima and Yuji Sugita

Exonucleases, Bacterial, Pages 66-72, Susan T. Lovett

F1-F0 ATP Synthase, Pages 73-79, Donata Branca

FAK Family, Pages 80-84, Steven K. Hanks

Fat Mobilization: Perilipin and Hormone-Sensitive Lipase, Pages 85-89, Constantine Londos and Alan R. Kimmel

Fatty Acid Oxidation, Pages 90-94, Horst Schulz

Fatty Acid Receptors, Pages 95-98, Christer Owman and Bjorn Olde

Fatty Acid Synthesis and its Regulation, Pages 99-103, Steven D. Clarke and Manabu T. Nakamura

Ferredoxin, Pages 104-106, Giuliana Zanetti and Vittorio Pandini

Ferredoxin-NADP+ Reductase, Pages 107-111, Giuliana Zanetti and Alessandro Aliverti

Fibroblast Growth Factor Receptors and Cancer-Associated Perturbations, Pages 112-117, Marko Kornmann and Murray Korc

Flavins, Pages 118-122, Barrie Entsch and David P. Ballou

Flippases, Pages 123-127, Charles J. Waechter

Focal Adhesions, Pages 128-133, Eli Zamir and Benjamin Geiger

Free Radicals, Sources and Targets of: Mitochondria, Pages 134-142, Alberto Boveris and Enrique Cadenas

Friedreich's Ataxia, Pages 143-145, Paul E. Hart and Anthony H. V. Schapira

G Protein Signaling Regulators, Pages 147-151, John H. Exton

G Protein-Coupled Receptor Kinases and Arrestins, Pages 152-157, Jeffrey L. Benovic

G12/G13 Family, Pages 158-161, Stefan Offermanns

GABAA Receptor, Pages 162-166, Richard W. Olsen and Gregory W. Sawyer

GABAB Receptor, Pages 167-170, S. J. Enna

Galectins, Pages 171-174, R. Colin Hughes

Genome-Wide Analysis of Gene Expression, Pages 175-180, Karine G. Le Roch and Elizabeth A. Winzeler

Gi Family of Heterotrimeric G Proteins, Pages 181-185, Maurine E. Linder

Giant Mitochondria (Megamitochondria), Pages 186-188, Bernard Tandler and Charles L. Hoppel

GlcNAc Biosynthesis and Function, O-Linked, Pages 189-192, Kaoru Sakabe and Gerald W. Hart

Glucagon Family of Peptides and their Receptors, Pages 193-196, Laurie L. Baggio and Daniel J. Drucker

Gluconeogenesis, Pages 197-203, Richard W. Hanson and Oliver E. Owen

Glucose/Sugar Transport in Bacteria, Pages 204-207, Lan Guan and H. Ronald Kaback

Glucose/Sugar Transport in Mammals, Pages 208-212, Silvia Mora and Jeffrey Pessin

Glutamate Receptors, Ionotropic, Pages 213-219, Derek B. Scott and Michael D. Ehlers

Glutamate Receptors, Metabotropic, Pages 220-223, P. Jeffrey Conn

Glutathione Peroxidases, Pages 224-228, Fulvio Ursini and Matilde Maiorino

Glycation, Pages 229-236, Suzanne R. Thorpe and John W. Baynes

Glycine Receptors, Pages 237-243, Bodo Laube and Heinrich Betz

Glycogen Metabolism, Pages 244-248, Peter J. Roach

Glycogen Storage Diseases, Pages 249-254, George H. Sack, Jr.

Glycogen Synthase Kinase-3, Pages 255-260, James R. Woodgett

Glycolipid-Dependent Adhesion Processes, Pages 261-265, Senitiroh Hakomori

Glycolysis, Overview, Pages 266-271, Robert A. Harris

Glycoprotein Folding and Processing Reactions, Pages 272-276, Armando J. Parodi

Glycoprotein-Mediated Cell Interactions, O-Linked, Pages 277-282, Robert S. Haltiwanger

Glycoproteins, N-Linked, Pages 283-292, Mark A. Lehrman

Glycoproteins, Plant, Pages 293-296, Carolyn J. Schultz

Glycosylation in Cystic Fibrosis, Pages 297-301, Andrew D. Rhim, Thomas F. Scanlin and Mary Catherine Glick

Glycosylation, Congenital Disorders of, Pages 302-307, Hudson H. Freeze

Glycosylphosphatidylinositol (GPI) Anchors, Pages 308-311, Anant K. Menon

Golgi Complex, Pages 312-315, Mark Stamnes

Gq Family, Pages 316-320, Wanling Yang and John D. Hildebrandt

Green Bacteria: Secondary Electron Donor (Cytochromes), Pages 321-324, Hirozo Oh-oka and Robert E. Blankenship

Green Bacteria: The Light-Harvesting Chlorosome, Pages 325-330, John M. Olson

Green Sulfur Bacteria: Reaction Center and Electron Transport, Pages 331-336, Gunter A. Hauska and Thomas Schodl

Gs Family of Heterotrimeric G Proteins, Pages 337-341, Susanne M. Mumby

Heat/Stress Responses, Pages 343-347, Davis T. W. Ng

Hematopoietin Receptors, Pages 348-353, Barbara A. Miller and Joseph Y. Cheung

Heme Proteins, Pages 354-361, Johannes Everse

Heme Synthesis, Pages 362-366, Gloria C. Ferreira

Hepatocyte Growth Factor/Scatter Factor Receptor, Pages 367-371, Selma Pennacchietti and Paolo M. Comoglio

Hexokinases/Glucokinases, Pages 372-377, Emile Van Schaftingen

Histamine Receptors, Pages 378-383, Stephen J. Hill and Jillian G. Baker

HIV Protease, Pages 384-387, Ben M. Dunn

HIV-1 Reverse Transcriptase Structure, Pages 388-392, Kalyan Das, Stefan G. Sarafianos, Eddy Arnold and Stephen H. Hughes

Homologous Recombination in Meiosis, Pages 393-397, Nancy M. Hollingsworth

HPLC Separation of Peptides, Pages 398-403, James D. Pearson

Imaging Methods, Pages 405-410, Gyorgy Szabadkai and Rosario Rizzuto

Immunoglobulin (Fc) Receptors, Pages 411-416, Mark Hogarth

Inorganic Biochemistry, Pages 417-420, Robert J. P. Williams

Inositol Lipid 3-Phosphatases, Pages 421-426, Gregory S. Taylor and Jack E. Dixon

Inositol Phosphate Kinases and Phosphatases, Pages 427-429, Stephen B. Shears

Insulin- and Glucagon-Secreting Cells of the Pancreas, Pages 430-435, Franz M. Matschinsky

Insulin Receptor Family, Pages 436-440, Paul F. Pilch and Jongsoon Lee

Integrin Signaling, Pages 441-445, Lawrence E. Goldfinger and Mark H. Ginsberg

Interferon Receptors, Pages 446-451, Christopher P. Elco and Ganes C. Sen

Intermediate Filament Linker Proteins: Plectin and BPAG1, Pages 452-457, Peter Fuchs and Gerhard Wiche

Intermediate Filaments, Pages 458-464, Kelsie M. Bernot and Pierre A. Coulombe

Intracellular Calcium Channels: cADPR-Modulated (Ryanodine Receptors), Pages 465-468, Antony Galione

Intracellular Calcium Channels: NAADP+-Modulated, Pages 469-472, Armando A. Genazzani and Marcella Debidda

Ion Channel Protein Superfamily, Pages 473-477, William A. Catterall

IP3 Receptors, Pages 478-481, Colin W. TaylorEdward Morris and Paula da Fonseca

Iron-Sulfur Proteins, Pages 482-489, Helmut Beinert

JAK-STAT Signaling Paradigm, Pages 491-496, Edward Cha and Christian Schindler

Keratins and the Skin, Pages 497-504, Pierre A. Coulombe and Kelsie M. Bernot

Ketogenesis, Pages 505-507, Janos Kerner and Charles L. Hoppel

Kinesin Superfamily Proteins, Pages 508-516, Nobutaka Hirokawa and Reiko Takemura

Kinesins as Microtubule Disassembly Enzymes, Pages 517-521, Susan L. Kline-Smith and Arshad Desai

Kinetic Isotope Effects, Pages 522-527, Justine P. Roth and Judith P. Klinman

lac Operon, Pages 529-534, Liskin Swint-Kruse and Kathleen S. Matthews

Lectins, Pages 535-540, Nathan Sharon and Halina Lis

Leptin, Pages 541-545, Thomas W. Gettys

LexA Regulatory System, Pages 546-550, Veronica G. Godoy, Penny J. Beuning and Graham C. Walker

Ligand-Operated Membrane Channels: Calcium (Glutamate), Pages 551-561, Elias K. Michaelis

Ligand-Operated Membrane Channels: GABA, Pages 562-566, F. Minier and Erwin Sigel

Light-Harvesting Complex (LHC) I and II: Pigments and Proteins, Pages 567-570, Stefan Jansson

Lipases, Pages 571-575, Howard L. Brockman

Lipid Bilayer Structure, Pages 576-579, Erwin London

Lipid Modification of Proteins: Targeting to Membranes, Pages 580-583, Marilyn D. Resh

Lipid Rafts, Pages 584-587, Deborah A. Brown

Lipoproteins, HDL/LDL, Pages 588-593, Fayanne E. Thorngate and David L. Williams

Low Barrier Hydrogen Bonds, Pages 594-598, Perry A. Frey

Luft's Disease, Pages 599-601, Salvatore DiMauro

Lysophospholipid Receptors, Pages 602-604, Gabor J. Tigyi

MDR Membrane Proteins, Pages 605-609, Nathan C. Rockwell

Meiosis, Pages 610-616, Neil Hunter

Melanocortin System, Pages 617-620, Roger D. Cone

Membrane Fusion, Pages 621-626, Joshua Zimmerberg and Leonid V. Chernomordik

Membrane Transport, General Concepts, Pages 627-630, Stanley G. Schultz

Membrane Transporters:Na+/Ca2+ Exchangers, Pages 631-636, Jonathan Lytton

Membrane-Associated Energy Transduction in Bacteria and Archaea, Pages 637-645, Gunter Schafer

Metabolite Channeling: Creatine Kinase Microcompartments, Pages 646-651, Uwe Schlattner and Theo Wallimann

Metalloproteases, Pages 652-656, David S. Auld

Metalloproteinases, Matrix, Pages 657-665, Hideaki Nagase and Gillian Murphy

Metaphase Chromosome, Pages 666-671, Sharron Vass and Margarete M. S. Heck

Methyl-CpG-Binding Proteins, Pages 672-675, David G. Skalnik

Microtubule-Associated Proteins, Pages 676-682, Nobutaka Hirokawa and Reiko Takemura

Mitochondrial Auto-Antibodies, Pages 683-688, Harold Baum

Mitochondrial Channels, Pages 689-692, M. Catia Sorgato and Alessandro Bertoli

Mitochondrial DNA, Pages 693-696, Gottfried Schatz

Mitochondrial Genes and their Expression: Yeast, Pages 697-702, Piotr P. Slonimski and Giovanna Carignani

Mitochondrial Genome, Evolution, Pages 703-708, B. Franz Lang, Dennis V. Lavrov and Gertraud Burger

Mitochondrial Genome, Overview, Pages 709-715, Douglas C. Wallace

Mitochondrial Inheritance, Pages 716-719, Eric A. Shoubridge

Mitochondrial Membranes, Structural Organization, Pages 720-724, Carmen A. Mannella

Mitochondrial Metabolite Transporter Family, Pages 725-732, Ferdinando Palmieri and Martin Klingenberg

Mitochondrial Outer Membrane and the VDAC Channel, Pages 733-736, Marco Colombini

Mitogen-Activated Protein Kinase Family, Pages 737-742, Hidemi Teramoto and J. Silvio Gutkind

Mitosis, Pages 743-747, Patricia Wadsworth and Nasser M. Rusan

mRNA Polyadenylation in Eukaryotes, Pages 748-752, Mary Edmonds

mRNA Processing and Degradation in Bacteria, Pages 753-757, Deborah A. Steege

Mucin Family of Glycoproteins, Pages 758-764, Juan Perez-Vilar and Robert L. Hill

Mucins in Embryo Implantation, Pages 765-769, Daniel D. Carson

Multiple Sequence Alignment and Phylogenetic Trees, Pages 770-774, Russell F. Doolittle

Muscarinic Acetylcholine Receptors, Pages 775-777, Neil M. Nathanson

Myosin Motors, Pages 778-781, Roy E. Larson

Volume 3

Natriuretic Peptides and their Receptors, Pages 1-5, Lincoln R. Potter

N-End Rule, Pages 6-10, Alexander Varshavsky

Neoglycoproteins, Pages 11-15, Y. C. Lee and Reiko T. Lee

Neuronal Calcium Signal, Pages 16-20, Hilmar Bading

Neuronal Intermediate Filaments, Pages 21-25, Ronald K. H. Liem

Neuropeptide Y Receptors, Pages 26-31, Eric M. Parker

Neurotensin Receptors, Pages 32-36, William Rostene, Patrick Kitabgi and Didier Pelaprat

Neurotransmitter Transporters, Pages 37-40, Aurelio Galli, Randy D. Blakely and Louis J. DeFelice

Neurotrophin Receptor Signaling, Pages 41-45, Jennifer J. Gentry and Bruce D. Carter

Nicotinamide Nucleotide Transhydrogenase, Pages 50-56, Jan Rydstrom

Nicotinic Acetylcholine Receptors, Pages 57-61, Nivalda O. Rodrigues-Pinguet and Henry A. Lester

Nitric Oxide Signaling, Pages 62-65, Michael A. Marletta

N-Linked Glycan Processing Glucosidases and Mannosidases, Pages 46-49, Linda O. Tremblay and Annette Herscovics

Non-Homologous End Joining, Pages 66-70, Penny A. Jeggo

Nonhomologous Recombination: Bacterial Transposons, Pages 71-79, Bao Ton Hoang and Michael G. Chandler

Nonhomologous Recombination: Retrotransposons, Pages 80-86, Siew Loon Ooi and Jef D. Boeke

Nuclear Compartmentalization, Pages 87-91, Kelly P. Smith and Jeanne B. Lawrence

Nuclear Envelope and Lamins, Pages 92-95, Bryce M. Paschal

Nuclear Factor kappaB, Pages 96-99, Thomas D. Gilmore

Nuclear Genes in Mitochondrial Function and Biogenesis, Pages 100-104, Alexander Tzagoloff and Carol L. Dieckmann

Nuclear Organization, Chromatin Structure, and Gene Silencing , Pages 105-108, Lori L. Wallrath, John R. Danzer, Oya Yazgan and Pamela K. Geyer

Nuclear Pores and Nuclear Import/Export, Pages 109-114, Anita H. Corbett

Nucleoid Organization of Bacterial Chromosomes, Pages 115-118, Charles J. Dorman

Nucleolus, Overview, Pages 119-122, Thoru Pederson

Nucleotide Excision Repair and Human Disease, Pages 123-129, James E. Cleaver

Nucleotide Excision Repair in Eukaryotes, Pages 130-133, Laura A. Lindsey-Boltz and Aziz Sancar

Nucleotide Excision Repair, Bacterial: The UvrABCD System, Pages 134-142, Bennett Van Houten and Lawrence Grossman

Nucleotide Excision Repair: Biology, Pages 143-147, Errol C. Friedberg

Olfactory Receptors, Pages 149-154, Sigrun I. Korsching

Oligosaccharide Analysis by Mass Spectrometry, Pages 155-160, Andrew J. Hanneman and Vernon N. Reinhold

Oligosaccharide Chains: Free, N-Linked, O-Linked, Pages 161-164, Tadashi Suzuki

Oncocytes, Pages 165-166, Bernard Tandler and Charles L. Hoppel

Opioid Receptors, Pages 167-171, P. Y. Law and Horace H. Loh

Ornithine Cycle, Pages 172-177, Malcolm Watford

Oxygenases, Pages 178-182, Osamu Hayaishi

P2X Purinergic Receptors, Pages 183-187, Annmarie Surprenant

P2Y Purinergic Receptors, Pages 188-191, George R. Dubyak

p53 Protein, Pages 192-195, Jamie Hearnes and Jennifer Pietenpol

p70 S6 Kinase/mTOR, Pages 196-200, Christopher G. Proud

Parathyroid Hormone/Parathyroid Hormone-Related Protein Receptor, Pages 201-207, Thomas J. Gardella

PCR (Polymerase Chain Reaction), Pages 208-210, Michael J. Brownstein

Pentose Phosphate (Hexose Mono Phosphate) Pathway, Pages 211-215, Bernard R. Landau

Pentose Phosphate Pathway, History of, Pages 216-225, John F. Williams

Peptide Amidation, Pages 226-230, Mark J. Niciu, Richard E. Mains and Betty A. Eipper

Periplasmic Electron Transport Systems in Bacteria, Pages 231-238, David J. Richardson, Gary Sawers and Rob J. M. Van Spanning

Peroxisome Proliferator-Activated Receptors, Pages 239-245, Mary C. Sugden, Edward A. Sugden and Mark J. Holness

Peroxisomes, Pages 246-250, Suresh Subramani

Phage Display for Protein Binding, Pages 251-255, Henry B. Lowman

Pheromone Receptors (Yeast), Pages 256-261, James B. Konopka and Jeremy W. Thorner

PHO Regulon, Pages 262-265, Bengt L. Persson

Phosphatidylinositol Bisphosphate and Trisphosphate, Pages 266-271, Alex Toker

Phosphatidylinositol-3-Phosphate, Pages 272-276, Joseph V. Virbasius and Michael P. Czech

Phosphofructokinase-2/Fructose Bisphosphatase-2, Pages 277-280, Daniel M. Raben

Phosphoinositide 3-Kinase, Pages 281-286, Khatereh Ahmadi and Michael Waterfield

Phosphoinositide 4- and 5-Kinases and Phosphatases, Pages 287-291, Shawn F. Bairstow, Matthew W. Bunce and Richard A. Anderson

Phosphoinositide-Dependent Protein Kinases, Pages 292-296, Nick R. Leslie and C. Peter Downes

Phospholipase A2, Pages 297-300, Timothy R. Smith and Edward A. Dennis

Phospholipase C, Pages 301-305, Fujio Sekiya, Yeun Ju Kim and Sue Goo Rhee

Phospholipase D, Pages 306-313, Mary M. LaLonde and Michael A. Frohman

Phospholipid Metabolism in Mammals, Pages 314-320, Claudia Kent

Phospholipid Synthesis in Yeast, Pages 321-325, Gil-Soo Han and George M. Carman

Photoreceptors, Pages 326-329, King-Wai Yau

Photosynthesis, Pages 330-335, Richard C. Leegood

Photosynthetic Carbon Dioxide Fixation, Pages 336-341, Matthew J. Paul

Photosystem I, Structure and Function, Pages 342-347, Petra Fromme

Photosystem I: FX, FA, and FB Iron-Sulfur Clusters, Pages 348-356, Mikhail L. Antonkine and John H. Golbeck

Photosystem II Light Harvesting System: Dynamic Behavior, Pages 357-362, Peter Horton and Alexander Ruban

Photosystem II: Assembly and Turnover of the D1 Protein, Pages 363-366, Eira Kanervo and Eva-Mari Aro

Photosystem II: Protein Components, Pages 367-374, James Barber

Photosystem II: Water Oxidation, Overview, Pages 375-380, Fabrice Rappaport and Pierre Joliot

Plant Signaling: Peptides, Pages 381-384, Clarence A. Ryan and Gregory Pearce

Plasma-Membrane Calcium Pump: Structure and Function, Pages 385-389, Emanuel E. Strehler

Plastocyanin, Pages 390-393, Elizabeth L. Gross

Platelet-Activating Factor Receptor, Pages 394-398, Katherine M. Howard and Merle S. Olson

Platelet-Derived Growth Factor Receptor Family, Pages 399-406, Marina Kovalenko and Andrius Kazlauskas

Polysialic Acid inMolecular Medicine, Pages 407-414, Frederic A. Troy, II

Porphyrin Metabolism, Pages 415-419, Mark Shepherd and Harry A. Dailey

Pre-tRNA and Pre-rRNA Processing in Bacteria, Pages 420-424, Sidney R. Kushner

Pre-tRNA and Pre-rRNA Processing in Eukaryotes, Pages 425-431, Hendrik A. Raue

Prions and Epigenetic Inheritance, Pages 432-436, Reed B. Wickner

Prions, Overview, Pages 437-440, Cedric Govaerts and Fred E. Cohen

Processivity Clamps in DNA Replication: Clamp Loading, Pages 441-446, Megan J. Davey and Mike O'Donnell

Propionyl CoA-Succinyl CoA Pathway, Pages 447-451, Wayne A. Fenton

Prostaglandins and Leukotrienes, Pages 452-456, William L. Smith and Robert C. Murphy

Proteases in Blood Clotting, Pages 457-463, John D. Kulman and Earl W. Davie

Proteasomes, Overview, Pages 464-468, Martin Rechsteiner

26S Proteasome, Structure and Function, Pages 469-473, Peter Zwickl and Wolfgang Baumeister

Protein Carboxyl Esterification, Pages 474-477, Shilpa G. Lalchandani and Jeffry B. Stock

Protein Data Resources, Pages 478-483, Philip E. Bourne

Protein Degradation, Pages 484-492, Tomo ari and Alfred L. Goldberg

Protein Folding and Assembly, Pages 493-499, David P. Goldenberg

Protein Glycosylation Inhibitors, Pages 500-503, Alan D. Elbein

Protein Glycosylation, Overview, Pages 504-509, Natasha E. Zachara and Gerald W. Hart

Protein Import into Mitochondria, Pages 510-515, Johannes M. Herrmann and Walter Neupert

Protein Kinase B, Pages 516-522, Bettina A. Dummler and Brian A. Hemmings

Protein Kinase C Family, Pages 523-526, Alexandra C. Newton

Protein N-Myristoylation, Pages 527-531, Erica Dutil Sonnenburg and Jeffrey I. Gordon

Protein Palmitoylation, Pages 532-535, Robert J. Deschenes

Protein Tyrosine Phosphatases, Pages 536-542, David J. Pagliarini, Fred L. Robinson and Jack E. Dixon

Proteinase-Activated Receptors, Pages 543-548, Kristina K. Hansen and Morley D. Hollenberg

Proteoglycans, Pages 549-555, Sara K. Olson and Jeffrey D. Esko

Pteridines, Pages 556-560, S. Colette Daubner and Paul F. Fitzpatrick

P-Type Pumps: Copper Pump, Pages 561-564, Ilia Voskoboinik and James Camakaris

P-Type Pumps: H+/K+ Pump, Pages 565-570, Jai Moo Shin and George Sachs

P-Type Pumps: Na+/K+ Pump, Pages 571-576, Peter L. Jorgensen

P-Type Pumps: Plasma-Membrane H+ Pump, Pages 577-581, A. Brett Mason and Carolyn W. Slayman

Purple Bacteria: Electron Acceptors and Donors, Pages 582-585, Evaldas Katilius and Neal W. Woodbury

Purple Bacteria: Photosynthetic Reaction Centers, Pages 586-594, C. Roy D. Lancaster

Pyridoxal Phosphate, Pages 595-599, David E. Metzler

Pyrimidine Biosynthesis, Pages 600-605, Monika Loffler and Elke Zameitat

Pyruvate Carboxylation, Transamination, and Gluconeogenesis, Pages 606-610, Sarawut Jitrapakdee and John C. Wallace

Pyruvate Dehydrogenase, Pages 611-615, Sam A. Johnson and James G. McCormack

Pyruvate Kinase, Pages 616-619, Kosaku Uyeda

Quinones, Pages 621-627, Giorgio Lenaz and Maria Luisa Genova

Rab Family, Pages 629-634, Mary W. McCaffrey and Andrew J. Lindsay

Ran GTPase, Pages 635-639, Mary Shannon Moore

Ras Family, Pages 640-644, Lawrence A. Quilliam

Recombination: Heteroduplexand Mismatch Repair in vitro, Pages 645-648, Leroy Worth

Recombination: Strand Transferases, Pages 649-653, Floyd R. Bryant

Recombination-Dependent DNA Replication, Pages 654-659, Kenneth N. Kreuzer

recQ DNA Helicase Family in Genetic Stability, Pages 660-664, Mary A. Risinger and Joanna Groden

Regulated Intramembrane Proteolysis (Rip), Pages 665-670, Jin Ye, Michael S. Brown and Joseph L. Goldstein

Respiratory Chain and ATP Synthase, Pages 671-675, David G. Whitehouse and Anthony L. Moore

Respiratory Chain Complex I, Pages 676-680, Ulrich Brandt

Respiratory Chain Complex II and Succinate: Quinone Oxidoreductases, Pages 681-687, C. Roy D. Lancaster

Respiratory Chain Complex IV, Pages 688-694, Hartmut Michel

Respiratory Processes in Anoxygenic and Oxygenic Phototrophs, Pages 695-699, Roberto Borghese and Davide Zannoni

Retinoblastoma Protein (pRB), Pages 700-703, Nicholas Dyson and Maxim Frolov

Retinoic Acid Receptors, Pages 704-707, Martin Petkovich

Reverse Transcriptase and Retroviral Replication, Pages 708-713, Laura Tarrago-Litvak, Marie-Line Andreola and Simon Litvak

Rho GTPases and Actin Cytoskeleton Dynamics, Pages 714-718, Priam Villalonga and Anne J. Ridley

Ribosome Assembly, Pages 719-724, John L. Woolford

Ribosome Structure, Pages 725-732, Brian T. Wimberly

Ribozyme Mechanisms, Pages 733-737, John Hsieh and Carol A. Fierke

Ribozyme Structural Elements: Group I Introns, Pages 738-742, Barbara L. Golden

Ribozyme Structural Elements: Hairpin Ribozyme, Pages 743-746, Adrian R. Ferre-D'Amare

Ribozymes and Evolution, Pages 747-752, Niles Lehman

RNA Editing, Pages 753-758, Charles E. Samuel

RNA Polymerase I and RNA Polymerase III in Eukaryotes, Pages 759-762, Robert J. White

RNA Polymerase II and Basal Transcription Factors in Eukaryotes, Pages 763-765, Joan Weliky Conaway and Ronald C. Conaway

RNA Polymerase II Elongation Control in Eukaryotes, Pages 766-769, David H. Price

RNA Polymerase II Structure in Eukaryotes, Pages 770-774, Patrick Cramer

RNA Polymerase Reaction in Bacteria, Pages 775-780, Arkady A. Mustaev and Alexander D. Goldfarb

RNA Polymerase Structure, Bacterial, Pages 781-784, Michael Anikin, Dmitri Temiakov and William T. McAllister

Volume 4

Secondary Structure in Protein Analysis, Pages 1-6, George D. Rose

Secretases, Pages 7-10, Robert L. Heinrikson

Secretory Pathway, Pages 11-16, Karen J. Colley

Selenoprotein Synthesis, Pages 17-21, August Bock

Septins and Cytokinesis, Pages 22-26, Makoto Kinoshita and Christine M. Field

Serine/Threonine Phosphatases, Pages 27-32, Thomas S. Ingebritsen

Serotonin Receptor Signaling, Pages 33-37, Paul J. Gresch and Elaine Sanders-Bush

Siglecs, Pages 38-40, Ajit Varki

Sigma Factors, Pages 41-44, John D. Helmann

Sliding Clamps in DNA Replication: E. coli -Clamp and PCNA Structure, Pages 45-47, Eric R. Goedken and John Kuriyan

Small GTPases, Pages 48-54, Adam Shutes and Channing J. Der

Somatostatin Receptors, Pages 55-60, Agnes Schonbrunn

Spastic Paraplegia, Pages 61-66, Elena Irene Rugarli and Andrea Ballabio

Spectrophotometric Assays, Pages 67-75, Britton Chance

Sphingolipid Biosynthesis, Pages 76-81, Martina Leipelt and Alfred H. Merrill

Sphingolipid Catabolism, Pages 82-87, Akira Abe and James A. Shayman

Spliceosome, Pages 88-92, Timothy W. Nilsen

Src Family of Protein Tyrosine Kinases, Pages 93-98, Jonathan A. Cooper

Starvation, Pages 99-110, Oliver E. Owen and Richard W. Hanson

Steroid/Thyroid Hormone Receptors, Pages 111-116, Ramesh Narayanan and Nancy L. Weigel

Store-Operated Membrane Channels: Calcium, Pages 117-122, Indu S. Ambudkar

Substrate Binding, Catalysis, and Product Release , Pages 123-126, W. Wallace Cleland

Sugar Nucleotide Transporters, Pages 127-129, Carlos B. Hirschberg

SUMO Modification, Pages 130-134, Frauke Melchior and Andrea Pichler

Superoxide Dismutase, Pages 135-138, Irwin Fridovich

Syk Family of Protein Tyrosine Kinases, Pages 139-145, Andrew C. Chan

T7 RNA Polymerase, Pages 147-151, Rui Sousa

Tachykinin/Substance P Receptors, Pages 152-157, Mark D. Richardson and Madan M. Kwatra

Taste Receptors, Pages 158-161, John D. Boughter, Jr. and Steven D. Munger

T-Cell Antigen Receptor, Pages 162-168, Andrea L. Szymczak and Dario A. A. Vignali

Tec/Btk Family Tyrosine Kinases, Pages 169-173, Shuling Guo and Owen N. Witte

Telomeres: Maintenance and Replication, Pages 174-179, Alessandro Bianchi and David Shore

Thyroid-Stimulating Hormone/Luteinizing Hormone/Follicle-Stimulating Hormone Receptors, Pages 180-186, Deborah L. Segaloff, Dario Mizrachi and Mario Ascoli

Tight Junctions, Pages 187-189, Shoichiro Tsukita

Title, Pages, Authors

Toll-Like Receptors, Pages 190-194, Himanshu Kumar, Kiyoshi Takeda and Shizuo Akira

Transcription Termination, Pages 195-199, Thomas J. Santangelo and Jeffrey W. Roberts

Transcriptional Silencing, Pages 200-203, Ann Sutton and Rolf Sternglanz

Transcription-Coupled DNA Repair, Overview, Pages 204-208, Isabel Mellon

Transforming Growth Factor-β Receptor Superfamily, Pages 209-213, Mark de Caestecker

Translation Elongation in Bacteria, Pages 214-223, Oliver Vesper and Knud H. Nierhaus

Translation Elongation in Eukaryotes, Pages 224-229, William C. Merrick and Anton A. Komar

Translation Initiation in Bacteria: Factors and Mechanisms, Pages 230-236, Cynthia L. Pon and Claudio O. Gualerzi

Translation Initiation in Eukaryotes: Factors and Mechanisms, Pages 237-241, Tatyana V. Pestova and Christopher U. T. Hellen

Translation Termination and Ribosome Recycling, Pages 242-246, Nadja Koloteva-Levin and Mick F. Tuite

Translesion DNA Polymerases, Eukaryotic, Pages 247-250, Alexandra Vaisman and Roger Woodgate

Trehalose Metabolism, Pages 251-255, Alan D. Elbein

Tricarboxylic Acid Cycle, Pages 256-262, Richard L. Veech

tRNA Synthetases, Pages 263-266, Karla L. Ewalt and Paul Schimmel

trp Operon and Attenuation, Pages 267-271, Paul Gollnick

Tubulin and its Isoforms, Pages 272-276, Eva Nogales

Tumor Necrosis Factor Receptors, Pages 277-283, Karen G. Potter and Carl F. Ware

Two-Dimensional Gel Electrophoresis, Pages 284-289, Gerhard Schmid, Denis Hochstrasser and Jean-Charles Sanchez

Two-Hybrid Protein-Protein Interactions, Pages 290-293, Ilya Serebriiskii and Erica A. Golemis

Tyrosine Sulfation, Pages 294-297, Denis Corbeil and Wieland B. Huttner

Ubiquitin System, Pages 299-303, Aaron Ciechanover and Michael H. Glickman

Ubiquitin-Like Proteins, Pages 304-307, Edward T. H. Yeh

UmuC, D Lesion Bypass DNA Polymerase V, Pages 308-312, Zvi Livneh

Uncoupling Proteins, Pages 313-318, Daniel Ricquier and Frederic Bouillaud

Unfolded Protein Responses, Pages 319-325, David Ron

Urea Cycle, Inborn Defects of, Pages 326-330, Marsha K. Fearing and Vivian E. Shih

Vacuoles, Pages 331-336, Christopher J. Stefan and Scott D. Emr

Vascular Endothelial Growth Factor Receptors, Pages 337-342, Kenneth A. Thomas

Vasopressin/Oxytocin Receptor Family, Pages 343-348, Michael J. Brownstein

V-ATPases, Pages 349-353, Michael Forgac

Vitamin A (Retinoids), Pages 354-359, Joseph L. Napoli

Vitamin B12 and B12-Proteins, Pages 360-366, Bernhard Krautler

Vitamin C, Pages 367-371, Robert B. Rucker and Francene Steinberg

Vitamin D, Pages 372-377, Hector F. DeLuca and Margaret Clagett-Dame

Vitamin D Receptor, Pages 378-383, Diane R. Dowd and Paul N. MacDonald

Vitamin E, Pages 384-388, Ute C. Obermuller-Jevic and Lester Packer

Vitamin K: Biochemistry, Metabolism, and Nutritional Aspects, Pages 389-393, J. W. Suttie

Vitamin K: Blood Coagulation and Use in Therapy, Pages 394-398, Matthew D. Stone and Gary L. Nelsestuen

Voltage-Dependent K+ Channels, Pages 399-404, Ramon Latorre and Francisco J. Morera

Voltage-Sensitive Ca2+ Channels, Pages 405-408, Harald Reuter

Voltage-Sensitive Na+ Channels, Pages 409-415, William J. Brammar

Von Hippel-Lindau (VHL) Protein, Pages 416-418, Ronald C. Conaway and Joan Weliky Conaway

XPV DNA Polymerase and Ultraviolet Damage Bypass, Pages 419-421, Alan R. Lehmann

X-Ray Determination of 3-D Structure in Proteins, Pages 422-428, Martha L. Ludwig

Yeast GAL1-GAL10 System, Pages 429-433, Dennis Lohr and Ralph Bash

Zinc Fingers, Pages 435-439, Mark Isalan

Lipids, Carbohydrates, Membranes and Membrane Proteins

Carbohydrate Chains: Enzymatic and Chemical Synthesis; Vol.1 - Pages 307-313, Thomas J. Tolbert and Chi-Huey Wong

Cell–Matrix Interactions; Vol.1 - Pages 362-366, Janet A. Askari and Martin J. Humphries

Detergent Properties; Vol.1 - Pages 577-581, Darrell R. McCaslin

Endocytosis; Vol.2 - Pages 16-19, Julie G. Donaldson

Flippases; Vol.2 - Pages 123-127, Charles J. Waechter

Galectins; Vol.2 - Pages 171-174, R. Colin Hughes

GlcNAc Biosynthesis and Function, O-Linked; Vol.2 - Pages 189-192, Kaoru Sakabe and Gerald W. Hart

Glycation; Vol.2 - Pages 229-236, Suzanne R. Thorpe and John W. Baynes

Glycolipid-Dependent Adhesion Processes; Vol.2 - Pages 261-265, Senitiroh Hakomori

Glycoprotein Folding and Processing Reactions; Vol.2 - Pages 272-276, Armando J. Parodi

Glycoprotein-Mediated Cell Interactions, O-Linked; Vol.2 - Pages 277-282, Robert S. Haltiwanger

Glycoproteins, N-Linked; Vol.2 - Pages 283-292, Mark A. Lehrman

Glycoproteins, Plant; Vol.2 - Pages 293-296, Carolyn J. Schultz

Glycosylation in Cystic Fibrosis; Vol.2 - Pages 297-301, Andrew D. Rhim, Thomas F. Scanlin and Mary Catherine Glick

Glycosylation, Congenital Disorders of; Vol.2 - Pages 302-307, Hudson H. Freeze

Glycosylphosphatidylinositol (GPI) Anchors; Vol.2 - Pages 308-311, Anant K. Menon

Ion Channel Protein Superfamily; Vol.2 - Pages 473-477, William A. Catterall

Lectins; Vol.2 - Pages 535-540, Nathan Sharon and Halina Lis

Lipases; Vol.2 - Pages 571-575, Howard L. Brockman

Lipid Bilayer Structure; Vol.2 - Pages 576-579, Erwin London

Lipid Rafts; Vol.2 - Pages 584-587, Deborah A. Brown

Lipoproteins, HDL/LDL; Vol.2 - Pages 588-593, Fayanne E. Thorngate and David L. Williams

MDR Membrane Proteins; Vol.2 - Pages 605-609, Nathan C. Rockwell

Membrane Fusion; Vol.2 - Pages 621-626, Joshua Zimmerberg and Leonid V. Chernomordik

Mucin Family of Glycoproteins; Vol.2 - Pages 758-764, Juan Perez-Vilar and Robert L. Hill

Mucins in Embryo Implantation; Vol.2 - Pages 765-769, Daniel D. Carson

Neoglycoproteins; Vol.3 - Pages 11-15, Y. C. Lee and Reiko T. Lee

N-Linked Glycan Processing Glucosidases and Mannosidases; Vol.3 - Pages 46-49, Linda O. Tremblay and Annette Herscovics

Oligosaccharide Chains: Free, N-Linked, O-Linked; Vol.3 - Pages 161-164, Tadashi Suzuki

Phospholipid Metabolism in Mammals; Vol.3 - Pages 314-320, Claudia Kent

Phospholipid Synthesis in Yeast; Vol.3 - Pages 321-325, Gil-Soo Han and George M. Carman

Prostaglandins and Leukotrienes; Vol.3 - Pages 452-456, William L. Smith and Robert C. Murphy

Protein Glycosylation Inhibitors; Vol.3 - Pages 500-503, Alan D. Elbein

Proteoglycans; Vol.3 - Pages 549-555, Sara K. Olson and Jeffrey D. Esko

Secretory Pathway; Vol.4 - Pages 11-16, Karen J. Colley

Siglecs; Vol.4 - Pages 38-40, Ajit Varki

Sphingolipid Biosynthesis; Vol.4 - Pages 76-81, Martina Leipelt and Alfred H. Merrill, Jr.

Sphingolipid Catabolism; Vol.4 - Pages 82-87, Akira Abe and James A. Shayman

Sugar Nucleotide Transporters; Vol.4 - Pages 127-129, Carlos B. Hirschberg

Trehalose Metabolism; Vol.4 - Pages 251-255, Alan D. Elbein

Metabolism, Vitamins and Hormones

Amino Acid Metabolism; Vol.1 - Pages 90-95, Luc Cynober

Anaplerosis; Vol.1 - Pages 105-110, Raymond R. Russell, III and Heinrich Taegtmeyer

Bile Salts and their Metabolism; Vol.1 - Pages 159-163, Ulrich Beuers and Thomas Pusl

Biliary Cirrhosis, Primary; Vol.1 - Pages 164-169, Marshall M. Kaplan

Branched-Chain -Ketoacids; Vol.1 - Pages 186-191, David T. Chuang

Carnitine and -Oxidation; Vol.1 - Pages 314-318, Janos Kerner and Charles L. Hoppel

Cholesterol Synthesis; Vol.1 - Pages 451-455, Peter A. Edwards

Diabetes; Vol.1 - Pages 582-592, David W. Cooke

Fat Mobilization: Perilipin and Hormone-Sensitive Lipase; Vol.2 - Pages 85-89, Constantine Londos and Alan R. Kimmel

Fatty Acid Oxidation; Vol.2 - Pages 90-94, Horst Schulz

Fatty Acid Synthesis and its Regulation; Vol.2 - Pages 99-103, Steven D. Clarke and Manabu T. Nakamura

Gluconeogenesis; Vol.2 - Pages 197-203, Richard W. Hanson and Oliver E. Owen

Glucose/Sugar Transport in Bacteria; Vol.2 - Pages 204-207, Lan Guan and H. Ronald Kaback

Glucose/Sugar Transport in Mammals; Vol.2 - Pages 208-212, Silvia Mora and Jeffrey Pessin

Glycogen Metabolism; Vol.2 - Pages 244-248, Peter J. Roach

Glycogen Storage Diseases; Vol.2 - Pages 249-254, George H. Sack, Jr.

Glycolysis, Overview; Vol.2 - Pages 266-271, Robert A. Harris

Hexokinases/Glucokinases; Vol.2 - Pages 372-377, Emile Van Schaftingen

Insulin- and Glucagon-Secreting Cells of the Pancreas; Vol.2 - Pages 430-435, Franz M. Matschinsky

Ketogenesis; Vol.2 - Pages 505-507, Janos Kerner and Charles L. Hoppel

Ornithine Cycle; Vol.3 - Pages 172-177, Malcolm Watford

Pentose Phosphate (Hexose Mono Phosphate) Pathway; Vol.3 - Pages 211-215, Bernard R. Landau

Pentose Phosphate Pathway, History of; Vol.3 - Pages 216-225, John F. Williams

Phosphofructokinase-2/Fructose Bisphosphatase-2; Vol.3 - Pages 277-280, Daniel M. Raben

Photosynthesis; Vol.3 - Pages 330-335, Richard C. Leegood

Photosynthetic Carbon Dioxide Fixation; Vol.3 - Pages 336-341, Matthew J. Paul

Porphyrin Metabolism; Vol.3 - Pages 415-419, Mark Shepherd and Harry A. Dailey

Propionyl CoA–Succinyl CoA Pathway; Vol.3 - Pages 447-451, Wayne A. Fenton

Pyruvate Carboxylation, Transamination, and Gluconeogenesis; Vol.3 - Pages 606-610, Sarawut Jitrapakdee and John C. Wallace

Pyruvate Dehydrogenase; Vol.3 - Pages 611-615, Sam A. Johnson and James G. McCormack

Pyruvate Kinase; Vol.3 - Pages 616-619, Kosaku Uyeda

Starvation; Vol.4 - Pages 99-110, Oliver E. Owen and Richard W. Hanson

Tricarboxylic Acid Cycle; Vol.4 - Pages 256-262, Richard L. Veech

Urea Cycle, Inborn Defects of; Vol.4 - Pages 326-330, Marsha K. Fearing and Vivian E. Shih

Vitamin A (Retinoids); Vol.4 - Pages 354-359, Joseph L. Napoli

Vitamin B12 and B12-Proteins; Vol.4 - Pages 360-366, Bernhard Krautler

Vitamin C; Vol.4 - Pages 367-371, Robert B. Rucker and Francene Steinberg

Vitamin D; Vol.4 - Pages 372-377, Hector F. DeLuca and Margaret Clagett-Dame

Vitamin E; Vol.4 - Pages 384-388, Ute C. Obermuller-Jevic and Lester Packer

Vitamin K: Biochemistry, Metabolism, and Nutritional Aspects; Vol.4 - Pages 389-393, J. W. Suttie

Vitamin K: Blood Coagulation and Use in Therapy; Vol.4 - Pages 394-398, Matthew D. Stone and Gary L. Nelsestuen

Cell Architecture and Function

Actin Assembly/Disassembly; Vol.1 - Pages 12-18, Henry N. Higgs

Actin-Capping and -Severing Proteins; Vol.1 - Pages 19-26, Sankar Maiti and James R. Bamburg

Actin-Related Proteins; Vol.1 - Pages 27-33, R. Dyche Mullins

Autophagy in Fungi and Mammals; Vol.1 - Pages 138-143, Daniel J. Klionsky and Ju Guan

Bax and Bcl2 Cell Death Enhancers and Inhibitors; Vol.1 - Pages 152-154, David L. Vaux

Cadherin-Mediated Cell–Cell Adhesion; Vol.1 - Pages 205-211, Frauke Drees and W. James Nelson

Caspases and Cell Death; Vol.1 - Pages 319-327, Don W. Nicholson, Pierluigi Nicotera and Gerry Melino

Cell Cycle Controls in G1 and G0; Vol.1 - Pages 328-331, WengeShi and Steven F. Dowdy

Cell Cycle: Control of Entry and Progression Through S Phase; Vol.1 - Pages 332-337, Susan L. Forsburg

Cell Cycle: DNA Damage Checkpoints; Vol.1 - Pages 338-344, Jean Y. J. Wang

Cell Cycle: Mitotic Checkpoint; Vol.1 - Pages 345-351, Tim J. Yen

Cell Migration; Vol.1 - Pages 356-361, J. Victor Small and Emmanuel Vignal

Centromeres; Vol.1 - Pages 367-371, Beth A. Sullivan

Centrosomes and Microtubule Nucleation; Vol.1 - Pages 372-376, Reiko Nakajima, Ming-Ying Tsai and Yixian Zheng

Chaperones for Metalloproteins; Vol.1 - Pages 383-386, Valeria C. Culotta and Edward Luk

Chaperones, Molecular; Vol.1 - Pages 387-392, Sue Wickner and Joel R. Hoskins

Chaperonins; Vol.1 - Pages 393-398, Arthur L. Horwich, Wayne A. Fenton and George W. Farr

Chromosome Organization and Structure, Overview; Vol.1 - Pages 469-474, Elena Gracheva and Sarah C. R. Elgin

Cytokinesis; Vol.1 - Pages 556-561, Masanori Mishima and Michael Glotzer

Desmosomes and Hemidesmosomes; Vol.1 - Pages 569-576, Rachel L. Dusek, Jonathan C. R. Jones and Kathleen J. Green

Dynactin; Vol.1 - Pages 823-826, Trina A. Schroer

Dynein; Vol.1 - Pages 827-831, K. Kevin Pfister

Endoplasmic Reticulum-Associated Protein Degradation; Vol.2 - Pages 20-23, Maurizio Molinari

Focal Adhesions; Vol.2 - Pages 128-133, Eli Zamir and Benjamin Geiger

Golgi Complex; Vol.2 - Pages 312-315, Mark Stamnes

Heat/Stress Responses; Vol.2 - Pages 343-347, Davis T. W. Ng

Inositol Lipid 3-Phosphatases; Vol.2 - Pages 421-426, Gregory S. Taylor and Jack E. Dixon

Intermediate Filament Linker Proteins: Plectin and BPAG1; Vol.2 - Pages 452-457, Peter Fuchs and Gerhard Wiche

Intermediate Filaments; Vol.2 - Pages 458-464, Kelsie M. Bernot and Pierre A. Coulombe

Keratins and the Skin; Vol.2 - Pages 497-504, Pierre A. Coulombe and Kelsie M. Bernot

Kinesin Superfamily Proteins; Vol.2 - Pages 508-516, Nobutaka Hirokawa and Reiko Takemura

Kinesins as Microtubule Disassembly Enzymes; Vol.2 - Pages 517-521, Susan L. Kline-Smith and Arshad Desai

Meiosis; Vol.2 - Pages 610-616, Neil Hunter

Metalloproteinases, Matrix; Vol.2 - Pages 657-665, Hideaki Nagase and Gillian Murphy

Microtubule-Associated Proteins; Vol.2 - Pages 676-682, Nobutaka Hirokawa and Reiko Takemura

Mitosis; Vol.2 - Pages 743-747, Patricia Wadsworth and Nasser M. Rusan

Myosin Motors; Vol.2 - Pages 778-781, Roy E. Larson

N-End Rule; Vol.3 - Pages 6-10, Alexander Varshavsky

Neuronal Intermediate Filaments; Vol.3 - Pages 21-25, Ronald K. H. Liem

Nuclear Compartmentalization; Vol.3 - Pages 87-91, Kelly P. Smith and Jeanne B. Lawrence

Nuclear Envelope and Lamins; Vol.3 - Pages 92-95, Bryce M. Paschal

Nuclear Pores and Nuclear Import/Export; Vol.3 - Pages 109-114, Anita H. Corbett

Peroxisomes; Vol.3 - Pages 246-250, Suresh Subramani

26S Proteasome, Structure and Function; Vol.3 - Pages 469-473, Peter Zwickl and Wolfgang Baumeister

Protein Glycosylation, Overview; Vol.3 - Pages 504-509, Natasha E. Zachara and Gerald W. Hart

Rho GTPases and Actin Cytoskeleton Dynamics; Vol.3 - Pages 714-718, Priam Villalonga and Anne J. Ridley

Septins and Cytokinesis; Vol.4 - Pages 22-26, Makoto Kinoshita and Christine M. Field

SUMO Modification; Vol.4 - Pages 130-134, Frauke Melchior and Andrea Pichler

Tight Junctions; Vol.4 - Pages 187-189, Shoichiro Tsukita

Transcriptional Silencing; Vol.4 - Pages 200-203, Ann Sutton and Rolf Sternglanz

Tubulin and its Isoforms; Vol.4 - Pages 272-276, Eva Nogales

Unfolded Protein Responses; Vol.4 - Pages 319-325, David Ron

Vacuoles; Vol.4 - Pages 331-336, Christopher J. Stefan and Scott D. Emr

Protein/Enzyme Structure Function and Degradation

Allosteric Regulation; Vol.1 - Pages 68-73, Barry S. Cooperman

Aminopeptidases; Vol.1 - Pages 96-98, Ralph A. Bradshaw

Amyloid; Vol.1 - Pages 99-104, Ronald Wetzel

Aspartic Proteases; Vol.1 - Pages 123-127, Ben M. Dunn

B12-Containing Enzymes; Vol.1 - Pages 145-151, Vahe Bandarian and Rowena G. Matthews

Biotin; Vol.1 - Pages 174-178, Steven W. Polyak and Anne Chapman-Smith

Biotinylation of Proteins; Vol.1 - Pages 179-181, Ronald A. Kohanski

Calpain; Vol.1 - Pages 300-306, Hiroyuki Sorimachi and Yasuko Ono

Chemiluminescence and Bioluminescence; Vol.1 - Pages 399-404, Thomas O. Baldwin

Coenzyme A; Vol.1 - Pages 475-477, M. Daniel Lane

Collagenases; Vol.1 - Pages 478-481, Kenn Holmbeck and Henning Birkedal-Hansen

Collagens; Vol.1 - Pages 482-487, Darwin J. Prockop

Cysteine Proteases; Vol.1 - Pages 516-520, David J. Buttle and John S. Mort

Disulfide Bond Formation; Vol.1 - Pages 598-602, Hiram F. Gilbert

Elastin; Vol.2 - Pages 10-12, Judith Ann Foster

Enzyme Inhibitors; Vol.2 - Pages 31-37, Vern L. Schramm

Enzyme Kinetics; Vol.2 - Pages 38-44, Irwin H. Segel

Enzyme Reaction Mechanisms: Stereochemistry; Vol.2 - Pages 45-50, Ming-Daw Tsai, Li Zhao and Brandon J. Lamarche

Flavins; Vol.2 - Pages 118-122, Barrie Entsch and David P. Ballou

Heme Proteins; Vol.2 - Pages 354-361, Johannes Everse

HIV Protease; Vol.2 - Pages 384-387, Ben M. Dunn

Kinetic Isotope Effects; Vol.2 - Pages 522-527, Justine P. Roth and Judith P. Klinman

Lipid Modification of Proteins: Targeting to Membranes; Vol.2 - Pages 580-583, Marilyn D. Resh

Low Barrier Hydrogen Bonds; Vol.2 - Pages 594-598, Perry A. Frey

Metalloproteases; Vol.2 - Pages 652-656, David S. Auld

Peptide Amidation; Vol.3 - Pages 226-230, Mark J. Niciu, Richard E. Mains and Betty A. Eipper

Phage Display for Protein Binding; Vol.3 - Pages 251-255, Henry B. Lowman

Prions, Overview; Vol.3 - Pages 437-440, Cedric Govaerts and Fred E. Cohen

Proteases in Blood Clotting; Vol.3 - Pages 457-463, John D. Kulman and Earl W. Davie

Proteasomes, Overview; Vol.3 - Pages 464-468, Martin Rechsteiner

Protein Carboxyl Esterification; Vol.3 - Pages 474-477, Shilpa G. Lalchandani and Jeffry B. Stock

Protein Degradation; Vol.3 - Pages 484-492, Tomo ari and Alfred L. Goldberg

Protein Folding and Assembly; Vol.3 - Pages 493-499, David P. Goldenberg

Protein N-Myristoylation; Vol.3 - Pages 527-531, Erica Dutil Sonnenburg and Jeffrey I. Gordon

Protein Palmitoylation; Vol.3 - Pages 532-535, Robert J. Deschenes

Pteridines; Vol.3 - Pages 556-560, S. Colette Daubner and Paul F. Fitzpatrick

Pyridoxal Phosphate; Vol.3 - Pages 595-599, David E. Metzler

Regulated Intramembrane Proteolysis (Rip); Vol.3 - Pages 665-670, Jin Ye, Michael S. Brown and Joseph L. Goldstein

Secretases; Vol.4 - Pages 7-10, Robert L. Heinrikson

Selenoprotein Synthesis; Vol.4 - Pages 17-21, August Bock

Substrate Binding, Catalysis, and Product Release; Vol.4 - Pages 123-126, W. Wallace Cleland

Two-Hybrid Protein–Protein Interactions; Vol.4 - Pages 290-293, Ilya Serebriiskii and Erica A. Golemis

Tyrosine Sulfation; Vol.4 - Pages 294-297, Denis Corbeil and Wieland B. Huttner

Ubiquitin System; Vol.4 - Pages 299-303, Aaron Ciechanover and Michael H. Glickman

Ubiquitin-Like Proteins; Vol.4 - Pages 304-307, Edward T. H. Yeh

Zinc Fingers; Vol.4 - Pages 435-439, Mark Isalan

Bioenergetics

ABC Transporters; Vol.1 - Pages 1-5, Andre Goffeau, Benoit De Hertogh and Philippe V. Baret

Amine Oxidases; Vol.1 - Pages 85-89, Giovanni Floris and Alessandro Finazzi Agro

ATP Synthesis in Plant Mitochondria: Substrates, Inhibitors, Uncouplers; Vol.1 - Pages 128-132, Kathleen L. Soole and R. Ian Menz

ATP Synthesis: Mitochondrial Cyanide-Resistant Terminal Oxidases; Vol.1 - Pages 133-137, James N. Siedow

Bioenergetics: General Definition of Principles; Vol.1 - Pages 170-173, David G. Nicholls

Calcium Buffering Proteins: Calbindin; Vol.1 - Pages 221-225, Willi Hunziker and Igor Bendik

Calcium Buffering Proteins: ER Luminal Proteins; Vol.1 - Pages 226-230, Jody Groenendyk and Marek Michalak

Calcium Oscillations; Vol.1 - Pages 231-234, Marisa Brini

Calcium Sensing Receptor; Vol.1 - Pages 235-240, Jacob Tfelt-Hansen and Edward M. Brown

Calcium Signaling: Calmodulin-Dependent Phosphatase; Vol.1 - Pages 241-245, Claude Klee, Hao Ren and Shipeng Li

Calcium Signaling: Cell Cycle; Vol.1 - Pages 246-249, Luigia Santella

Calcium Signaling: Motility (Actomyosin–Troponin System); Vol.1 - Pages 250-255, Takeyuki Wakabayashi and Setsuro Ebashi

Calcium Signaling: NO Synthase; Vol.1 - Pages 256-260, Zhi-Qiang Wang and Dennis J. Stuehr

Calcium Transport in Mitochondria; Vol.1 - Pages 261-266, Rosario Rizzuto and Marisa Brini

Calcium Waves; Vol.1 - Pages 267-269, Lionel F. Jaffe

Calcium, Biological Fitness of; Vol.1 - Pages 270-273, Robert J. P. Williams

Calcium/Calmodulin-Dependent Protein Kinase II; Vol.1 - Pages 274-280, Andy Hudmon and Howard Schulman

Calcium-Binding Proteins: Cytosolic (Annexins, Gelsolins, C2-Domain Proteins); Vol.1 - Pages 287-293, Joachim Krebs

Calcium-Modulated Proteins (EF-Hand); Vol.1 - Pages 294-299, Robert H. Kretsinger

Cell Death by Apoptosis and Necrosis; Vol.1 - Pages 352-355, Pierluigi Nicotera

Chemiosmotic Theory; Vol.1 - Pages 405-412, Keith D. Garlid

Chemolithotrophy; Vol.1 - Pages 419-424, Alan B. Hooper

Chlorophylls and Carotenoids; Vol.1 - Pages 430-437, Hugo Scheer

Chloroplast Redox Poise and Signaling; Vol.1 - Pages 438-445, John F. Allen

Chloroplasts; Vol.1 - Pages 446-450, Nicoletta Rascio

Cytochrome b6f Complex; Vol.1 - Pages 521-527, Gunter A. Hauska and Thomas Schodl

Cytochrome bc1 Complex (Respiratory Chain Complex III); Vol.1 - Pages 528-534, Bernard L. Trumpower

Cytochrome c; Vol.1 - Pages 535-538, Hans Tuppy and Gunther Kreil

Cytochrome Oxidases, Bacterial; Vol.1 - Pages 539-543, Peter Brzezinski and Pia Adelroth

Cytochrome P-450; Vol.1 - Pages 544-549, Rita Bernhardt

Energy Transduction in Anaerobic Prokaryotes; Vol.2 - Pages 24-30, Gottfried Unden

ER/SR Calcium Pump: Function; Vol.2 - Pages 56-60, Giuseppe Inesi

ER/SR Calcium Pump: Structure; Vol.2 - Pages 61-65, Chikashi Toyoshima and Yuji Sugita

F1–F0 ATP Synthase; Vol.2 - Pages 73-79, Donata Branca

Ferredoxin; Vol.2 - Pages 104-106, Giuliana Zanetti and Vittorio Pandini

Ferredoxin-NADP+ Reductase; Vol.2 - Pages 107-111, Giuliana Zanetti and Alessandro Aliverti

Free Radicals, Sources and Targets of: Mitochondria; Vol.2 - Pages 134-142, Alberto Boveris and Enrique Cadenas

Friedreich's Ataxia; Vol.2 - Pages 143-145, Paul E. Hart and Anthony H. V. Schapira

Giant Mitochondria (Megamitochondria); Vol.2 - Pages 186-188, Bernard Tandler and Charles L. Hoppel

Glutathione Peroxidases; Vol.2 - Pages 224-228, Fulvio Ursini and Matilde Maiorino

Green Bacteria: Secondary Electron Donor (Cytochromes); Vol.2 - Pages 321-324, Hirozo Oh-oka and Robert E. Blankenship

Green Bacteria: The Light-Harvesting Chlorosome; Vol.2 - Pages 325-330, John M. Olson

Green Sulfur Bacteria: Reaction Center and Electron Transport; Vol.2 - Pages 331-336, Gunter A. Hauska and Thomas Schodl

Heme Synthesis; Vol.2 - Pages 362-366, Gloria C. Ferreira

Intracellular Calcium Channels: cADPR-Modulated (Ryanodine Receptors); Vol.2 - Pages 465-468, Antony Galione

Intracellular Calcium Channels: NAADP+-Modulated; Vol.2 - Pages 469-472, Armando A. Genazzani and Marcella Debidda

IP3 Receptors; Vol.2 - Pages 478-481, Colin W. TaylorEdward Morris and Paula da Fonseca

Iron–Sulfur Proteins; Vol.2 - Pages 482-489, Helmut Beinert, Jacques Meyer and Roland Lill

Ligand-Operated Membrane Channels: Calcium (Glutamate); Vol.2 - Pages 551-561, Elias K. Michaelis

Ligand-Operated Membrane Channels: GABA; Vol.2 - Pages 562-566, F. Minier and Erwin Sigel

Light-Harvesting Complex (LHC) I and II: Pigments and Proteins; Vol.2 - Pages 567-570, Stefan Jansson

Luft's Disease; Vol.2 - Pages 599-601, Salvatore DiMauro

Membrane Transport, General Concepts; Vol.2 - Pages 627-630, Stanley G. Schultz

Membrane Transporters:Na+/Ca2+ Exchangers; Vol.2 - Pages 631-636, Jonathan Lytton

Membrane-Associated Energy Transduction in Bacteria and Archaea; Vol.2 - Pages 637-645, Gunter Schafer

Metabolite Channeling: Creatine Kinase Microcompartments; Vol.2 - Pages 646-651, Uwe Schlattner and Theo Wallimann

Mitochondrial Auto-Antibodies; Vol.2 - Pages 683-688, Harold Baum

Mitochondrial Channels; Vol.2 - Pages 689-692, M. Catia Sorgato and Alessandro Bertoli

Mitochondrial DNA; Vol.2 - Pages 693-696, Gottfried Schatz

Mitochondrial Genes and their Expression: Yeast; Vol.2 - Pages 697-702, Piotr P. Slonimski and Giovanna Carignani

Mitochondrial Genome, Evolution; Vol.2 - Pages 703-708, B. Franz Lang, Dennis V. Lavrov and Gertraud Burger

Mitochondrial Genome, Overview; Vol.2 - Pages 709-715, Douglas C. Wallace

Mitochondrial Inheritance; Vol.2 - Pages 716-719, Eric A. Shoubridge

Mitochondrial Membranes, Structural Organization; Vol.2 - Pages 720-724, Carmen A. Mannella

Mitochondrial Metabolite Transporter Family; Vol.2 - Pages 725-732, Ferdinando Palmieri and Martin Klingenberg

Mitochondrial Outer Membrane and the VDAC Channel; Vol.2 - Pages 733-736, Marco Colombini

Neuronal Calcium Signal; Vol.3 - Pages 16-20, Hilmar Bading

Nicotinamide Nucleotide Transhydrogenase; Vol.3 - Pages 50-56, Jan Rydstrom

Nuclear Genes in Mitochondrial Function and Biogenesis; Vol.3 - Pages 100-104, Alexander Tzagoloff and Carol L. Dieckmann

Oncocytes; Vol.3 - Pages 165-166, Bernard Tandler and Charles L. Hoppel

Oxygenases; Vol.3 - Pages 178-182, Osamu Hayaishi

Periplasmic Electron Transport Systems in Bacteria; Vol.3 - Pages 231-238, David J. Richardson, Gary Sawers and Rob J. M. Van Spanning

Phosphatidylinositol-3-Phosphate; Vol.3 - Pages 272-276, Joseph V. Virbasius and Michael P. Czech

Photosystem I, Structure and Function; Vol.3 - Pages 342-347, Petra Fromme

Photosystem I: FX, FA, and FB Iron–Sulfur Clusters; Vol.3 - Pages 348-356, Mikhail L. Antonkine and John H. Golbeck

Photosystem II Light Harvesting System: Dynamic Behavior; Vol.3 - Pages 357-362, Peter Horton and Alexander Ruban

Photosystem II: Assembly and Turnover of the D1 Protein; Vol.3 - Pages 363-366, Eira Kanervo and Eva-Mari Aro

Photosystem II: Protein Components; Vol.3 - Pages 367-374, James Barber

Photosystem II: Water Oxidation, Overview; Vol.3 - Pages 375-380, Fabrice Rappaport and Pierre Joliot

Plasma-Membrane Calcium Pump: Structure and Function; Vol.3 - Pages 385-389, Emanuel E. Strehler

Plastocyanin; Vol.3 - Pages 390-393, Elizabeth L. Gross

Protein Import into Mitochondria; Vol.3 - Pages 510-515, Johannes M. Herrmann and Walter Neupert

P-Type Pumps: Copper Pump; Vol.3 - Pages 561-564, Ilia Voskoboinik and James Camakaris

P-Type Pumps: H+/K+ Pump; Vol.3 - Pages 565-570, Jai Moo Shin and George Sachs

P-Type Pumps: Na+/K+ Pump; Vol.3 - Pages 571-576, Peter L. Jorgensen

P-Type Pumps: Plasma-Membrane H+ Pump; Vol.3 - Pages 577-581, A. Brett Mason and Carolyn W. Slayman

Purple Bacteria: Electron Acceptors and Donors; Vol.3 - Pages 582-585, Evaldas Katilius and Neal W. Woodbury

Purple Bacteria: Photosynthetic Reaction Centers; Vol.3 - Pages 586-594, C. Roy D. Lancaster

Pyrimidine Biosynthesis; Vol.3 - Pages 600-605, Monika Loffler and Elke Zameitat

Quinones; Vol.3 - Pages 621-627, Giorgio Lenaz and Maria Luisa Genova

Respiratory Chain and ATP Synthase; Vol.3 - Pages 671-675, David G. Whitehouse and Anthony L. Moore

Respiratory Chain Complex I; Vol.3 - Pages 676-680, Ulrich Brandt

Respiratory Chain Complex II and Succinate: Quinone Oxidoreductases; Vol.3 - Pages 681-687, C. Roy D. Lancaster

Respiratory Chain Complex IV; Vol.3 - Pages 688-694, Hartmut Michel

Respiratory Processes in Anoxygenic and Oxygenic Phototrophs; Vol.3 - Pages 695-699, Roberto Borghese and Davide Zannoni

Spastic Paraplegia; Vol.4 - Pages 61-66, Elena Irene Rugarli and Andrea Ballabio

Secondary Structure in Protein Analysis

George D. Rose
The Johns Hopkins University, Baltimore, Maryland, USA

Proteins are linear, unbranched polymers of the 20 naturally occurring amino acid residues. Under physiological conditions, most proteins self-assemble into a unique, biologically relevant structure: the native fold. This structure can be dissected into chemically recognizable, topologically simple elements of secondary structure: α-helix, 3_{10}-helix, β-strand, polyproline II helix, turns, and Ω-loops. Together, these six familiar motifs account for ~95% of the total protein structure, and they are utilized repeatedly in mix-and-match patterns, giving rise to the repertoire of known folds. In principle, a protein's three-dimensional structure is predictable from its amino acid sequence, but this problem remains unsolved. A related, but ostensibly simpler, problem is to predict a protein's secondary structure elements from its sequence.

Protein Architecture

A protein is a polymerized chain of amino acid residues, each joined to the next via a peptide bond. The backbone of this polymer describes a complex path through three-dimensional space called the "native fold" or "protein fold."

Covalent Structure

Amino acids have both backbone and side chain atoms. Backbone atoms are common to all amino acids, while side chain atoms differ among the 20 types. Chemically, an amino acid consists of a central, tetrahedral carbon atom, (–$\overset{|}{\underset{|}{C}}$–), linked covalently to (1) an amino group (–NH_2), (2) a carboxyl group (–COOH), (3) a hydrogen atom (–H) and (4) the side chain (–R). Upon polymerization, the amino group loses an –H and the carboxy group loses an –OH; the remaining chemical moiety is called an "amino acid residue" or, simply, a "residue." Residues in this polymer are linked via peptide bonds, as shown in Figure 1.

Degrees of Freedom in the Backbone

The six backbone atoms in the peptide unit [C$\alpha(i)$–CO–NH–C$\alpha(i+1)$] are approximately coplanar, leaving only two primary degrees of freedom for each residue. By convention, these two dihedral angles are called ϕ and ψ (Figure 2). The protein's backbone conformation is described by the ϕ,ψ-specification for each residue.

Classification of Structure

Protein structure is usually classified into primary, secondary, and tertiary structure. "Primary structure" corresponds to the covalently connected sequence of amino acid residues. "Secondary structure" corresponds to the backbone structure, with particular emphasis on hydrogen bonds. And "tertiary structure" corresponds to the complete atomic positions for the protein.

Secondary Structure

Protein secondary structure can be subdivided into repetitive and nonrepetitive, depending upon whether the backbone dihedral angles assume repeating values. There are three major elements (α-helix, β-strand, and polyproline II helix) and one minor element (3_{10}-helix) of repetitive secondary structure (Figure 3). There are two major elements of nonrepetitive secondary structure (turns and Ω-loops).

Repetitive Secondary Structure: the α-Helix

When backbone dihedral angles are assigned repeating ϕ,ψ-values near ($-60°$, $-40°$), the chain twists into a right-handed helix, with 3.6 residues per helical turn. First proposed as a model by Pauling, Corey, and Branson in 1951, the existence of this famous structure was experimentally confirmed almost immediately by

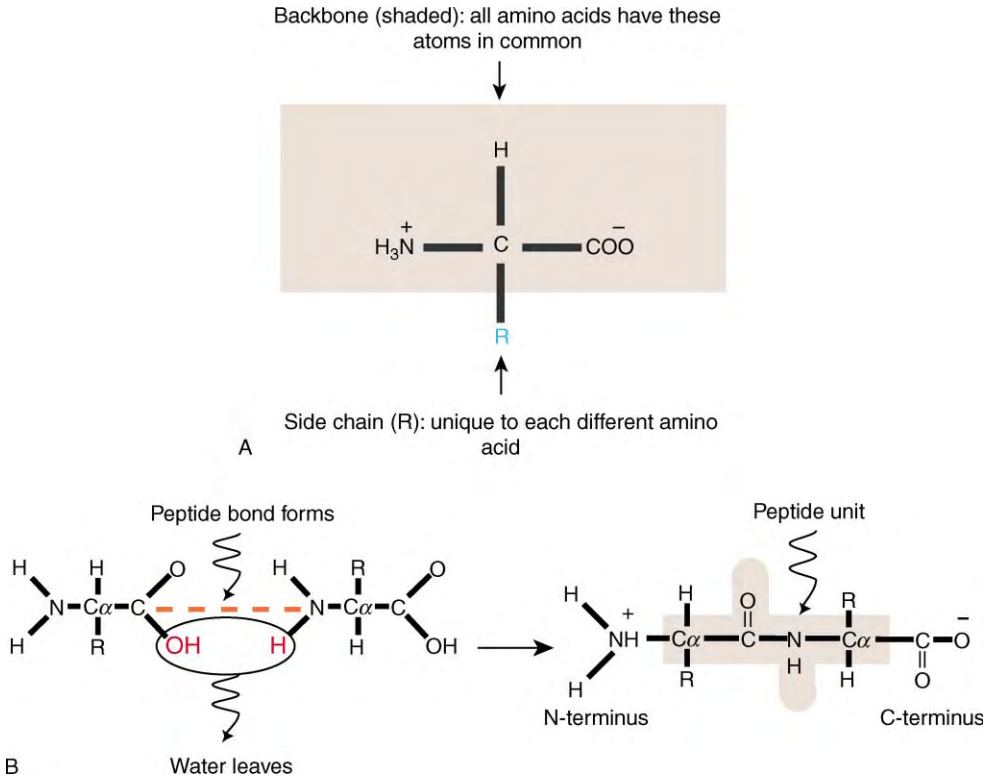

FIGURE 1 (A) A generic amino acid. Each of the 20 naturally occurring amino acids has both backbone atoms (within the shaded rectangle) and side chain atoms (designated R). Backbone atoms are common to all amino acids, while side chain atoms differ among the 20 types. Chemically, an amino acid consists of a tetrahedral carbon atom (–C–), linked covalently to (1) an amino group ($-NH_2$), (2) a carboxyl group (–COOH), (3) a hydrogen atom (–H), and (4) the side chain (–R). (B) Amino acid polymerization. The α-amino group of one amino acid condenses with the α-carboxylate of another, releasing a water molecule. The newly formed amide bond is called a *peptide bond* and the repeating unit is a *residue*. The two chain ends have a free α-amino group and a free α-carboxylate group and are designated the amino-terminal (or N-terminal) and the carboxy-terminal (or C-terminal) ends, respectively. The *peptide unit* consists of the six shaded atoms (Cα–CO–NH–Cα), three on either side of the peptide bond.

Perutz in ongoing crystallographic studies, well before elucidation of the first protein structure.

In an α-helix, each backbone N–H forms a hydrogen bond with the backbone carbonyl oxygen situated four residues away in the linear sequence chain (toward the N-terminus): N–H(i)$\cdots$O=C(i − 4). The two sequentially distant hydrogen-bonded groups are brought into spatial proximity by conferring a helical twist upon the chain. This results in a rod-like structure, with the hydrogen bonds oriented approximately parallel to the long axis of the helix.

In globular proteins, the average length of an α-helix is 12 residues. Typically, helices are found on the outside of the protein, with a hydrophilic face oriented toward the surrounding aqueous solvent and a hydrophobic face oriented toward the protein interior.

Inescapably, end effects deprive the first four amide hydrogens and last four carbonyl oxygens of Pauling-type, intra-helical hydrogen bond partners. The special hydrogen-bonding motifs that can provide partners for these otherwise unsatisfied groups are known as "helix caps."

In globular proteins, helices account for ~25% of the structure on average, but this number varies. Some proteins, like myoglobin, are predominantly helical, while others, like plastocyanin, lack helices altogether.

Repetitive Secondary Structure: the 3_{10}-Helix

When backbone dihedral angles are assigned repeating ϕ,ψ-values near (−50°, −30°), the chain twists into a right-handed helix. By convention, this helix is named using formal nomenclature: 3_{10} designates three residues per helical turn and 10 atoms in the hydrogen bonded ring between each N–H donor and its C=O acceptor. (In this nomenclature, the α-helix would be called a 3.6_{13} helix.)

Single turns of 3_{10} helix are common and closely resemble a type of β-turn (see below). Often, α-helices terminate in a turn of 3_{10} helix. Longer 3_{10} helices are sterically strained and much less common.

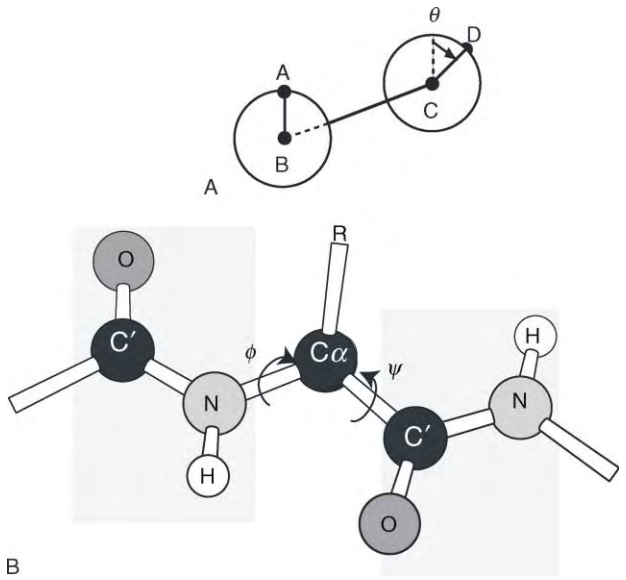

FIGURE 2 (A) Definition of a dihedral angle. In the diagram, the dihedral angle, θ, measures the rotation of line segment CD with respect to line segment AB, where A, B, C, and D correspond to the x,y,z-positions of four atoms. (θ is calculated as the scalar angle between the two normals to planes A–B–C and B–C–D.) By convention, clockwise rotation is positive and $\theta = 0°$ when A and D are eclipsed. (B) Degrees of freedom in the protein backbone. The peptide bond (C′–N) has partial double bond character, so that the six atoms, Ca(i)–CO–Ca($i+1$), are approximately co-planar. Consequently, only two primary degrees of freedom are available for each residue. By convention, these two dihedral angles are called ϕ and ψ. ϕ is specified by the four atoms C′(i)–N–Cα–C′($i+1$) and ψ by the four atoms N(i)–Cα–C′–N($i+1$). When the chain is fully extended, as depicted here, $\phi = \psi = 180°$.

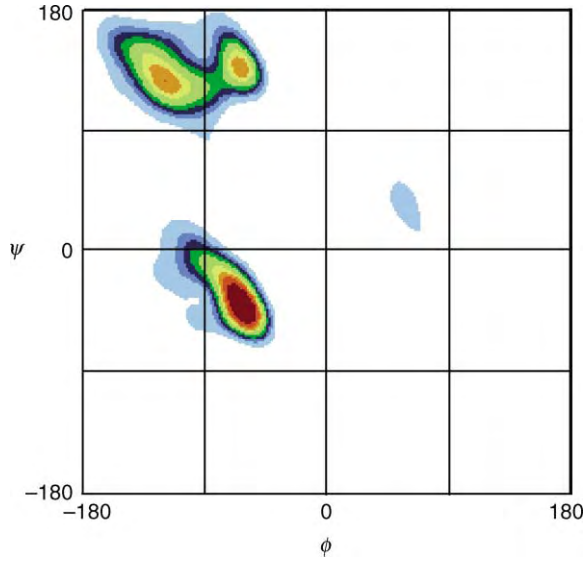

FIGURE 3 A contoured Ramachandran (ϕ, ψ) plot. Backbone ϕ,ψ-angles were extracted from 1042 protein subunits of known structure. Only nonglycine residues are shown. Contours were drawn in population intervals of 10% and are indicated by the ten colors (in rainbow order). The most densely populated regions are colored red. Three heavily populated regions are apparent, each near one of the major elements of repetitive secondary structure: α-helix ($\sim -60°$, $-40°$), β-strand ($\sim -120°$, $120°$), P_{II} helix ($\sim -70°$, $140°$). Adapted from Hovmöller, S., Zhou, T., and Ohlson, T. (2002). Conformation of amino acids in proteins. *Acta Cryst.* **D58**, 768–776, with permission of IUCr.

Repetitive Secondary Structure: the β-Strand

When backbone dihedral angles are assigned repeating ϕ,ψ-values near $(-120°, -120°)$, the chain adopts an extended conformation called a β-strand. Two or more β-strands, aligned so as to form inter-strand hydrogen bonds, are called a β-sheet. A β-sheet of just two hydrogen-bonded β-strands interconnected by a tight turn is called a β-hairpin. The average length of a single β-strand is seven residues.

The classical definition of secondary structure found in most textbooks is limited to hydrogen-bonded backbone structure and, strictly speaking, would not include a β-strand, only a β-sheet. However, the β-sheet is tertiary structure, not secondary structure; the intervening chain joining two hydrogen-bonded β-strands can range from a tight turn to a long, structurally complex stretch of polypeptide chain. Further, approximately half the β-strands found in proteins are singletons and do not form inter-strand hydrogen bonds with another β-strand. Textbooks tend to blur this issue.

Typically, β-sheet is found in the interior of the protein, although the outermost parts of edge-strands usually reside at the protein's water-accessible surface.

Two β-strands in a β-sheet are classified as either parallel or anti-parallel, depending upon whether their mutual N- to C-terminal orientation is the same or opposite, respectively.

In globular proteins, β-sheet accounts for about 15% of the structure on an average, but, like helices, this number varies considerably. Some proteins are predominantly sheet while others lack sheet altogether.

Repetitive Secondary Structure: the Polyproline II Helix (P_{II})

When backbone dihedral angles are assigned repeating ϕ,ψ-values near $(-70°, +140°)$, the chain twists into a left-handed helix with 3.0 residues per helical turn. The name of this helix is derived from a poly-proline homopolymer, in which the structure is forced by its stereochemistry. However, a polypeptide chain can adopt a P_{II} helical conformation whether or not it contains proline residues.

Unlike the better known α-helix, a P_{II} helix has no intrasegment hydrogen bonds, and it is not included in the classical definition of secondary structure for this reason. This extension of the definition is also needed in the case of an isolated β-strand. Recent studies have shown that the unfolded state of proteins is rich in P_{II} structure.

Nonrepetitive Secondary Structure: the Turn

Turns are sites at which the polypeptide chain changes its overall direction, and their frequent occurrence is the reason why globular proteins are, in fact, globular.

Turns can be subdivided into β-turns, γ-turns, and tight turns. β-turns involve four consecutive residues, with a hydrogen bond between the amide hydrogen of the 4th residue and the carbonyl oxygen of the 1st residue: N–H(i)$\cdots$O=C($i-3$). β-turns are further subdivided into subtypes (e.g., Type I, I′, II, II′, III,…) depending upon their detailed stereochemistry. γ-turns involve only three consecutive, hydrogen-bonded residues, N–H(i)$\cdots$O=C($i-2$), which are further divided into subtypes.

More gradual turns, known as "reverse turns" or "tight turns," are also abundant in protein structures. Reverse turns lack intra-turn hydrogen bonds but nonetheless, are involved in changes in overall chain direction.

Turns are usually, but not invariably, found on the water-accessible surface of proteins. Together, β,γ- and reverse turns account for about one-third of the structure in globular proteins, on an average.

Nonrepetitive Secondary Structure: the Ω-Loop

Ω-loops are sites at which the polypeptide loops back on itself, with a morphology that resembles the Greek letter "Ω" although often with considerable distortion. They range in length from 6–16 residues, and, lacking any specific pattern of backbone-hydrogen bonding, can exhibit significant structural heterogeneity.

Like turns, Ω-loops are typically found on the outside of proteins. On an average, there are about four such structures in a globular protein.

Identification of Secondary Structure from Coordinates

Typically, one becomes familiar with a given protein structure by visualizing a model – usually a computer model – that is generated from experimentally determined coordinates. Some secondary structure types are well defined on visual inspection, but others are not. For example, the central residues of a well-formed helix are visually unambiguous, but the helix termini are subject to interpretation. In general, visual parsing of the protein into its elements of secondary structure can be a highly subjective enterprise. Objective criteria have been developed to resolve such ambiguity. These criteria have been implemented in computer programs that accept a protein's three-dimensional coordinates as input and provide its secondary structure components as output.

Inherent Ambiguity in Structural Identification

It should be realized that objective criteria for structural identification can provide a welcome self-consistency, but there is no single "right" answer. For example, turns have been defined in the literature as chains sites at which the distance between two α-carbon atoms, separated in sequence by four residues, is not more than 7Å, provided the residues are not in an α-helix: distance[C$\alpha(i)$–C$\alpha(i+3)$] $\leq$ 7Å and C$\alpha(i)$–C$\alpha(i+3)$ not α-helix. Indeed, turns identified using this definition agree quite well with one's visual intuition. However, the 7Å threshold is somewhat arbitrary. Had 7.1Å been used instead, additional, intuitively plausible turns would have been found.

Programs to Identify Structure from Coordinates

Many workers have devised algorithms to parse the three-dimensional structure into its secondary structure components. Unavoidably, these procedures include investigator-defined thresholds. Two such programs are mentioned here.

The *D*atabase of *S*econdary *S*tructure Assignments in *P*roteins

This is the most widely used secondary structure identification method available today. Developed by Kabsch and Sander, it is accessible on the internet, both from the original authors and in numerous implementations from other investigators as well.

The *d*atabase of *s*econdary *s*tructure assignments in *p*roteins (DSSP) identifies an extensive set of secondary structure categories, based on a combination of backbone dihedral angles and hydrogen bonds. In turn, hydrogen bonds are identified based on geometric criteria involving both the distance and orientation between a donor–acceptor pair. The program has criteria for recognizing α-helix, 3_{10}-helix, π helix, β-sheet (both parallel and anti-parallel), hydrogen-bonded turns and reverse turns. (Note: the π-helix is rare and has been omitted from the secondary structure categories.)

*Pro*tein *S*econdary *S*tructure Assignments

In contrast to DSSP, protein secondary structure assignments (PROSS) identification is based solely on backbone dihedral angles, without resorting to hydrogen

bonds. Developed by Srinivasan and Rose, it is accessible on the *internet*.

PROSS identifies only α-helix, β-strand, and turns, using standard ϕ,ψ definitions for these categories. Because hydrogen bonds are not among the identification criteria, PROSS does not distinguish between isolated β-strands and those in a β-sheet.

Prediction of Protein Secondary Structure from Amino Acid Sequence

Efforts to predict secondary structure from amino acid sequence dates back to the 1960s to the works of Guzzo, Prothero and, slightly later, Chou and Fasman. The problem is complicated by the fact that protein secondary structure is only marginally stable, at best. Proteins fold cooperatively, with secondary and tertiary structure emerging more or less concomitantly. Typical peptide fragments excised from the host protein, and measured in isolation, exhibit only a weak tendency to adopt their native secondary structure conformation.

Predictions Based on Empirically Determined Preferences

Motivated by early work of Chou and Fasman, this approach uses a database of known structures to discover the empirical likelihood, f, of finding each of the twenty amino acids in helix, sheet, turn, *etc*. These likelihoods are equated to the residue's normalized frequency of occurrence in a given secondary structure type, obtained by counting. Using alanine in helices as an example

$$\text{fraction Ala in helix} = \frac{\text{occurrences of Ala in helices}}{\text{occurrences of Ala in database}}$$

This fraction is then normalized against the corresponding fraction of helices in the database:

$$f_{\text{Ala}}^{\text{helix}} = \frac{\text{fraction Ala in helix}}{\text{fraction helices in database}} = \frac{\dfrac{\text{occurrences of Ala in helices}}{\text{occurrences of Ala in database}}}{\dfrac{\text{number of residues in helices}}{\text{number of residues in database}}}$$

A normalized frequency of unity indicates no preference – i.e., the frequency of occurrence of the given residue in that particular position is the same as its frequency at large. Normalized frequencies greater than/less than unity indicate selection for/against the given residue in a particular position.

These residue likelihoods are then used in combination to make a prediction. When only a small number of proteins had been solved, these data-dependent f-values fluctuated significantly as new structures were added to the database. At this point there are more than 22 000 structures in the Protein Data Bank (www.rcsb.org), and the f-values have reached a plateau.

Database-Independent Predictions: the Hydrophobicity Profile

Hydrophobicity profiles have been used to predict the location of turns in proteins. A hydrophobicity profile is a plot of the residue number versus residue hydrophobicity, averaged over a running window. The only variables are the size of the window used for averaging and the choice of hydrophobicity scale (of which there are many). No empirical data from the database is required. Peaks in the profile correspond to local maxima in hydrophobicity, and valleys to local minima. Prediction is based on the idea that apolar sites along the chain (i.e., peaks in the profile) will be disposed preferentially to the molecular interior, forming a hydrophobic core, whereas polar sites (i.e., valleys in the profile) will be disposed to the exterior and correspond to chain turns.

Neural Networks

More recently, neural network approaches to secondary structure prediction have come to dominate the field. These approaches are based on pattern-recognition methods developed in artificial intelligence. When used in conjunction with the protein database, these are the most successful programs available today.

A neural network is a computer program that associates an input (e.g., a residue sequence) with an output (e.g., secondary structure prediction) through a complex network of interconnected nodes. The path taken from the input through the network to the output depends upon past experience. Thus, the network is said to be "trained" on a dataset.

The method is based on the observation that amino acid substitutions follow a pattern within a family of homologous proteins. Therefore, if the sequence of interest has homologues within the database of known structures, this information can be used to improve predictive success, provided the homologues are recognizable. In fact, a homologue can be recognized quite successfully when the sequence of interest and a putative homologue have an aligned sequence identity of 25% or more.

Neural nets provide an information-rich approach to secondary structure prediction that has become increasingly successful as the protein databank has grown.

Physical Basis of Secondary Structure

An impressive number of secondary structure prediction methods can be found in the literature and on the web. Surprisingly, almost all are based on empirical likelihoods or neural nets; few are based on physicochemical theory.

In one such theory, secondary structure propensities are predominantly a consequence of two competing local effects – one favoring hydrogen bond formation in helices and turns, and the other opposing the attendant reduction in sidechain conformational entropy upon helix and turn formation. These sequence-specific biases are densely dispersed throughout the unfolded polypeptide chain, where they serve to pre-organize the folding process and largely, but imperfectly, anticipate the native secondary structure.

Why Aren't Secondary Structure Predictions Better?

Currently, the best methods for predicting helix and sheet are correct about three-quarters of the time. Can greater success be achieved?

Several measures to assess predictive accuracy are in common use, of which the Q3 score is the most widespread. The Q3 score gives the percentage of correctly predicted residues in three categories: helix, strand, and coil (i.e., everything else):

$$\mathrm{Q3} = \frac{\text{number of correctly predicted residues}}{\text{total number of residues}} \times 100$$

where the "correct" answer is given by a program to identify secondary structure from coordinates, e.g., DSSP. At this writing, (Position-Specific PREDiction algorithm) PSIPRED has an overall Q3 score of 78%.

Is greater prediction accuracy possible? It has been argued that prediction methods fail to achieve a higher rate of success because some amino acid sequences are inherently ambiguous. That is, these "conformational chameleons" will adopt a helical conformation in one protein, but the identical sequence will adopt a strand conformation in another protein. Only time will tell whether current efforts have encountered an inherent limit.

Glossary

α-helix The best-known element of secondary structure in which the polypeptide chain adopts a right-handed helical twist with 3.6 residues per turn and an $i \rightarrow i - 4$ hydrogen bond between successive amide hydrogens and carbonyl oxygens.

β-strand An element of secondary structure in which the chain adopts an extended conformation. A β-sheet results when two or more aligned β-strands form inter-strand hydrogen bonds.

Chou–Fasman Among the earliest attempts to predict protein secondary structure from the amino acid sequence. The method, which uses a database of known structures, is based on the empirically observed likelihood of finding the 20 different amino acids in helix, sheet or turns.

DSSP The most widely used method to parse x, y, z-coordinates for a protein structure into elements of secondary structure.

hydrophobicity A measure of the degree to which solutes, like amino acids, partition spontaneously between a polar environment (like the outside of a protein) and an organic environment (like the inside of a protein).

hydrophobicity profile A method to predict the location of peptide chain turns from the amino acid sequence by plotting averaged hydrophobicity against residue number. The method does not require a database of known structure.

neural network A pattern recognition method – adapted from artificial intelligence – that has been highly successful in predicting protein secondary structure when used in conjunction with an extensive database of known structures.

peptide chain turn A site at which the protein changes its overall direction. The frequent occurrence of turns is responsible for the globular morphology of globular (i.e., sphere-like) proteins.

secondary structure The backbone structure of the protein, with particular emphasis on hydrogen bonded motifs.

tertiary structure The three-dimensional structure of the protein.

Biography

George Rose is Professor of Biophysics and Director of the Institute for Biophysical Research at Johns Hopkins University. He holds a Ph.D. from Oregon State University. His principal research interest is in protein folding, and he has written many articles on this topic. He serves as the consulting editor of *Proteins: Structure, Function and Genetics* and as a member of the editorial advisory board of *Protein Science*. Recently, he was a Fellow of the John Simon Guggenheim Memorial Foundation.

Secretases

Robert L. Heinrikson
The Pharmacia Corporation, Kalamazoo, Michigan, USA

Secretases are proteolytic enzymes involved in the processing of an integral membrane protein known as Amyloid precursor protein, or APP. β-Amyloid (Aβ) is a neurotoxic and highly aggregative peptide that is excised from APP by secretase action, and that accumulates in the neuritic plaque found in the brains of Alzheimer's disease (AD) patients. The amyloid hypothesis holds that the neuronal dysfunction and clinical manifestation of AD is a consequence of the long-term deposition and accumulation of Aβ, and that this peptide of 40–42 amino acids is a causative agent of AD. Accordingly, the secretases involved in the liberation, or destruction of Aβ are of enormous interest as therapeutic intervention points toward treatment of this dreaded disease.

Background

Proteolytic enzymes play crucial roles in a wide variety of normal and pathological processes in which they display a high order of selectivity for their substrate(s) and the specific peptide bonds hydrolyzed therein. This article concerns secretases, membrane-associated proteinases that produce, or prevent formation of, a highly aggregative and toxic peptide called β-amyloid (Aβ). This Aβ peptide is removed from a widely distributed and little understood Type I integral membrane protein called amyloid precursor protein (APP). The apparent causal relationship between Aβ and AD has fueled an intense interest in the secretases responsible for its production. Herein will be discussed the current understanding of three of the most-studied secretases, α-, β-, and γ-secretases. A schematic representation of the Aβ region of APP showing the amino acid sequence of Aβ and the major sites of cleavage for these three secretases is given in Figure 1. Aβ is produced by the action of β- and γ-secretases, and there is an intense search underway for inhibitors of these enzymes that might serve as drugs in treatment of Alzheimer's disease (AD). The α-secretase cleaves at a site near the middle of Aβ, and gives rise to fragments of Aβ that lack the potential for aggregation; therefore, amplification of α-secretase activity might be seen as another approach to AD therapy.

α-Secretase

The activity responsible for cleavage of the Lys^{16}-Leu^{17} bond within the Aβ region (Figure 1) is ascribed to α-secretase. This action prevents formation of the 40–42 amino acid residue Aβ and leads to release of soluble APPα and the membrane-bound C83-terminal fragment. α-Secretase competes with β-secretase for the APP substrate, but the α-secretase product, soluble APPα (pathway A, Figure 1) is generated at a level about 20 times that of the sAPPβ released by β-secretase (pathway B). Because α-secretase action prevents formation of the toxic Aβ peptide, augmentation of this activity could represent a useful strategy in AD treatment, and this has been done experimentally by activators of protein kinase C (PKC) such as phorbol esters and by muscarinic agonists. The specificity of the α-secretase for the Lys^{16}-↓-Leu^{17} cleavage site (Figure 1) appears to be governed by spatial and structural requirements that this bond exist in a local α-helical conformation and be within 12 or 13 amino acids distance from the membrane. α-Secretase has not been identified as any single proteinase, but two members of the ADAM (a disintegrin and metalloprotease) family, ADAM-10 and ADAM-17 are candidate α-secretases. ADAM-17 is known as TACE (tumor necrosis factor-α-converting enzyme) and TACE cleaves peptides modeled after the α-secretase site at the Lys^{16}-↓-Leu position. This was also shown to be the case for ADAM-10; overexpression of this enzyme in a human cell line led to several-fold increase in both basal and PKC-inducible α-secretase activity. As of now, it remains to be proven whether α-secretase activity derives from either or both of these ADAM family metalloproteinases, or whether another as yet unidentified proteinase carries out this processing of APP.

β-Secretase

The enzyme responsible for cleaving at the amino-terminus of Aβ is β-secretase (Figure 1). In the mid-1980s, when Aβ was recognized as a principal component of AD neuritic plaque, an intense search was begun to identify the β-secretase. Finally, in 1999, several independent

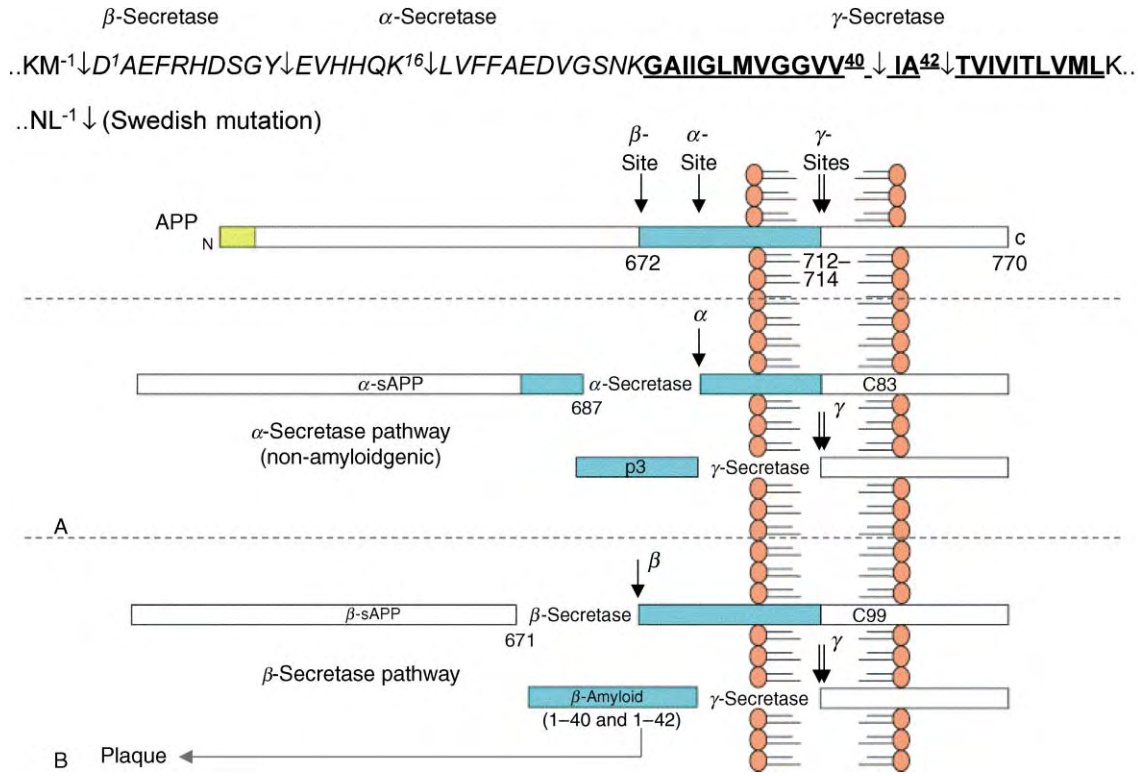

FIGURE 1 A schematic overview of APP processing by the α-, β-, and γ-secretases. The top panel shows the amino acid sequence of APP upstream of the transmembrane segment (underlined, bold), and encompassing the sequences of $A\beta_{1-40}$ and $A\beta_{1-42}$ (D^1–V^{40}, and D^1–A^{42}, respectively). The β-secretase cleaves at D^1 and Y^{10}; the α-secretase at Lys^{16}, and the γ-secretase at Val^{40} and/or Ala^{42}. Below the sequence is a representation of APP emphasizing its membrane localization and the residue numbers of interest in β- and γ-secretase processing. Panel A represents the non-amyloidogenic α-secretase pathway in which sAPPα and C83 are generated. Subsequent hydrolysis by the γ-secretase produces a p3 peptide that does not form amyloid deposits. Panel B represents the amyloidogenic pathway in which cleavage of APP by the β-secretase to liberate sAPPβ and C99 is followed by γ-secretase processing to release β-amyloid peptides ($A\beta_{1-40}$ and $A\beta_{1-42}$) found in plaque deposits.

laboratories published evidence demonstrating that β-secretase is a unique member of the pepsin family of aspartyl proteinases. This structural relationship to a well-characterized and mechanistically defined class of proteases gave enormous impetus to research on β-secretase. The preproenzyme consists of 501 amino acids, with a 21-residue signal peptide, a prosegment of about 39 residues, the catalytic bilobal unit with active site aspartyl residues at positions 93 and 289, a 27-residue transmembrane region, and a 21-residue C-terminal domain. The membrane localization of β-secretase makes it unique among mammalian aspartyl proteases described to date. Another interesting feature of the enzyme is that, unlike pepsin, renin, cathepsin D, and other prototypic members of the aspartyl proteases, it does not appear to require removal of the prosegment as a means of activation. A furin-like activity is responsible for cleavage in the sequence Arg-Leu-Pro-Arg-↓-Glu^{25} of the proenzyme, but this does not lead to any remarkable enhancement of activity, at least as is seen in recombinant constructs of pro-β-secretase. β-Secretase has been referred to by a number of designations in the literature, but the term BACE (β-site APP cleaving enzyme) has become most widely adopted. With the discovery of the β-secretase, it was recognized that there was another human homologue of BACE with a transmembrane segment and this has now come to be called BACE2. This may well be a misnomer, since the function of BACE2 has yet to be established, and it is not clear that APP is a normal substrate of this enzyme. At present, BACE2 is not considered to be a secretase.

There is considerable experimental support for the assertion that BACE is, in fact, the β-secretase involved in APP processing. The enzyme is highly expressed in brain, but is also found in other tissues, thus explaining the fact that many cell types can process Aβ. Use of antisense oligonucleotides to block expression of BACE greatly diminishes production of Aβ and, conversely, overexpression of BACE in a number of cell lines leads to enhanced Aβ production. BACE knockout mice show no adverse phenotype, but have dramatically reduced levels of Aβ. This not only demonstrates that BACE is the true β-site APP processor, but also that its elimination does not pose serious consequences for the animal, a factor of great importance in targeting BACE for inhibition in AD therapy.

Much of the evidence in support of the amyloid hypothesis comes from the observation of mutations near the β- and γ-cleavage sites in APP that influence production of Aβ and correlate directly with the onset of AD. One such mutation in APP, that invariably leads to AD in later life, occurs at the β-cleavage site where Lys-Met^{-1} is changed to Asn-Leu^{-1} (Figure 1). This so-called Swedish mutation greatly enhances production of Aβ, and as would be expected, β-secretase hydrolyzes the mutated Leu-Asp^{1} bond in model peptides $\sim$50 times faster than the wild-type Met-Asp^{1} bond. It is important to recognize that BACE cleavage is required for subsequent processing by the γ-secretase; in this sense, a BACE inhibitor will also block γ-secretase. Another BACE cleavage point is indicated in Figure 1 by the arrow at Y$^{10}\downarrow$E^{11}; the A$\beta_{11-40\text{ or }42}$ subsequently liberated by γ-secretase action also forms amyloid deposits and is found in neuritic plaque.

In all respects, therefore, BACE fits the picture expected of β-secretase, and because of its detailed level of characterization and its primary role in Aβ production, it has become a major target for development of inhibitors as drugs to treat AD. Great strides in this direction have become possible because of the availability of three-dimensional (3-D) structural information on BACE. The crystal structure of BACE complexed with an inhibitor is represented schematically in Figure 2. Homology with the pepsin-like aspartyl proteases is reflected in the similar folding pattern of BACE, with extensive β-sheet organization, and the proximal location of the two aspartyl residues that comprise the catalytic machine for peptide bond cleavage. The C-terminal lobe of the molecule is larger than is customarily seen in the aspartyl proteases, and contains extra elements of structure with as yet unexplained impact on function. In fact, before the crystal structure was solved, it was thought that this larger C-terminal region might contribute a spacer to distance the catalytic unit from the membrane and to provide mobility. This appears not to be the case. As denoted by the arrow in Figure 2, there is a critical disulfide bridge linking the C-terminal region just upstream of the transmembrane segment to the body of the molecule. Therefore, the globular BACE molecule is proximal to the membrane surface and is not attached via a mobile stalk that would permit much motion. This steric localization would be expected to limit the repertoire of protein substrates that are accessible to BACE as it resides in the Golgi region. Crystal structures of BACE/inhibitor complexes have revealed much about the nature of protein-ligand interactions, and information regarding the nature of binding sites obtained by this approach will be of critical importance in the design and development of inhibitors that will be effective drugs in treatment of AD.

FIGURE 2 Schematic representation of the 3-D structure of the BACE (β-secretase) catalytic unit as determined by x-ray crystallography. Arrows and ribbons designate β-strands and α-helices, respectively. An inhibitor is shown bound in the cleft defined by the amino- (left) and carboxyl- (right) terminal halves of the molecule. The C-terminus of the catalytic unit is marked C to indicate the amino acid residue immediately preceding the transmembrane and cytoplasmic domains of BACE. These latter domains were omitted from the construct that was solved crystallographically. The arrow marks a disulfide bridge, which maintains the C-terminus in close structural association with the body of the catalytic unit. The catalytic entity as depicted sits directly on the membrane surface, thereby restricting its motion relative to protein substrates. (Courtesy of Dr. Lin Hong, Oklahoma Medical Research Foundation, Oklahoma City, OK.)

γ-Secretase

γ-Secretase activity is produced in a complex of proteins and is yet to be understood in terms of the actual catalytic entity and mechanism of proteolysis. This secretase cleaves bonds in the middle of the APP segment that traverses the membrane (underlined and boldface in Figure 1), and its activity is exhibited subsequent to cleavages at the α- or β-sites. In Figure 1, the γ-secretase cleavage sites are indicated by two arrows. Cleavage at the Val^{40}-Ile^{41} bond liberates the more abundant 40-amino acid residue Aβ (Aβ_{1-40}). Cleavage at Ala^{42}-Thr^{43} produces a minor Aβ species, Aβ_{1-42}, but one that appears to be much more hydrophobic and aggregative, and it is the 42-residue Aβ that is believed to be of most significance in AD pathology. As was the case for APP β-site mutations, there are human APP mutants showing alterations in the vicinity of the γ-site, and these changes, powerfully associated with onset of AD, lead to higher ratios of Aβ_{1-42}.

Central to the notion of the γ-secretase is the presence of presenilins, intregral membrane proteins with mass $\sim$50 kDa. There are a host of presenilin mutations in familial AD (FAD) that are associated with early onset disease and an increased production of the toxic Aβ_{1-42}. This correlation provides strong

support for the involvement of presenilin in AD, and its presence in γ-secretase preparations implies that it is either a proteolytic enzyme in its own right, or can contribute to that function in the presence of other proteins. In fact, much remains to be learned about the presenilins; it has been difficult to obtain precise molecular and functional characterization because of their close association with membranes and other proteins in a complex. Modeling studies have predicted a variable number of transmembrane segments (6–8), but presenilin function is predicated upon processing by an unknown protease to yield a 30 kDa N-terminal fragment (NTF) and a 20 kDa C-terminal fragment (CTF). These accumulate *in vivo* in a 1:1 stoichiometry within high molecular weight complexes with a variety of ancillary proteins. Some of the cohort proteins identified in the multimeric presenilin complexes displaying γ-secretase activity include catenins, armadillo-repeat proteins that appear not to be essential for γ-secretase function, and nicastrin. Nicastrin is a Type I integral membrane protein with homologues in a variety of organisms, but its function is unknown. It shows intracellular colocalization with presenilin, and is able to bind the NTF and CTF of presenilin as well as the C83 and C99 C-terminal APP substrates of γ-secretase. Interestingly, down-regulation of the nicastrin homologue in *Caenorhabditis elegans* gave a phenotype similar to that seen in worms deficient in presenilin and notch. Evidence that nicastrin is essential for γ-secretase cleavage of APP and notch adds to the belief that nicastrin is an important element in presenilin, and γ-secretase function. Efforts to delineate other protein components of γ-secretase complexes and to understand their individual roles in the enzyme function represent a large current research effort. Recently, two additional proteins associated with the complex have been identified through genetic screening of flies and worms. The *aph-1* gene encodes a protein with 7 transmembrane domains, and the *pen-2* gene codes for a small protein passing twice through the membrane. Both of these putative members of the γ-secretase complex are new proteins whose functions, either with respect to secretase activity or in other potential systems, remain to be elucidated.

At present, it is still unclear as to how γ-secretase exerts its function. What is known, however, is that γ-secretase is able to cleave at other peptide bonds in APP near the γ-site in addition to those indicated in Figure 1, and is involved with processing of intra-membrane peptide bonds in a variety of additional protein substrates, including notch. This lack of specificity is a major concern in developing drugs for AD targeted to γ-secretase that do not show side effects due to inhibition of processing of these additional, functionally diverse protein substrates.

Glossary

Aβ The peptide produced from APP by the action of β- and γ-secretases. Aβ shows neurotoxic activity and aggregates to form insoluble deposits seen in the brains of Alzheimer's disease patients. The α-secretase hydrolyzes a bond within the Aβ region and releases fragments which do not aggregate.

Alzheimer's disease (AD) A disease first described by Alois Alzheimer in 1906 characterized by progressive loss of memory and cognition. AD afflicts a major proportion of our aging population and is one of the most serious diseases facing our society today, especially in light of increasing human longevity. The secretases represent important potential therapeutic intervention points in AD treatment.

proteinases Enzymes that hydrolyze, or split peptide bonds in protein substrates; also referred to as proteolytic enzymes.

secretase A proteinase identified with respect to its hydrolysis of peptide bonds within a region of a Type I integral membrane protein called APP. These cleavages are responsible for liberation, or destruction of an amyloidogenic peptide of about 40 amino acid residues in length called Aβ.

Biography

Robert L. Heinrikson is a Distinguished Fellow at the Pharmacia Corporation in Kalamazoo, MI. Prior to his industrial post, Dr. Heinrikson was Full Professor of Biochemistry at the University of Chicago. His principal area of research is protein chemistry, with an emphasis on proteolytic enzymes as drug targets. Dr. Heinrikson is on the editorial board of four journals, including the *Journal of Biological Chemistry*. He is a member of the American Society of Biochemistry and Molecular Biology and Phi Beta Kappa.

Secretory Pathway

Karen J. Colley
University of Illinois at Chicago, Chicago, Illinois, USA

The eukaryotic cell is separated into several functionally distinct, membrane-enclosed compartments (Figure 1). Each compartment contains proteins required to accomplish specific functions. Consequently, each protein must be sorted to its proper location to ensure cell viability. Proteins possess specific signals, either encoded in their amino acid sequences or added as posttranslational modifications, which target them for the various compartments of the cell. The pioneering work of Dr. George Palade provided scientists with their first picture of the functional organization of the mammalian secretory pathway. Later work showed that the secretory pathway acts as a folding, modification, and quality control system for proteins that function in the endoplasmic reticulum (ER) and Golgi apparatus, and for those that are targeted to the lysosome, plasma membrane, and extracellular space. This article will focus on protein targeting to and within the compartments of the secretory pathway, and how proteins within this pathway function to ensure that correctly folded and modified proteins are delivered to the cell surface and secreted from cells.

Targeting of New Proteins to the Secretory Pathway

What Kinds of Proteins are Targeted to the Secretory Pathway?

The proteins that are targeted to the secretory pathway can be separated into two groups – those that function in the ER and Golgi to ensure proper protein folding and modification (i.e., resident proteins), and those that are processed in the ER and Golgi, and are transported to later compartments like the lysosome, plasma membrane, and extracellular space (Figure 1). Each of these proteins not only possesses a signal to enter the secretory pathway, but also may have a secondary signal to localize it to a particular organelle within the pathway.

Signals and Mechanisms of Secretory Pathway Entry

The 1999 Nobel Prize in physiology or medicine was awarded to Dr. Günter Blobel for his contributions to our understanding of the mechanism of secretory pathway entry. Dr. Blobel and his colleagues found that in order to enter the secretory pathway, proteins are synthesized with an amino terminal signal peptide that allows them to cross the membrane of the endoplasmic reticulum (ER). The signal peptide is recognized by a complex of proteins and ribonucleic acid called the signal recognition particle (SRP) (Figure 2). As the signal peptide emerges from the ribosome during translation, SRP binds to it and halts translation, and then targets the new protein–ribosome complex to the cytoplasmic face of the ER membrane where it binds to the SRP receptor. Subsequently, the new protein–ribosome complex is released from SRP and its receptor, and transferred to an aqueous membrane channel known as the "translocon." Translation resumes and the new protein is co-translationally transferred through the translocon into the lumen of the ER, where in many cases the signal peptide is cleaved by a specific signal peptidase (Figure 2).

Soluble and Integral Membrane Proteins

Soluble proteins are completely translocated across the ER membrane into the lumen (Figure 2). These proteins will either remain in the ER, be targeted to another organelle, or be secreted from the cell. Integral membrane proteins that possess one or more hydrophobic membrane-spanning regions will use these sequences to insert into the membrane of the ER and either stay as ER-resident transmembrane proteins, or be targeted to another cellular membrane. A type-I membrane protein has a cleavable signal peptide and a separate hydrophobic stretch of amino acids that acts as a membrane-spanning region. This type of protein has its amino terminus in the lumen of an organelle or the outside of the cell (which are topologically equivalent), and its carboxy terminus in the cytoplasm (Figure 2). In contrast, a type-II membrane protein has an uncleavable signal peptide, or signal anchor that is not at the protein's amino terminus and serves a dual function as both signal peptide and a membrane-spanning region. Type-II membrane proteins employ a more elaborate insertion mechanism than do type-I membrane proteins.

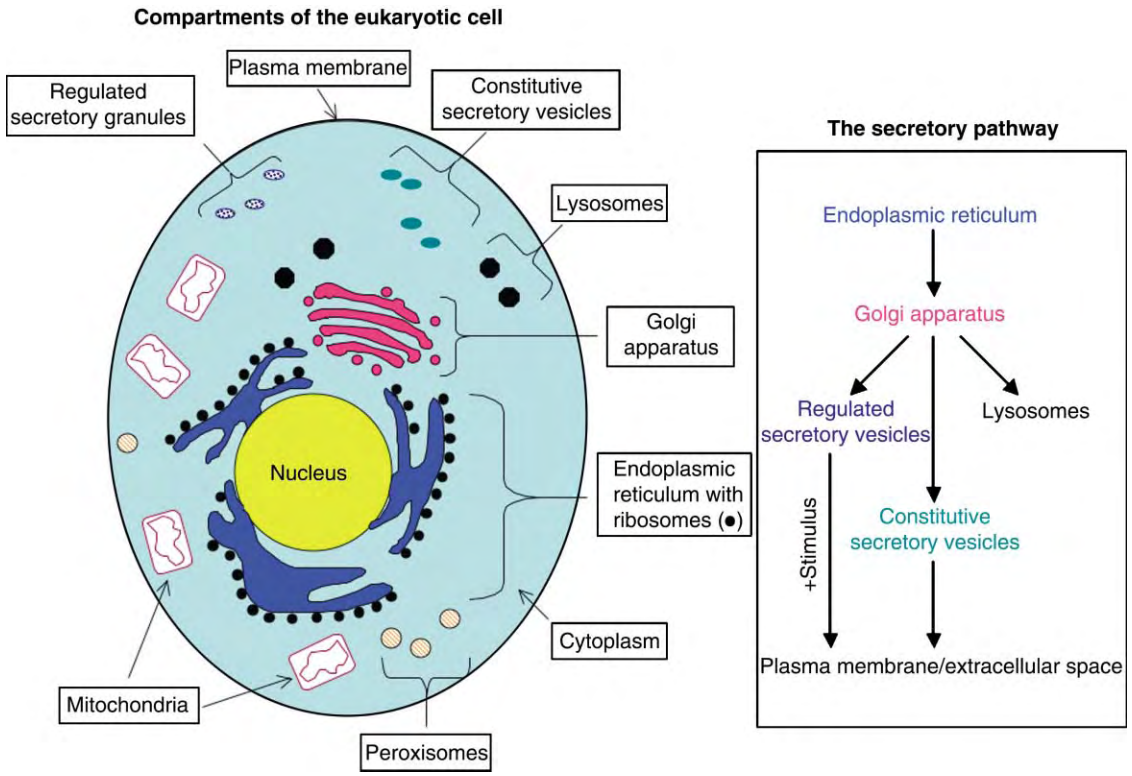

FIGURE 1 Compartments of eukaryotic cells and the organization of the secretory pathway. Diagrammatic representation of the compartments of the eukaryotic cell is shown. The anterograde flow of membrane and protein traffic in the secretory pathway is shown in the box. Anterograde flow is indicated by arrows. Retrograde flow between the ER and Golgi, endosome/lysosome system and Golgi, and plasma membrane and Golgi does occur, but is not shown.

For this reason, a type-II membrane protein will have its carboxy terminus in the lumen of an organelle or outside the cell, and its amino terminus in the cytoplasm (Figure 2). Other proteins span the membrane several times and are called type-III membrane proteins. They can start with either cleavable signal peptides or uncleavable signal anchors and possess variable numbers of hydrophobic membrane-spanning segments.

Protein Folding and Modification in the ER

The Initiation of Protein N-Linked Glycosylation in the ER

As proteins enter the ER lumen, they fold and assemble with the help of chaperone proteins. Many proteins are also co-translationally modified by the addition of carbohydrates to asparagine residues in the process of N-linked glycosylation (Figure 2). A preformed oligosaccharide, consisting of three glucoses, nine mannoses, and two N-acetylglucosamine residues ($Glc_3Man_9GlcNAc_2$) is transferred to accessible asparagine residues in the tripeptide sequence asparagine-X-serine or threonine (X cannot be proline) by the oligosaccharide protein transferase complex. Subsequent modification by glycosidases (enzymes that remove monosaccharides) and glycosyltransferases (enzymes that add monosaccharides) in the ER and Golgi lead to the remodeling of the N-linked oligosaccharides. These N-linked carbohydrates help proteins fold, protect them from proteolytic degradation and, in some cases, are critical for modulating and mediating protein and cell interactions at the cell surface and in the extracellular space.

Chaperones and the ER Quality Control System

An important function of the ER is to serve as a site of protein folding and quality control. Protein folding in the ER includes the formation of intra-molecular disulfide bonds, prolyl isomerization, and the sequestration of hydrophobic amino acids into the interior of the protein. Protein disulfide bonds are formed as the protein exits the translocon and may at first form incorrectly between cysteine residues close together in the protein's linear amino acid sequence. Thiol-oxidoreductases, such as protein disulfide isomerase (PDI), help to form and reorganize proteins' disulfide bonds into the most energetically favorable configuration. Different types of chaperones monitor a protein's

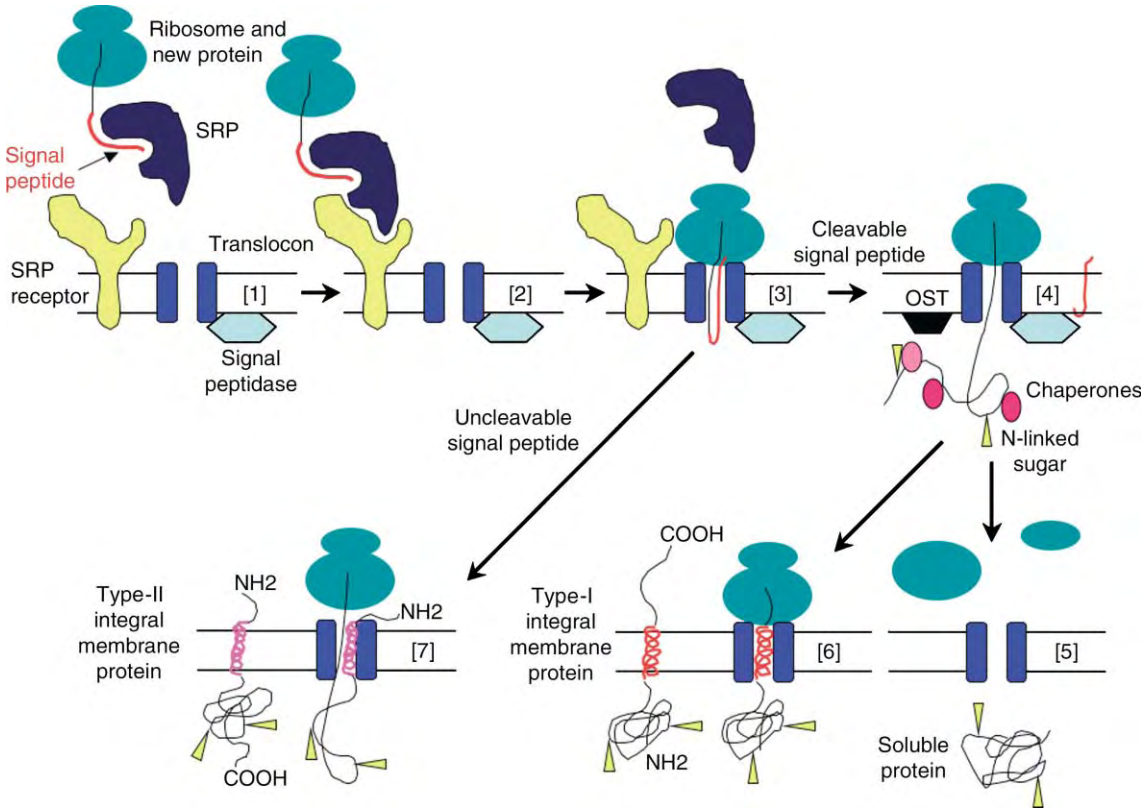

FIGURE 2 Entry into the secretory pathway. Many proteins are targeted for the secretory pathway by an amino terminal hydrophobic signal peptide that allows their co-translational translocation across the ER membrane. [1] Signal recognition particle (SRP) recognizes the new protein's signal peptide. [2] The ribosome–new protein–SRP complex interacts with the SRP receptor on the cytoplasmic face of the ER membrane. [3] The ribosome–new protein complex is transferred to the translocon channel, protein synthesis continues and the protein moves through the aqueous channel. [4] As the new protein enters the lumen of the ER, its signal peptide is cleaved by the signal peptidase, chaperone proteins bind to aid in folding and oligosaccharide protein transferase complex (OST) transfers oligosaccharides (arrowheads) to asparagine residues in the process of N-linked glycosylation. [5] Soluble proteins lack additional hydrophobic sequences and are translocated through the translocon to complete their folding and modification in the ER lumen. [6] Type-I integral membrane proteins have a second hydrophobic sequence that partitions into the lipid bilayer and acts as a membrane-spanning segment. These proteins have their amino termini in the lumen of an organelle or outstide the cell and their carboxy-termini in the cell cytoplasm. [7] Unlike proteins with cleavable amino-terminal signal peptides, type-II integral membrane proteins have an uncleavable signal anchor that target the protein to the secretory pathway and then partitions into the lipid bilayer to act as a membrane-spanning segment. These proteins have their amino termini in the cell cytoplasm and their carboxy-termini in the lumen of an organelle or outside the cell. Soluble and integral membrane proteins that enter at the level of the ER need not stay there, and can be transported out of the ER to other locations in the pathway (see Figure 1, Secretory Pathway box).

folding and prevent exit of unfolded and unassembled proteins from the ER. The chaperone BiP, originally identified as an immunoglobulin heavy-chain-binding protein, interacts with the exposed hydrophobic sequences of folding intermediates of many proteins and prevents their aggregation. Two chaperones called calnexin and calreticulin recognize a monoglucosylated carbohydrate structure ($Glc_1Man_9GlcNAc_2$) that is formed by a special glucosyltransferase that recognizes unfolded or misfolded proteins and adds a single glucose to the $Man_9GlcNAc_2$ structure. Proteins that are not folded properly or are not assembled into oligomers with partner subunits, are prevented from exiting the ER by chaperone interactions, and can be targeted back across the ER membrane through the translocon into the cytoplasm where they are degraded by the proteosome complex in a process called ER associated degradation (ERAD).

Protein Transport through and Localization in the Secretory Pathway

Vesicular Transport between the ER and Golgi

Proteins move between the ER and Golgi in vesicular carriers. These vesicles are coated with specific sets of cytoplasmic proteins that form the COP-I and COP-II coats. COP-II-coated vesicles move from the ER to the

intermediate compartment (IC)/*cis* Golgi, while COP-I-coated vesicles move from the Golgi back to the ER and may also mediate transport between Golgi cisternae in both the anterograde (toward the plasma membrane) and retrograde (toward the ER) directions (Figure 3). The process of vesicular transport can be separated into three stages—cargo selection and budding, targeting, and fusion. In the first stage, the COP coats serve to select cargo for exit from a compartment and help to deform the membrane for vesicle budding. They assemble on the membrane with the help of small GTPases called ARF (specific for COP I) and Sar1p (specific for COP II). After vesicle budding, the hydrolysis of GTP by ARF and Sar1p leads to the uncoating of the vesicle. This uncoating reveals other vesicle proteins that are essential for vesicle targeting and fusion. In the second and third stages, tethering proteins on the transport vesicle and target membrane interact weakly bringing the membranes together. This allows vesicle-associated SNARE proteins and target membrane-associated SNARE proteins to form complexes. Subsequent conformational changes in the SNARE protein complex bring the membranes together for fusion. Another group of small GTPases (Rabs) control the process of vesicular transport at several levels by recruiting and activating various proteins in the pathway.

Protein Localization in the ER

Proteins involved in protein folding, modification, and quality control must remain in the ER, while proteins destined for the Golgi, lysosome, cell surface or those that are secreted from the cell must exit. Exit from the ER is a selective process that involves cargo receptors that interact with COP-II coat components (Figure 3). It is likely that most resident ER proteins are not selected to exit the ER. It is clear, however, that some resident proteins escape from the ER and are retrieved from the Golgi and intermediate compartment by COP-I vesicles (Figure 3). These proteins have specific amino acid signals that allow their incorporation into COP-I vesicles either by direct interaction with COP-I components or indirectly by interaction with cargo

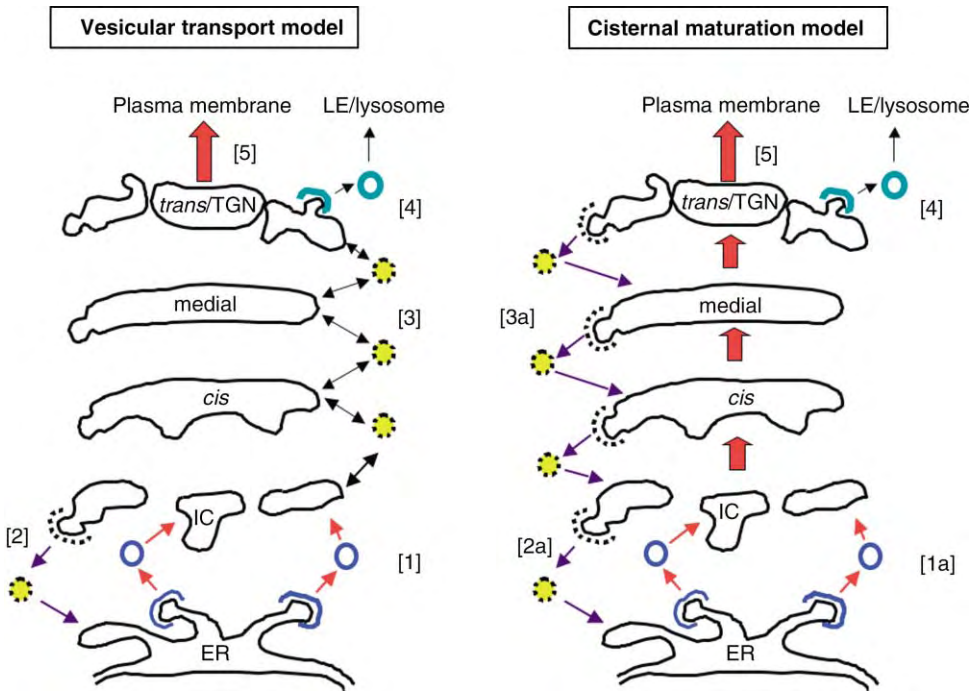

FIGURE 3 Comparison of two models of protein transport through the Golgi apparatus. In the vesicular transport model cargo proteins move between the cisternae in vesicles, while Golgi enzymes are retained in their resident cisternae. [1] COP-II-coated vesicles transport new proteins from the ER to the intermediate compartment (IC). [2] Resident ER proteins that escape the ER can be retrieved from the IC in COP-I-coated vesicles. [3] COP-I-coated vesicles also transport anterograde cargo proteins between the Golgi cisternae in both a retrograde and anterograde fashion ("percolating vesicles"). In the cisternal maturation model, cargo proteins enter a new cisterna at the cis face of the stack, and are modified (matured) by "resident" Golgi enzymes that are continuously transported in a retrograde fashion into the sequentially maturing cisternae. [1a] COP-II-coated vesicles transport new proteins from the ER to the IC where a new *cis* cisterna forms. [2a] Resident ER proteins that escape the ER can be retrieved from the IC in COP-I-coated vesicles. [3a] Golgi enzymes are transported in a retrograde fashion in COP-I-coated vesicles to modify the cargo proteins in earlier cisternae. Mechanisms of protein exit from the TGN are common to both models: [4] clathrin-coated vesicles mediate late endosome (LE)-lysosome transport, while [5] other proteins are secreted in either a regulated or constitutive fashion to the plasma membrane or extracellular space.

receptors. For example, mammalian BiP is a soluble ER protein that has the carboxy-terminal four amino acid sequence lysine–aspartate–glutamate–leucine (KDEL). This KDEL sequence is recognized by the KDEL receptor that mediates their incorporation into COP I vesicles moving from the intermediate compartment (IC) back to the ER.

Protein Modification in the Golgi

The Golgi apparatus consists stacks of flattened cisternae that contain enzymes and other proteins involved in the further modification and processing of newly made proteins. It is separated into cis, medial, and trans cisternae, followed by a meshwork of tubules and vesicles called the trans Golgi network (TGN). The process of N-linked glycosylation is completed through the action of glycosidases and glycosyltransferases localized in specific cisternae. Likewise, the glycosylation of serine and threonine residues (O-linked glycosylation) is accomplished by other glycosyltransferases. Additional modifications also occur in the Golgi. For example, proteins and carbohydrate are sulfated by sulfotransferases and some proteins are phosphorylated on serine and threonine residues by Golgi kinases. In addition, proteins like digestive enzymes (trypsin, carboxypeptidase) and hormones (insulin) are made as inactive precursors that must be proteolytically processed to their active forms in the late Golgi or post-Golgi compartments.

Transport of Proteins through the Golgi

Currently there are two different models to explain protein transport through the Golgi (Figure 3). The vesicular transport model proposes that proteins move sequentially between the Golgi cisterna in COP-I-coated vesicles, while the cisternae themselves are stationary. Proteins not retained in the *cis* Golgi, for example, would be incorporated into coated vesicles and be transported to the *medial* Golgi, and then to the *trans* Golgi. Proteins destined for post-Golgi compartments move through successive Golgi cisternae in this fashion, being modified by the resident enzymes in each compartment (Figure 3). In the cisternal maturation model a new cisterna is formed on *cis* face of the Golgi stack from ER-derived membrane. This requires both the anterograde transport of newly synthesized proteins from the ER in COP-II-coated vesicles and the retrograde transport of *cis* Golgi enzymes from the pre-existing *cis* cisterna in COP I-coated vesicles. The new *cis* cisterna and its contents progressively mature through the stack as resident Golgi enzymes are successively introduced by COP-I coated vesicles (Figure 3). In the vesicular transport model, the resident Golgi enzymes are retained in the cisternae while the cargo moves in vesicles between the different cisternae. In contrast, in the cisternal maturation model, the "resident" enzymes are continuously moving in a retrograde fashion, while the anterograde cargo remains in the cisternae. Evidence for both mechanisms is compelling, suggesting that both mechanisms may work in parallel.

Localization of Resident Golgi Enzymes

In the context of the vesicular transport model, Golgi enzymes are retained in specific cisternae. Two mechanisms have been suggested for Golgi protein retention. The "bilayer thickness" mechanism suggests that the relatively short transmembrane regions of Golgi proteins prevent their incorporation into the wider, cholesterol-rich lipid bilayers of the transport vesicles destined for post-Golgi compartments (such as the plasma membrane), and as a result, these proteins are retained in the relatively cholesterol-poor Golgi. The "oligomerization" mechanism predicts that once an enzyme has reached its resident cisterna it forms homo- or hetero-oligomers that prevent its incorporation into transport vesicles moving to the next compartment. In the context of the cisternal maturation model, resident Golgi enzymes are actively incorporated into COP-I vesicles for retrograde transport to a new cisterna, and one might predict that the cytoplasmic tails of these proteins would interact with COP-I-coat components to allow vesicle incorporation. Interestingly, there are only a few examples where the cytoplasmic tail of a Golgi enzyme plays a primary role in its localization, whereas the membrane-spanning regions of these proteins seem to be more critical. Again, it is possible that some or all of these mechanisms work together to maintain the steady-state localization of the resident Golgi proteins.

Protein Exit from the Golgi and Targeting to Post-Golgi Locations

Protein Exit from the Golgi

Once proteins reach the TGN they are sorted to post-Golgi compartments that include the lysosome, the plasma membrane, and the extracellular space (Figure 3). Trafficking to the lysosome–endosome system involves clathrin-coated vesicles similar to those that function in the uptake of proteins in endocytosis. In contrast, transport to the plasma membrane, or exocytosis, can occur either constitutively in secretory vesicles/tubules or in a regulated fashion from secretory granules found in specific cell types.

Protein Targeting to the Lysosome

The lysosome is a degradative compartment that contains numerous acid hydrolases that function to digest proteins, lipids, and carbohydrates. The trafficking of the majority of lysosomal enzymes to the lysosome requires mannose 6-phosphate residues on these enzymes' N-linked sugars. The mannose 6-phosphate residues are recognized by receptors in the TGN that mediate the incorporation of the new lysosomal enzymes into clathrin-coated vesicles destined for the late endosome compartment (Figure 3). These clathrin-coated vesicles move from the TGN and fuse with the late endosome, where a decrease in lumenal pH causes the lysosomal enzymes to dissociate from the mannose 6-phosphate receptors. The enzymes are then transported to the lysosome, while the receptors recycle to the TGN. Some lysosomal membrane proteins are also trafficked in clathrin-coated vesicles to the lysosome like the soluble enzymes but without the use of a mannose 6-phosphate marker, while others are transported to the cell surface, incorporated into a different set of clathrin-coated vesicles used in the process of endocytosis, and then trafficked to the lysosome via the late endosome.

Constitutive and Regulated Secretion

In many cell types, membrane-associated and soluble proteins move to the plasma membrane constitutively without a requirement for specific signals. Constitutively secreted proteins include receptors, channel proteins, cell adhesion molecules, and soluble extracellular matrix and serum proteins. Other proteins like hormones and neurotransmitters are targeted to secretory granules that are involved in regulated secretion from endocrine and exocrine cells, some types of immune cells, and neurons. These granules remain in a secretion-ready state until extracellular signals that lead to an increase in intracellular calcium levels trigger the exocytosis of their contents.

Glossary

chaperone A protein that aids in the folding and assembly of other proteins, frequently by preventing the aggregation of folding intermediates.

cisternal maturation/progression One model of protein transport through the Golgi apparatus that suggests that secretory cargo enters a new cisternae that forms at the *cis* face of the Golgi stack, and that this cisternae and its cargo progresses or matures through the stack by the sequential introduction of Golgi modification enzymes.

glycosylation The modification of lipids and proteins with carbohydrates in the endoplasmic reticulum and Golgi apparatus of the secretory pathway.

secretory pathway An intracellular pathway consisting of the endoplasmic reticulum, Golgi apparatus, and associated vesicles that is responsible for the folding, modification, and transport of proteins to the lysosome, plasma membrane, and extracellular space.

vesicular transport One model of protein transport through the Golgi apparatus, which suggests that secretory cargo moves sequentially between stationary Golgi cisternae in transport vesicles and is modified by resident Golgi enzymes in the process.

Biography

Karen J. Colley is a Professor in the Department of Biochemistry and Molecular Genetics at the University of Illinois College of Medicine in Chicago. She holds a Ph.D. from Washington University in St. Louis, and received her postdoctoral training at the University of California, Los Angeles. Her principal research interests are in protein trafficking and glycosylation. Her recent studies focus on the elucidation of the signals and mechanisms of Golgi glycosyltransferase localization.

Selenoprotein Synthesis

August Böck
University of Munich, Munich, Germany

Selenoproteins contain one or more residues of the nonstandard amino acid selenocysteine, which is an analogue of cysteine in which a selenol group replaces a thiol. The majority of these proteins catalyze some oxidation/reduction function in which the selenol of the selenocysteine that is present in the active site of the respective enzyme takes part in the reaction. The advantage of having a selenol instead of a thiol lies in the fact that it confers to these enzymes a higher kinetic efficiency. In some biological systems, selenoproteins may also fulfill a structural role because of their capacity to oligomerize proteins via the formation of diselenide or mixed disulfide–selenide bridges. The biosynthesis of selenoproteins is unique since the incorporation of selenocysteine occurs co-translationally by the ribosome and not posttranslationally. Selenocysteine insertion is DNA encoded, requires the function of a cognate tRNA and of a specific translation elongation factor different from elongation factor Tu. Selenocysteine, therefore, has been designated as the 21st amino acid.

Bacterial Selenoprotein Synthesis

The structure and the function of the components involved in selenocysteine biosynthesis have been characterized to a considerable extent in the case of the bacterial system. The process can be divided into three functional steps, namely the biosynthesis of selenocysteine in the tRNA-bound state, the formation of a complex between elongation factor SelB, GTP, selenocysteyl-tRNA^{Sec} and the mRNA, and the decoding event at the ribosome. As far as it is known, though there are some major differences, similarities also exist between bacterial selenoprotein synthesis and the process characteristic of eukarya and archaea.

Selenocysteine Biosynthesis

Figure 1 summarizes the process of selenocysteine biosynthesis as it has been worked out for *Escherichia coli*. It requires the activities of three enzymes, namely seryl-tRNA synthetase (SerS), selenophosphate synthetase (SelD), and selenocysteine synthase (SelA) plus the specific tRNA (tRNA^{Sec}). Seryl-tRNA synthetase charges tRNA^{Sec} with L-serine, selenocysteine synthase converts the seryl-tRNA^{Sec} into selenocysteyl-tRNA^{Sec} using selenophosphate as a source for activated selenium. Selenophosphate is provided by selenophosphate synthetase from selenide in an ATP-dependent reaction. The genes for these components had been identified with the aid of *E. coli* mutants isolated by Mandrand–Berthelot as being pleiotropically deficient in formate dehydrogenase activities.

tRNA^{Sec}

tRNA^{Sec} (Figure 2) is the key molecule of selenoprotein synthesis since it serves both as the adaptor for selenocysteine biosynthesis and for incorporation of the amino acid at the ribosome. It deviates in size, secondary structure, and in normally conserved sequence positions from canonical elongator tRNA species. Because of the elongated extra arm and the one base-pair-extended aminoacyl acceptor arm, tRNA^{Sec} species are the largest members of the elongator tRNA family. All tRNA^{Sec} species identified thus far possess a UCA anticodon which enables them to pair with UGA stop codons (but only if these are in a special mRNA sequence context). Moreover, tRNA^{Sec} species deviate from canonical elongator tRNA species in sequence positions which are usually invariant and which are involved in the establishment of novel tertiary interactions within the molecule.

On the basis of its serine identity elements, tRNA^{Sec} is charged by the cellular seryl-tRNA synthetase which also aminoacylates serine inserting isoacceptors. However, both the affinity and the rate of aminacylation are diminished in comparison to the charging of tRNA^{Ser}, resulting in an overall 100-fold reduced efficiency.

Selenocysteine Synthase

The overall reaction catalyzed by selenocysteine synthase consists in the exchange of the hydroxylgroup of the serine moiety of seryl-tRNA^{Sec} by a selenol group (Figure 1). The reaction occurs in two steps; first, the amino group of serine forms a Schiff base with the carbonyl of the pyridoxal 5′-phosphate cofactor of selenocysteine synthase leads to the 2,3-elimination of a water molecule and the formation of dehydroalanyl-tRNA^{Sec} and second, nucleophilic addition of reduced

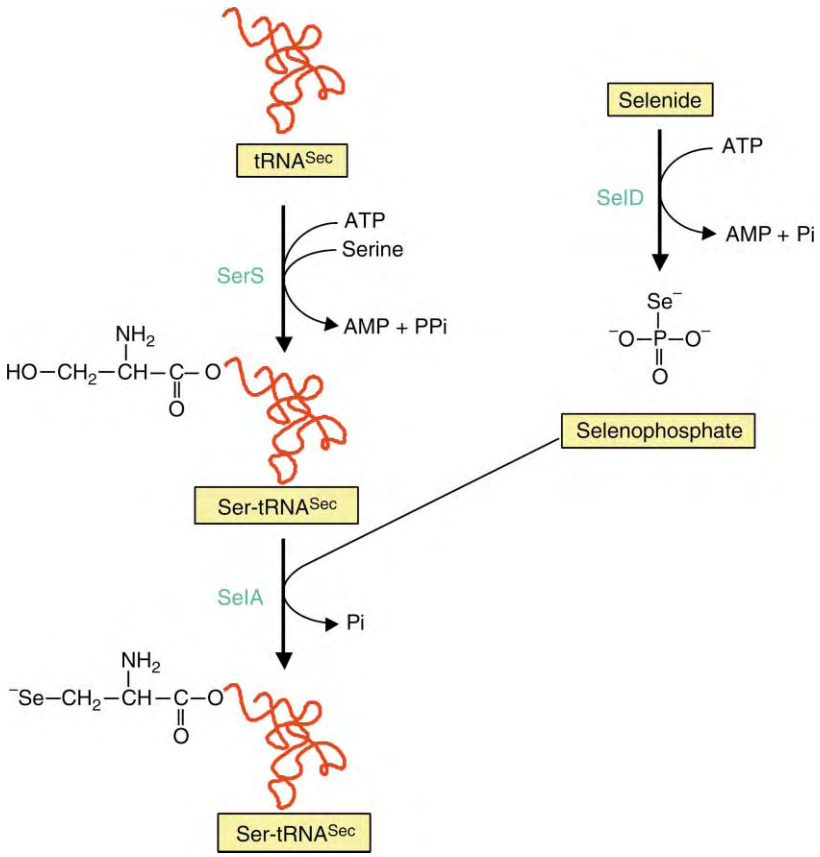

FIGURE 1 Path of selenocysteine biosynthesis. For explanation see text.

selenium to the double bond of dehydroalanyl-tRNA^{Sec} from selenophosphate as a donor yields selenocysteyl-tRNA^{Sec}.

Selenocysteine synthase from *E. coli* is a homodecameric enzyme and low resolution electron microscopy revealed that it is made up of two pentameric rings stacked on top of each other. Two subunits each are able to bind one molecule of seryl-tRNA^{Sec}, so the fully loaded enzyme can complex five charged tRNA molecules. As serine isoacceptor tRNAs are not recognized, the tRNA must have determinants for the specific recognition of seryl-tRNA^{Sec} by selenocysteine synthase and antideterminants for the rejection of seryl-tRNA^{Ser} species. The specificity for discrimination of the selenium donor is not as strict since the purified enzyme accepts thiophosphate instead of selenophosphate as a substrate. This results in the formation of cysteyl-tRNA^{Sec}. So the discrimination between sulfur and selenium must take place at some other step of selenocysteine biosynthesis.

Selenophosphate Synthetase

Purified selenocysteine synthase does not exhibit an absolute requirement for selenophosphate, as a substrate to convert seryl-tRNA^{Sec} into selenocysteyl-tRNA^{Sec}, since the reaction also occurs in the presence of high concentrations of selenide. Even sulfide is accepted although at a very low efficiency. So, the necessity for selenophosphate as a substrate may reside in one or more of the following three aspects, i.e., (1) to discriminate sulfide from selenide, (2) to efficiently use low concentrations of selenium compounds, and (3) to accelerate the reaction rate effected by the activation of the trace element. Indeed, selenophosphate synthetase efficiently discriminates between sulfide and selenide, and thus excludes sulfur from intrusion into the selenium pathway. Selenophosphate synthetase from *E. coli* is a monomeric enzyme with a unique reaction mechanism since formally it transfers the γ-phosphate of ATP to selenide with the intermediate formation of enzyme-bound ADP which is subsequently hydrolysed into AMP and inorganic phosphate.

Formation of the SelB × GTP × Selenocysteyl-tRNA × SECIS Complex

Elongation factor Tu, which forms a complex with all 20 standard aminoacyl-tRNAs and donates them to the ribosomal A-site, displays only minimal binding affinity

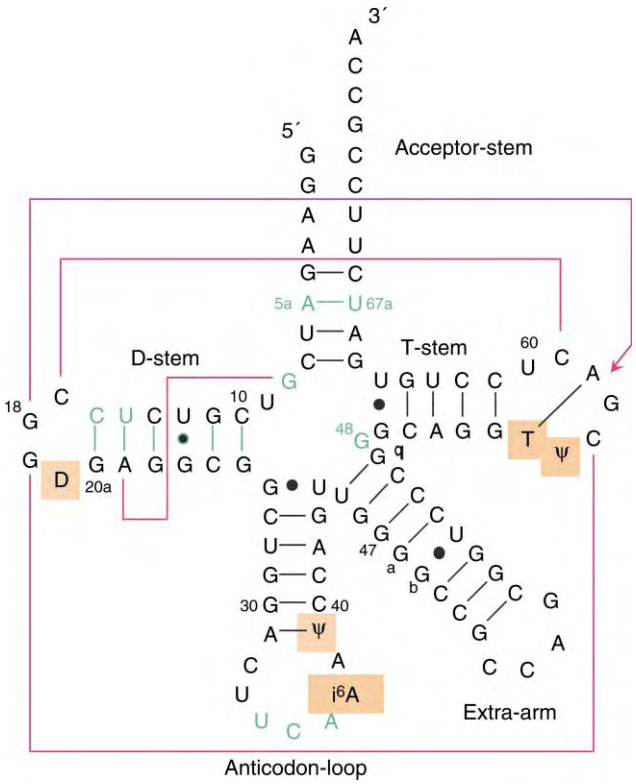

FIGURE 2 Cloverleaf presentation of the structure of $tRNA^{Sec}$ from *E. coli*. Modified bases are shaded. Tertiary interactions via base pairing are indicated by connecting red lines, and those involving intercalation are denoted by arrows. Bases and base pairings deviating from the consensus are indicated in green.

for selenocysteyl-$tRNA^{Sec}$. Consequently, insertion of selenocysteine requires the function of an alternate elongation factor which is SelB. SelB from *E. coli* is a 70 kDa protein which contains the sequence elements of elongation factor Tu in the N-terminal two-third of the molecule (designated domains I, II, and III) plus a domain IV of about 25 kDa which can be subdivided into domains IVa and IVb. Domains I, II and III share their functions with those of elongation factor Tu, namely the binding of guanosine nucleotides and of charged tRNA. An important difference, however, is that they can discriminate between the serylated and the selenocysteylated forms of $tRNA^{Sec}$. In this way, the insertion of serine instead of selenocysteine, which would lead to an inactive enzyme, is prevented. The structural basis for this discrimination ability has not yet been resolved. A second difference is that the overall affinity for GTP is about 10-fold higher than that for GDP which obviates the need for the function of a guanosine nucleotide release factor since GDP is chemically replaced by GTP. In accordance, the structure of SelB lacks those subdomains which in elongation factor Tu are responsible for interaction with the GDP release factor EF-Ts. The 25 kDa C-terminal extension of SelB (domain IV) is required for the function in selenoprotein synthesis since its truncation inactivates the molecule. The reason is that subdomain IVb binds to a secondary structure of the mRNA (the SECIS element) coding for selenoprotein synthesis. SelB, thus, is able to form a quaternary complex with GTP and two RNA ligands, namely selenocysteyl-tRNA and the SECIS element (Figure 3). The isolated domains IV or IVb retain the binding capacity for the SECIS element. Formation of the quaternary complex follows random order kinetics. An important feature also is that the stability of the complex is increased when both RNA ligands are bound.

The SECIS element itself is a hairpin structure formed within a section of 39 bases of the selenoprotein mRNA which follows the codon specifying selenocysteine insertion at the 3′-side. Binding of SelB takes place to its apical stem loop minihelix of 17 nucleotides. Genetic and structural analysis showed that bases in the loop region plus a bulged-out U in the helix are required for the interaction with SelB. This apical part of the SECIS element is separated by a short unpaired region from a helix at the base of the hairpin. Pairing within this second helix is not essential but it increases the efficiency of selenocysteine insertion. An absolute requirement,

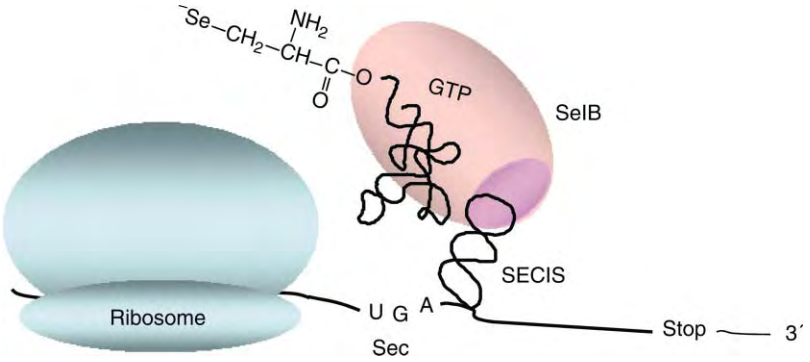

FIGURE 3 Translation of prokaryotic selenoprotein mRNA. Note that the SECIS element is within the mRNA reading frame and is complexed to domain IVb of SelB carrying selenocysteyl-$tRNA^{Sec}$ and GTP.

however, is that the codon determining selenocysteine insertion lies within a critical distance relative to the binding site of SelB.

Bacterial SECIS elements lie within the reading frame of their selenoprotein mRNAs; they are thus subject to stringent sequence constraints in order to deliver a functional gene product. However, they do not need to be translated since they also function when placed in the 3′-untranslated region at the correct distance to the selenocysteine codon within an upstream reading frame. The sequence constraint (which depends on the protein to be formed) and the requirement for binding of SelB restricts the number of selenoprotein mRNAs to be expressed in a single organism and explains why the vast majority of selenoprotein genes cannot be heterologously expressed unless the cognate SelB gene is coexpressed. Thus, SelB and their SECIS elements are subject to coevolution.

Decoding Event at the Ribosome

In all biological systems analyzed thus far, selenocysteine insertion is directed by the opal stop codon UGA but only if it is followed by an SECIS element at the correct distance. This violates the dogma that no codon can have more than one meaning within a single cell. The questions to be answered therefore are: (1) what prevents the UGA to be used as a termination signal, and (2) which mechanism interferes with insertion of selenocysteine at ordinary UGA stop codons?

Counteraction of Stop at the UGA?

A convincing answer to the question why the selenocysteine-specific UGA codon does not function as an efficient termination signal must await structural information on the decoding complex. It is, however, clear that termination always competes with selenocysteine insertion, especially under conditions when the capacity for decoding the UGA with selenocysteine is a limiting factor. This can be, for example, a surplus of selenoprotein mRNA in relation to the amount of SelB quaternary complex which forces the ribosome to stall at the UGA. One fact identified to be involved in the suppression of termination is that the base following the UGA at the 3′-side in selenoprotein mRNAs is prodominately an A or C, which renders the UGA a weak termination signal. Also, the two amino acids preceding selenocysteine in the nascent polypeptide chain are predominantly hydrophobic which counteracts the dissociation of the nascent polypeptide from the ribosome, when translation pauses at a "hungry" codon present in the A site. Additional mechanisms, however, must exist which contribute to the suppression of termination.

Selenocysteine Specificity of UGA Codons

From the colinearity between the mRNA nucleotide sequence and the amino acid sequence of the translation product, it is clear that UGA determines the *position* where selenocysteine is to be inserted during translation. The *specificity* of the UGA, however, is determined by the codon context, i.e., by the existence of a SECIS element at the 3′ side. The results of extensive biochemical and biophysical analysis suggest the following scenario for the decoding process: (1) SelB forms the quaternary complex at the mRNA in which the two RNA ligands display cooperativity in their interaction with the protein; (2) in this quaternary complex SelB attains a conformation compatible for interaction with the ribosome which then results in stimulation of GTP hydrolysis by SelB which in turn causes the release of the charged tRNA in the vicinity of the ribosomal A-site; (3) loss of the tRNA ligand causes the SelB protein to return to a conformation with about tenfold lower affinity for the SECIS element. As a consequence, the mRNA is released from the protein and freed for the translation of codons downstream of the UGA. The consequence of the complex cascade of reactions is that the efficiency of the decoding of UGA with selenocysteine is lower than that of any of the standard sense codons. It is also reflected by a considerable pause taking place when the ribosome encounters the quaternary complex at the mRNA. In the absence of selenocysteyl-tRNA, binding of SelB alone to the mRNA does not retard the rate of translation.

Archaeal and Eukaryal Selenoprotein Synthesis

$tRNA^{Sec}$ species from archaea and eukarya share several structural similarities with the bacterial counterparts but they are more related to each other than either one is to bacterial $tRNA^{Sec}$. There is also considerable sequence similarity between selenophosphate synthetases from all three lines of descent rendering their annotation in genome projects easy. On the other hand, homologues for the bacterial selenocysteine synthase have not been identified yet in any of the genomic sequences from organisms known to synthesize selenoproteins.

Whereas UGA directs selenocysteine insertion also in archaea and eukarya, a fundamental difference is that the SECIS element is not positioned within the reading frame but in the 3′-nontranslated region of the mRNA. SECIS elements from organisms of the three lines of descent are different by sequence and by secondary structure. They may be positioned at different distances from the actual termination codon and/or the selenocysteine inserting UGA codon but a critical distance must not be underpassed. It is thought that the selective value for having the SECIS element in the nontranslated

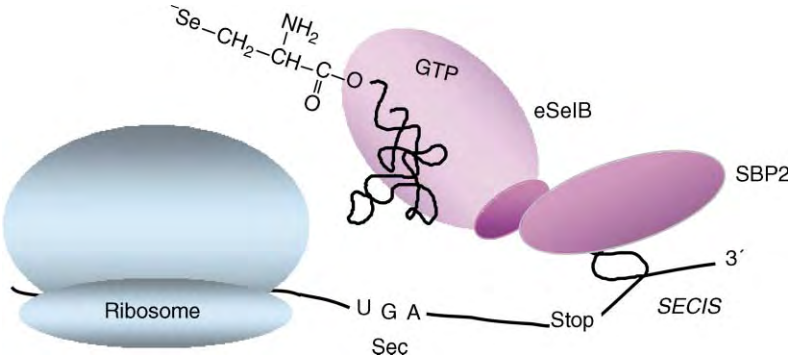

FIGURE 4 Translation of eukaryal selenoprotein mRNA. Note that the SECIS element is in the 3′-nontranslated region and serves as the binding site for SBP2 which in turn interacts with eukaryal SelB protein.

region consists in liberating it from the sequence constraint, and thus, allowing the translation of mRNAs with more than one UGA codon specifying selenocysteine insertion. Indeed, proteins with up to 17 selenocysteine residues are formed in some eukaryotes and in one instance a polypeptide with two such amino acids is synthesized in an archaeon.

Parallel to this deviation in both sequence, structure and position of the SECIS element, there is an alteration of the structure of the archaeal and eukaryal SelB-like translation factors. Domains I, II, and III closely resemble the three homologous domains from the bacterial SelB. However, the C-terminal extension is only short, less than 10 kDa, and accordingly and not unexpectedly, the archaeal and eukaryal SelB homologues do not bind to their cognate SECIS structures. In eukarya a second protein is fulfilling this task, namely SBP2 (SECIS binding protein 2) (Figure 4). There is evidence that SBP2 interacts with the SelB protein by direct contact in the decoding process. This interaction is stabilized in the presence of selenocysteyl-tRNA^{Sec}. However, the precise function of SBP2 has not yet been resolved.

Biography

August Böck is Professor Emeritus and former holder of the chair in Microbiology at the University of Regensburg from 1971 to 1978 and at the University of Munich from 1978 to 2002. He pursued his education at the University of Munich and his postdoctoral training at Purdue University. His main research interests are in microbial physiology with special emphasis on selenium biochemistry, bacterial metabolism and its regulation, and prokaryotic protein synthesis.

Septins and Cytokinesis

Makoto Kinoshita and Christine M. Field
Harvard Medical School, Boston, Massachusetts, USA

Septins are a family of conserved GTPases that has been identified in most animals from yeast to mammals. Each organism has multiple family members. Biochemical and genetic evidence indicate that multiple septin polypeptides form large, discrete complexes that further multimerize into filaments and higher order assemblies. Septins have been implicated in a variety of cellular processes including cytokinesis, vesicle trafficking, and axon migration. In yeast, they are involved in bud-site selection, cell polarity, and cytokinesis. Their name derives from their requirement during the final separation of the daughter cells in yeast, a process termed septation. While the precise molecular functions of septins are not known, a unifying hypothesis considers septin assemblies as scaffolds that localize, and perhaps regulate, diverse proteins involved in cortical dynamics. The septin scaffold may also have a fence-like function, limiting diffusion of proteins in the plane of the plasma membrane.

Cytokinesis

Cytokinesis is the process that physically separates the two daughter cells at the end of each division cycle. It must be temporally and spatially coupled to chromosome segregation to ensure that each daughter cell receives the correct number of chromosomes. The initiation of cytokinesis is controlled by cell-cycle-regulatory proteins, with the first step, the positioning of the cleavage plane (the site of division) beginning in late anaphase. In metazoa, the division site is determined by microtubules derived from the mitotic spindle. Next, a contractile ring made of actin, myosin-II, and other associated proteins, including septins, assembles at the plasma membrane at the specified position. The cleavage furrow ingresses by a combination of ring contraction driven by myosin-II, and targeted insertion of vesicles near the furrow to supply new plasma membrane. Finally, cytokinesis is completed in a complex process that involves the disassembly of the cleavage furrow and underlying microtubule structures, plasma membrane sealing and abscission (the actual separation) of the daughter cells. Targeted exocytosis and protein degradation are implicated in this completion phase (see Figure 1).

Septins localize to the cleavage furrow in all organisms that have been studied. Deletion, mutation,or inhibition of septins typically results in incomplete or abortive cytokinesis, though the severity of the defect varies between organisms. This suggests a conserved function of septins in cytokinesis that is not required for cleavage plane specification, but is required for normal furrow ingression, and/or completion.

Biochemical and Structural Properties of the Septins

Septins Bind Guanine Nucleotide and Form Complexes and Filaments

Sequence analysis shows that all septins have a central globular domain containing conserved motifs found in small GTPases, and most septins have a C-terminal predicted coiled-coil region of variable length. On purification, septins are found in large complexes containing multiple septin polypeptides. The septin complex purified from *Drosophila* embryos is composed of three septin polypeptides with a stoichiometry of 2:2:2. Yeast complexes contain a fourth septin polypeptide, and complexes from mammalian brain are heterogeneous, and may be built from at least six different septin proteins. When viewed by negative-stain electron microscopy (EM) a typical septin preparation appears as filaments 7–9 nm thick and of variable lengths. The shortest filament represents the complex itself and is the building block from which the longer filaments are formed (see Figure 2A and 2B) which show a purified yeast complex.

Purified septin complexes contain tightly bound guanine nucleotide at a level of one molecule per septin polypeptide. The GDP:GTP ratio is ~2:1 for both *Drosophila* embryos and yeast complexes. The role of bound nucleotide in septin biochemistry is still under investigation, and appears to be distinctly different from small GTPases whose function employs

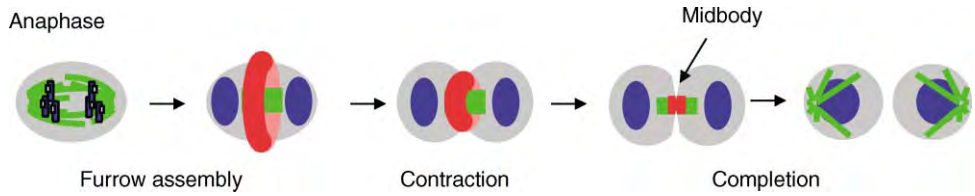

FIGURE 1 Schematic illustration of the different subprocesses of cytokinesis. DNA is shown in blue, microtubules (MT) in green, and the cleavage furrow/contractile ring (CR) in red. When the cleavage furrow assembles and contracts, microtubules become bundled and compacted into the midbody. Cytokinesis is completed by disassembly of the CR and MT structures and fusion of the membrane to create two daughter cells.

rapid exchange and hydrolysis. Isolated septin complexes exchange bound nucleotide very slowly, and in yeast, the majority of bound nucleotide does not turn over. These data suggest that GTP is bound during septin folding or complex assembly, and thereafter is not exchanged, at least on the majority of septins. Thus bound GTP may play a structural role, analogous to GTP bound to α-tubulin, and not a regulatory role, analogous to nucleotide in β-tubulin or small GTPases. However it is possible that GTP exchange and hydrolysis plays a more dynamic regulatory role for a subset of septins.

Septin Filaments Can Form Higher-Order Assemblies

Unit septin complexes are able to assemble into several different higher-order structures *in vitro*. Septin complexes from all organisms studied tend to polymerize end-to-end to form long filaments of the same thickness as the unit complexes. With yeast septins, these filaments tend to associate side by side in pairs a fixed distance apart, suggesting they may be cross-bridged by one of the septin polypeptides (see Figure 2C).

(C) Shows yeast at various stages of the cell cycle stained with an antibody against Cdc3p. (Courtesy of J. Pringle.)

Purified mammalian septin filaments tend to assemble into bundles, that under some conditions curl up into rings and coils of ~0.7 μm diameter (see Figures 2D and 2E). Mammalian septins also tend to assemble into rings in cells. This tendency to curve is apparently intrinsic to the septin complex, and may play a role in deforming the plasma membrane in cells. The rings are comparable in size and shape to several septin assemblies in cells, including the yeast bud neck (Figure 3) and septin rings formed in cells under stress (Figure 4C).

Mammalian septin filaments can be recruited to actin bundles by another cytokinesis furrow protein, anillin. Anillin was originally identified as an actin-bundling protein in *Drosophila*. Septins and anillin are abundant in intracellular bridges between daughter cells in conventional cytokinesis and also stable bridges formed as the result of incomplete cytokinesis in *Drosophila* embryos. It is possible that these two proteins have a structural role in supporting a narrow neck in the plasma membrane after the contractile apparatus that formed the neck disassembles at the end of cytokinesis.

Septins Interact with Inositol Phospholipids

A number of studies have suggested that septins can bind directly to lipid bilayers containing inositol lipids, an activity which may be important in septin targeting or in regulating exocytosis. The question of exactly how septins target to plasma membranes, and how these proteins are involved in vesicular trafficking, are important topics for future study.

Septin Behavior and Function in Cytokinesis

Budding Yeast

Septin proteins were originally identified in budding yeast (*Saccharomyces cerevisiae*) as the protein products of four genes *CDC3*, *CDC10*, *CDC11*, and *CDC12*. Temperature sensitive mutations of these genes exhibited hyperpolarized growth and defects in cell wall deposition and cytokinesis. These septin polypeptides localize to the mother/bud neck late in the G1 phase of the *S. cerevisiae* cell cycle, before the localization of other cleavage furrow components. Septin localization and assembly is controlled at least in part by the GTPase Cdc42, the master regulator of yeast cell polarity, and is independent of other cytoskeleton proteins including actin filaments. By EM, septins appear as 10 nm diameter filaments, termed neck filaments that appear to coil around the bud neck (Figure 3A and 3B). By immunofluorescence they appear as an hourglass-shaped assembly coating the inside of the bud neck. In projection, this hourglass can resemble two rings (Figure 3C). Photobleaching of GFP-tagged septins reveals that septins are quite dynamic before bud emergence, but once they assemble into neck filaments, their turnover rate is slowed considerably, and they can be considered static. This datum correlates well with their GTP exchange properties.

In budding yeast, septin localization at the bud neck is required for the sequential recruitment of all of the cytokinetic machinery including a type II myosin heavy chain (Myo1p), its associated light chain (Mlc1p), a formin homology (FH) protein Bni1p, probably responsible for nucleating contractile ring actin, a PCH protein (Hof1p/Cyk2p), and an IQGAP protein (Iqg1p/Cyk1p). All of these proteins have conserved roles in cytokinesis in other organisms, but it is not clear if their recruitment to the furrow depends on septins in metazoans. Neck filaments are also thought to anchor a chitin synthase complex (Chs3p/4p + Bni4p) responsible for cell-wall deposition during cytokinesis.

In budding yeast, septins are required for localization of many different proteins to the bud neck in addition to the basic cytokinesis machinery. A recent genome wide screen identified 98 proteins that localize to bud necks, and many of these depend on septins for their localization. Well-characterized examples include; the checkpoint kinases, Hsl1p, Gin4p, and Kcc4p, a component of the mitotic exit network (MEN), Dbf2/Mob1, and several proteins involved in bud site selection including Bud4.

Septins also act to restrict diffusion of proteins in the plane of the plasma membrane. The neck filaments form a fence that restricts membrane proteins to the bud, and presumably plays an important role in polarizing the yeast cell. This function may be direct as opposed to being mediated by other proteins dependent on septins for their localization.

Overall, septins play a central role in the cell biology of budding yeast. This role reflects the importance of the bud neck in cell polarity and cell division, and the function of septins as a scaffold for localizing other proteins to this site, and restricting diffusion through it. In organisms that do not grow by polarized budding, septins may be important, but perhaps their role is not as central to the overall biology of the cell.

Fission Yeast

In fission yeast, *Schizosaccharomyces pombe*, disruption of the septin genes result in a delay in septation (cell–cell separation), but not severe cytokinetic defects as seen in budding yeast. Septins assemble into a single ring structure in late cytokinesis, and are not required to recruit actin, myosin, or other contractile ring components. Stability of the septin ring requires the protein mid2p, that is related to metazoan anillin, suggesting this interaction is conserved. Interestingly, mutations in components of the exocyst, a large complex involved in exocytosis, have a similar septation defect. Thus, in *S. pombe*, the septin scaffold is involved only in the completion stage of cytokinesis, perhaps to target exocytotic vesicles required for membrane fusion or enzymes required for final digestion of the septum.

Metazoa

In animal cells, septin polypeptides are recruited in late anaphase to the equatorial cortex and assemble into the contractile ring at the same time as actin and myosin-II. Perturbation of septins by gene disruption, RNA interference, or microinjection of anti-septin antibodies blocks normal cytokinesis in mammalian cells and fly embryos. However, septins are dispensable in some cases. For instance, nematode eggs can complete cytokinesis without septins at early developmental stages, although, cytokinesis defects manifest in some cell lineages at postembryonic stages. This difference in requirement for septins indicates a divergence in cytokinesis mechanism that we do not understand.

While the concept of septins as a scaffold for recruiting other factors is probably relevant, the exact function of septins during cytokinesis is even less clear in metazoans than it is in yeast. Septins tend to colocalize with actin filaments in interphase cells, and they tightly colocalize with anillin during cytokinesis (Figure 4). Combined with biochemical data reconstituting an actin–septin–anillin interaction *in vitro*, these data suggest a cytokinesis function involving actin filaments. However, disruption of septins does not block positioning or initial contraction of the actomyosin ring, so

septin function is not as central as it is in *S. cerevisiae*. Most likely, septins and anillin function together late in cytokinesis, perhaps during the complex process of completion.

How might septins function in completion? Physical and functional interactions have been shown between mammalian septins and syntaxins (SNARE proteins involved in membrane fusion during secretion) and the exocyst complex (a complex of proteins required for exocytosis). As previously mentioned exocyst mutants in *S. pombe* have a similar phenotype to septin mutants. Thus, it is reasonable to speculate that septins play a role in regulating or targeting vesicle insertion associated with furrow ingression and completion. This role has not yet been explored in budding yeast. Additionally, septins and anillin may assemble into a structure that stabilizes the fully ingressed membrane after the contractile ring has disassembled, but before cytokinesis is completed. These roles might explain why septins are more important during cytokinesis in some cells than others: (1) the amount of new membrane required for cytokinesis may vary according to cell type and (2) the time delay between completing ingression and actually separating the daughter cells is quite variable between species and cell type.

Glossary

cell cortex A specialized layer of cytoplasm beneath the plasma membrane. In animal cells it contains actin and actin-binding proteins.

cell cycle The sequence of events by which a cell duplicates its contents and divides in two. There is a network of regulatory proteins that govern the progression through the key events such as DNA replication, formation of the mitotic spindle, and segregation of the chromosome. The cell cycle ends with cytokinesis.

exocyst complex Complex of conserved proteins that are an essential part of the exocytotic apparatus.

FH proteins Conserved proteins required to assemble some types of actin structures such as actin cables (in yeast), stress fibers, and the contractile ring.

guanosine di-/tri-phosphate (GDP/GTP) Plays an important role in tubulin stability and microtubule assembly and in signal transduction pathways via small GTPases.

inositol phospholipids Membrane lipids containing inositol and phosphate(s) that are important in various cell-signaling pathways.

midbody The thin intercellular bridge of cytoplasm connecting two daughter cells in late cytokinesis. It contains a tightly packed antiparallel array of microtubules and an electron dense matrix at its center.

photobleach The exposure of a fluorescent probe to light such that it is rendered nonfluorescent or "bleached." Examining the recovery of fluorescence after photobleaching a tagged protein gives an indication of how dynamic it is.

septation In yeast, the formation of a new cell wall or septum to separate two daughter cells. Septation is separable from cytokinesis.

small GTPase GTP-binding and -hydrolyzing switch proteins. They alternate between an active/on state when they are GTP bound and an inactive GDP bound state.

Serine/Threonine Phosphatases

Thomas S. Ingebritsen
Iowa State University, Ames, Iowa, USA

Phosphorylation of proteins on serine, threonine, and tyrosine residues is a major mechanism for regulating the activity of cell proteins and it plays a central role in virtually all signal transduction pathways in eukaryotes. The steady-state level of phosphorylation of a protein at a particular site depends on the balance of the activities of the protein kinase(s) and protein phosphatase(s) acting on that site. Both protein kinases and protein phosphatases are important targets of cell regulation. This article will focus on the structure, regulation, and function of the two families of protein Ser/Thr phosphatases (PPP and PPM). Members of each family are present in all three domains of life (archae, bacteria, and eukarotes).

Protein Ser/Thr Phosphatase Catalytic Subunit Families

PPP Family

Members of this family possess a common catalytic core (280 residues) and can be further divided into four subfamilies termed PPP1, PPP2A, PPP2B, and PPP5. Three prokaryotic phosphatases: diadenosine tetraphosphatase, Φ80 phosphatase, λ phosphatase exhibit weaker similarity to the PPP family.

PPM Family

Members include PP2C, *Arabidopsis* ABI1 and ABI2, *Arabidopsis* KAPP, *Bacillus subtilis* SpoIIE phosphatase and pyruvate dehydrogenase phosphatase. The core PPM catalytic domains occur in diverse contexts. For example the catalytic domain of *Arabidopsis* ABI1 is fused to an EF-hand domain, the *Arabidopsis* kinase associated protein phosphatase (KAPP) catalytic domain is fused to a kinase-interaction domain. The kinase interaction domain of KAPP associates with a phosphorylated receptor-like protein. The N terminus of *Bacillus subtilis* SpoIIE phosphatase is fused to a domain with ten membrane-spanning segments.

Biochemical Characterization of Signature Protein Ser/Thr Phosphatases

PP1, PP2A, and PP2B are signature members of the PPP1, PPP2A, and PPP2B subfamilies while PP2C is the signature member of the PPM family. These four enzymes account for the majority of protein Ser/Thr phosphatase activity in cell extracts. The activities of these enzymes can be distinguished in cell extracts based on divalent cation requirements and the effects of physiological and pharmacological inhibitors (Table I). PP1, PP2A, and PP2C have broad and overlapping substrate specificities whereas the substrate specificity of PP2B is more restricted.

Three-Dimensional Structures and Catalytic Mechanism

Three-dimensional structures have been determined for two members of the PPP family (PP1 and PP2B) and for one member of the PPM family. A surprising finding was that the PPP and PPM families have similar three-dimensional architectures even though the primary structures of the two families are unrelated. The three-dimensional structure of the two families is quite distinct from that of the PTP family of protein Tyr phosphatases.

Three-Dimensional Structures

For both the PPM and PPP families, the core structure consists of a pair of mixed β-sheets that form a β-sandwich structure. The catalytic sites possess a binuclear metal ion center which has some similarity to the binuclear metal ion center of purple acid phosphatase (Figure 1). For the PPM family, the two metal ions are Mn^{2+}. In the case of the PPP family, the two metal ions are probably Fe^{2+} and Zn^{2+}, although there is some controversy about whether the second metal ion is Zn^{2+} or Mn^{2+} and also about whether the

TABLE I

Biochemical Characterization of Signature Protein Phosphatases

Type	Protein phosphatase	Substrate specificity	Divalent cation requirement	I_1 and I_2 inhibition	Okadaic acid inhibition (IC_{50})
1	PP1	Broad	None	Yes	20 nM
2	PP2A	Broad	None	No	0.2 nM
2	PP2B	Narrow	Ca^{2+}	No	5 μM
2	PP2C	Broad	Mg^{2+}	No	No effect

PP2B requires μM Ca^{2+} for activity whereas PP2C requires mM Mg^{2+}. Inhibitor-1 (I_1) and inibitor-2 (I_2) are PP1 modulator proteins. Okadaic acid is a pharmacological inhibitor of PPP family members. It is a polyether carboxylic acid that is a diarrhetic shell fish poison and a powerful tumor promoter. There are a number of other pharmacological inhibitors of the PPP family (e.g., microcystin, calyculin A, cantharidin). Okadaic acid, microcystin, and calyculin A inhibit by binding to the phosphatase active site.

Fe is in the 2+ or 3+ oxidation state. In both cases, metal ions are coordinated with water molecules.

Catalytic Mechanism

For both the PPP and PPM family hydrolysis of serine or threonine phosphate esters occurs through a single-step mechanism in which a metal-bound water acts as a nucleophile to attack the phosphorus atom of the substrate phosphate group (Figure 1). The metal ion acts as a Lewis acid to enhance the nucleophilicity of metal-bound water and it also enhances the electrophilicity of the phosphorus atom by coordinating the two oxyanions of the phosphate group. An active site His sidechain donates a proton to the leaving oxygen of Ser or Thr. This catalytic mechanism is quite different from that used by the PTP family which involves formation of a phospho-enzyme intermediate.

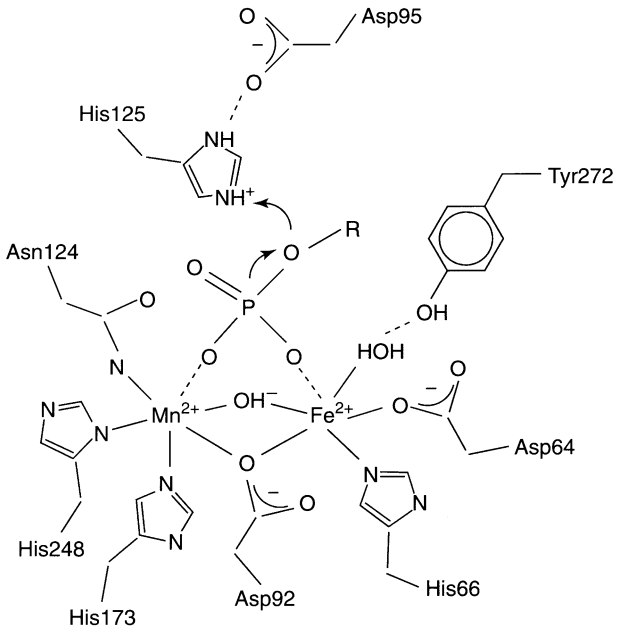

FIGURE 1 Active site structure and catalytic mechanism of PP1 catalytic subunit. (Reprinted from Barford, D. (1996). Molecular mechanisms of the protein serine/threonine phosphatases. *TIBS* **21**, 407–412.)

Subunit Structure of PPP Family Members

Members of the PPP family interact with diverse sets of regulatory subunits, which direct the catalytic subunits to specific subcellular locations, alter substrate specificity and/or confer regulatory properties.

Interaction of PP1 with Diverse Regulatory Subunits

The catalytic subunit of PP1 (PP1c) interacts with >50 regulatory subunits, which fall into two classes: targeting subunits and modulator proteins. Targeting subunits direct PP1c to a wide variety of subcellular locations including: glycogen particle, myosin/actin, spliceosomes/RNA, endoplasmic reticulum, proteasomes, nuclear membranes, plasma membranes/cytoskeleton, centrosomes, microtubules, and mitochondria. Targeting subunits also modulate substrate specificities and may regulate phosphatase activity.

Modulators are generally low-molecular-weight, heat-stable proteins that alter PP1 activity or substrate specificity. The activity of some of the modulators (e.g., inhibitor-1, DARPP-32, CPI-17, and G subunit) is regulated through reversible phosphorylation.

Strong binding of many of the regulatory proteins to PP1c is mediated through a short motif termed RVxF. This motif is found in two-thirds of the targeting subunits and one-half of the modulator proteins. The consensus sequence of the motif is: (K/R)x_1(V/I)x_2(F/W) where x_1 and x_2 may be any residue except a large hydrophobic residue. In some motifs x_1 is absent.

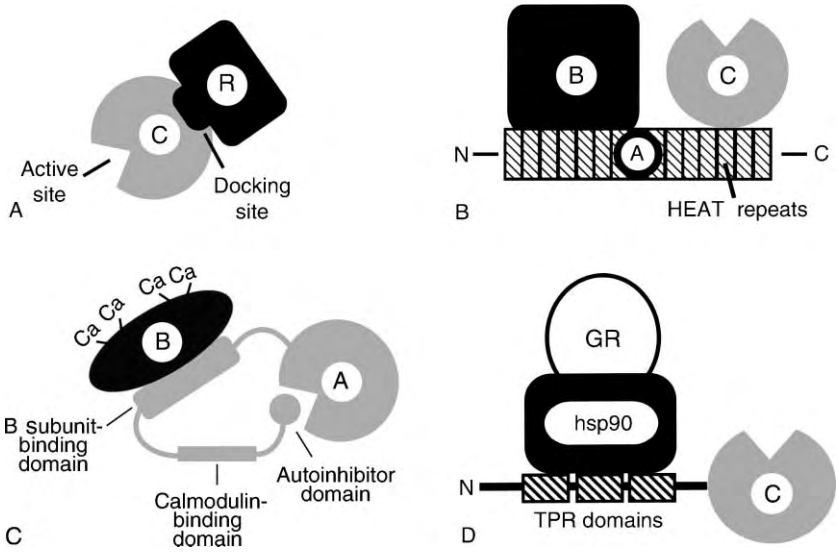

FIGURE 2 Subunit structure of PPP family members. (A) PP1. C and R designate catalytic and regulatory subunits, respectively. The docking site on the C subunit interacts with the RVxF motif of the regulatory subunit. (B) PP2A. The labels C, B, and A designate the catalytic, regulatory, and adaptor subunits, respectively. The three-dimensional structure of the A subunit has been determined. Tandem arrays of HEAT (*h*untingtin-*e*longation factor-*A* subunit-*T*OR) motifs are present in a variety of other proteins. The labels N and C designate the amino and carboxyl termini of the A subunit. (C) PP2B. The labels A and B designate the catalytic and regulatory subunits, respectively. The B subunit has four Ca^{2+}-binding sites. The B subunit-binding, calmodulin-binding and autoinhibitor domains are on a carboxyl-terminal extension of the A subunit. The region from the end of the B subunit-binding domain to the beginning of the autoinhibitor domain is disordered in the absence of calmodulin and thus not visible in the crystal structure. (D) PP5. C and GR designate the catalytic subunit and the glucocorticoid receptor, respectively. TPR domains are characterized by a degenerate 34 amino acid sequence. The label N designates the amino terminus of the C subunit. The three-dimensional structure of the amino terminal extension of C has been determined in the absence of the core catalytic domain.

The RVxF motif binds to a docking site that is remote from the active site (Figure 2A). The docking site consists of a hydrophobic groove which binds the two large hydrophobic residues of the RVxF motif and a cluster of negatively charged residues which interact with basic residues at the N-terminal end of the motif.

Additional interactions between the PP1c and the targeting and modulator proteins are thought to strengthen binding and mediate effects on PP1 activity. For example residues 7–11 of DARPP-32 (KKIQF) bind to the PP1c docking site whereas thr 34 which is phosphorylated by PKA binds to the active site of the phosphatase.

Interaction of PP2A with a Diverse Set of Regulatory Subunits

PP2A diversity is also generated by the interaction of a common catalytic (C) subunit with a diverse set of regulatory (B) subunits. However in this case, the regulatory subunits interact with the C subunit indirectly through an adapter subunit (A), thus forming a heterotrimeric phosphatase complex (Figure 2B).

Over 15 different B subunits are expressed in a tissue- and developmental-specific manner from four families of genes, termed PR55/B, PR61/B′, PR72/B′, and B′. Additional gene products are generated through alternate splicing. Functions of the B subunits include regulation of PP2A activity, subcellular targeting, and alteration of substrate specificity.

The A subunit is made up of 15 HEAT repeats which form an extended and curved structure reminiscent of a hook or the letter C. The catalytic subunit interacts with the C-terminal HEAT repeats (11–15) whereas the B subunits interact with N-terminal repeats (1–10).

Subunit Structure of PP2B

The catalytic (A) subunit of PP2B interacts with two EF-hand-type Ca^{2+}-binding proteins, an integral B subunit which binds in the absence of calcium, and calmodulin which requires calcium for binding. The A subunit has a regulatory C-terminal extension which has binding sites for the two Ca^{2+}-binding proteins as well as an autoinhibitor site (Figure 2C). Binding of Ca^{2+} to the B subunit is absolutely required for phosphatase activity. PP2B activity is further stimulated by Ca^{2+}-calmodulin.

PP5

The catalytic subunit of PP5 has an amino-terminal extension with three TPR domains. These domains are found in a variety of proteins and act as a scaffold that mediates protein–protein interaction. The TPR domains of PP5 mediate interaction of the phosphatase with the heat shock protein, hsp90, and the glucocorticoid

receptor (Figure 2D). TPR domains also suppress the catalytic activity of PP5 25-fold.

Examples of Functions and Regulation of Protein Ser/Thr Phosphatases

PPM Family

PPM family members are involved in stress responses in animals, plants, fungi, and prokaryotes. PP2C antagonizes stress response pathways involving two types of protein kinase cascades: mitogen-activated protein kinase (MAPK) and AMP-activated protein kinase (AMPK). Two other PPM family members (ABI1 and ABI2) play an essential role in the abscisic acid-mediated stress response of plants to water deprivation and in prokaryotes SpoIIE is involved in controlling sporulation.

PPM family members also have other cell functions. For example, the PDH phosphatase is involved in controlling the types of metabolic fuels used in body tissues through a dephosphorylation reaction that activates pyruvate dehydrogenase in mitochondria.

PPP Family

Regulation of PP1 Involving Targeting Subunits

There are four modes of regulation of PP1c involving targeting subunits: inducible expression of targeting subunits, allosteric regulation through targeting subunits, phosphorylation near the RVxF docking motif, and phosphorylation at sites remote from the docking motif.

The expression of two glycogen-targeting subunits in rat liver, G_L and R5, is decreased by diabetes and starvation and is restored by insulin treatment and refeeding, respectively.

G_L-PP1c is subject to allosteric regulation by glycogen phosphorylase *a* (phosphorylated, active form) which binds to a short segment at the C terminus of G_L with nanomolar affinity. Phosphorylase *a* binding inhibits the glycogen synthase phosphatase activity of G_L-PP1c but has no effect on phosphorylase phosphatase activity of the complex. This helps to coordinate the regulation of glycogen breakdown and synthesis in response to glucagon and perhaps to insulin.

G_M (muscle-specific glycogen targeting), NIPP1 (nuclear targeting), and Neurabin I (actin targeting) are phosphorylated by protein kinase A at sites near the RVxF docking motif leading to dissociation of PP1c. In the case of G_M-PP1c this results in decreased activity towards glycogen-bound substrates (glycogen synthase, phosphorylase *a*, and phosphorylase kinase).

The myosin-targeting protein M110 is phosphorylated on sites (Thr 697 and Ser 435) that are distant from the docking motif. The complex of PP1c with M110 is involved in regulating muscle contraction in smooth muscle and nonmuscle cells. Phosphorylation of Ser 435 occurs during mitosis and leads to activation of PP1c and enhanced binding to myosin II.

PP2A

One of the best-documented roles of PP2A is in the regulation of animal growth and development. A role in cell growth was first suggested by the potent inhibition of PP2A by the tumor promoter okadaic acid. Additionally the β-isoform of the A subunit of PP2A has been identified as a candidate tumor-suppressor gene and the myeloid-leukemia-associated protein SET is a potent inhibitor of PP2A.

PP2A dephosphorylates and inactivates protein kinases involved in growth-regulatory signal transduction pathways (e.g., ERK and Mek MAP kinases, protein kinase C, and protein kinase B). Additionally, PP2A is an important cellular target of the SV40 and polyoma DNA tumor viruses. Viral proteins associate with the AC dimer and displace B subunits. This leads to stimulation of growth-related (ERK/Mek) MAP kinase pathways and cell growth.

Genetic approaches in budding and fission yeast as well as in *Drosophila* demonstrate that PP2A has an essential role in regulating the cell cycle. Additionally, PP2A interacts with components of the Wnt signaling cascade, which controls the epithelial–mesenchymal transition during vertebrate development.

Central Role of PP2B in T Cell Activation

Stimulation of the T cell receptor leads to the activation of dual signal transduction pathways involving Ca^{2+} and Ras (Figure 3, left). Elevation of intracellular Ca^{2+} results in activation of PP2B which dephosphorylates NFAT. This leads to activation of NFAT as a transcription factor and translocation of the NFAT from the cytoplasm to the nucleus. The Ras pathway activates a nuclear transcription factor (AP-1) through a protein kinase cascade. NFAT and AP-1 bind cooperatively to DNA regulatory sites resulting in enhanced transcription of cytokine, cell surface receptor, and transcription factor genes.

PP2B is the site of action for the immune-suppressant drugs, Cyclosporin A and FK506, used to prevent rejection in organ transplant procedures. The use of these drugs has revolutionized organ transplant therapy. The two drugs interact with separate intracellular-binding proteins (cyclophin and FK506-binding protein) and the resulting complexes bind to and inhibit the activity of PP2B. This in turn inhibits T cell activation by

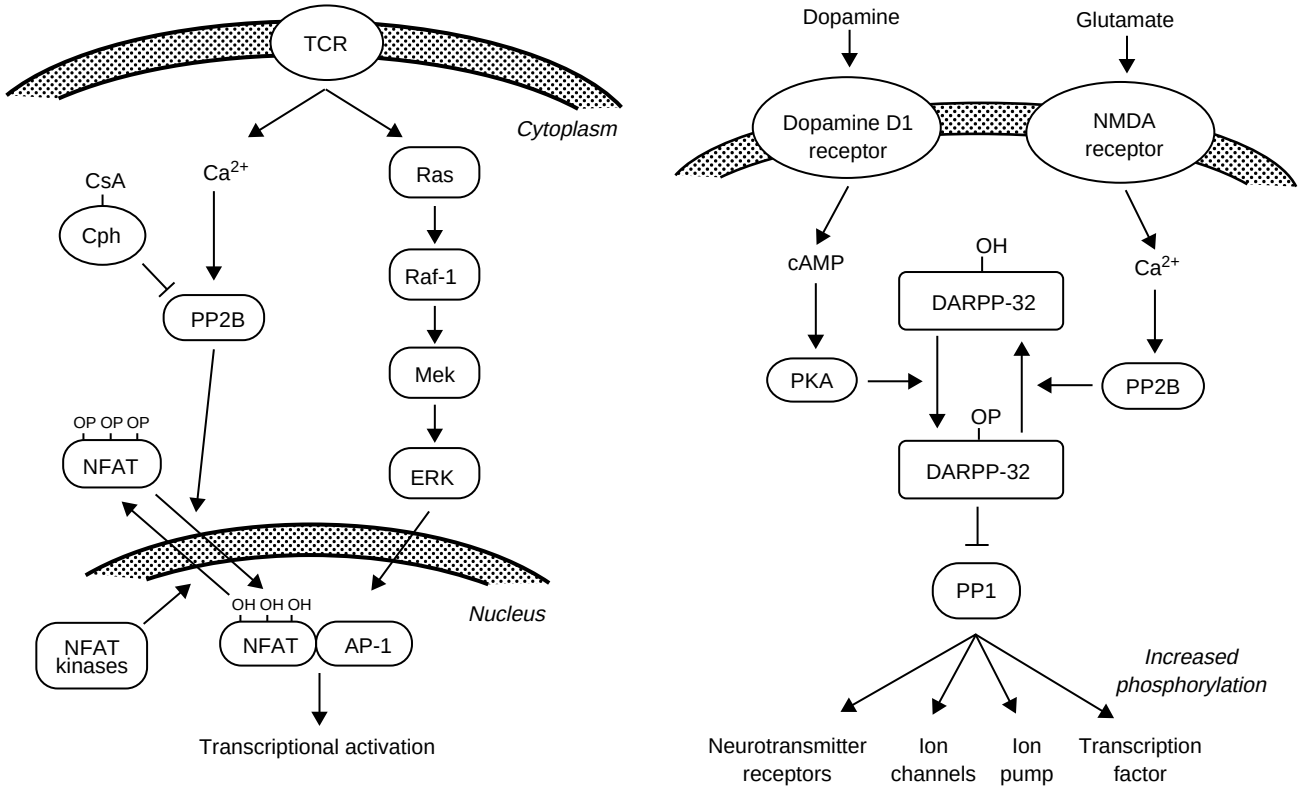

FIGURE 3 (Left) Role of PP2B in T cell activation. Raf-1, Mek, and ERK are protein kinases in the Ras signaling pathway. NFAT and AP-1 are transcription factors. NFAT are a family of transcription factors that exist in an inactive, phosphorylated state in the cytoplasm of resting T cells. These proteins are phosphorylated on multiple serine residues in a regulatory region in the amino-terminal half of the molecule. CsA and Cph designate cyclosporin and cyclophilin, respectively. (Right) Central role of DARPP-32 in the regulation of dopaminoceptive neurons. Inhibition of PP1 is associated with increased activity of NMDA and AMPA glutamate receptors, of L, N, and P type Ca^{2+} ion channels and CREB and with decreased activity of $GABA_A$ receptor, Na^+ channels, and Na^+/K^+ ATPase. There are a variety of other neurotransmitter receptors (opiate, adenosine, VIP) which elevate cAMP in medium spiny neurons. Glutamate acting through AMPA receptors and GABA acting through $GABA_A$ receptors also elevate Ca^{2+} in these neurons.

suppressing transcriptional activation through the NFAT:AP-1 complex.

Similar dual pathways involving PP2B and NFAT family members have been implicated in angiotensin-II-induced cardiac hypertrophy and in the morphogenesis of heart valves.

DARPP-32

DARPP-32 (dopamine and cyclic adenosine 3′,5′-monophosphate-regulated phosphoprotein, 32 kDa) is a specific inhibitor of PP1. It is expressed at high concentrations in medium spiny neurons of the neostriatum where it plays a central role in integrating responses to dopamine (acting via the cAMP) and glutamate (acting via Ca^{2+}) in dopaminoceptive neurons (Figure 3, right). Diseases associated with defects in dopaminergic neurotransmission include Parkinson's disease, Huntington's disease, ADHD, and schizophrenia.

Activation of the cAMP pathway in dopaminoceptive neurons leads to increased phosphorylation of DARPP-32 on Thr 34 and inhibition of PP1. This results in increased phosphorylation of neurotransmitter receptors, voltage-gated ion channels, an electrogenic ion pump (Na^+/K^+ ATPase), and a transcription factor (CREB).

In contrast, glutamate acting through NMDA receptors promotes dephosphorylation of brain proteins through activation of a protein phosphatase cascade involving PP2B and PP1. Activation of NMDA receptors elevates Ca^{2+} which activates PP2B. This leads to DARPP-32 dephosphorylation by PP2B and activation of PP1 through relief of inhibition by DARPP-32.

Glossary

modulator protein Generally a low-molecular-weight, heat-stable protein that alters protein phosphatase activity or substrate specificity.

protein kinase cascade A series of protein kinases arranged in a linear fashion in a signal transduction pathway such that an upstream protein kinase phosphorylates and activates the immediate downstream kinase.

protein phosphatase An enzyme whose physiological function is to remove phosphate groups from serine, threonine, or tyrosine residues of proteins.

targeting subunit A protein that directs a phosphatase to a specific subcellular location or a specific substrate and may also modulate substrate specificity and regulate phosphatase activity.

transcription factor A protein that binds to a regulatory site on a gene leading to enhanced transcription of the gene.

Biography

Thomas S. Ingebritsen is an Associate Professor in the Department of Genetics, Development and Cell Biology at Iowa State University. His research interest is the structure, regulation, and function of protein phosphatases. He holds a Ph.D. in Biochemistry from Indiana University and received his postdoctoral training at the University of Dundee, Scotland. Together with Philip Cohen, he developed the scheme for classification of protein serine/threonine phosphatases and he has published extensively in the area of protein phosphorylation and protein phosphatases.

Serotonin Receptor Signaling

Paul J. Gresch and Elaine Sanders-Bush
Vanderbilt University, Nashville, Tennessee, USA

Serotonin (5-hydroxytryptamine; 5-HT) receptors are a family of G-protein-coupled receptors (GPCRs) and one ligand-gated ion channel that transduce an extracellular signal by the neurotransmitter serotonin to an intracellular response. 5-HT receptors are involved in multiple physiological functions such as cognition, sleep, mood, eating, sexual behavior, neuroendocrine function, and gastrointestinal (GI) motility. Since many physiological processes are influenced by 5-HT receptors, it is not surprising that dysfunction and regulation of 5-HT receptors are implicated in numerous disorders and disease states including migraine, depression, anxiety, schizophrenia, obesity, and irritable bowel syndrome. Therefore, understanding 5-HT receptor second messenger systems, their effector linkage, the multiplicity of coupling pathways, and how these pathways are regulated is critical to disease etiology and therapeutic discovery.

Serotonin Synthesis and Metabolism

The neurotransmitter serotonin (5-hydroxytryptamine; 5-HT) is found in the central nervous system, enterochromaffin cells, gastrointestinal tract, and platelets. 5-HT is synthesized from the essential amino acid tryptophan by the rate-limiting enzyme tryptophan hydroxylase and a ubiquitous l-aromatic amino acid decarboxylase. 5-HT is released into the synaptic cleft by exocytosis of vesicles in a TTX-sensitive and Ca^{2+}-dependent manner. Inactivation of 5-HT is mediated by reuptake into the presynaptic terminal through an Na^{+}-dependent 5-HT transporter. 5-HT is metabolized into the inactive form, 5-hydroxyindole acetic acid, by the enzymes monoamine oxidase and aldehyde dehydrogenase. Levels of synaptic 5-HT can be regulated. For instance, restriction of dietary tryptophan or chemical inhibitors of tryptophan hydroxylase reduce brain levels of 5-HT, while selective 5-HT reuptake inhibitors such as fluoxetine (Prozac) increase the amount of synaptic 5-HT. Released serotonin acts on multiple 5-HT receptors found throughout the body in various tissues including brain, spinal cord, heart, blood, and gut.

Serotonin Receptor Structure and Function

5-HT receptors are classified and characterized by their gene organization, amino acid sequences, pharmacological properties, and second messenger coupling pathways. With the exception of the 5-HT_3 receptor, the 5-HT receptor family consists of G- protein-coupled receptors (GPCRs). The basic protein structure is predicted to contain seven transmembrane regions, three intracellular loops, and three extracellular loops, with the amino terminus being extracellular and carboxy terminus, intracellular (Figure 1A). These receptors are linked to their signal transduction pathways through guanine nucleotide triphosphate (GTP)-binding proteins (G protein). The sequence of events involves the activation of the cell surface receptor by 5-HT or drugs, binding of receptor and G protein, which promotes the exchange of bound GDP for GTP on the G protein. The G protein is comprised of α-, β-, γ-subunits; the $\beta\gamma$ dimer dissociates when receptor binds and both Gα and G$\beta\gamma$ have the ability to interact with effector enzymes. The subunit interactions promote activation or inhibition of adenylate cyclase or activation of phospholipase C. In turn, the effector enzymes generate second messengers that regulate cellular processes such as Ca^{2+} release, and protein kinases and phosphatases. This multistep enzymatic process amplifies receptor signal, and provides the possibility of regulation and crosstalk at multiple levels. The numerous 5-HT receptors are grouped in Table 1 by their traditional (primary) G protein second messenger linkage. The multiple levels of diversity generated by RNA splicing, RNA editing, and promiscuity of receptor G-protein activation are discussed later.

Serotonin Receptors that Inhibit Adenylyl Cyclase

The five members of the 5-HT_1 receptor family (5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, and 5-HT_{1F}) and the 5-HT_5

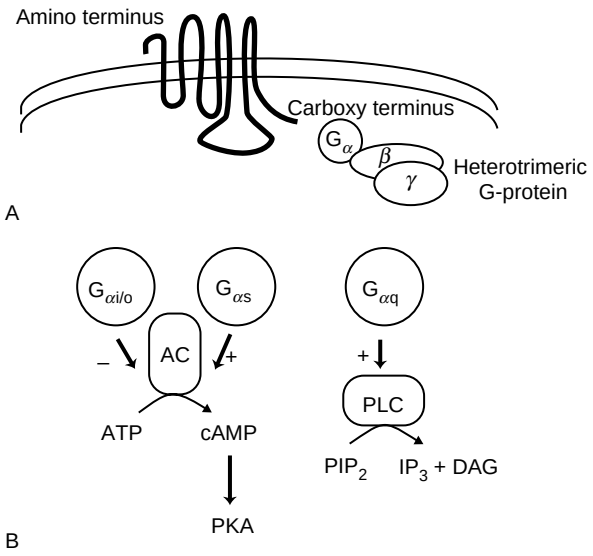

FIGURE 1 A. Schematic drawing of the basic components of a G-protein coupled receptor illustrating the extracellular amino terminus, seven transmembrane domains, three intracellular loops, three extracellular loops, intracellular carboxy terminus, and heterotrimeric G protein. B. The primary signaling pathways of the G-protein coupled receptors. Activation of $G_{\alpha i}$ protein inhibit AC resulting in the decrease of cAMP production. Receptors that stimulate AC through $G_{\alpha s}$ results in increased production of cAMP, with subsequent activation of PKA. Stimulation of PLCβ through $G_{\alpha q}$ results in the cleavage of PIP_2 into IP_3 and DAG.

receptor (5-HT_{5A}, 5-HT_{5B} subtype) couple primarily through $G_{i/o}$ proteins to inhibit the membrane-bound enzyme, adenylyl cyclase (AC). This inhibition of AC leads to a decrease of 3′5′-adenosine monophosphate (cAMP) molecules (Figure 1B). The 5-HT_1 receptors are the best characterized of this family. High densities of 5-HT_{1A} receptors are found on the cell bodies of 5-HT neurons in the brainstem nuclei, especially the dorsal raphe. In the dorsal raphe, the 5-HT_{1A} receptor functions as an autoreceptor that reduces cell firing when activated. The receptor elicits neuronal membrane hyperpolarization by activating G protein-linked K^+ channels. In addition, 5-HT_{1A} receptors are located on postsynaptic sites in the hippocampus and other limbic brain regions where they also produce hyperpolarization by opening K^+ channels. 5-HT_{1A} receptors are targets of a class of antianxiety drugs. Of the other 5-HT_1 receptors, much more is known about the 5-HT_{1B} and 5-HT_{1D} subtypes. These receptors are found in basal ganglia and frontal cortex, and function as terminal autoreceptors or heteroreceptors that modulate neurotransmitter release. 5-$HT_{1B/1D}$ heteroreceptors have been proposed to regulate the release of acetylcholine, glutamate, dopamine, norepinephrine, and γ-aminobutyric acid (GABA). Pharmacological and genomic (knock out/deletions) studies suggest that 5-HT_{1B} receptors are involved in aggressive behavior. 5-HT_{1D} receptors have a role in migraine headaches and many antimigraine drugs target this receptor. Less is known about 5-HT_{1F}, 5-HT_{1E}, and 5-HT_5 receptors.

G_q/G_{11}	2A	Activation of phospholipase C
	2B	
	2C	
No G protein	3	Ligand-gated ion channel

Serotonin Receptors Linked to Activation of Adenylate Cyclase

5-HT_4, 5-HT_6, and 5-HT_7 receptors are all coupled to activation of AC. These receptors are linked via the G protein G_s to AC producing an increase cAMP production (Figure 1B). Historically, the first signal-transduction pathway to be linked to a 5-HT receptor was stimulation of AC, characterized in mouse collicular neurons. This receptor now known as the 5-HT_4 receptor is also found in hippocampus and peripheral tissues. In the periphery, it releases acetylcholine in the ileum, contracts the esophagus and colon, promotes ion transport in the gut, and elicits cardiac contraction. In the brain, the receptor has been linked to modulation of release of acetylcholine, dopamine, 5-HT, and GABA. Little is known about the 5-HT_6 receptor. It is found in the striatum, amygdala, nucleus accumbens, hippocampus, and cortex. 5-HT_7 receptors are widely expressed in the brain, with highest expression levels in the thalamus and the hippocampus. The 5-HT_7 receptor may have role in circadian rhythms and thermoregulation. Both the 5-HT_6 and 5-HT_7 receptor have high affinity for many of the atypical antipsychotics leading to speculation of a role for this receptor in schizophrenia.

Serotonin Receptors Coupled to the Activation of Phospholipase C

The 5-HT_2 class of receptor (subtype 2A, 2B, 2C) activates the membrane-bound enzyme phospholipase C (PLC) which catalyzes the degradation of the inositol lipid, phosphotidylinositol 4,5 bisphosphate (PIP_2) with the production of inositol 1,4,5 triphosphate (IP_3) and diacylglycerol (DAG) (Figure 1B). IP_3 mobilizes Ca^{2+} from intracellular storage sites; Ca^{2+} then induces multiple responses in the cell including activation of calcium/calmodulin-dependent protein kinase enzymes that phosphorylate protein substrates in the cell. DAG activates another kinase, protein kinase C. The 5-HT_2 receptors are coupled via the G protein G_q or G_{11} to activation of PLC.

The 5-HT_{2A} receptor is involved in smooth muscle contraction and platelet aggregation. In the brain, 5-HT_{2A} receptors are found in cerebral cortex, claustrum, and basal ganglia. It is thought that hallucinogenic drugs exert their psychotrophic action by activating 5-HT_{2A} receptors. The 5-HT_{2B} receptor was first described from the stomach fundus and later was identified in the gut, heart, kidney, and lung. Its presence in the brain is less certain. The 5-HT_{2C} receptor is found in choroid plexus, where it regulates cerebral spinal fluid production and ion exchange between the cerebral spinal fluid and brain. The 5-HT_{2C} receptor is also found in various brain regions such as frontal cortex and amygdala. Activation of brain 5-HT_{2C} receptors can lead to hypoactivity and hypophagia. Moreover, atypical antipsychotic drugs block the activation of 5-HT_{2A} and 5-HT_{2C} receptors, indicating that these receptors may be involved in the pathophysiology of schizophrenia.

The Serotonin-3 Receptor is a Ligand-Gated Ion Channel

The 5-HT_3 receptor is different from the other 5-HT receptors in that it forms an ion channel that regulates the flux of ions. The structure of receptor is a pentamer, similar to the nicotinic acetylcholine receptor. The receptors are found on neurons in the hippocampus, nucleus tractus solitarius, and area postrema, as well as in the periphery. They are located on pre and postganglionic autonomic neurons and alter GI tract motility and intestinal secretion. When activated by 5-HT, the receptor triggers rapid depolarization due to an inward current by opening a nonselective cation channel (Na^+, Ca^{2+} influx and K^+ efflux). The receptor is possibly involved in nausea, vomiting, and irritable bowel syndrome.

Alternative Splice Variants of Serotonin Receptors

Functional diversity of proteins can be produced by alternative splicing events. Many of the 5-HT receptor genes contain introns that are subject to alternative splicing with the generation of multiple-receptor mRNAs encoding slightly different proteins, referred to as isoforms. Seven carboxy-terminal splice variants of the 5-HT_4 receptor have been described. The most interesting feature of these splice variants is the level of constitutive activity of the receptor, which is markedly increased. Constitutive activity is the ability of a receptor to activate second-messenger pathways spontaneously without the binding of an external ligand. Four carboxy-terminal splice variants of the 5-HT_7 receptor have been identified. The functional consequence of these variants is uncertain. An alternatively spliced variant of the 5-HT_{2C} receptor has been described, which encodes a truncated, nonfunctional protein. More work needs to be done to determine the physiological relevance of these RNA splicing events; nonetheless, is it clear that this process leads to additional diversity in 5-HT receptor signaling.

RNA Editing Produces Multiple Functional 5-HT_{2C} Receptor Isoforms

The 5-HT_{2C} receptor undergoes a unique process termed RNA editing to yield multiple-receptor variants. RNA editing is an enzymatic reaction that alters nucleotide sequences of RNA transcripts. For the 5-HT_{2C} receptor, five encoded adenosine residues are converted to inosines by double-stranded RNA adenosine deaminases. In the human 5-HT_{2C} receptor, the adenosines within the predicted intracellular second loop can be converted to inosine at the RNA level resulting in multiple mRNA species with the potential to encode 24 different protein variants (Figure 2). The extensively edited isoforms have different abundances in brain tissue, and the translated proteins exhibit different binding properties, and differential activation of second-messenger systems. For example, 5-HT exhibits a decreased potency when activating the fully edited, VGV, isoform of the human receptor compared with the unedited, INI, form and there is a rightward shift in the dose-response curve for phosphoinositide hydrolysis. In addition, editing can alter the ability of 5-HT_{2C} receptors to couple to multiple G-proteins. For example, the non-edited 5-HT_{2C} receptor functionally couples to G_q and G_{13}, whereas the edited 5-HT_{2C} receptors has less coupling to G_{13}. RNA editing may have clinical

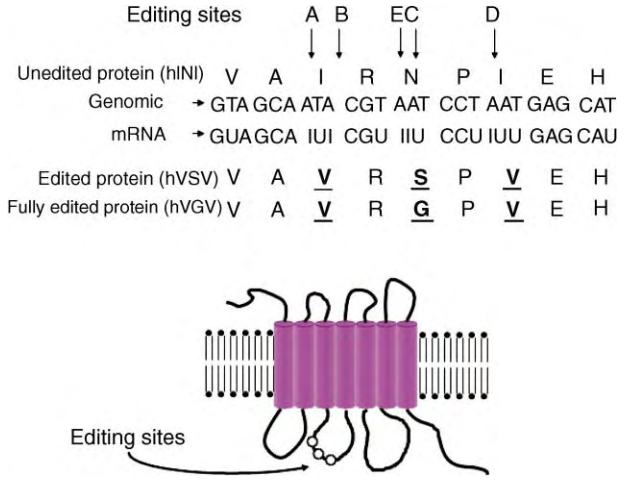

FIGURE 2 The positions of the editing sites within human 5-HT_{2C} receptors RNA and amino acid sequences are shown for hINI, hVSV, and hVGV edited isoforms of the 5-HT_{2C} receptor. These editing sites are located in the putative second intracellular loop.

significance; recent studies have indicated that alterations in the editing profile of the 5-HT_{2C} receptor are associated with the incidence of suicide and schizophrenia.

Single Nucleotide Polymorphisms Occur in the Serotonin Receptor Family

Normal genetic variations (single-nucleotide polymorphism, SNP) have been identified in almost all 5-HT receptors. Polymorphisms in the coding region of the gene have the potential to alter the receptor's ability to bind ligand, to activate signal-transduction pathways, or to adapt to environmental influences. For example, a polymorphism in the amino terminus of the human 5-HT_{1A} receptor attenuates the down-regulation and desensitization produced by the agonist 8-OH-DPAT. A polymorphic variant in the 5-HT_{1B} receptor in the putative third transmembrane domain alters the binding of the antimigraine drug, sumatriptan. In addition, a polymorphism in the carboxy terminus of 5-HT_{2A} receptor reduces the receptor's ability to mobilize internal Ca^{2+}. Currently, efforts are being made to link the occurrence of 5-HT receptor polymorphisms with various pathological disorders. Future progress in pharmacogenomics (using genetic information to predict drug response) may potentially lead to better design of serotonergic drugs to reduce side effects and target subpopulations of patients with specific therapies dependent on their genetic profile.

Promiscuous Coupling and Crosstalk between 5-HT Receptor Signal-Transduction Pathways

Promiscuous coupling is the ability of a receptor to couple to more than one signal transduction pathway. For example, the 5-HT_{1A} receptor can both inhibit and activate AC. As mentioned above, the primary coupling of this receptor is $G_{\alpha i/o}$ with subsequent inhibition of AC; this has been demonstrated both *in vivo* and in cultured cell systems. However, this receptor has been shown to activate AC, mediated by $\beta\gamma$ subunits released from $G_{\alpha i/o}$, rather than $G_{\alpha s}$ protein. This activation seems to require high receptor occupancy and high expression levels in cell expression systems. In addition, depending on cell type and experimental conditions, the 5-HT_{1A} receptor can activate or inhibit PLC. Many studies suggest that the G-protein $\beta\gamma$-subunits play a role in such crosstalk between signaling pathways. The 5-HT_{2C} receptor (as well as the 5-HT_{2A} receptor) is another promiscuous receptor that may activate multiple signal transduction pathways. The primary coupling of 5-HT_{2C} receptors is to activate PLC activity via G_q/G_{11} proteins to produce IP_3 and DAG. However, this receptor can activate other phospholipases, for example, phospholipase D through G_{13} proteins and free $\beta\gamma$-subunits. Phospholipase D can influence many neuronal functions including endocytosis, exocytosis, vesicle trafficking, and cytoskeletal dynamics. In addition, 5-HT_{2A} and 5-HT_{2C} receptors can activate phospholipase A-2 activity, which leads to the release of arachidonic acid and potential formation of bioactive eicosanoids such as the prostaglandins. There is evidence that 5-HT_{2A} and 5-HT_{2C} receptors differentially activate PLC compared to PLA2, dependent on the specific agonists employed. Moreover, there may be differences in the desensitization of these two pathways after repeated agonist treatment. The release of arachidonic acid can result in the activation of K^+ channels, regulation of neurotransmitter release, and can be a retrograde messenger. It is becoming apparent that specific 5-HT receptors interact with many G proteins, thereby regulating multiple signal-transduction pathways. This diversity may be a target for future therapeutics and interventions.

Summary: Potential Role of Receptor Diversity

There has been much speculation on the origin and significance of the 5-HT receptor diversity. One possible explanation for the numerous subtypes and variants is that the 5-HT neurotransmitter system emerged early

during evolution. Thus, there has been ample time for genetic variation and divergence to occur in the genetic encoding for the receptor proteins. Whatever the process of receptor diversity, the multiple receptor signaling has considerable biological significance. For example, inputs to the dorsal raphe nucleus are integrated into global 5-HT release, via both synaptic and volume transmission, that in turn can modulate multiple and diverse neuronal functions based on receptor subtype. Thus, one transmitter (5-HT) with multiple receptors/multiple pathways can introduce levels of complexity, yet specific physiological responses, that are localized to a given brain region or neural system. These responses can be cell-type specific or even cell-compartment specific. Furthermore, a level of fidelity is introduced based on the receptor's relative affinity for 5-HT. The exact nature of this diversity is at present unclear however the physiological implications are quite apparent, when considering the diverse role of these receptors in many physiological functions and disease states.

Glossary

autoreceptor A receptor on the neuronal cell body or presynaptic terminal can regulate its own cell firing and/or neurotransmitter release and synthesis.

constitutive activity Ability of a receptor to activate second-messenger pathways without the binding of an external ligand.

heteroreceptor A presynaptic receptor that regulates the release of neurotransmitter other than its own natural ligand.

promiscuous coupling The ability of a receptor to couple to more than one signal cascade.

RNA editing A process whereby the nucleotide sequence of RNA transcripts is chemically altered.

Biography

Elaine Sanders-Bush is a Professor of Pharmacology and Psychiatry at Vanderbilt University School of Medicine, Nashville, Tennessee. She earned a Ph.D. in pharmacology at Vanderbilt in 1967. Her research focuses on serotonin receptors, applying a multidisciplinary approach to define the role of signal transduction molecules and posttranscriptional and posttranslational modifications that alter receptor function. Dr. Sanders-Bush received a Merit Award from the National Institute of Mental Health in recognition of her research accomplishments.

Paul Gresch is a Postdoctoral Fellow in Dr. Sanders-Bush's laboratory. He earned a Ph.D. in cellular and clinical neurobiology from Wayne State University in Detroit, Michigan in 1999.

Siglecs

Ajit Varki
University of California, San Diego, Calfornia, USA

Sialic acid recognizing Ig-superfamily Lectins (Siglecs) are a major subset of the "I-type lectins." The latter are defined as animal proteins other than antibodies that can mediate carbohydrate (glycan) recognition via immunoglobulin(Ig)-like domains. Siglecs share characteristic amino-terminal structural features that are involved in their sialic acid-binding properties, and can be broadly divided into two groups: an evolutionarily conserved subgroup (Siglecs-1, -2, and -4) and a CD33/Siglec 3-related subgroup (Siglecs -3 and -5 to -11). While the precise functions of Siglecs are unknown, they seem to send inhibitory signals to the cells that express them, in response to recognition events on cell surfaces.

Historical Background and Definition

Sialic acids (Sias) are a family of nine-carbon acidic sugars that typically occupy a terminal position on glycan chains attached to the cell surface of "higher" animals. The immunoglobulin superfamily (IgSf) is an evolutionarily ancient group of proteins whose appearance predated the emergence of the immunoglobulins themselves. Until the 1990s, it was assumed that IgSf members (other than some antibodies) did not mediate carbohydrate recognition. Independent work on CD22 (eventually Siglec-2, a protein on mature resting B cells) and on sialoadhesin (Sn, eventually Siglec-1, a protein on certain macrophage subsets) revealed that their first Ig V-set-like domains could mediate Sia recognition. Homologous features of this V-set Ig-like domain and the adjacent C2-set domain then led to the discovery that two other previously cloned molecules—CD33 (eventually Siglec-3) and Myelin-associated Glycoprotein (MAG, eventually Siglec-4)—also had Sia-binding properties. Following consultation among all researchers working on these proteins, the common name "Siglec" and a numbering system were agreed upon. Criteria for inclusion of IgSf-related proteins as Siglecs are: (1) the ability to recognize sialylated glycans; and (2) significant sequence similarity within the N-terminal V-set and adjoining C2-set domains. Evaluation of the human and mouse genomes eventually defined 11 human and 8 mouse molecules that fulfill these criteria. Since humans have more Siglecs than mice and cloning of the mouse molecules initially lagged behind, the primary numbering system is based on the human molecules.

Two Broad Subgroups of Siglecs

While Siglecs -1, -2, and -4 appear to be evolutionarily rather conserved, the CD33/Siglec-3-related subgroup (Human Siglecs -3 and -5 to -11) appear to be rapidly evolving. Some CD33/Siglec-3-related Siglecs appear to have evolved as hybrids of pre-existing genes and/or by gene conversion. For these reasons, sequence comparisons alone do not allow the conclusive designation of the orthologue status of all mouse genes, and additional features such as gene position and exon structure must be taken into account. Until such issues are resolved, some mouse Siglecs have been assigned a temporary alphabetical designation.

Common Structural Features

All are single-pass Type 1 integral membrane proteins with extra-cellular domains consisting of uniquely similar N-terminal V-set Ig domains, followed by variable numbers of C2-set Ig domains, ranging from 16 in Sn/Siglec-1 to 1 in CD33/Siglec-3. Crystal structures for mouse Siglec-1 and human Siglec-7 indicate that the V-set immunoglobulin-like fold has several unusual features, including an intra-beta sheet disulphide and a splitting of the standard beta strand G into two shorter strands. These features along with certain key amino acid residues appear to be requirements for Sia recognition. In particular, a conserved arginine residue is involved in a salt bridge with the carboxylate of Sia in all instances studied to date.

Cell-Type Specific Expression

With the exception of MAG/Siglec-4 and Siglec-6, expression appears to be confined to the hematopoeitic

and immune systems. Within these systems each Siglec is expressed in a cell-type specific fashion, suggesting that each may be involved in discrete functions. However, systematic studies of Siglec expression outside the hematopoeitic system and during development have not yet been done.

Genomic Organization and Phylogeny

Based on probing for the canonical functional amino acids in the V-set domain of the typical Siglec, there is no evidence for Siglec-like molecules in prokaryotes, fungi or plants, nor in animals of the Protostome lineage, including organisms for which the complete genome is available. In contrast, it is relatively easy to find Siglec-like V-set domains in many vertebrate taxa (Sia recognition by fish and reptile Siglec candidates has not been formally shown as yet). While the relatively conserved Siglecs (-1, -2, and -4) have clear-cut single orthologues that are easy to identify in various species, the remaining "CD33/Siglec-3 related" Siglecs appear to have been evolving rapidly. Most of the latter genes are clustered together in a ~500 kb region on human chromosome 19q13.3–13.4.

Siglec Recognition of Sialic Acids and Their Linkages

The first two Siglecs discovered (Sn/Siglec-1 and CD22/Siglec-2) had strikingly different binding properties for sialosides—with Sn preferring alpha2–3 linked targets and CD22 being highly specific for alpha2–6 linkages. In the latter case, the binding affinity was in the low micromolar range. MAG/Siglec-4 also has an extended binding site that is even highly specific for the underlying sugar chain. There is also variable preference for certain types of sialic acids, with Sn and MAG not tolerating the common N-glycolyl modification of Sias. However the CD33/Siglec-3-related Siglecs are more promiscuous in their preferences for different types and linkages of Sias. Of course, many of the less common linkages and types of sialic acids have not been studied for Siglec recognition. The Golgi enzymes that are potential regulators of Siglec functions are primarily the sialyltransferases, and to some extent the enzymes which modify sialic acids. Some Siglecs show preferences for certain macromolecular ligands e.g., CD45 for CD22/Siglec-2, the mucins CD43, and Muc-1 for Sn/Siglec-1, and certain brain glycolipids for MAG/Siglec-4.

Potential Effects of Neu5Gc Loss on Human Siglec Biology

The most common Sias of mammalian cells are N-acetylneuraminic acid (Neu5Ac) and N-glycolylneuraminic acid (Neu5Gc). Humans are an exception, because of a mutation in CMP-sialic acid hydroxylase, which occurred after the time (~5–7 Ma) when we shared a common ancestor with great apes. The resulting loss of Neu5Gc and increase in Neu5Ac in humans could have potentially altered the biology of the Siglecs. For example, human cells have a higher density of Sn/Siglec-1 ligands than great apes, the distribution of Sn-positive macrophages in humans is different, and a much larger fraction of human macrophages is positive. Other emerging evidence suggests that there are further human-specific changes in Siglec biology that may be related to the loss of Neu5Gc.

Masking and Unmasking of Siglecs Binding Sites on Cell Surfaces

The initial assumption was that Siglecs were involved in intercellular adhesion. However, in most instances, their binding sites appear to be masked by Sias on the same cell surfaces on which they are expressed. Of course, external ligands with very high affinity/avidity may still compete for the endogenous masking ligands. There is also some evidence that unmasking can occur under certain conditions, but it is not known if this is biologically relevant. Overall, the significance of Siglec masking is unclear at this time.

Signaling Motifs in Cytosolic Tails

The CD33-related Siglecs have conserved tyrosine residues in the cytosolic tails, one of which corresponds to a canonical immunoreceptor tyrosine-based inhibition motif (ITIM). Various *in vitro* manipulations of these receptors indicate that these tyrosines are indeed targets for phosphorylation, and that they can modulate signaling events by recruiting certain tyrosine phosphatases. However, the true *in vivo* biological functions of these signaling motifs remain obscure. Another major unresolved question is: what is the connection between extra-cellular sialic acid recognition and signaling via the cytosolic motifs?

Known and Putative Functions of the Siglecs

Various lines of evidence indicate that MAG/Siglec-4 is involved in the maintenance of myelin organization

and in the inhibition of neurite outgrowth during regeneration after injury. It is also reasonably clear that CD22/Siglec-2 functions as an inhibitory component of the antigen receptor complex of B Cells, and is thus involved in regulating the humoral immune response. While Sn/Siglec-1 appears to mediate various macrophage adhesion events *in vitro* and *in vivo*, it is as yet unclear what the functions of these interactions are. Little is known about the functions of CD33-related Siglecs. It has been suggested that these molecules are involved in innate immunity. One hypothesis currently being tested is that Siglecs may be sensors for pathogens that have sialylated cell surfaces and/or express extra cellular sialidases.

Sigma Factors

John D. Helmann
Cornell University, Ithaca, New York, USA

The sigma(σ)-subunit of bacterial RNA polymerase is essential for the process of promoter selection. Interactions between σ and promoter region DNA allow RNAP to recognize and physically open the start sites for transcription initiation. The majority of transcription under most conditions requires a single, essential σ-factor (primary σ). However, in most bacteria there are a number of alternative σ-factors that can activate specific sets of target genes, as defined by their distinct promoter sequences, in response to changing environmental conditions. The activation of groups of coregulated genes (regulons) by alternative σ-factors complements the more familiar gene-regulation mechanisms that rely upon transcription repressors and activators.

Introduction

DNA serves as a storehouse for the genetic information of each organism, but is itself a silent repository. Only upon copying of DNA segments into RNA (transcription), and translation into protein, is the genetic potential of each organism (and each cell type in multicellular organisms) able to be realized. For example, our skin, blood, hair, liver, and lung cells all contain the same DNA, yet they have differentiated into functionally distinct cell types based largely on the selective expression of a small subset of the genes contained within each cell. Similarly, comparative genomics has led to the realization that the evolutionary processes that have led to the divergence of humans and mice, for example, have more to do with changes in "how" genes are regulated than with "which" genes are actually present in each organism. These examples highlight the importance of gene regulation: those mechanisms that selectively activate and repress different genes depending on cell type and local environment.

Gene Regulation in Bacteria

Most of the principles of gene regulation were first developed from studies of bacterial cells and, in particular, *Escherichia coli*. The first step in gene expression is the transcription of the genetic code from DNA into an RNA copy that usually serves to direct protein synthesis (translation). RNA polymerase (RNAP) is the enzyme that copies (transcribes) DNA into RNA.

In bacterial cells, most gene regulation occurs at the level of transcription. Genes that are expressed are actively transcribed and translated into their corresponding protein products. Conversely, genes that are silent are not copied into RNA. Thus, factors that act to control the activity of RNAP are central to many processes of gene regulation. These regulators include activator proteins, repressor proteins, and σ-factors. In order to appreciate how these factors can control gene expression, the biochemical properties of RNAP and the overall features of the transcription cycle are discussed first, followed by σ-factors.

Bacterial RNA Polymerase and the Transcription Cycle

In bacteria, RNAP is a multisubunit protein complex and contains both a catalytic core enzyme and a specificity subunit known as σ. The core enzyme (containing the β, β', two α, and the ω polypeptide chains) is able to catalyze the synthesis of RNA directed by a DNA template. Core enzyme associates reversibly with another polypeptide chain, σ, to form the holoenzyme.

RNAP copies particular DNA segments into RNA chains by first initiating RNA synthesis at a promoter site, elongating the RNA chain, and finally terminating transcription (the transcription cycle). In bacteria, many protein-coding genes are organized into cotranscribed groups called operons. In these cases, each mRNA product can direct the synthesis of multiple protein products.

The first step in the transcription cycle is promoter site localization and requires the presence of the σ-subunit: only holoenzyme can recognize promoter sites. Promoter sites are typically characterized by defined DNA sequences located just upstream of the site where RNA synthesis begins (designated the +1 site). For example, sequences centered ~10 bp upstream often have a sequence, designated the "−10 region", similar to 5′TATAAT3′. A different conserved sequence

(TTGACA) is usually located between 16 and 18 bp further upstream and is designated the "−35 region." Together, the −35 and −10 sequences provide the necessary information to allow RNAP to identify a promoter. Specific interactions between the σ-subunit of holoenzyme and the −35 and −10 elements allow RNAP to tightly engage the promoter region. Once bound, RNAP interacts with an extended region of DNA, ultimately contacting the DNA over a region of 60 or more base pairs (from −40 to +20).

Once bound at a promoter site RNAP melts the DNA over approximately one turn of the helix (from about −10 to +2) to expose the template strand of the DNA. The process of converting the double-stranded promoter region DNA into a locally melted structure (called the open complex) requires the action of σ-factor to initiate the melting process and is then driven by the association of the template strand of the DNA with the RNAP active site (comprised largely of the β- and β'-subunits). The open complex is then poised to initiate synthesis of an RNA chain. The region of DNA strand-separation is often referred to as the transcription bubble, to distinguish it from the otherwise double-stranded DNA in the surrounding regions of the genome.

The process of transcription elongation involves the assembly of ribonucleoside triphosphate precursors into an RNA chain containing the sequence complementary to the template DNA. During transcription elongation the DNA template is threaded through the active site of RNAP and, as a result, the transcription bubble is propagated down the DNA with melting of the DNA occurring as the DNA enters the active site and reannealing of the template occurring as the DNA exits the RNAP. The complex containing the DNA template, RNAP, and the growing RNA chain is often referred to as the ternary complex. As the growing RNA chain emerges from RNAP, it is thought to displace the σ-subunit, and the process of transcription elongation is continued by the core RNAP subunits. Elongating RNAP sometimes associates with additional protein factors known as elongation factors which can modulate its properties. In general, elongation is highly processive: the RNAP that begins an RNA chain continues synthesis until the chain is terminated.

The process of transcription termination, like that of initiation, is critical for the controlled expression of genetic information. At the end of many transcription units the DNA sequence encodes a G:C-rich stem loop structure in the RNA chain followed by a short region rich in uridine. This structure functions as a transcription terminator and interacts with the core RNAP leading to dissociation of the ternary complex and release of the terminated RNA chain. In other cases, protein factors such as the rho protein can bind to unstructured regions of RNA and trigger transcription termination. Once released by the termination reaction, the core RNAP must rebind to a σ-subunit to reform holoenzyme and thereby complete the transcription cycle.

Since bacteria lack a nuclear membrane, the processes of transcription and translation can be coupled: ribosomes can bind to the mRNA chain as it emerges from RNAP and immediately initiate protein synthesis. Indeed, along actively transcribed genes several RNAP molecules may be simultaneously engaged in RNA chain elongation with each RNA chain in turn bound by one or more ribosomes engaged in protein synthesis.

Biochemical Properties

As expected for a critical component of the transcription apparatus, σ-factors have been highly conserved through evolution. Indeed, σ-factors from one bacterium can function, at least in some cases, with the core RNAP from distantly related species. In general, all σ-factors share certain defining properties. They all bind to the core RNAP, apparently at a common binding site, to form a holoenzyme. The presence of σ-factor determines the sequence of the promoters that can be bound by the corresponding holoenzyme. The σ-subunit, in those cases that have been studied, also plays a role in the initiation of the DNA-melting step that is an obligatory prelude to transcription initiation. Often, although perhaps not always, σ is released from the ternary complex during the process of RNA chain elongation.

Bacterial σ-factors can be divided, based in part on their protein sequences, into two families: the σ^{70} and the σ^{54} families. All bacteria contain at least one member of the σ^{70} family that is required for the transcription of those genes essential for growth under virtually all conditions (so-called "housekeeping" functions). This is referred to as the primary (or class 1) σ-factor. In addition, most bacteria contain at least one (and as many as 50 or more) alternative σ-factors (Table I). These factors typically control genes needed for specialized functions that may only be expressed under particular growth conditions. Examples include genes needed for stress responses, motility, sporulation, uptake or transport of specific nutrients, or antibiotic production.

Most alternative σ-factors are structurally related to the primary (class 1) σ-factors and are therefore considered to be members of the σ^{70} family. Some alternative σ-factors (class 2) are very similar to the primary σ-factors but are, however, dispensable for growth. One example is the *E. coli* σ^{S} (RpoS) protein that becomes active in stationary phase cells. A much larger class of alternative σ-factors are those more distantly related in sequence to the primary σ-factor, and often lacking one or more the conserved regions characteristic of the class 1 and 2 proteins. These alternative σ-factors (classes 3, 4, and 5) control a wide-range of physiological processes and are often only

	σ^{ylaC}	*ylaC*	Unknown (ECF)

[a] ECF indicates a factor that is a member of the large extracytoplasmic function family of alternative σ factors.

active under very specific growth conditions. Prominent among these alternative σ-factors are the numerically abundant extracytoplasmic function (ECF) σ-factors (class 4 proteins) that appear, in general, to control functions related to the cell surface. Finally, many bacteria have alternative σ-factors with a distinctly different protein sequence and define the σ^{54} family. Unlike members of the σ^{70} family, the σ^{54}-factors form holoenzymes that almost always require ATP-dependent activator proteins to activate their target promoters. The prototype of the σ^{54}-family is the *E. coli* σ^{54} (RpoN) protein that is important for nitrogen regulation of gene expression (Table I). Similar proteins in other bacteria control a variety of other functions.

The division of σ^{70}-family members into different structural classes is based in large part on the comparison of their protein sequences. All primary (class 1) σ-factors (and the closely related class 2 factors) have four conserved regions. Region 1 contains an autoinhibitory domain that prevents the free σ-factor from interacting with DNA. This inhibition is relieved when σ associates with core RNAP. Region 2 contains the key determinants for recognition of the −10 promoter element and for initiation of DNA-melting. Region 3 functions as a spacer domain between regions 2 and 4. Region 4 contains the elements that recognize the −35 promoter element and also serves as a site of contact for some transcription activator proteins. Recent advances in the determination of three-dimensional structures for both σ-factors and holoenzyme have made it clear that these protein sequence regions correspond to folded domains in the σ-structure. The two domains that are required for recognition of promoters, domains 2 and 4, are common to all σ^{70}-family members. In contrast, much of domains 1 and 3 is often deleted in alternative σ-factors.

Roles of σ in Gene Regulation

Just as DNA-binding transcriptional repressors and activators can control the activity of RNAP at promoter sites, alternative σ-factors provide a powerful avenue for the activation of specific sets of genes (the σ-factor regulon) during cell differentiation or in response to various stress conditions. The activity of alternative σ-factors can, in turn, be controlled in numerous ways. In some cases, the σ-factor is only synthesized under very specific conditions. In other cases, the σ-factor is synthesized but is maintained in an inactive state by binding to an inhibitory protein (called an anti-σ-factor) or it is synthesized as an inactive precursor protein that only becomes active when an inhibitory peptide is cleaved by proteolysis. Anti-σ-factors are, in many cases, associated with the cell membrane and thereby able to perceive signals from the external environment. In any event, once the active σ-factor is synthesized or released it can compete with other σ-factors for binding to core RNAP and thereby redirect some of the RNAP to its cognate target promoters.

Roles for alternative σ-factors in bacterial gene regulation are legion. For example, alternative σ-factors play key roles in the expression of heat shock genes, iron uptake systems, the developmental program of sporulation (in gram-positive bacteria), synthesis of flagella and chemotaxis machinery, and various stress responses. A summary of the roles of σ-factors in the two best-studied bacterial systems is presented in Table I.

Phylogenetic Distribution

σ-factors are always found associated with bacterial RNAP but have been functionally replaced by other proteins in the more complex RNAP characteristic of eukaryotes and Archaea. However, σ-like factors

are found in the chloroplasts of photosynthetic eukaryotes which are descended from a cyanobacterium. In contrast to chloroplasts, the transcription apparatus in present day mitochondria is most similar to certain bacteriophage-encoded, single-subunit RNAPs and is unlike the multisubunit RNAP of either bacteria or eukarya.

Biography

John D. Helmann is a Professor in the Department of Microbiology at Cornell University in Ithaca, New York. His principal research interest is the mechanisms of gene regulation in the gram-positive bacterium *Bacillus subtilis*. Major research directions include the characterization of alternative σ-subunits and regulators that respond to metal ions and oxidative stress. He received a Ph.D. in biochemistry from the University of California, Berkeley and did postdoctoral research at Harvard Medical School.

Sliding Clamps in DNA Replication: *E. coli* β-Clamp and PCNA Structure

Eric R. Goedken and John Kuriyan
University of California, Berkeley, California, USA

In the absence of additional protein factors, the DNA polymerases responsible for replicating entire genomes have a strong tendency to release from the DNA template after synthesizing short segments of DNA. Such enzymes are described as having low "processivity," meaning that polymerase adds only a small number of nucleotides to the growing chain before coming off the DNA template. Rapid replication of the millions of base pairs that constitute the genetic material of cells requires DNA polymerases with extremely high processivity. This is achieved by the utilization of proteins known as "sliding DNA clamps" that convert the poorly processive core polymerase enzymes (capable of synthesizing only tens of nucleotides without dissociation) to highly processive enzymes (capable of synthesizing several thousand nucleotides without dissociation).

Sliding clamps are dimeric or trimeric proteins that form a circular collar through which DNA is threaded. The polymerase enzyme is loosely tethered to the sliding clamp, thereby maintaining proximity to the DNA even when it does let go of the template. The detailed molecular architecture of these clamps is highly conserved from bacteria to eukaryotes, reflecting the fundamentally important role played by these proteins in DNA replication in all organisms.

Clamp Structure and Function

In the well-studied *Escherichia coli* system, the processivity clamp is called the β-subunit or β-clamp, and the polymerase responsible for replicating the genome is DNA polymerase III. The β-clamp is placed at primer/template junctions in an ATP-dependent manner by a complex of protein subunits known as the clamp loader (γ/τ) complex. In eukaryotes, the homologous sliding clamp is called proliferating cell nuclear antigen (PCNA), and the polymerase chiefly responsible for DNA replication is polymerase δ and its clamp loader is the replication factor C(RFC) complex.

Interestingly, clamps from bacteria and eukaryotes differ in the number of subunits that make up the clamp. Prokaryotic clamps such as β, are dimers, whereas eukaryotic PCNA is a trimer. Despite this difference in subunit stoichiometry, the crystal structures of the clamps from both *E. coli* and the yeast PCNA (as well as a number of others) reveal a very similar overall architecture (Figure 1). Each monomer in β consists of three similar domains containing two helices and two four-stranded β sheets, whereas in PCNA there are two of these conserved domains per monomer. Each assembled clamp complex then contains six of these domains despite the difference in subunit number. The conservation of this overall structure of the clamps throughout evolution is demonstrated by the presence of similarly shaped sliding clamps in archaebacteria and in certain bacteriophages such as T4 and RB69.

Both PCNA and β are highly negatively charged proteins. The distribution of charge has a marked asymmetry with positive charge concentrated around the interior hole through which negatively charged DNA can pass (Figure 1). In both proteins the α-helices of DNA, that line this central hole are oriented roughly perpendicular to the direction of the phosphate backbone of DNA as modeled inside the clamp. The orientation of the helices as well as their separation from DNA suggests that the electrostatic interaction between the protein and DNA is non-specific, thereby facilitating the sliding of the protein ring along the nucleic acid strands.

Biochemical results have indicated that the clamp is not broken into separate monomers prior to loading onto DNA and that only one of the two interfaces of the *E. coli* β-clamp dimer is opened before loading. Molecular dynamics simulations of β suggest that each monomer has an energetic preference for a state that is less "curved" than required to close both interfaces in the circular dimeric ring. This may provide a "spring-loaded" tension that makes it easier for the clamp loader to open the clamp.

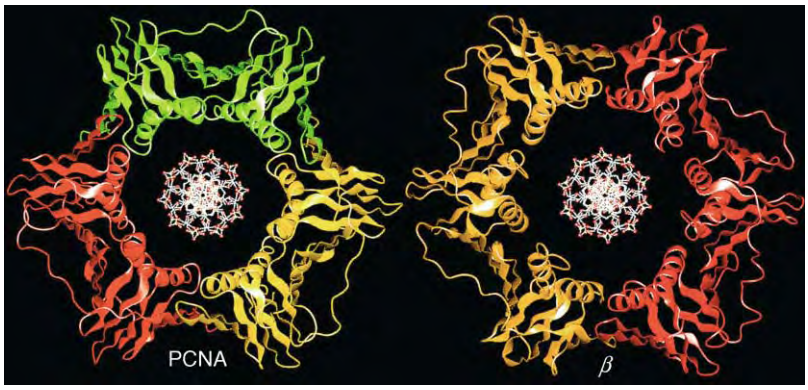

FIGURE 1 Ribbon diagrams of the structures of processivity clamps. DNA is shown as modeled in the interior of each clamp. Left, yeast PCNA; right, *E. coli* β-clamp.

Interaction with Other Proteins

Extended and flexible C-terminal segments of DNA polymerases are responsible for their interaction with the sliding clamps. A crystal structure of a trimeric bacteriophage clamp bounds to a peptide corresponding to the C-terminal region of the cognate DNA polymerase has been determined, showing the region of the clamp that interacts with the polymerase. This binding region turns out to be similar to the one seen earlier for the interaction between an inhibitory peptide (a segment of the cell-cycle protein p21/waf1-cip1) bound to PCNA. The peptide binds in a hydrophobic interface between the two domains that make up the clamp subunit. A recent crystal structure has revealed that the interaction between the clamp loader and the clamp has elements that resemble the polymerase-clamp interaction. A specific helix in the N-terminal domain of the δ-subunit of the *E. coli* clamp loader complex plugs into hydrophobic region of the clamp between the second and third domain of β. This suggests that the site of interaction for both the clamp loader and polymerase is located on the same region of the clamp and is likely conserved throughout the diversity of sliding clamps utilized in nature.

Clamp Loader Structure

The clamp loader in *E. coli* (γ complex) consists of five polypeptide chains: three γ-subunits, a δ-subunit and a δ′-subunit. The δ-subunit mentioned above is the "wrench" that opens the β-clamp. The wrench subunit is controlled by the coordinated actions of three γ "motor" subunits that hydrolyze ATP and an inert, δ′ "stator" subunit. A similar pentameric complex having sequence homology exists in eukaryotes (the RFC complex), and this loads the eukaryotic clamp (PCNA) onto DNA.

Structural studies have shown that each of the subunits of the *E. coli* clamp loader has a similar three-domain fold, with the first two domains being structurally related to the subunits of AAA+ATPases. Similar results have been obtained for the small subunit of the archaebacterial clamp loader complex. A flexible linker region tethers these nucleotide-binding domains to a helical C-terminal domain that clusters the five subunits into a pentameric assembly (Figure 2). ATP binding is required for the activation of the clamp loader, and nucleotide is potentially bound in each of the three γ-subunits. Once ATP is bound, the γ complex can bind to β and open one of its dimeric interfaces.

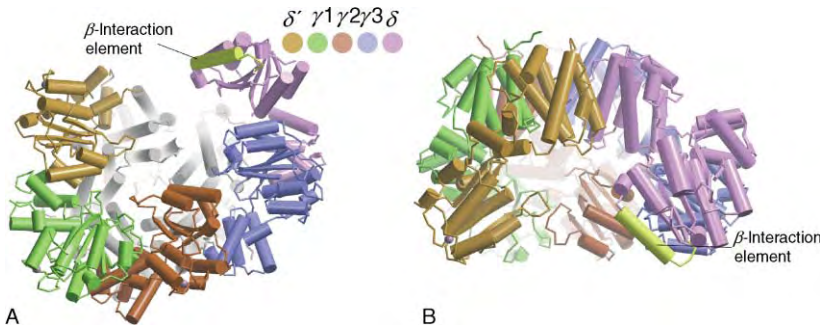

FIGURE 2 Two ribbon diagram of the structure of the *E. coli* clamp loader.

Upon interaction with DNA, the γ complex hydrolyzes these bound nucleotides and releases the β-clamp around the nucleic acid, where it is ready to tether the polymerase.

The mechanism by which ATP binding activates the clamp loader for binding to the clamp remains poorly understood, as is mechanism for coupling ATP hydrolysis to release the clamp around DNA at the proper sites.

Biography

John Kuriyan is Chancellor's Professor in the Department of Molecular and Cell Biology and Department of Chemistry at the University of California at Berkeley and is an investigator in the Howard Hughes Medical Institute. His principal fields of interest are DNA replication and signal transduction. These areas are under study in his research group through structural techniques like X-ray crystallography, but also through molecular dynamics simulations and biophysics. He holds a Ph.D. from the Massachusetts Institute of Technology and received postdoctoral training at Harvard University.

Eric R. Goedken is an American Cancer Society postdoctoral fellow at the University of California, Berkeley, where he studies the mechanism of DNA polymerase clamp loaders.

Small GTPases

Adam Shutes and Channing J. Der
University of North Carolina, Chapel Hill, North Carolina, USA

Small GTPases (20–25 kDa) are a class of guanine nucleotide-binding proteins involved in the regulation of numerous signaling pathways and cellular processes in eukaryotic cells. The small GTPases are monomeric, distinguishing them from the heterotrimeric GTPases which are comprised of three separate subunits, α, β, and γ. Similar to the G α-subunits, the small GTPases bind GDP and GTP with high affinity and catalyze the hydrolysis of the covalent bond between the two terminal phosphate groups of bound GTP producing protein-bound GDP and a solvent-free phosphate group. The cleavage of this bond releases energy that changes the conformation of small GTPase from a GTP-bound one to an inactive GDP-bound conformation. An intrinsic GDP/GTP exchange activity allows the formation of the active GTP-bound conformation, which then interacts with one or more effector targets to promote a specific cellular response. This two-state structural change is fundamental for small GTPase biological function as a regulated binary switch.

Identification and Classification of Small GTPases

The first and prototypical small GTPases were identified as the proteins encoded by the retrovirus oncogenes of the Harvey and Kirsten rat sarcoma (Ras) viruses (Figure 1). Since its initial discovery, over 150 mammalian proteins have been identified which show varying degrees of both amino acid sequence and structural similarity with Ras proteins. Small GTPases were identified by a variety of approaches, some fortuitously (e.g., Rho), in yeast genetic studies (e.g., Rabs), and others by nucleic acid sequence homology (e.g., Ral, Rap). These 'Ras superfamily' proteins are further divided into families (e.g., the Rho and Rab families) by sequence identity and cellular function. The major branches are the Ras, Rho, and Rab families, with smaller branches including Arf, Sar, Rad/Gem, and Ran proteins (Figure 2). Small GTPases are well conserved in evolution, with structural and functional homologues of many of the mammalian proteins found in yeast, flies, worms, and plants.

In addition to the GTPase activity, a feature of many small GTPases is their modification by lipids. Members of the Ras, Rho, and Rab families are modified by either the C15 farnesyl or C20 geranylgeranyl isoprenoid lipid (Figure 3). Protein prenylation is signaled by carboxyl-terminal sequences. For Ras and Rho small GTPases, this lipid modification occurs at a particular motif, the CAAX tetrapeptide motif, consisting of a cysteine followed by any two hydrophobic amino acids, and a terminal X residue that determines whether the protein will be modified by farnesyltransferase (X = S, M) or geranylgeranyl transferase I (X = L, F). Rab proteins possess cysteine-containing carboxyl-terminal motifs (CC, CXC, CCX, CCXXX) that signal geranylgeranyl isoprenoid post-translational modification by a third prenyltransferase, geranylgeranyltransferase. Arf proteins are cotranslationally modified by the C14 myristate fatty acid at the amino-termini. Lipid modification is typically critical for protein function and facilitates the association of small GTPases with specific membrane compartments. Ran is unusual among the small GTPases and does not undergo any lipid modification.

GDP/GTP Regulation and Structure

The Small GTPase Cycle and its Regulation

The "on" and "off" switching nature of small GTPases can be best described as a GDP/GTP cycle (Figure 1). The processes of nucleotide exchange and GTP hydrolysis are able to occur at basal intrinsic rates that are characteristic to each small GTPase. However, there are two classes of regulatory proteins which act to increase the rate of these processes by several orders of magnitude: guanine nucleotide exchange factors (GEFs) increase the rate of nucleotide exchange, and GTPase-activating proteins (GAPs) increase the rate of the GTP hydrolysis. The Rho and Rab families of small GTPases have further regulatory proteins called guanine nucleotide dissociation inhibitors (GDIs).

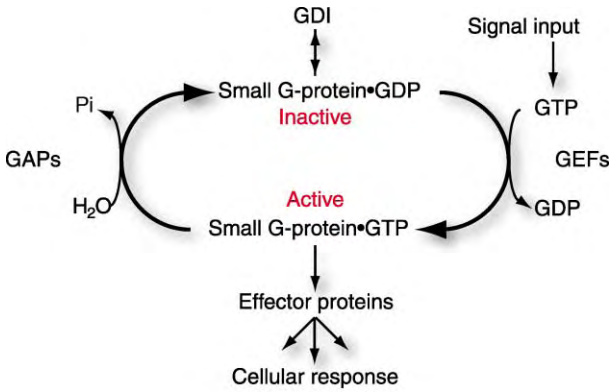

FIGURE 1 Small GTPases function as GDP/GTP-regulated molecular switches. The intrinsic GDP/GTP exchange activity is accelerated by guanine nucleotide-exchange factors (GEFs) to promote formation of the active, GTP-bound protein, whereas GTPase-activating proteins (GAPs) stimulate the intrinsic GTP hydrolysis activity to stimulate formation of the inactive, GDP-bound protein and the release of free phosphate (P_i). Guanine nucleotide dissociation inhibitors (GDIs) prevent nucleotide exchange as well as GAP stimulation. Small GTPase activation is most commonly mediated by a signal input that activates GEF function. The GTP-bound GTPase displays higher affinity for downstream effector targets, leading to stimulation of various cellular responses.

Guanine Nucleotide Exchange Factors

GEFs provide an important mechanism for regulated activation of small GTPases, and therefore their downstream effects. They are responsible for exchanging free cytosolic GTP for bound GDP. Exchange is not an active process; rather GEFs act to facilitate exchange of one nucleotide for another nucleotide, and it is the large excess of cytosolic GTP that favors the GTP exchange rather than GDP exchange. Furthermore, the binding of GTP to a small GTPase·GEF complex weakens the affinity of the GEF for the small GTPase causing their dissociation. The binding of GDP does not cause dissociation of the complex.

GEFs have been identified for many small GTPases. They are related by sequence within, but not between, the GEFs for specific small GTPase families. For example, there are currently two structurally distinct families of GEFs, which act upon either the Ras family (CDC25 homology domain-containing proteins) or the Rho family (Dbl homology domain-containing proteins) small GTPases. These two families act on the different Ras/Rho proteins since their catalytic domains are different, although their overall mechanism appears to be the same.

Different GEFs are Activated by Different Signaling Cascades Specific members of the Ras and Rho GTPases can be activated by multiple GEFs; for example, there are at least 30 characterized Ras family GEFs, and over 150 Rho family GEFs. GEFs often contain a large number of different signaling protein domains which allow them to respond to a wide variety of signals and thus allow divergent signals to converge on a common small GTPase (Figure 4). In contrast, only a handful of GEFs have been identified for Rab family proteins, the largest family of small GTPases.

A common mechanism for activation of GEFs is through their recruitment to the membrane. The classical model of small GTPase activation is that of Ras and its GEF, son of sevenless (Sos). Upon activation of a receptor protein tyrosine kinase (e.g., EGFR) and its autophosphorylation of specific tyrosine residues, an adaptor protein, Grb2, is recruited to the plasma membrane via its Src homology 2 (SH2) domain (Figure 4). Grb2 interacts

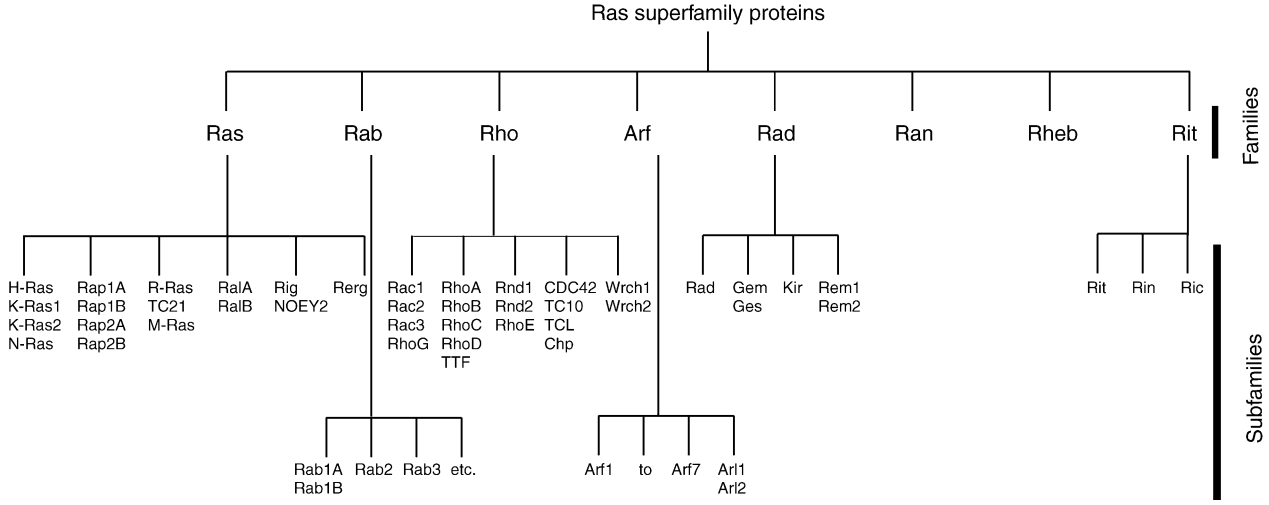

FIGURE 2 Small GTPase family.

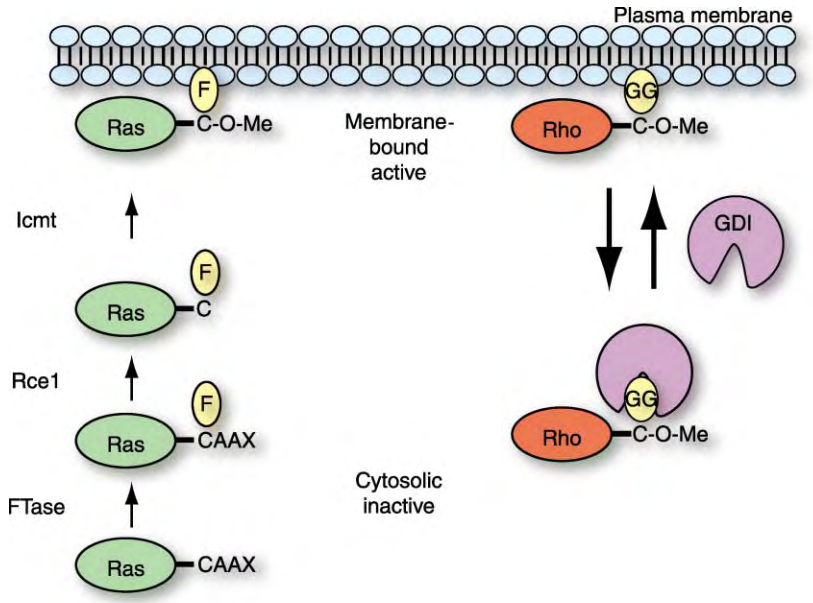

FIGURE 3 Post-translational modification by prenylation is important for the function of some small GTPases. Members of the Ras and Rho family of small GTPases terminate with CAAX tetrapeptide sequences that signal a series of post-translational modifications that promote association with membranes that is critical for function. For example, Ras proteins are synthesized initially as inactive, cytosolic proteins. Ras proteins are first modified by farnesyltransferase (FTase) which catalyzes the covalent addition of a C15 farnesyl isoprenoid (F) lipid to the cysteine residue of the CAAX motif. This is followed by Rce1-mediated proteolytic removal of the AAX peptide and Icmt-catalyzed carboxylmethylation (O-Me) of the now terminal farnesylated cysteine residue. Rho GTPases undergo the same series of modifications, with the first step catalyzed by geranylgeranyltransferase I (GGTaseI) and addition of the geranylgeranyl isoprenoid (GG). Rho GDIs recognize the prenylated form of Rho GTPases and prevent its association with membranes, thus leading to Rho GTPase inactivation.

via Src homology 3 (SH3) domain interaction with specific sequences on Sos, and recruits Sos to the membrane. The plasma membrane-bound Ras family proteins are now activated. Regulation of the production of membrane-bound lipids, such as diacylglycerol (DAG) or phosphatidylinositol 3,4,5-trisphosphate (PIP_3), are other mechanisms that regulate GEF membrane association and activation (Figure 4).

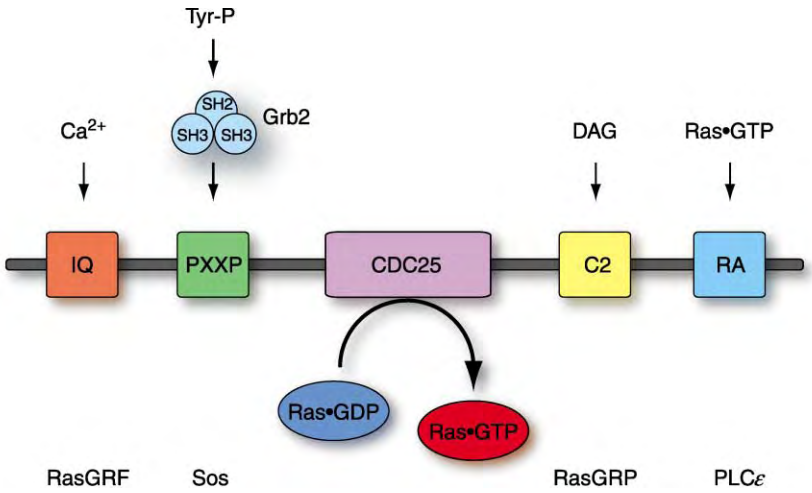

FIGURE 4 Ras guanine nucleotide exchange factors are activated by diverse upstream signals. Diverse extracellular signals promote Ras activation by stimulating the activity of different Ras GEFs. All Ras GEFs share a common CDC25 homology domain that catalyzes nucleotide exchange. The different Ras GEFs can be activated by calcium (RasGRF) through an IQ GAP homology domain, by tyrosine phosphorylation and interaction with the Grb2 adaptor protein and proline-rich sequences (PXXP) in Sos, by diacylglycerol (DAG) association with a C2 domain (RasGRP) or by association of Ras Association domains (RA) with other activated Ras family members.

GTPase Activating Proteins

The intrinsic hydrolysis rate of the majority of small GTPases is surprisingly slow, and sufficiently slow to be of little consequence in signaling cascades. Signals would not only be transduced too slowly, but the "on" state would persist for an excessive period of time. GEFs act to accelerate small GTPase activation, whereas GAPs act to accelerate the small GTPase hydrolysis and therefore make the signaling more transient (Figure 1).

In comparison to the vast number of Ras and Rho GEFs, the number of GAPs which act upon small GTPases is significantly smaller, fewer than ten for all the Ras family GAPs. There are structurally distinct GAPs for Ras and Rho family GTPases. Similar to the GEFs, these GAPs also typically contain additional sequences beyond the GAP catalytic domain. These sequences are involved in regulation, although much less is known about GAP regulation. Additionally, GAPs may possess functions, such as the effector function described for some Ras GAPs. Finally, the mutated Ras proteins found in human cancers contain single amino acid substitutions at glycine 12 (G12) or glutamine 61 (Q61), which render these mutants insensitive to GAP stimulation (Figure 5). These GTPase-deficient mutants are persistently GTP-bound in the absence of upstream stimulation and consequently cause deregulated effector activation. The experimental introduction of analogous mutations at residues corresponding to G12 and Q61 also renders other small GTPases GAP-insensitive and constitutively activated. Some wild-type small GTPases, however, possess naturally occurring sequence variation at these two residues, and are persistently GTP-bound proteins (e.g., RhoE/Rnd3). Thus, while GDP/GTP regulation is the major mode of small GTPase regulation, for some GTPases, regulation by other mechanisms (e.g., gene transcription, membrane association) is also important.

Other Small GTPase Regulatory Mechanisms

Guanine Nucleotide Dissociation Inhibitors (GDIs) GDIs have been identified for Rho and Rab proteins. Two distinct negative regulatory functions have been ascribed to GDIs. First, they bind to and mask the isoprenoid lipid modification in the carboxyl terminus of the small GTPase, thus preventing the association of the small GTPase with membranes (Figure 4). Second, their binding perturbs GAP and GEF regulation, preventing small GTPase activation. Three Rho GDIs and one Rab GDI have been described and can recognize multiple family members. The mechanisms of regulation of GDI activity are unclear, but may involve phosphorylation.

Small GTPase Structure

Small GTPases and Conserved Structural Elements

The structure of many forms of Ras proteins has been determined and has established the general rules and requirements for all small GTPases. H-Ras was the first small GTPase to have its structure solved, and

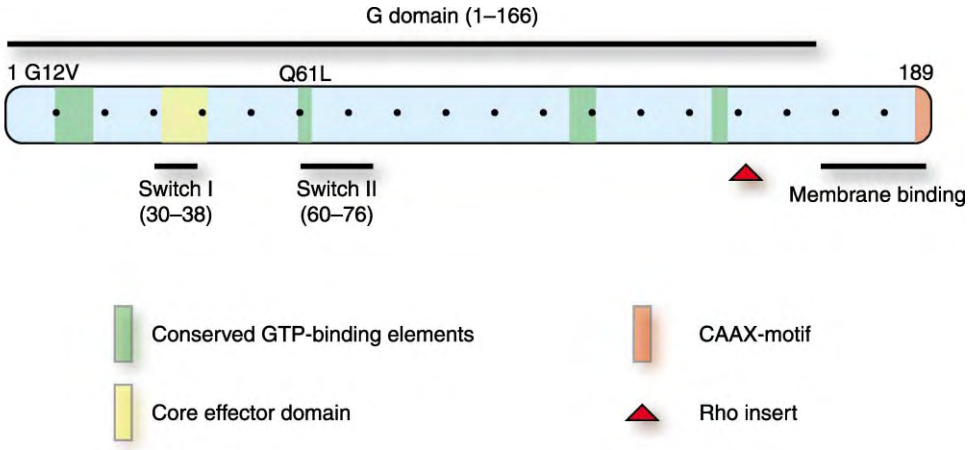

FIGURE 5 Small GTPase functional domains. Members of the small GTPase family share sequence similarities that define distinct functional domains. The residue numbers corresponding to H-Ras are shown. The G domain is comprised of a set of four conserved sequence elements involved in GTP-binding it alone is sufficient for the guanine nucleotide binding and GTPase activity, and is structurally similar among small GTPases. Mutated forms of Ras proteins are found in human cancers and possess single amino acid substitutions (e.g., G12V or Q61L) that render the protein insensitive to GAP stimulation and result in constitutively activated proteins. Similar mutations in other GTPases also result in constitutively activated proteins. Ras and Rho membrane association is facilitated by COOH-terminal sequences that include the CAAX motif as well as sequences upstream of this sequence. Effector binding involves the core effector domain (residues 32–40) and residues that change in conformation in the GDP- and GTP-bound states (switches I and II). Rho GTPases possess additional sequences (Rho insert) not found in other small GTPases. Some small GTPases contain additional NH_2- or COOH-terminal sequence extensions.

subsequent structures of related proteins have demonstrated a conserved overall canonical structural fold (designated the G domain) shared with all GTPases, but with variations in features for different small GTPase-family members (Figure 6).

All small GTPases possess a set of conserved sequence elements shared with other GTPases which represent the GDP/GTP nucleotide-binding pocket and GTP hydrolytic machinery (some, however, are GTPase deficient due to key residue changes), since the binding and hydrolysis of guanine nucleotides is the uniting element throughout small GTPases. A significant observation from Ras structural studies was the discovery of structural differences between the GDP- and GTP-bound forms, which are localized in two regions, termed switch I (residues 32–38) and switch II (residues 59–67). Similar switch-I and switch-II conformation changes have also been identified for the GDP- and GTP-bound states of other small GTPases.

Switch I and switch II show sequence divergence between families, although their loop-like structures are conserved. In addition to reflecting the nucleotide-bound state of the small GTPase, the switch regions are also involved in the interaction of small GTPases with effectors as well as GAPs and GEFs. The divergent sequence composition of these two regions contributes to the specificity of different small GTPases for these different binding partners.

Members of the Rho-family small GTPases possess a unique structural feature absent on all other small GTPases. The Rho family contains an insertion of 13 amino acids, called the insert region, positioned between Ras residues 122 and 123, which forms a surface-exposed loop (Figure 5). The primary sequence and secondary conformation of this insert region varies within the Rho family. Although the conformation of the insert region is not influenced by nucleotide binding, there is evidence that it is involved in effector interaction and activation.

Finally, other small GTPases possess additional amino- or carboxyl-terminal extensions important for function. For example, Arf and Sar1 proteins contain an amino-terminal extension necessary for insertion into and interaction with the membrane, whereas Ran has an elongated carboxyl-terminus that is crucial for its function in nuclear transport.

Diverse Biology and Function of Small GTPase

Despite their strong structural and biochemical similarities, small GTPases facilitate a remarkably divergent spectrum of cellular functions. This diversity is accomplished by the input signals that regulate the distinct GAPs and GEFs to modulate GDP/GTP cycling, and by the unique set of effectors that are recognized by the GTP-bound forms of small GTPases within and between families, resulting in many different cellular responses.

Ras Proteins as Signaling Nodes and Regulators of Cell Proliferation

The frequent mutation of Ras proteins in human cancers has made these small GTPases the most intensely studied

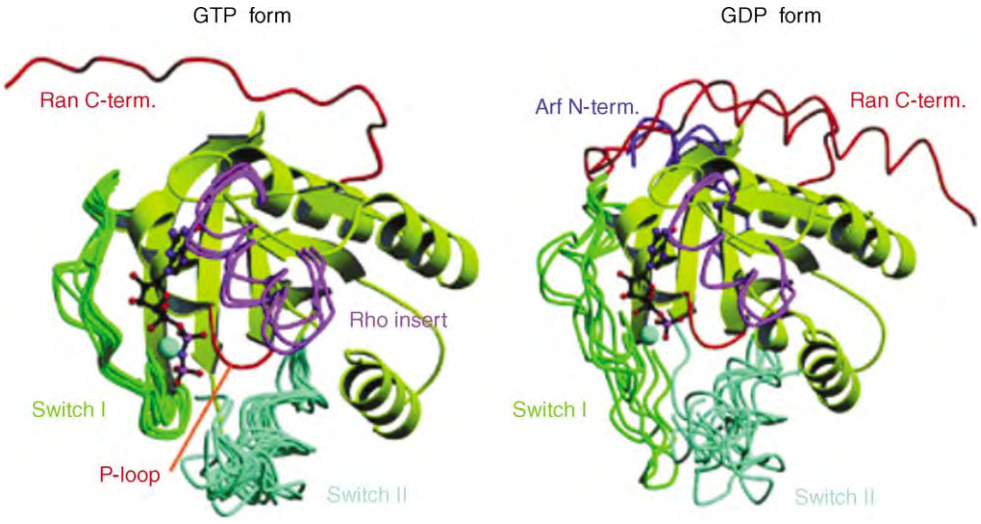

FIGURE 6 Canonical GTP conformation of small GTPases. Superimposition of a selection of Ras superfamily proteins on the G domain show the similar conformation changes in the switch-I and switch-II regions in the GDP- and GTP-bound forms. Rho GTPases possess additional sequences (Rho insert) not present in any other Ras superfamily proteins. Some small GTPases possess additional NH_2- and COOH-terminal sequences: the COOH-terminus of Ran is in red, the Rho insert in magenta and the Arf NH_2-terminal helix in blue.

and best characterized. Ras proteins serve as signaling nodes, where a wide diversity of extracellular signals such as growth factors (epidermal growth factor, platelet-derived growth factor), hormones (insulin), cytokines (interleukin-1), and the extracellular matrix proteins (via integrins) converge on and cause activation of Ras. Activated Ras in turn interacts with and regulates the activities of downstream effectors with highly divergent biochemical functions. Recent reviews have provided detailed discussions of Ras effector utilization. Therefore, we have highlighted various themes.

The Raf serine/threonine kinases are important effectors of Ras and facilitate activation of the ERK mitogen-activated protein kinase cascade (Figure 7). Ras promotes Raf activation by promoting the association of the normally cytosolic Raf with the plasma membrane, where a complex set of events, which includes protein phosphorylation, activates Raf kinase function. Activated Raf then phosphorylates and activates the MEK1 and MEK2 dual specificity protein kinases, which phosphorylate and activate ERK1 and ERK2. Activated ERK translocates to the nucleus and phosphorylates a variety of targets that include Ets family transcription factors. The Raf/MEK/ERK kinase cascade contributes significantly to the growth-regulatory functions of Ras.

The second best-characterized class of Ras effectors is the phosphatidylinositol 3-kinases (PI3K), a family of lipid kinases (Figure 7). A major activity of PI3K is the conversion of membrane-associated phosphatidylinositol 4,5-bisphosphate (PIP_2) to phosphatidylinositol 3,4,5-trisphosphate (PIP_3). PIP_3 in turn can regulate the activity of a diverse range of targets, including activation of the Akt serine/threonine kinase and Rac GEFs, via PIP_3 interaction with pleckstrin homology domains present in these proteins.

One significant theme that has emerged is that a number of Ras effectors are GEFs that link Ras with other small GTPases (Figure 7). First, there is a family of Ral GEFs that binds activated Ras and promotes activation of RalA and RalB, members of the Ras family of small GTPases. Second, Rin1 functions as a GEF for Rab5, thus linking Ras activity with regulation of vesicular trafficking. Third, Ras binds and activates Tiam1, which functions as a GEF for Rac. Fourth, Ras binds phospholipase C epsilon, which also contains a CDC25 homology domain that may activate the R-Ras small GTPase.

While Ras GTPases function as positive regulators of cell proliferation, some small GTPases appear to possess opposing functions and may function as tumor suppressors rather than oncogene proteins. This includes Rerg, NOEY2/ARH1, Rig, and DBC2. Thus, while these proteins share significant sequence and biochemical functions with Ras, clearly their effector functions are quite distinct. Additionally, whereas mutational activation of Ras proteins is associated with oncogenesis, it is the loss of gene expression of these proteins that accounts for their loss of function in tumor cells.

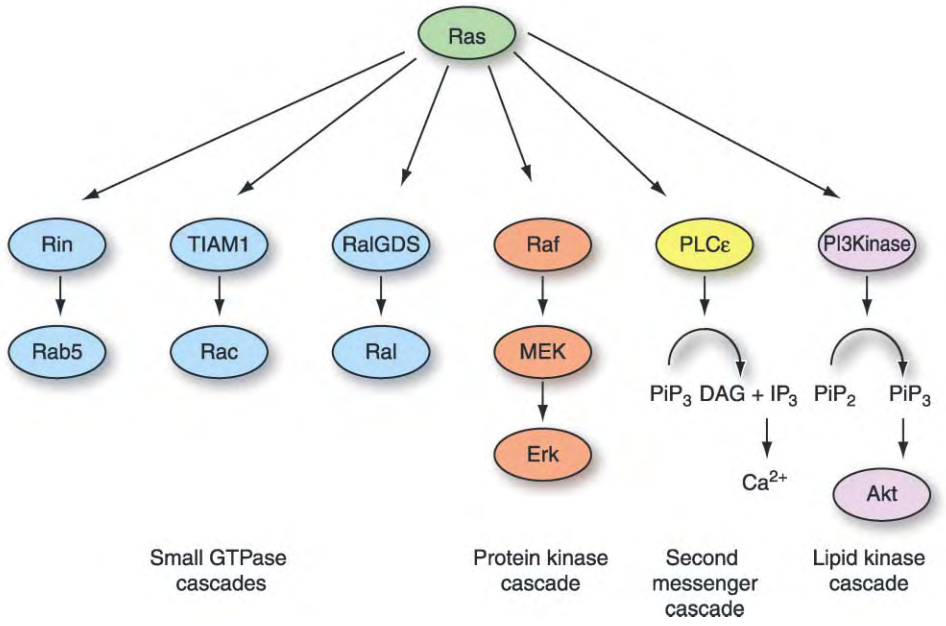

FIGURE 7 Ras effectors mediate diverse signaling outcomes. Activated, GTP-bound Ras can bind and regulate functionally diverse downstream effector targets. These include activation of a protein kinase cascade (Raf), activation of the PI3K lipid kinase, and activation of PLCE and the production of second messengers (DAG and calcium). Several Ras effectors are GEFs that activate other members of the Ras superfamily, including Rab5 (Rin1), Ral (RalGEFs), and Rac (Tiam1). Thus, Ras functions as a signaling node, where diverse signals converge and cause its activation (Figure 4), and once activated, results in activating of diverse downstream signaling pathways.

Rho-Family Proteins and Actin Cytoskeletal Organization, Cell Morphology, and Cell Movement

Similar to Ras proteins, Rho-family small GTPases also function as signaling nodes activated by diverse extracellular signals. Perhaps the best-characterized cellular function of these proteins is their regulation of actin cytoskeletal organization, which in turn influences cell morphology, cell–matrix and cell–cell interactions, and cell movement. For example, RhoA causes actin stress fiber formation, Rac causes actin accumulation at the leading edge of a motile cell and lamellipodia formation, whereas Cdc42 promotes actin microspikes and filopodia formation. These changes in actin organization can influence cell shape, cell motility, and cell–cell interactions.

Small GTPases and Membrane Trafficking

Rab proteins constitute the largest subfamily of small GTPases, with more than 60 mammalian members. Rab proteins are involved in the modulation of specific steps in eukaryotic membrane trafficking in the secretory and endocytic pathways. Arf and Sar small GTPases are also involved in the regulation of cytoplasmic vesicular trafficking. By contrast, Ran is a regulator of nucleocytoplasmic transport. The regulation of the GDP/GTP cycle is also critical for the functions of these small GTPases in their distinct transport function.

Glossary

cytoskeleton A dynamic network of filaments, microfilaments, microtubules, and intermediate filaments.

effector proteins Proteins that bind preferentially to the GTP-bound form of small GTPases and facilitate the biological response of small GTPases.

GTPase High-affinity GDP-, GTP-binding, and GTP-hydrolyzing proteins that act as molecular switches and timers that cycle between inactive GDP-bound and active GTP-bound states.

GTPase activating protein Negative regulatory protein that accelerates the intrinsic GTP hydrolysis activity of small GTPases.

guanine nucleotide exchange factors Regulatory protein that accelerates the intrinsic GDP/GTP exchange activity of small GTPases.

guanine nucleotides Amine nucleotide bases composed of a guanine moiety attached to one (guanosine monophosphate, GMP), two (guanosine diphosphate, GDP), or three (guanosine triphosphate, GTP) phosphate groups.

isoprenylation Post-translational, covalent modification of proteins at carboxyl-terminal cysteine residues, by either C15 farnesyl or C20 geranylgeranyl isoprenoid lipids.

kinase An enzyme with phosphorylating activity on either proteins or lipids.

superfamily, family, and subfamily Small GTPases are classified into hierarchical phylogenies on the basis of structural, sequence, and functional similarity between members. Members of the Ras family share ~50% amino acid identity with the four Ras proteins whereas members of the Rho, Rab, and other Ras superfamily GTPases share ~25–30% amino acid identity with Ras proteins.

Somatostatin Receptors

Agnes Schonbrunn
The University of Texas Health Science Center, Houston, Texas, USA

Somatostatin receptors (sst receptors) comprise a family of five distinct plasma membrane receptors that bind the neuroendocrine peptides somatostatin and cortistatin. These receptors exhibit the seven-transmembrane domain structure typical of G protein-coupled receptors (GPCRs) and signal primarily through pertussis toxin-sensitive G proteins. The different sst receptor subtypes are found in specific endocrine and exocrine tissues, including the pituitary and the pancreas, in addition to being widely distributed in the central and peripheral nervous systems and the gastrointestinal tract. They have important physiological roles in inhibiting hormone secretion, particularly the secretion of growth hormone, insulin, glucagon, and gastrin, inhibiting exocrine secretion by the pancreas and stomach, and modulating neuronal excitability and smooth muscle contraction. Additionally, many neuroendocrine tumors express high levels of somatostatin receptors, and, because of their ability to inhibit tumor cell secretion as well as proliferation, somatostatin analogues are now used to target these receptors for both cancer therapy and diagnosis.

Physiological Somatostatin Receptor Ligands

Somatostatin (SS), originally called somatotropin-release inhibiting factor or SRIF, was discovered accidentally over 30 years ago while investigators were hunting for the brain peptide responsible for stimulating the release of growth hormone, or somatotropin. Surprisingly, they found that extracts of the hypothalamus, a specialized brain region that regulates pituitary hormone secretion, inhibited rather than stimulated the secretion of growth hormone. Using this inhibition as an assay, R. Guillemin, A. Schally, and their co-workers purified the active factor from hypothalamic extracts and identified the 14-amino-acid form of somatostatin, a discovery that contributed to their receiving the Nobel Prize in 1977 for studies of hormone production in the brain.

SS is now known to exist in two biologically active isoforms, 14 (SS14) and 28 (SS28) amino acids in length, which are produced by alternate proteolytic processing from a common precursor of 116 amino acids. These cyclic peptides are synthesized by specific endocrine, gastrointestinal, immune, and neuronal cells, as well as some tumors, and act either locally as paracrine, autocrine, or neuronal modulators or through the bloodstream as hormones.

The cDNA for the related peptide cortistatin was discovered much later, in 1996, in the process of characterizing region-specific rat brain mRNAs. Cortistatin was named for its predominant expression in the brain cortex and its ability to depress cortical neuronal activity. Cortistatin is also synthesized as a precursor and is proteolytically processed into two biologically active products: a short (rat CST-14 and human CST-17) and an amino-terminally extended (CST-29) form. Although cortistatin is produced from a different gene than somatostatin, the two peptides have 10 of their 14 carboxy-terminal amino acids in common (Figure 1). Cortistatins are produced primarily by central nervous system neurons but have also been found in immune cells, lymphoid tissues, bone marrow, and the pancreas.

Because all forms of somatostatin and cortistatin bind to the different somatostatin receptor subtypes (sst's) with similar high affinities, it is not surprising that the peptides share many functional properties. However, they also produce some distinct biological effects. For example, intracerebroventricular injection of cortistatin in rats increases slow-wave sleep but not REM sleep, whereas somatostatin injection increases REM sleep. Thus, the identification of a human cortistatin selective G protein-coupled receptor (MrgX2, or Mas-related gene X2) fulfills prior predictions for the existence of distinct cortistatin-specific receptors. However, the rodent orthologue of this receptor has not been identified, and the relative roles of somatostatin receptors and cortistatin receptors in mediating the physiological actions of these peptides remain to be determined.

Biochemical and Molecular Characterization of Somatostatin Receptors

Somatostatin Receptor Subtypes

Five somatostatin receptor genes, located on different chromosomes, have been identified and named *sst1* to

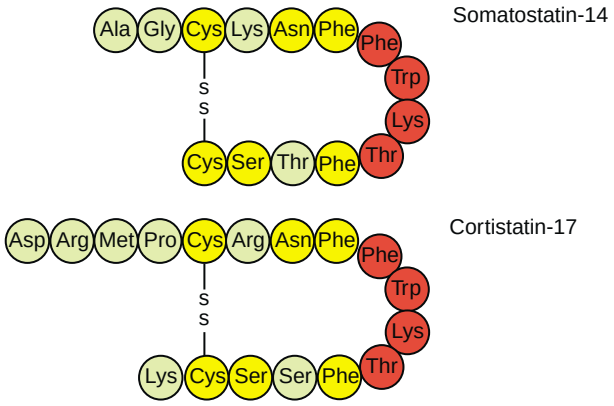

FIGURE 1 Structure of mammalian somatostatin-14 and human cortistatin-17. The amino acids in the red circles are required for high-affinity binding to somatostatin receptors. The amino acid differences between the two peptides are shown by the green circles.

sst5 in the order of their discovery (Table I). The coding regions of sst1, sst3, sst4, and sst5 all occur within a single exon. However, at least in some mouse and rat tissues, the mRNA for sst2 undergoes alternative splicing at the 3′ end, producing two protein products. The sst2A variant is the product of the unspliced mRNA, whereas the sst2B variant contains an alternative exon that encodes a different and somewhat shorter receptor carboxy terminus. Only the sst2A variant has been detected in normal human tissues.

Somatostatin receptors belong to the G protein-coupled receptor (GPCR) family and are predicted to contain seven α-helical transmembrane domains. Receptors for somatostatin have been cloned from a variety of mammals as well as from several nonmammalian species, including a number of fish. The human sst receptors exhibit between 40 and 57% amino acid identity with each other, and sequence identity among the rat, mouse, and human orthologues of each receptor subtype is even higher. The greatest sequence similarity between sst receptor subtypes occurs within the transmembrane domains; these domains, therefore, are thought to be involved in ligand binding. Sequence differences in the intra- and extracellular domains are presumably responsible for the unique signaling and trafficking properties of individual sst receptor subtypes.

Based on sequence similarity, sst receptors have been subdivided into two groups: sst1 and sst4 receptors form the SRIF2 subgroup, and sst2, sst3, and sst5 constitute the SRIF1 subgroup. In addition to a closer phylogenetic relationship (Figure 2), members of each group share several functional properties, such as their affinity for short synthetic somatostatin analogues, including octreotide and lanreotide, and sensitivity to agonist-induced receptor internalization (Table I).

The GPCRs most closely related to the sst receptor family are GPR7 and GPR8, which encode receptors for two paralogous brain peptides, neuropeptide B (NPB) and neuropeptide W (NPW) (Figure 2). The next most closely related family is the opioid receptor family, which also shares substantial sequence identity with the cortistatin receptor MrgX2 (Figure 2).

Somatostatin Receptor Structure

Somatostatin receptors contain many of the structural features characteristic of GPCRs, including consensus sites for Asn-linked glycosylation within the amino terminus and multiple Ser and Thr phosphorylation sites in the intracellular loops and carboxy-terminal tail (Table I). All sst receptor subtypes except sst3 also contain a conserved Cys residue in the carboxy-terminal region, which provides a site for receptor palmitoylation. Lipid modification has yet to be demonstrated biochemically for any of the sst subtypes. However, sst1, sst2, sst3, and sst5 are known to be glycosylated from

TABLE I

Properties of Human Somatostatin Receptor Subtypes

Property	sst1	sst2A/B	sst3	sst4	sst5

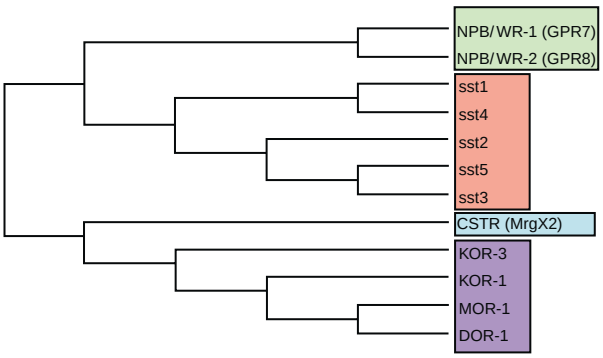

FIGURE 2 Sequence relationships between somatostatin receptors and closely related peptide receptors. The dendrogram was generated with the Clustal W program using MacVector's default parameters to align the peptide sequences. Human sequences were used in all cases and were obtained either from SwissProt or RefSeq. Somatostatin receptors: hsst1, P30872; hsst2A, P30874; hsst3, P32745; hsst4, P31391; hsst5, P35346. Cortistatin receptor: MrgX2, NP_473371. Opioid receptors: KOR-1, P41145; MOR-1, P35372; DOR-1, P41143; and KOR-3, P41146. Neuropeptide B/W receptors: NPBWR-1 or GPR7, P48145; and NPBWR-2 or GPR8, P48146. The plot shows that hsst1 and hsst4 form one subgroup and hsst2, hsst3, and hsst5 form a second subgroup within the somatostatin receptor family and that the cortistatin receptor is not a member of the sst receptor family.

the observation that treatment of these receptors with peptide-N-glycosidase F (PNGaseF), an enzyme that catalyzes the cleavage of N-glycosidically linked carbohydrate chains from Asn, causes a large decrease in their apparent molecular weights. Such a shift in molecular weight was not observed for sst4, either because it is not glycosylated or because glycosylation at its single consensus site does not significantly affect its apparent molecular weight.

Receptor phosphorylation, a covalent modification known to be important for GPCR regulation and signaling, has been examined biochemically for some but not all sst receptor subtypes. Somatostatin stimulates the incorporation of $^{32}PO_4$ into sst1, sst2A, and sst3 receptors, and protein kinase C activation also increases phosphorylation of sst1 and sst2A. However, phosphorylation of sst4 was not detected following agonist stimulation, and sst5 phosphorylation has not been investigated biochemically.

Pharmacology of Somatostatin Receptor Subtypes

The native somatostatin peptides exhibit little selectivity among the different receptor subtypes and have a very short lifetime in plasma (half-life < 3 min). Thus, analogues with increased metabolic stability and greater receptor specificity have been developed for therapy.

The earliest pharmaceuticals to target somatostatin receptors were short peptides, 6 to 8 amino acids in length, containing amino acids 7 to 10 of SS14, the region required for receptor binding (Figure 1). These agonists, including octreotide (SMS201-995), lanreotide (BIM 23014), and seglitide (MK-678), also contain D-amino acid substitutions and carboxy- or amino-terminal modifications to increase metabolic stability. These truncated peptides bind selectively to the SRIF1 group of receptors, exhibiting subnanomolar affinity for sst2 and nanomolar affinities for sst3 and sst5 (Table I). Further, octreotide does not bind to the MrgX2 cortistatin receptor. Both octreotide and lanreotide are used clinically to treat hormone-secreting pituitary adenomas and gastroenteropancreatic (GEP) tumors and comprise the only FDA-approved pharmaceuticals targeting sst receptors for therapy.

In an effort to generate receptor subtype specific analogues that are resistant to proteolytic degradation, S. Rohrer and co-workers at Merck screened combinatorial libraries to successfully identify the first highly selective, high-affinity, nonpeptide agonists for all sst subtypes. Such reagents offer the possibility of oral bioavailability, although they are not presently approved for clinical use. Nonetheless, they supply valuable tools for identifying the physiological roles of individual sst receptor subtypes.

The recognition that many tumors express several different sst receptors concomitantly has stimulated a search for stable somatostatin analogues that can bind to multiple somatostatin receptors. The hexapeptide analogue SOM230 shows high affinity for four of the five somatostatin receptor subtypes (sst1, sst2, sst3, and sst5), whereas the nonapeptide analogue KE108 appears to be truly universal since it binds to all five sst subtypes with nanomolar affinity. Because of their excellent metabolic stability, these broad-spectrum agonists have significant therapeutic potential.

The first somatostatin receptor antagonist, CYN-154806, described in 1996, showed high selectivity for the sst2 receptor. Since then, antagonists have been identified for all five somatostatin receptor subtypes, although none are used clinically.

In addition to their therapeutic applications, analogues of somatostatin have been developed to localize and stage sst receptor-positive tumors *in situ*. The radiolabeled derivatives used for tumor diagnosis contain a chelating group covalently attached to a stabilized somatostatin peptide, such that its receptor-binding properties are not compromised. The chelating group is then bound to a short-lived radioisotope, such as the gamma emitter ^{111}In, and injected into patients. After 24 h, accumulation of the radiolabel can be visualized in tumors expressing high levels of sst receptors by gamma camera scintigraphy, thus permitting localization of the tumors and their metastases. The analogue in current

clinical use is an indium-labeled octreotide derivative, [^{111}In-DTPA-D-Phe^1, Tyr^2]octreotide (OctreoScan), and hence is selective for the SRIF1 group of sst receptors, showing the most sensitive detection of sst2-expressing tumors. Unfortunately, this method cannot be used to localize tumors expressing sst1 or sst4 receptors, as appropriate somatostatin analogues are not yet available.

Somatostatin Receptor Signaling

Somatostatin receptors regulate a number of diverse signaling effectors, including adenylyl cyclase, phospholipases C and A2, calcium and potassium channels, protein and lipid kinases, and tyrosine and serine/threonine phosphatases. All sst receptors inhibit adenylyl cyclase via pertussis toxin-sensitive G proteins and thus decrease intracellular cyclic adenosine monophosphate (cAMP). However, other signal transduction pathways modulated by somatostatin receptors vary both with the receptor subtype and with the target cell.

The mechanism by which somatostatin receptors inhibit secretion in endocrine cells and neurons is understood in some detail. In addition to reducing intracellular cAMP levels, several sst receptors have been shown to reduce intracellular calcium levels in excitatory cells, also via pertussis toxin-sensitive G proteins. The reduction in cytosolic calcium can result either from a stimulation of various potassium channels, which hyperpolarize the cell membrane and thereby decrease influx through voltage-dependent calcium channels, or from direct calcium channel inhibition. The decrease in intracellular cAMP and calcium concentrations together contribute to the inhibitory action of somatostatin on secretion: when either signaling pathway is blocked, the magnitude of somatostatin's inhibitory effect is reduced.

Somatostatin stimulates contraction of intestinal smooth muscle cells by inhibiting adenylyl cyclase and activating phospholipase C-β3 via the α- and $\beta\gamma$-subunits, respectively, of pertussis toxin-sensitive G proteins. The activated phospholipase catalyzes the hydrolysis of the membrane lipid phosphatidylinositol 4,5-bisphosphate to form the second messengers inositol trisphosphate (IP_3) and diacylglycerol (DG). The binding of IP_3 to receptors on the sarcoplasmic reticulum results in the release of calcium from intracellular stores, producing a rise in cytosolic calcium concentrations. The released calcium forms a complex with the protein calmodulin, and this complex then activates myosin light-chain kinase (MLCK) to phosphorylate the light chain of myosin, leading to smooth muscle contraction. Because protein kinase A (PKA) decreases the sensitivity of MLCK to calcium, somatostatin inhibition of cAMP formation facilitates the calcium effect by reducing the activity of PKA. These pathways are also activated by somatostatin in aortic vascular smooth muscle cells. Interestingly, somatostatin does not activate phospholipase C-β3 in pituitary cells, even though the level of this enzyme in the pituitary appears to be similar to that in smooth muscle cells. The explanation for the signaling differences in these tissues remains to be elucidated, but could be due to differences either in the sst subtypes or in the signaling machinery present.

In endothelial cells, somatostatin inhibits cell migration, stress fiber assembly, and cytoskeletal reorganization produced by thrombin and other stimulators. In humans, these effects are mediated by the sst1 receptor and have been implicated in somatostatin's antiangiogenic actions. Although the molecular steps involved have not yet been identified, the mechanism includes an unusual pertussis toxin-independent inhibition of Rho, a low molecular mass GTPase that plays a central role in regulating cytoskeletal organization.

The mechanisms by which somatostatin inhibits cell proliferation and stimulates apoptosis are also poorly understood and appear to vary in the different cell types in which they have been examined. In most (though not all) cells, somatostatin activates the mitogen-activated protein kinase (MAPK) pathway and increases extracellular signal-related kinase (ERK)1/2 phosphorylation by a pertussis toxin-sensitive mechanism. However, this activation is often observed whether somatostatin inhibits or stimulates cell proliferation. Thus, it is likely that some of the other effectors activated by the sst receptors contribute to the final biological response. For example, in pancreatic acinar cells, which express sst2 receptors endogenously, somatostatin-induced growth arrest involves enhanced expression of the cyclin-dependent kinase inhibitor p27Kip and results from inhibition of the phosphatidylinositol-3-kinase (PI3K) pathway. In contrast, in sst2 transfected CHO cells, somatostatin induction of p27Kip appears to be dependent on stimulation rather than inhibition of PI3K, in that PI3K inhibitors block the effect of somatostatin analogues on ERK2 phosphorylation, which in turn is required for p27Kip up-regulation. These and other potential signaling pathways are under intense investigation in order to elucidate the clinically important actions of somatostatin to inhibit cell proliferation and stimulate apoptosis.

In summary, most but not all signaling by sst receptors involves the pertussis toxin-sensitive G_i/G_o family. However, depending on the sst receptor subtype and the cellular environment, a spectrum of nonoverlapping signaling pathways can be activated. The link between the different effectors regulated by sst

receptors and particular biological responses is understood for some but by no means all of somatostatin's actions.

Somatostatin Receptor Regulation

Alterations in sst receptor responsiveness during somatostatin exposure vary dramatically between tissues, depending both on the response being measured and on the nature of the target cell. In some instances, desensitization occurs within minutes following initiation of somatostatin treatment, whereas in others no desensitization is detected even after years of somatostatin analogue exposure. For example, in chick sympathetic neurons, somatostatin inhibition of N-type Ca currents desensitizes with a half-life of 3 min. In contrast, desensitization to pharmacologic doses of the somatostatin analogue octreotide does not occur in months or years of therapy for pituitary tumors. The molecular basis for such dramatic differences in somatostatin receptor regulation remains poorly understood.

Studies of the different sst receptor subtypes in transfected cells indicate receptor-specific differences in their regulation. As has been shown for many GPCRs, hormone treatment leads to the rapid phosphorylation of several sst receptor subtypes (Table I). Interestingly, however, this phosphorylation appears to have different consequences for the different sst receptors. For example, in CHO cells, although both sst1 and sst2 receptors are phosphorylated and desensitized within minutes following somatostatin exposure, only the sst2 receptor is rapidly internalized.

The cellular environment also plays an important role in the observed differences in the regulation of somatostatin responsiveness. Interestingly, the sst2 receptor, which desensitizes within minutes of somatostatin exposure in cultured cells but is resistant to desensitization in human tumors, was recently shown to be phosphorylated *in situ* in a human tumor. Hence, at least this first step in the desensitization process appears to be intact in human tumor tissue. As the other molecular components of sst receptor desensitization are characterized, it will be interesting to determine whether their functions are altered in the desensitization-resistant tumors.

Summary

The five known somatostatin receptors play important physiological roles in the regulation of the endocrine, neuronal, gastrointestinal, and immune systems. In addition, they are recognized to be important targets in the diagnosis and therapy of a number of neuroendocrine tumors.

Although a great deal remains to be learned about many of somatostatin's functions, studies with sst1, sst2, and sst5 knockout mouse models, all of which are viable, have begun to delineate the biological importance of the individual receptor subtypes. Future focus on these receptors in their normal cellular environments can take advantage of the many new receptor-specific agonists and antagonists that have become available and will undoubtedly provide much-needed insight into the function of this physiologically and therapeutically important G protein-coupled receptor family.

Glossary

acromegaly A condition caused by the excess secretion of pituitary growth hormone after maturity, usually by a pituitary tumor. The disease is characterized by enlargement of the extremities, including the nose, jaws, fingers, and toes, as well as certain internal organs.

cortistatins The short (rat CST-14 and human CST-17) and long (CST-29) biologically active products produced by proteolytic processing of the precursor peptide encoded by the cortistatin gene.

G protein One of a family of related heterotrimeric proteins that bind GTP and GDP. The heterotrimeric forms, which are inactive, become activated at the plasma membrane by agonist occupied G protein-coupled receptors (GPCRs) that stimulate the binding of GTP to the G protein α-subunit and cause dissociation of the α-subunit from the $\beta\gamma$-subunit complex. When activated, the G protein subunits regulate downstream effectors, such as ion channels and enzymes that generate second messengers. G proteins become inactivated by hydrolyzing GTP to GDP, which then permits the reassociation of the α-subunit with the $\beta\gamma$-subunit complex.

somatostatins (SSs) The 14-amino-acid (SS-14) and 28-amino-acid (SS-28) peptides produced by alternative proteolytic processing from a single 92-amino-acid precursor called prosomatostatin.

BIOGRAPHY

Agnes Schonbrunn is a Professor in the Department of Integrative Biology and Pharmacology at the University of Texas–Houston, School of Medicine. She holds a Ph.D. in Biochemistry from Brandeis University and received her postdoctoral training at Harvard Medical School. Her principal research interests include the signaling and regulation of somatostatin receptors and the functional role that these receptors play in neuroendocrine cancers.

Spastic Paraplegia

Elena Irene Rugarli
Telethon Institute of Genetics and Medicine, Naples, Italy

Andrea Ballabio
University of Naples, Federico II, Naples, Italy

Hereditary spastic paraplegia (HSP) is a group of neurodegenerative diseases characterized by weakness and spasticity of the lower limbs, loss of the vibratory sense, and urinary urgency. In 1983, Harding classified HSP in "pure" forms, when the symptoms are restricted to lower limbs weakness and spasticity, and in "complicated" forms, when the clinical picture is associated to a variety of neurological symptoms. These may include cerebral and cerebellar atrophy, optic atrophy, peripheral neuropathy, dementia, retinitis pigmentosa, amyotrophy. Age of onset is extremely variable, with a few forms arising in childhood, and most cases between 20 and 40 years of age. Usually the later the onset of the disease, the faster is the progression of its course. Although HSP is an invalidating disease, it never causes shortening of the life-span of patients.

Neuropathology

Hereditary spastic paraplegia (HSP) is characterized by the retrograde degeneration of the longest axons of the central nervous system: those of the crossed corticospinal tracts and of the fasciculus gracilis. In about half of the autoptic cases examined, the spinocerebellar tracts were also involved.

Axons of the corticospinal tracts arise from pyramidal neurons in layer V of the motor cortex and project through the internal capsule to reach the ventral surface of the medulla where they form two elongated swellings, the pyramids. These axons cross the midline at the junction between the bulb and the spinal cord and descend in the contralateral funiculus of the spinal cord. The crossed corticospinal tract conveys voluntary motor impulses to the secondary motor neurons located in the ventral horns of the spinal cord. The fasciculus gracilis is composed of the central branches of axons of pseudounipolar neurons located in dorsal root ganglia and ascend in the most medial part of the dorsal funiculus. These axons transmit deep sensory information from the lower extremities to secondary sensory neurons in the nucleus gracilis.

Characteristically, axonal degeneration in HSP involves preferentially the distal region of the axons. Degeneration of the corticospinal tracts is marked at lumbar levels, and less pronounced at cervical levels. In most cases the neuronal cell bodies are preserved. This pattern of axonal degeneration, also referred to as dying-back, is slowly progressive and occurs in several other conditions following a toxic, metabolic or genetic insult.

Genetics

It has become clear in the last decade that HSP is extremely heterogeneous from a genetic point of view. So far, 21 different loci have been mapped and it is expected that more will be identified. HSP can be transmitted as an X-linked (SPG1, SPG2, SPG16), autosomal dominant (SPG3A, SPG4, SPG6, SPG8, SPG9, SPG10, SPG12, SPG17, SPG19) or autosomal recessive trait (SPG5A, SPG7, SPG11, SPG14, SPG15, SPG20, SPG21). The molecular bases of the disease are also being unraveled with a quick pace. Eleven *HSP* genes have been identified, thus providing clues on the cellular pathways underlying the disease. Table I summarizes the current knowledge on the genetic bases of HSP. The following paragraphs describe the known *HSP* genes and classify them based on the existing functional information.

The Mitochondrial Forms

Two of the known HSP genes, SPG7 and SPG13, encode proteins that are involved in mitochondrial protein quality control. Their identification strongly indicates that at least a subgroup of HSPs should be regarded as mitochondrial diseases.

SPG7/Paraplegin

SPG7 was cloned in 1998 by Casari and colleagues, as the first autosomal recessive gene responsible for both pure and complicated forms of HSP. SPG7 encodes paraplegin, a 795 amino acid protein highly homologous to two yeast metalloproteases of the AAA family,

SPG21	248900	AR	15q22.31	Complicated	Maspardin	

Note: the loci SPG3B, SPG5B, and SPG18 are listed as "reserved" in the Hugo Gene Nomenclature Committee Database.

Yta10p (Afg3p), and Yta12p (Rca1p). Like its yeast homologues, paraplegin has an N-terminal mitochondrial leader sequence and two transmembrane domains that anchor the protein to the inner mitochondrial membrane. Paraplegin is composed of two functional domains: an ATPase domain typical of proteins of the AAA family (*A*TPases *a*ssociated with diverse cellular *a*ctivities) and a proteolytic domain with a consensus metal-binding site.

The yeast Yta10p and Yta12p assemble to form a high molecular weight complex of about 1 MDa, the *m*-AAA protease, which is embedded in the inner mitochondrial membrane but exposes proteolytic sites to the mitochondrial matrix (hence the prefix "*m*" in the name). The *m*-AAA protease ensures protein quality control system for inner membrane proteins, by guaranteeing the removal of non-assembled or misfolded proteins, and by performing crucial steps in mitochondrial biogenesis. Yeast cells lacking the *m*-AAA protease exhibit deficiencies in the expression of mitochondrially-encoded polypeptides and in the posttranslational assembly of respiratory chain complexes. These defects can be reproduced in yeast cells harbouring proteolytically inactive subunits, indicating that the phenotype is largely due to the loss of proteolytic activity. A recent study by Atorino *et al.* has shown that paraplegin co-assembles with the highly homologous AFG3L2 protein in human mitochondria to form a high-molecular-weight complex very similar to the one described in yeast. This complex complements the respiratory deficiency of yeast lacking the *m*-AAA protease, indicating functional conservation of the *m*-AAA protease across species and assigning proteolytic activity to the paraplegin/AFG3L2 complex.

Advancement in the understanding of the pathogenic basis of this form of HSP comes from the development by Ferreirinha *et al.* of a mouse model in which the *Spg7* gene has been knocked-out. Paraplegin-deficient mice recapitulate the human disease, being affected by a late-onset progressive distal axonopathy, characterized by axonal swelling and degeneration, and involving the longest axons in the central and peripheral nervous systems. Axons swell because of accumulation of membranous organelles and neurofilaments, suggesting that axonal transport is impaired. Neurotracer studies in the peripheral nervous system of symptomatic Spg7 $-/-$ mice indicated that retrograde axonal transport is delayed, suggesting that impairment of axonal trafficking processes may play a crucial role in the pathogenic process.

However, the first ultrastructural pathological sign that can be observed in paraplegin-deficient mice occurs several months before any evidence of axonal swelling and degeneration, and consists in the appearance of

abnormal mitochondria, first in synaptic terminals and then in the distal regions of the long spinal axons, that will later on undergo degeneration. Abnormal mitochondria include hypertrophic mitochondria, gigantic mitochondria, and mitochondria with disrupted or abnormal organization of cristae. This mitochondrial phenotype correlates with the onset of a measurable neurological impairment of the paraplegin-deficient mice on the rotarod apparatus, and is therefore the primary trigger of the pathological process. Since nothing is known so far about the substrates of paraplegin, the question of how lack of paraplegin is affecting mitochondrial morphology still awaits an answer. It is possible that abnormal mitochondria result from the accumulation of misfolded polypeptides that are not correctly cleared away by the paraplegin–AFG3L2 complex. Alternatively, this phenotype could underlie the abnormal processing of a regulatory molecule involved in some aspect of mitochondrial morphology.

Recent studies by Atorino *et al.* on fibroblast cell lines obtained from HSP patients with SPG7 mutations found a reduction of complex I activity and an increased sensitivity to oxidative stress, suggesting a potential mechanism for mitochondrial damage. This could be especially important in mitochondria located in nerve terminals where high energetic demands and increased concentration of free radicals are present.

SPG13/HSP60

Further support to the role of mitochondria in the pathogenesis of HSP came from the identification by Hansen *et al.* in 2002 of a missense mutation in the mitochondrial chaperonin heat shock protein 60 (HSP60) in one French family with an autosomal dominant form of pure HSP, mapping to chromosome 2q24–34. Hsp60 proteins belong to a conserved subgroup of chaperone proteins, termed chaperonins, which promote protein folding in the mitochondrial matrix, often in cooperation with the cochaperonin Hsp10. The mutation identified in the HSP family results in the V72I substitution. An elegant complementation assay performed in *E. coli* showed that only wild-type Hsp60, but not Hsp60–V72I, together with the cochaperonin Hsp10, can support the growth of bacteria in which the homologous chromosomal *groESgroEL* chaperonin genes have been deleted, indicating that the V72I mutant is functionally inactive. It is unclear whether this mutant leads to haploinsufficiency through the formation of functionally inactive mixed chaperonin rings made up by both normal and mutated subunits, or may exert a genuine dominant-negative effect.

Mitochondrial Protein Quality Control and Axonal Degeneration: A Pathogenic Hypothesis

The reason why the loss of ubiquitous mitochondrial proteins such as paraplegin and HSP60 causes the specific degeneration of a subset of axons, such as the corticospinal axons, is still to be unraveled. The most accepted hypothesis states that primary motor neurons would be particularly susceptible to any impairment of mitochondrial function due to their peculiar cellular homeostasis. These neurons have extremely long axons that can reach the length of more than 1 m in humans and depend for their life on efficient transport of organelles, molecular cargoes, and synaptic vesicles from the cell body to the distal tip of the axon, and back to the cell body. This process requires energy and is supported through the coordinated movement of mitochondria themselves along axons. Mitochondria located very distal to the cell body could be required to endure for longer period of time, and could be much less efficient in adapting to inefficient protein quality control mechanisms.

Genes Involved in Cellular Trafficking Events

A second group of genes involved in HSP appears to play a more or less direct role in cellular trafficking. Their identification supports the notion that axonal transport represents a key event for axonal homeostasis, and that any derangement from normal trafficking processes may lead with time to axonal degeneration. The long axons composing the corticospinal tracts and the fasciculus gracilis would be a privileged pathological target.

SPG10/KIF5A

The best example of the pathogenic role of impaired axonal transport in HSP comes from the identification by Reid *et al.* of a mutation in the gene encoding a specific neuronal kinesin heavy chain, KIF5A, in a family with an autosomal-dominant pure form of HSP. Kinesins are multisubunit complexes that work as motors for anterograde transport (from the cell body to the distal end of the axons) of membranous organelles and other macromolecular cargoes along microtubules. KIF5A is abundantly expressed in neurons, which is found in cell bodies, dendrites, and axons. The gene for the heavy chain of KIF5A is located within a large interval of chromosome 12 in which the SPG13 locus was mapped by cross-overs defined in a single large family affected by an autosomal-dominant pure form of HSP. A N256S missense mutation in KIF5A was identified in the

original family, and found to segregate with the disease. This mutation occurs at an invariant asparigine residue within the motor domain of the protein. Intriguingly, mutations at the corresponding residue in both the yeast Kar3 protein, a motor of the mitotic spindle, and the *Drosophila* Ncd kinesin motor, were found to block the microtubule-dependent stimulation of motor ATPase activity, thus acting with a dominant-negative mechanism. So far, the N256S mutation is the only one identified in HSP families.

SPG4/Spastin

Hazan *et al.* identified in 1999 the most frequent form of autosomal-dominant spastic paraplegia. SPG4 maps to chromosome 2p21-p22 and encodes a 616-amino-acid-protein, named spastin. Similarly to paraplegin, spastin belongs to the AAA (*A*TPases *A*ssociated with various cellular *A*ctivities) family, which is characterized by a conserved domain of 230 amino acids with ATPase activity. Based on sequence homology and phylogenetic analysis, spastin belongs to the subfamily-7 of AAA proteins, whose members are implicated in completely divergent cellular processes, such as microtubule severing and endosomal morphology and trafficking. The N-terminal part of the protein contains a newly recognized domain, the EPS or MIT domain, which is present in molecules involved in endosome trafficking, such as Vps4 and SNX15 (sortin nexin 15), and in spartin, another protein involved in HSP.

Mutations in SPG4 account for at least 40% of all autosomal-dominant HSP families. Missense, nonsense, and splice-site mutations as well as deletions or insertions have all been observed in the spastin gene. Notably, all the missense mutations fall into the AAA domain, with the exception of the S44L substitution that appears to be disease-causing only in the homozygous state, underlying the functional significance of this domain. The other mutations are scattered along the coding region of the gene and lead to premature termination codons, and mRNA instability, suggesting that haplo-insufficiency is the molecular cause of the disease.

The functional data available on spastin point to a complex cellular role. Recently, Charvin *et al.* found endogenous spastin to be localized in the nucleus, by using polyclonal antibodies raised against synthetic peptides. However, transient transfection experiments by Errico *et al.* suggested that the onset of spastin expression may be in the microtubule-organizing center and that, upon longer periods of expression, spastin may accumulate in cytoplasmic aggregates. The reason for the discrepancy between endogenous and exogenously expressed spastin is still to be determined.

Experimental evidence obtained in overexpression system suggests that spastin may interact dynamically with the microtubule cytoskeleton. In fact a stable association with a subset of microtubules and the formation of thick perinuclear bundles of microtubules are achieved when spastin mutants in the AAA domain are expressed in eukaryotic cells. A microtubule-binding domain was mapped to the N-terminal region of spastin. To explain these results, a hypothesis has been put forward that binding of spastin to microtubules may be transient *in vivo* and regulated through ATPase cycles. Mutations in the AAA domain would alter the ability of spastin to bind or hydrolyse ATP, and therefore entrap the protein in a microtubule-bound state.

To reinforce the idea that spastin is involved in microtubule dynamics, overexpression of wild-type spastin was found to promote microtubule disassembly in transfected cells. Although these data suggest that the degeneration of corticospinal axons, in HSP patients, could be due to impairment of fine regulation of the microtubule cytoskeleton, more studies are needed to demonstrate an interaction of endogenous spastin with the neuronal cytoskeleton, and to unravel its function in the nucleus.

SPG3A/Atlastin

The second most common gene involved in autosomal-dominant pure HSP with juvenile onset (~10% of the cases) has been linked to the SPG3A locus and found to encode a novel protein, atlastin, by Zhao *et al.* Four different missense mutations have been identified so far in SPG3A, all clustering in exons 7 and 8. Their mechanism of action is still to be determined. Although very little is known about the function of atlastin, this molecule shares very interesting homologies with members of the dynamin family of large GTPases, particularly with guanilate-binding protein-1. Dynamins are involved in important trafficking events in axons, including recycling of synaptic vesicles and mainteinance and distribution of mitochondria, again suggesting that abnormal axonal transport may be at the basis of this form of HSP.

SPG20/Spartin

SPG20 is the gene involved in Troyer syndrome, an autosomal recessive form of HSP complicated by disarthria, distal amyotrophy, mild developmental delay, and short stature, that occurs with high frequency in the Amish population. The cloning of this gene by Ciccarelli *et al.* in 2002 has revealed that its protein product, spartin, shares homology in the N-terminal region with spastin within the ESP/MIT domain. This has led to the hypothesis that spartin may be somehow involved in ensodome trafficking. This theory still awaits experimental confirmation.

SPG21/Maspardin

Mast syndrome is mutated in an autosomal recessive complicated form of HSP associated with dementia present at high frequency in the Old Order Amish population. Simpson *et al.*, in 2003, have mapped this condition to chromosome 15q22.31 and identified the causative gene, SPG21. SPG21 encodes an acid-cluster protein of 33 kDa (ACP33), renamed maspardin, previously shown to localize in the endosomal/trans-Golgi network. This data again emphasize the causative role of proteins involved in cellular sorting and trafficking in the pathogenesis of HSP.

Developmental Genes

HSP may result from mutations in genes involved in the development of the corticospinal tracts. This is the case of SPG1, which has been linked to mutations in the cell adhesion molecule L1CAM. Consistently, the available data from neuropathological studies found absent or severely reduced pyramids. In this form of HSP, spastic paraplegia begins in the first two decades of life, with delayed acquisition of motor milestones and slow progression of symptoms. Although this form may manifest as pure HSP, it is more often observed in association with a complex disorder, referred to either as MASA syndrome (*m*ental retardation, *a*dducted thumbs, *s*pasticity, and *a*phasia) or CRASH syndrome (*c*orpus callosum hypoplasia, mental *r*etardation, *a*dducted thumbs, *s*pastic paraplegia, and *h*ydrocephalus). L1CAM is a transmembrane glycoprotein, which is expressed during development on the surface of long axons and growth cones, including those of the corticospinal tracts. L1 mediates cell adhesion, neurite outgrowth, axon pathfinding, and fasciculation through homophilic and heterophilic binding with a variety of extracellular and transmembrane molecules, and plays an important role in mediating guidance of corticospinal axons through the pyramidal decussation.

Myelin-Associated Genes

Disruption of intimate glia to axon interactions underlies the axonal degeneration observed in SPG2 patients. SPG2 maps to Xq22 and results from mutations in the

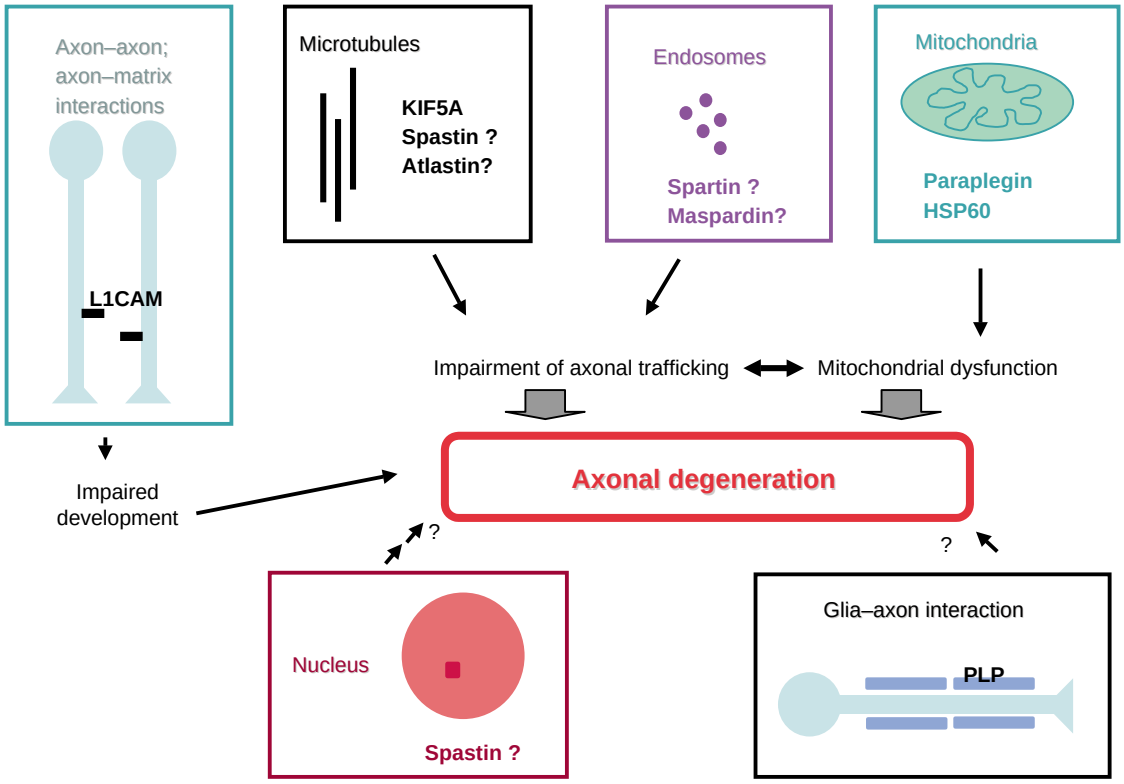

FIGURE 1 Proposed pathogenic mechanisms underlying axonal degeneration in HSP. Known proteins involved in HSP belong to different cellular compartments. Several of them, however, are believed to cause axonal degeneration either through mitochondrial dysfunction (paraplegin and Hsp60) or impairment of axonal transport (KIF5A, spastin, atlastin, spartin, and maspardin). Since mitochondria travel along axons, and play a major role in providing the energy necessary for axonal transport, the two pathways are likely to communicate. HSP can also be the result of defective development of the corticospinal tracts, as in the case of mutations in L1CAM, or of aberrant communications between glial cells and axons due to mutations in PLP1 protein. The role of spastin in the nucleus is still to be elucidated.

proteolipid protein (PLP), one of the major protein components of myelin in the central nervous system (CNS). PLP is a four-helix-spanning membrane protein that stabilizes the structure of the CNS myelin, by forming the intraperiod line. SPG2 comprises both pure and complicated forms of HSP, and is allelic to the severe hypomyelinating Pelizaeus–Merzbacher disease (PMD). A genotype-phenotype correlation between the nature of PLP mutation and the severity of the clinical picture has been described. In general, the milder phenotypes, such a pure spastic paraplegia, are observed when the gene mutations lead to the formation of protein products that are still able to traverse the secretory pathway and reach the cell surface. Surprisingly, knockout mice with complete absence of PLP, assemble compact myelin sheaths, but subsequently develop widespread axonal swelling and degeneration, most likely secondary to impaired axonal transport. It is still a mystery how the correct expression of PLP in olygodendrocytes provides support for myelinated axons. The future identification of putative signaling molecules would probably lead to a better understanding of this pathological cascade.

SPG6/NIPA1

In 2003, Rainier *et al.* reported mutations in the NIPA1 gene in a family with autosomal-dominant HSP linked to chromosome 15q11–q13 (SPG6). NIPA1 encodes for a predicted transmembrane protein, highly expressed in the brain. The function of NIPA1 is still unknown.

A Common Pathogenic Mechanism for HSP

The recent identification of several genes involved in HSP is beginning to shed light on the pathogenesis of this disorder. Although the known genes all belong to different families and have distinct subcellular localization (Figure 1), two common pathogenic themes have begun to emerge: (1) impairment of mitochondrial protein quality control and (2) defective axonal trafficking. These two routes likely intersect, since mitochondria themselves need to be transported along axons, and ATP is required to support transport of endosomes, cytoskeletal elements, synaptic vesicles, and other organelles. Future functional studies of the known HSP proteins, together with the identification of new genes, will provide new exciting insights in this chapter of neuro-degenerative diseases.

Glossary

haplo-insufficiency A locus shows haplo-insufficiency when the amount of the gene product produced by a single allele is not sufficient to achieve a normal phenotype.

paraplegia Paralysis of both lower limbs.

spasticity Muscular weakness associated with increased stiffness and overactive reflexes.

Biography

Elena Irene Rugarli is a Group Leader at the Telethon Institute of Genetics and Medicine (TIGEM) in Naples, Italy. Her principal research interest is in the field of neuro-degeneration, in particular, the pathogenic mechanisms of hereditary spastic paraplegia. She holds an M.D. from the University of Milan, Italy, and received her postdoctoral training at Baylor College of Medicine in Houston, TX.

Andrea Ballabio is Director of the Telethon Institute of Genetics and Medicine (TIGEM) and Professor of Medical Genetics of the Federico II University in Naples, Italy. He holds an M.D. and is board-certified in Pediatrics. His main scientific interests comprise the identification of the molecular basis and pathogenetic mechanisms of genetic diseases as well as the use of functional genomics in medicine.

Spectrophotometric Assays

Britton Chance
University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania, USA

This brief history describes the impact of technical developments upon the progress of biophysics and biochemistry and focuses upon the contributions of optical spectroscopy. The optical method (now termed spectroscopy) served Otto Warburg well, and in the mid-1930s he developed a unique spectrophotometer. The device was so complicated that it was likely never used. However, it had some nice features; particularly, instead of balancing with slits and neutral density filters, it balanced intensities in the two beams by means of rotating sector discs. Furthermore, it had a high-quality monochromator that allowed Warburg to identify the important absorption bands of NADH (nicotinamide adenine dinucleotide; called DPNH at the time) and furthermore to identify the fluorescence of the reduced state. The optical determination of NADH was one of the great triumphs of analytical biochemistry, as evidenced by the large number of assays through which it was developed, primarily in Germany, where it eventually becomes the basis of the Boehringer company, and providing Olle Lowry, Janet Passoneau, and collaborators with a unique handle on micro-enzymatic assays. This quantitative method far surpassed the visual spectroscopic studies of David Keilin. Indeed, even the keen eyes of Keilin failed to confirm the absorption bands of flavoprotein and NADH as respiratory carriers. Surely flavoprotein was detectable, but because both flavoprotein and NADH were considered "Warburg's territory," it is not surprising that Keilin did not concentrate on flavin.

Manual Spectrometers

The rightfully famous physicist R. W. Wood made a high-quality plastic replica grating and incorporated a pair of them in the Coleman spectrophotometer to make a double-grating instrument that was valid from 400 to 700 nm, had a very good *f* number, and had a resolution independent of wavelength (~20 nm). This was an essential element of the kinetic and spectroscopic study of the enzyme–substrate compounds of catalases and peroxidase, as carried out in the laboratory of Hugo Theorell. While it was an excellent commercial instrument for laboratory work in a visible region, Cary's quartz monochromator, however, together with Beckman's unreferenced exploitation of DuBridge's ingenious electrometer (of the pH meter as well), made the Beckman DU instrument superior. However, if Charles Chaplin were to make a film of the biochemist similar to "City Lights," this instrument would serve the purpose. Dark current adjustment, slit-adjustment, cuvette holder shifting, and balancing to a null by hand were the earmarks of the instrument that most biochemists used from the 1940s to the early 1960s. Not that there were no alternatives. C. C. Yang invented what was called the "Yang machine," a very simple and robust instrument used by many in the Johnson Foundation laboratory, which used a vibrating mirror system to send light through a reference cuvette and a measure cuvette, together with dynode feedback, and gave a logarithmic output. Concurrently, Lenart Åckerman in the laboratory of Bo, Thorell in Stockholm invented the same machine that also provided spectral scans but that was held off the market for about a decade so the DU could have an orderly and prosperous senescence.

Dual-Wavelength Technology

The development of dual-wavelength systems began with Glen Millikan, who ingeniously scribed a barrier in the Weston photovoltaic cell and used green and red filters to measure myoglobin spectral changes in the visible region. However, he connected the output to a mirror galvanometer so that the system was intrinsically quite slow and thus unsuitable for the rapid measurements required for the flow apparatus. The dual-wavelength principle was continued in the Millikan ear oximeter used so effectively during World War II.

Rapid spectrophotometry required phototubes. The significant experience Britton Chance had acquired with them by inventing an automatic steering device while still in his teens led him to use cesium oxide on silver and then antimony as photocathodes. These were combined with the technology of high-gain DC amplification from the electrophysiologists Adrian, Gasser, Erlanger, and the Schmitt brothers, who all had to develop an entire field of electronic amplification for studying nerve action potentials. The three-wavelength system used to measure the kinetics of

enzyme–substrate compound formation in the Soret region, together with the overall formation of leucomalachite green to malachite green, provided measurements of enzyme–substrate compounds that required a mechanical differential analyzer for the transient solution of the Michaelis–Menten/Briggs–Haldane equations for enzyme kinetics (Figure 1). Indeed, the rapid flow apparatus led the field of fast spectrophotometric determinations, not only of the enzyme–substrate compounds of peroxidase but also, in the hands of Quentin Gibson, for measuring hemoglobin kinetics.

The introduction of the chopper-stabilized amplifiers in systems exploited during World War II by the Group 63 of Chance and colleagues (Precision Circuits Group at MIT RadLabs) led to a whole new generation of low-level amplifiers and was the basis for many commercial instruments. Furthermore, the basis for the integrated circuit was afforded by the subminiature triodes developed for the proximity fuse, for which the rejection rate was so high that thousands of these diodes suitable for peacetime applications became available and were made in the first step of integrated circuits, precursors of the integrated chips that were soon to come in the post-war era.

Photochemical Action Spectra

One historic experiment, which now seems almost to have been forgotten, was performed by the Schmitt brothers in order to validate the Warburg hypothesis, namely, to obtain the photochemical action spectrum for the propagation of action potentials in nerves. The results did, in fact, coincide with Warburg's hypothesis and provided the much-needed link between prokaryote and eukaryote. The Schmidt brothers received very

Michaelis-Menten Theory

These reactions are represented by Briggs and Haldane as the bimolecular combination of the enzyme, E, and substrate, S, to form an intermediate compound, ES, followed by a monomolecular decomposition into free enzyme and activated or altered substrate, Q, representative of the products of the "over-all" enzyme action.

$$E + S \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_3} E + Q \tag{4}$$

If e is the total molar enzyme concentration, x the molar substrate concentration, p the molar concentration of ES, k_1 the second order rate constant, and k_2 and k_3 the first order rate constants, then

$$\frac{dp}{dt} = k_1 x(e - p) - (k_2 + k_3)p \tag{5}$$

$$\frac{dx}{dt} = -k_1 x(e - p) + k_2 p \tag{6}$$

These two equations represent the rate of formation of the intermediate compound and the rate of disappearance of the substrate.

The solution of these equations has been already obtained by Briggs and Haldane for the special conditions of the steady state, when

$$p = p_{\max.}, \qquad \frac{dp}{dt} = 0, \qquad \text{and} \qquad \frac{p_{\max.}}{e} = \frac{x}{x - Km} \tag{7}$$

where

$$Km = \frac{k_2 + k_3}{k_1} = x\,\frac{(e - p_{\max.})}{p_{\max.}} \tag{8}$$

A further solution valid during the steady state is obtained by adding Equations 5 and 6,

$$\frac{dx}{dt} = -k_3 p_{\max.} \tag{9}$$

where dx/dt is the rate of disappearance of substrate.

FIGURE 1 Michaelis–Menten theory.

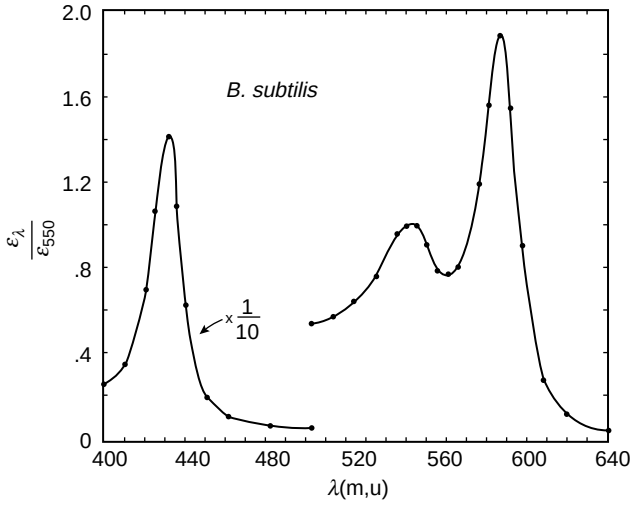

FIGURE 2 Photochemical action spectrum of cytochrome oxidase as obtained by the LeRoy Castor using the oxygen electrode to measure light activated respiration. It is seen that this spectrum is much better defined than Warburg's classic spectrum of yeast where mainly the lines of the mercury arc were employed. Here a continuous monochromated light would be used and the σ bands were clearly delineated as are the Soret bands.

little credit for their work, without which Warburg's and Keilin's work, based on yeast cells only, would have been less acceptable (Figure 2). At the time, there was no reason to believe that the eukaryotic yeast cell was a model for tissue studies. LaRoy Castor quickly improved the action spectral method and also discovered a heme prosthetic group oxidase (cytochrome *o*).

Tissue Spectroscopy

Glen Millikan was a pioneer in shining light through tissue and recording myoglobin deoxygenation in functional activity. During the same time, there were many microspectroscopic studies by Arvanitaki and Chalazonitis, and also, notably, by the laboratory of Casperson with his colleague Bo Thorell. Lundegårth was a pioneer in applying the spectroscopic technique to bundles of plant roots, but was unable to correct for the large changes of scattering due to the osmotic activity of the roots. However, Lou Duysens developed a sensitive single-beam method that he applied with diligence and effectiveness to cytochrome components of green leaves.

A time multiplex dual-wavelength system made possible by simply mounting on top of the "Brown" converter, or vibrating a small mirror at 60 Hz, allowed time sharing of two wavelengths through suspensions of highly scattered material derived from heart muscle or from liver as intact mitochondria. This dual-wavelength machine was the precursor of the time multiplex systems that have been used for exploiting near infrared spectroscopy.

The Scattered Light Problem

It was recognized early on that the scattered light would confound spectrophotometric measurements of pigments of tissue. Yet, in 1949, Chance recognized that the scattered light effect would be greatly diminished if the solid angle of the detector system were large instead of small, as in commercial spectrophotometers (for long cuvettes). Thus, instead of a 10-cm-long sample compartment, as used in most of the Beckman/Cary devices, Chance and colleagues placed a large area detector and an "end-on" photomultiplier almost in contact with the sample, particularly using the time-shared dual-wavelength system, from which very flat baselines were obtained for spectroscopic differences as long as the wavelength difference was not too great. The difference spectrum obtained from guinea pig liver mitochondria is shown in Figure 3 as an example of the data that were obtained with the dual-wavelength spectrophotometer, where the baseline was set at the suspected isosbestic points of 540 and 630 nm. The action spectrum for reduction of the oxidized form of the electron carriers was measured. This spectrum, although validating Keilin's microspectroscopy, clearly showed some anomalies. Cytochrome c_1 was a separate component. A trough due to the disappearance of oxidized flavin and peaks due to appearance of reduced NADH were not identified by Keilin's keen eye, which proved to be the most useful components of the respiratory chain because they were highly fluorescent. But most importantly, they were inhabitants of the mitochondrial matrix space where most of the citric acid cycle reactions were carried out. The instrument was surely very worthwhile. It had not only identified three components of the respiratory chain that had been previously underestimated or remained completely unobserved, but also, for example, the difference spectrum obtained by Lucille Smith and Aristid Lindenmeyer showed the P450 compound of carbon monoxide, an observation confirmed by G.R. Williams and used by P450 enthusiasts today.

Control of Respiration

No other phenomenon was as important to physiologists as the control of respiration. The topic had received very little attention until Lardy and Wellman's historic paper, which showed that isolated prepared mitochondria very nearly completely ceased respiration in the absence of ADP and phosphate but restarted respiration upon addition of ADP and phosphate. This led Chance and

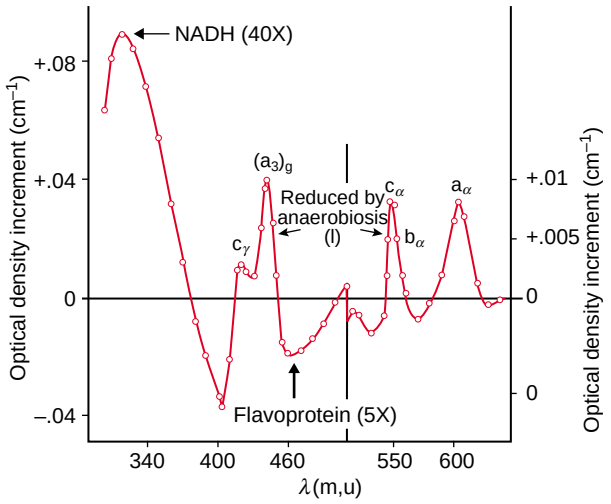

FIGURE 3 The difference spectrum of intact phosphorylating mitochondria. This was the first difference spectrum for oxidized minus reduced guinea pig liver mitochondria obtained with the dual wavelength method employing reference wavelengths of 540 nm for the alpha bands and 450 nm for the Soret band. The incremental absorption with respect to that reference is indicated giving the ratio of the Soret to the alpha bands to be 4 and the NADH peak to be 40 times that of the alpha peaks. The flavoprotein trough, i.e., oxidized flavoproprotein is the absorber, is shown at 460 nm. While the Soret peak of cytochrome oxidase was visible at 444 nm by Keilin's microspectroscope, the flavin trough and the NADH peak (the latter being responsible for the intense autofluorescence of cells) was not available to Keilin in Hartree's heart muscle preparation in which the absorbance of these two components was greatly diminished by the elimination of cytric acid cycle enzymes.

Williams to explore the nature of activation of the electron carrier in the respiratory chain. They found that that all spectroscopically identifiable components changed their steady-state values when ADP was added to the suspension of resting mitochondria. This phenomenon now provides the basis for all of the metabolic activations studied by magnetic resonance imaging (MRI) as the bulb effect, and for using the saturation of oxyhemoglobin *in vivo* as a measure of metabolic activity.

At the same time, Lehninger, Chance, and others studied the uptake of calcium into the mitochondrial matrix, and Chance and Williams found that calcium activated the suspensions of mitochondria to the same extent and with the same speed as did ADP suggesting, as recently discussed by Carafoli, the presence of a calcium carrier in the mitochondrial membrane.

Low-Temperature Technology

Perhaps the most secure instrumental data were those obtained at low temperature in liquid nitrogen, where the spectra were more intense. The delineation of the absorption bands, particularly in the bc_1 region, turned out to be essential in showing the two kinds of cytochromes *b*.

Lubbers' Rapid Scan

Tissue absorption and scattering occupied the minds of a number of workers, particularly those of Lubber and Thews, who not only did much theoretical work on scattering but also perfected a galvanometer-driven wavelength scanning device, whose speed far exceeded that of anything else available at the time and which has only been perfected recently by the work of Desr and his colleagues.

Photoactivation Studies

Perhaps the greatest advantage of the technique for observing tissue properties was the fact that it was possible to photoactivate the system under spectroscopic examination and observe the photoinduced absorption spectrum, a specialty of the Laboratory of Lou Duysems. This, of course, required a measure of common mode rejection, at which the dual-wavelength system excelled because the light flashes shared a single detector with an AC coupling, allowing the system to reject leakage of not only the photolysis light but also other disturbances that affected the common mode. Furthermore, illumination at subzero temperatures of the solid phase allowed the study of many photoactivated systems containing derivatives of chlorophyll or those rendered photoactivatable by combining with a ligand such as carbon monoxide. Thus, optical measurements in the region of the Soret band and illumination in the region of the alpha band allowed a measure of protection of the dual-wavelength detector system from very strong photolysis light, for example, that provided by intense sources such as the carbon arc. These studies bridged the gap between Otto Warburg's unbridgeable action spectrum experiment on yeast and Keilin and Hartree's microspectroscopical observations of cytochrome oxidase in yeast and in a pigeon heart muscle preparation.

Not only the cytochrome oxidase–CO complex CO, but also the splitting and recombination of myoglobin CO compounds were studied in detail, with optical spectroscopy as well as structural methods such as EXAFS (X-ray absorption spectroscopy), with results that make headlines even today for the subject of ligand docking concomitant with structural changes, confirming the X-ray structural studies in which the E7 histidine was altered by a ligation of myoglobin with CO.

The Ruby Laser and Electron Tunneling

Lacking powerful light sources of short duration, Chance and colleagues relied mainly upon xenon flash

lamps, particularly those of Edgerton and colleagues. However, construction of the first ruby laser used in biological studies by Bunkenberg and DeVault opened up a whole new time domain, not only because of the monochromaticity of the laser (which greatly simplified the filter leakages) but also because of the duration of the light pulse (in the microsecond region), which for the time was extraordinarily short. From this study came the totally unexpected observation that the photochemical oxidation of cytochrome *c* by photoactivated chlorophyll of *Chromatium* was temperature independent, not only from room temperature to liquid nitrogen temperature, but eventually at liquid helium temperatures, extending the time range of the spectroscopic method to one of the primary or near primary results and/or reactions of photosynthesis (Figure 4), and also introducing the concept of electron tunneling in biochemical reactions, a concept pursued by Les Dutton and Harry Gray.

The history of spectroscopy is checkered with unexpected results and meaningful interpretations on the nature of electron transfer reactions. In fact, the study of reactions obtained from photolysis activation of CO compounds in the presence of O_2 caused ligand exchange to occur, especially in the case of CO. Together with Carlo Saronio, Chance discovered a number of intermediate steps involving higher oxidation states of iron mirroring those obtained with peroxidase and H_2O_2, but much faster and more complex. This was because copper oxidation was involved in the active site of CO, enabling donation of four electrons sequentially for the reduction of oxygen to water without significant amounts of free radical intermediates. This contrasted with the photoactivation of porphyrins in the absence of electron donors, resulting in the creation of singlet oxygen, a process used extensively in photodynamic therapies.

Fluorochromes of Tissues

Spectroscopy of biological fluorochromes, such as NADH and flavoprotein compounds that exhibit strong fluorescence in mitochondria, led Chance and co-workers to study them extensively *in vivo* by a simple method in which excitation was obtained by the very strong 366 and 436 lines of the mercury arc. This yielded emission spectra characteristic of the chromophores in a variety of functional states, characterizing electron transfer through the citric acid cycle as reductant and the cytochrome chain as oxidants, giving essential features of the redox state of the mitochondrial matrix. Interpretations of the importance of metabolic control and thermodynamic principles of the system were derived from these, particularly by R. L. Veech.

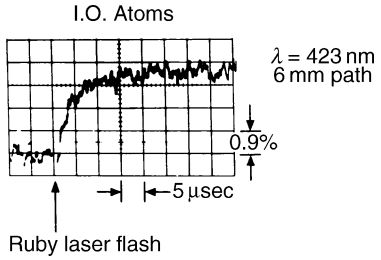

FIGURE 4 Typical recording of the oxidation of cytochrome c of photosynthetic bacteria at low temperatures as activated by a light flash of the ruby laser. Remarkably this reaction rate was affected very little by the transition from room temperature to liquid nitrogen temperature due to electron tunneling.

Hemoglobin and Cytochrome

It is perhaps ironic that the cell biologists and etymologists of the Molteno Institute focused on the cytochromes of hemoglobin-free cells and tissues and that the "real" physiology of oxygen delivery to tissues by hemoglobin and its utilization by CO had to wait for more sophisticated methods. Even now, the observation of cytochrome oxidase absorption bands in the presence of physiological concentrations of oxy and deoxy-hemoglobin is fraught with controversy, to the point that no reliable spectroscopic distinction of the copper component of cytochrome oxidase and the overlapping spectra of oxy-hemoglobin has been obtained. In fact, nearly all studies find that the so-called cytochrome oxidase Cu changes track those of HbO_2 due to the similarity of their spectroscopic absorption bands in the near infrared (NIR) region, and the great predominance of hemoglobin absorption over that of cytochrome oxidase.

NADH as an Oximeter

It has been shown that the fluorescence of NADH and flavoprotein, when used in a ratiometric manner, can exhibit a reasonable immunity to changes of hemoglobin concentration, and has afforded standards for the independent changes of hemoglobin and NADH in transient hypoxia and re-oxidation. Such independence of the measures of cytochrome and hemoglobin has never been clearly demonstrated for the copper component of cytochrome oxidase, due to the overlapping spectra of oxyhemoglobin.

An alternate approach was based upon the fluorescence of the newly discovered NADH and flavoprotein components of the mitochondrial respiratory chain, particularly by using the ratio of these two fluorochromes. Fortunately, NADH fluoresced in the reduced state while flavoprotein fluoresced in the oxidized state, so their ratio was a measure of the redox state of mitochondria, a signal that was found to be only marginally affected by changes in the oxygenation of hemoglobin in model systems. Using this criterion on the

very strong signal of NADH only, it was possible to show that the fluorescence of NADH was unchanged until the oxy/deoxy transition of hemoglobin was almost complete in a system in which functional activity was measured by the photoaction potential of an animal model, removing any doubt about the higher oxygen affinity of cytochrome *in vivo* as compared to hemoglobin (~20 Torr). This was a very important milestone for physiologists, who know that the deoxygenation of hemoglobin is very high and the critical pO_2 of mitochondrial function is compromised. Thus, the calibration of tissue oximeters in the region of intravenous saturation of hemoglobin (i.e., 20–30%) must be precisely measured to indicate critical tissue hypoxia *in vivo*. This indeed was subsequently validated by measurements of tissue energetics through phosphorus nuclear magnetic resonance (^{31}P NMR), particularly by measurements of the phosphocreatine:phosphate ratio.

NIR Spectroscopy

Jobsis used Kramer's technique to measure in the infrared, and developed a technology for the measurement of absorption of the copper component of cytochrome oxidase in the region of 830 nm based upon studies of the cat model and the heads of neonates, which he termed "transcranial spectroscopy." He further developed algorithms based upon fluorocarbon-perfused cat brain to give optical pathlengths that were believed to be transferable to the neonate brain and allow a deconvolution of blood volume and saturation changes from those of cytochrome oxidase signals using the full-length light algorithm. Delpy and co-workers avidly followed the lead of Jobsis and developed a close correlation between the decreased concentration of oxyhemoglobin and the so-called copper signal in a number of models, suggesting that the mitochondria in tissues contained a low-affinity cytochrome oxidase and responded to pO_2 (in a slice) in a way similar to that of hemoglobin. However, isolation of rat brain mitochondria failed to support this contention. Furthermore, the freeze-trapped hypoxic brain failed to show the absorption band of reduced cytochrome *c* in mild hypoxic stress that caused deoxygenated hemoglobin. In fact, the absorption band of reduced cytochrome *c* was not observed until the band of oxyhemoglobin was no longer detectable, according to the work of Bashford.

While attempts were made to detect the copper absorption band of hemoglobin in the NIR region, animal studies showed that the fluorescence of NADH and the flavoprotein could be used to detect anoxia in the presence of hemoglobin, particularly when the ratio of the fluorescent oxidized flavoprotein and the fluorescent reduced NADH were employed; this value was relatively insensitive to the hemoglobin concentration. In fact, further demonstrations showed that the fluorescence of NADH was unaffected by the deoxygenation of hemoglobin in animal model brain. The NADH fluorescence increased in hypoxia only when the hemoglobin was already almost completely deoxygenated. This observation suggests that measurements of the critical pO_2 in hypoxia require accurate measurement of extreme values of hemoglobin desaturation, at the critical pO_2 for mitochondrial function.

NIR Spectroscopy of Brain and the BOLD Effect Measured by MRI

Much interest in the NIR method is based upon Ogawa's finding that changes in deoxyhemoglobin concentration (changes of the paramagnetic species of deoxyhemoglobin) enhanced water relaxation in the brain. This opened up the field of study of the activation phenomenon in the human brain, in which changes in deoxyhemoglobin levels are measured by NMR and by NIR tissue spectroscopy. The MRI changes are precisely imaged, while the NIR images, although crude, are measures of the rapidity of the changes. But in addition to incremental changes of deoxyhemoglobin, NIR could measure the saturation value of hemoglobin, which, for reasons involving Beer's law, originates mainly from the arteriolar/capillary/venolar bed. This feature, namely, the value of local oxygen extraction due to incremental changes of mitochondrial functional activity (i.e., localized activation), is not measured by MRI. The two techniques are now widely accepted as indicative of localized brain activation and have afforded the basis for in-depth studies of visual and sensory motor function. But, most importantly, NIR gives an excellent rendition of prefrontal cortex (PFC) signals without the difficulty of the large water content of the ocular system encountered with NMR (Figure 5). The use of activation images is appropriate to the NIR system, where baseline values may be somewhat variable and difficult to calibrate. The incremental changes of blood volume measured as changes of total hemoglobin, together with the aforementioned oxygen extraction measure, i.e., desaturation of hemoglobin, can be directly related to local metabolic activity, opening up a new field of NIR study of the semi-quantitative nature of the hemoglobin signals.

NIR Imaging

While the above-mentioned studies used dual-wavelength technology stemming from that of Glenn Millikan, a completely new concept was introduced by the discovery that photon migration through tissues can
