Structurally, both CNG and HCN channels are members of the superfamily of voltage-gated cation channels. Like other subunits encoded by this large gene family CNG and HCN channel subunits assemble to tetrameric complexes. The proposed structure and the phylogenetic relationship of mammalian CNG and HCN channel subunits is shown in Figure 1. The transmembrane channel core consists of six α-helical segments (S1–S6) and an ion-conducting pore loop between the S5 and S6. The amino- and carboxy-termini are localized in the cytosol. CNG and HCN channels contain a positively charged S4 helix carrying three to nine regularly spaced arginine or lysine residues at every third position. In HCN channels, as in most other members of the channel superfamily, the S4 helix functions as "voltage-sensor" conferring voltage-dependent gating. In CNG channels which are not gated by voltage, the specific role of S4 is not known.

CNG and HCN channels reveal different ion selectivities. CNG channels conduct both Ca^{2+} and monovalent cations with permeability ratios P_{Ca}/P_{Na} ranging from about 2 to 25 depending on the respective channel type and the cyclic nucleotide concentration. By providing an entry pathway for Ca^{2+}, CNG channels control a variety of cellular processes that are triggered by this cation. In contrast, HCN channels are not permeable to Ca^{2+}. These channels pass Na^+ and K^+ ion with a relative permeability ratio P_{Na}/P_K of about 0.15–0.25.

In the carboxy-terminus, CNG and HCN channels contain a cyclic nucleotide-binding domain (CNBD) that has significant sequence similarity to the CNBDs of most other types of cyclic nucleotide receptors. In CNG channels, the binding of cyclic nucleotides to the CNBD initiates a sequence of allosteric transitions that lead to the opening of the ion-conducting pore. In HCN channels, the binding of cyclic nucleotides is not required for activation. However, cyclic nucleotides shift the voltage-dependence of channel activation to more positive membrane potentials and thereby facilitate voltage-dependent channel activation. Despite the fact that the CNBDs of HCN and CNG channels show significant sequence homology, the two channel classes reveal different selectivities for cyclic nucleotides. HCN channels display an approximately 10-fold higher affinity for cAMP than for cGMP, whereas CNG channels select cGMP over cAMP.

CNG Channels

CNG channels are expressed in retinal photoreceptors and olfactory neurons and they play a key role in

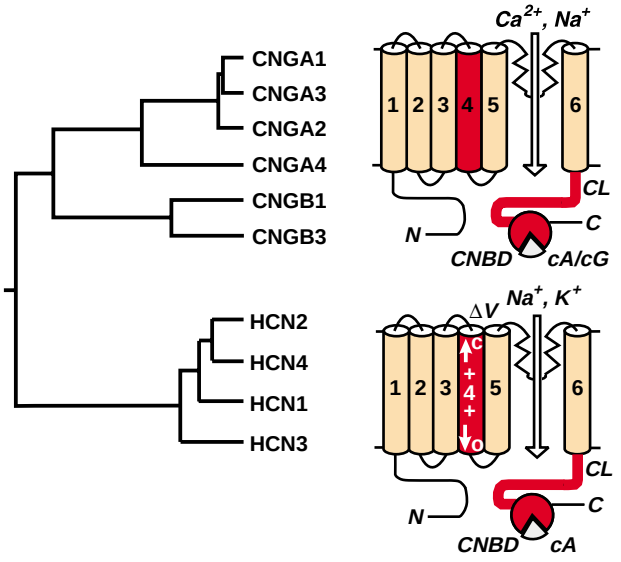

FIGURE 1 Phylogenetic tree and structural model of cyclic nucleotide-regulated cation channels. The CNG channel family comprises six members, which are classified into A subunits (CNGA1–4) and B subunits (CNGB1 and CNGB3). The HCN channel family comprises four members (HCN1–4). CNG and HCN channels share a common transmembrane topology, consisting of six transmembrane segments (1–6), a pore loop, and a cyclic nucleotide-binding domain (CNBD). CNG channels are activated *in vivo* by binding of either cAMP (cA) or cGMP (cG), depending on the channel type. HCN channels activate on membrane hyperpolarization (ΔV) and are enhanced by binding of cAMP. Structures involved in channel gating are shown in red. The positively charged amino acid residues in the S4 segment of HCN channels are indicated by (+). The movement of the S4 leading to channel closure (c) or opening (o) is indicated by arrows. CL denotes the C-linker involved in activation gating of CNG and HCN channels.

visual and olfactory signal transduction. CNG channels are also found at low density in some other cell types and tissues such as brain, testis, and kidney. While the function of CNG channels in sensory neurons has been unequivocally demonstrated, the role of these channels in other cell types remains to be established. Based on phylogenetic relationship, the six CNG channels identified in mammals are divided in two subfamilies, the A subunits (CNGA1-4) and the B subunits (CNGB1 and CNGB3) (Figure 1). CNG channel A subunits (with the exception of CNGA4) can form functional homomeric channels in various heterologous expression systems. In contrast, B subunits do not give rise to functional channels when expressed alone. However, together with CNGA1–3 they confer novel properties (e.g., single-channel flickering, increased sensitivity for cAMP and L-cis diltiazem) that are characteristic of native CNG channels. The physiological role and subunit composition is known for three native CNG channels: the rod photoreceptor channel, the cone photoreceptor channel, and the olfactory channel. The CNG channel of rod photoreceptors is a tetramer composed of three CNGA1 and one long isoform of the CNGB1 subunit (CNGB1a). The cone photoreceptor channel consists of the CNGA3 and the CNGB3 subunit. CNG channels control the membrane potential and the calcium concentration of photoreceptors. In the dark, both channels are maintained in the open state by a high concentration of cGMP. The resulting influx of Na^+ and Ca^{2+} (dark current) depolarizes the photoreceptor and promotes synaptic transmission. Light-induced hydrolysis of cGMP leads to the closure of the CNG channel. As a result, the photoreceptor hyperpolarizes and shuts off synaptic glutamate release. Mutations in CNG channel genes have been linked to retinal diseases. Mutations in the CNGA and CNGB1 subunits have been identified in the genome of patients suffering from retinitis pigmentosa. The functional loss of either the CNGA3 or the CNGB3 subunit causes total color blindness (achromatopsia) and degeneration of cone photoreceptors.

The CNG channel expressed in cilia of olfactory neurons consists of three different subunits: CNGA2, CNGA4, and a short isoform of the CNGB1 subunit (CNGB1b). The channel is activated *in vivo* by cAMP that is synthesized in response to the binding of odorants to their cognate receptors. The olfactory CNG channel is thought to conduct almost exclusively Ca^{2+} under physiological ionic conditions. The resulting increase in cellular Ca^{2+} activates a Ca^{2+}-activated Cl^- channel that further depolarizes the cell membrane. Ca^{2+} is not only a permeating ion of the olfactory CNG channel, it also represents an important modulator of this channel. By forming a complex with calmodulin, which binds to the CNGA2 subunit, Ca^{2+} decreases sensitivity of the CNG channel to cAMP.

The resulting inhibition of channel activity is the principal mechanism underlying odorant adaptation. Recent studies indicate that CNGA4 and the CNGB1b units also contribute to the CaM-dependent feedback inhibition.

HCN Channels

A cation current that is slowly activated by membrane hyperpolarization (termed I_h, I_f, or I_q) is found in a variety of excitable cells including neurons, cardiac pacemaker cells, and photoreceptors. The best understood function of I_h is the control of heart rate and rhythm by acting as "pacemaker current" in the sinoatrial (SA) node. I_h is activated during the membrane hyperpolarization following the termination of an action potential and provides an inward Na^+ current that slowly depolarizes the plasma membrane. Sympathetic stimulation of SA node cells raises cAMP levels and increases I_h by a positive shift of the current activation curve, thus accelerating diastolic depolarization and heart rate. Stimulation of muscarinic receptors slows

down heart rate by the opposite action. In the brain, I_h fulfills diverse functions: it controls the activity of spontaneously spiking neurons (neuronal pacemaking), it is involved in the determination of resting potential, it provides rebound depolarizations in photoreceptors in response to pronounced hyperpolarizations, it is involved in the transduction of sour taste and it is involved in the control of synaptic plasticity.

HCN channels represent the molecular correlate of the I_h current. In mammals, the HCN channel family comprises four members (HCN1–4) that share about 60% sequence identity to each other and about 25% sequence identity to CNG channels. The highest degree of sequence homology between HCN and CNG channels is found in the CNBD. When expressed in heterologous systems, all four HCN channels generate currents displaying the typical features of native I_h: (1) activation by membrane hyperpolarization, (2) permeation of Na^+ and K^+, (3) positive shift of the voltage-dependence of channel activation by direct binding of cAMP, (4) channel blockade by extracellular Cs^+. HCN1–4 mainly differ from each other with regard to their speed of activation and the extent by which they are modulated by cAMP. HCN1 is the fastest channel, followed by HCN2, HCN3, and HCN4. Unlike HCN2 and HCN4 whose activation curves are shifted by about + 15 mV by cAMP, HCN1 is only weakly affected by cAMP (shift of less than +5 mV). Site-directed mutagenesis experiments have provided insight into the complex mechanism underlying dual HCN channel activation by voltage and cAMP. Surprisingly, the voltage-dependent movement of the positively charged S4 helix is fully conserved between HCN channels and depolarization-activated channels such as Shaker K-channels. However, the allosteric coupling between S4 movement and the activation gate is different in the two channel types. In HCN channels, inward movement of S4 leads to the opening of the channel gate, whereas it closes Shaker channels. Major determinants affecting channel activation are the intracellular S4–S5 loop, the S5–P linker, the S1 segment, and the extracellular S1–S2 loop. The CNBD fulfills the role of an auto-inhibitory channel domain. In the absence of cAMP, the cytoplasmic carboxy-terminus inhibits HCN channel gating by interacting with the channel core and thereby shifts the activation curve to more hyperpolarizing voltages. Binding of cAMP to the CNBD relieves this inhibition. Differences in the magnitude of the response to cAMP among the four HCN channel isoforms are largely due to differences in the exent to which the CNBD inhibits basal gating. It remains to be determined if the inhibitory effect of the CNBD is conferred by a direct physical interaction with the channel core domain or by some indirect pathway. There is initial evidence that the so-called C-linker, a peptide of about 80 amino acids that connects the last transmembrane helix (S6) to the CNBD, plays an important role in this process (Figure 1). The C-linker was also shown to play a key role in the gating of CNG channels, suggesting that the functional role of this domain has been conserved during channel evolution.

Genetic deletion experiments in mice have been performed to facilitate the analysis of the physiological and pathophysiological role of individual HCN channel subunits in neuronal and cardiac function. Mice lacking the HCN2-subunit are viable but display a complex neurological–cardiological phenotype including absence epilepsy, ataxia, and sinus arrhythmia. As a likely explanation for this phenotype it was found that the loss of HCN2 induces a pronounced shift of the resting membrane potential and thereby impairs regular cardiac and neuronal rhythmicity. HCN4 represents the predominantly expressed HCN channel isoform in SA node. Deletion of HCN4 results in embryonic lethality after day 9.5 dpc. Electrophysiological studies with HCN4-deficient embryonic heart cells revealed that HCN4 underlies most if not all of the cardiac I_f current at early embryonic stages. Furthermore, HCN4 seems to be required for normal differentiation of the cardiac pacemaker system. Mice lacking the brain-specific HCN1 show a motor deficit, which is likely a result of altered firing rhythms in Purkinje neurons.

Glossary

channel states Voltage-gated channels have at least three states: a closed, an open, and an inactivated state. Ions conduct through the channel at the open state.

ligand-gated channel In contrast to voltage-gated channels, ligand-gated channels are opened by the occupation of the ligand binding site. HCN channels are gated by the membrane potential and are modulated by the binding of cAMP.

olfaction The processing of smell in the nose and olfactory bulb.

pacemaker Specialized cells that depolarize at a known frequency. The best-known example is the sino-atrial node of the heart.

photoreceptor Part of the rod or cone in the retina that senses light.

Biography

Martin Biel is a Professor in Pharmacology and Chair of the Institute of Pharmakologie für Naturwissenschaftler, Science Faculty at the Ludwigs-Maximillian-University München. His research interests are cyclic nucleotide regulated ion channels and CNG and HCN channels. He holds a Ph.D. in Pharmacy. He obtained his Habilitation in Pharmacology at the Medical Faculty of the Technische Universität München.

Franz Hofmann is Professor in Pharmacology and Chair of the Institute for Pharmakologie und Toxikologie, Medical Faculty at the Technische Universität München. His primary research interest is cyclic nucleotide-regulated cellular functions, including cGMP protein kinases and ion channels. He holds an M.D. from the Universität Heidelberg. His group has contributed many seminal papers on the regulation of L-type calcium channels, CNG-channels, pacemaker channels, and the biology of cGMP kinase.

Cysteine Proteases

David J. Buttle
University of Sheffield, Sheffield, UK

John S. Mort
Shriners Hospital for Children, Montréal, Canada

Cysteine proteases represent one of the four main groups of peptide-bond hydrolases. They all use a S^- anion of a cysteine side chain as the nucleophile in peptide-bond hydrolysis. Cysteine proteases are found in all forms of life and mediate a wide variety of physiological and pathological processes, from the bulk digestion of protein, on the one hand, to highly regulated rate-determining and specific peptide-bond cleavages at the opposite extreme. They are implicated in a number of human pathologies, and the development of cysteine protease inhibitors as drugs is a very active field.

Phylogenetic Relationships

The use of the cysteine residue thiolate ion as the nucleophile for peptide-bond cleavage appears to have been derived at least five times during evolution using different structural frameworks, and members of each of these protease families are widely distributed. However, the bulk of these enzymes are members of clans CA and CD as classified in the MEROPS database (a regularly updated and invaluable source of information on proteases) (Figure 1). Clan CA contains the earliest identified cysteine proteases, such as the papaya protease papain, and the mammalian proteases, for example cathepsins B, L, S, and K. These enzymes are generally present in lysosomes or in other membrane-bound compartments where they mediate antigen processing and presentation, or they are secreted from the cell. As a group, clan CA proteases show cleavage selectivity for the residue 2 positions N-terminal to the cleavage site. A related subfamily of papain-like enzymes is the calcium-dependent calpains, which are found in the cytoplasm and mediate various intracellular processes.

The second major group of cysteine proteases, clan CD, has been described much more recently and includes the caspases, legumains, several viral proteases, and separase, which is responsible for the separation of sister chromatids during mitosis. Unlike the papain family, these proteases generally show exquisite specificity for cleavage C-terminal to particular amino acid residues – aspartic acid in the case of caspases, asparagine for legumains, and arginine for separase. The caspases are the mediators of apoptosis.

Mechanism

Proteolytic enzymes are very efficient catalysts that can increase the rate of peptide-bond hydrolysis a billion-fold. In the case of the cysteine proteases, the catalytic mechanism has been most extensively investigated for the clan CA enzymes. Despite their distinct evolutionary origins, it appears that the mechanism of other cysteine proteases is quite similar (an example of convergent evolution). Cleavage of the peptide bond is dependent on a thiolate-imidazolium ion pair provided by the cysteine and histidine residues in the active site (Figure 2). The environment of the active site results in an unusually low pK_a of around 4 for the cysteine thiol group. Nucleophilic attack on the carbonyl group results in the formation of a tetrahedral oxyanion intermediate. This then accepts a proton from the imidazolium group, resulting in the formation of an acyl enzyme intermediate and the release of the C-terminal portion of the substrate. In a second reaction, the acyl enzyme intermediate is deacylated by a water molecule and the remaining portion of the substrate is released.

Control

Activation

As is the case with most proteolytic enzymes, cysteine proteases are synthesized as inactive precursors, allowing them to be delivered to their intended site of action without harming the biosynthetic machinery of the cell. Often these proenzymes are retained in an inactive form until their services are required. Very different strategies have evolved for the activation of the precursors of the different cysteine protease groups. In the case of the

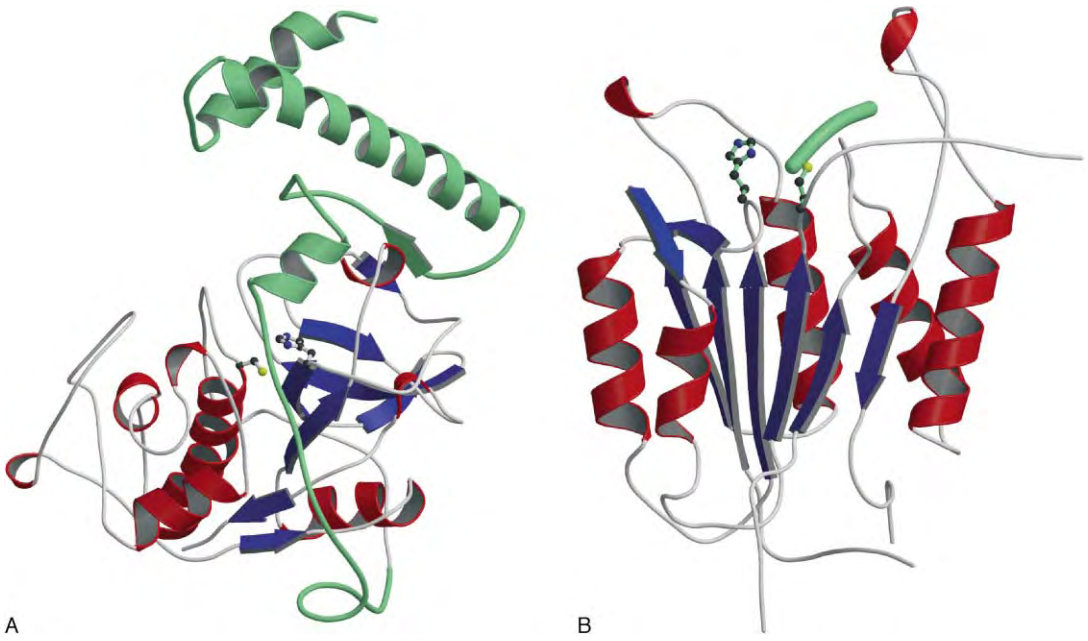

FIGURE 1 Cysteine protease structure. Ribbon diagrams of representative members of the two principal cysteine peptidase clans: (A) cathepsin K (pdb 1by8), a member of the papain family in Clan CA shown as the proenzyme, and (B) caspase-3 (pdb 1cp3), a member of clan CD. The active site cysteine and histidine residues are shown in ball and stick representation. For caspase-3, the position occupied by the substrate is indicated by the green rod. For procathepsin K, the proregion is depicted in green. The extended coil linking the helical region of the propiece passes through the active site in the region normally occupied by the substrate. Processing of the proforms of papain family members requires the proteolytic removal of the proregion without any change to the structure of the protease component. In contrast, major restructuring of the active site occurs during caspase activation and the active form of the enzyme is a dimer of the structure shown.

papain family, an N-terminal propeptide blocks access to the fully functional active site by binding in the reverse orientation to that required for peptide-bond cleavage (Figure 1). Its removal via inter- or intramolecular proteolysis liberates the functional protease. In contrast, the caspases undergo dimerization, which signals a rearrangement of the protein to form the previously incomplete active site.

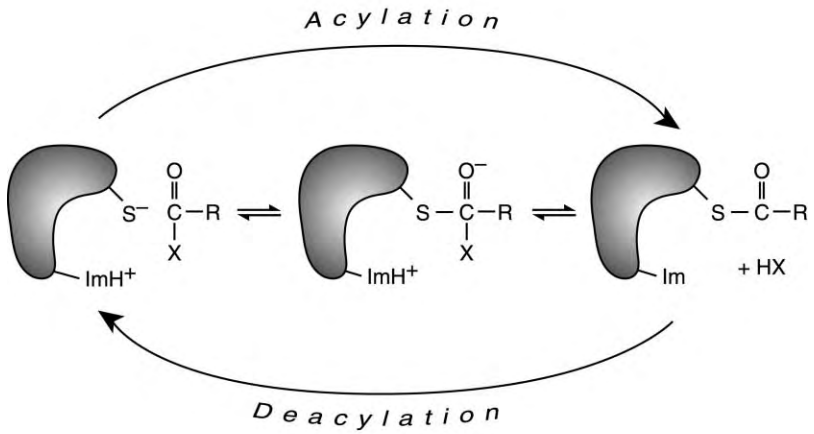

FIGURE 2 Cysteine protease mechanism. Scheme for the reaction mechanism of cysteine protease action. The active-site cysteine and histidine residues are present as a thiolate (S^-)-imidazolium (ImH^+) ion pair. The substrate is represented by the carbonyl group under attack connected to the N-terminal peptide component R and the C-terminal component X. Upon substrate binding, nucleophilic attack by the thiolate ion results in the formation of a tetrahedral oxyanion intermediate. This, following proton donation from ImH^+, breaks down to form an acyl enzyme (thiol ester) intermediate with the release of the C-terminal fragment HX. Adapted from Polgár and Asbóth (1986). The basic difference in catalysis by serine and cysteine proteinases resides in charge stabilization in the transition state. *J. Theor. Biol.* **121**, 323–326.

Inhibitors

A further level of control for unwanted proteolytic activity is provided by the action of a series of cysteine protease inhibitors. Members of the cystatin family are highly effective inhibitors of papain-like enzymes. The N terminus of the cystatin molecule binds in the active site cleft in a substrate-like manner, but the inhibitor evades cleavage by the target protease due to the presence of a glycine residue at what would normally be the site of cleavage. Additional elements in the inhibitor bind to the protease to maneuver the N-terminal substrate region just out of the range of the catalytic residues. A separate family of inhibitors, termed inhibitors of apoptosis proteins (IAPs), is available for the caspases. These proteins bind across the active caspase, obstructing normal substrate access but making limited interactions with the protease. Analogous to the propeptides of the papain family members, IAPs ensure their resistance to proteolysis by binding in the reverse direction to that required for substrate cleavage.

Physiology

Lysosomal Proteolysis

Virtually all eukaryotic cells possess membrane-enclosed organelles known as lysosomes This structure is the site of breakdown of endocytosed or phagocytosed material, and it is also the location for the turnover of certain cytosolic proteins and organelles. In most eukaryotic cells, the lysosome has the highest concentration of cysteine proteases and other hydrolases, which implies that these enzymes are involved in protein degradation for the recycling of amino acids for protein synthesis. This is indeed likely to be the major physiological function of ubiquitously expressed cysteine proteases such as cathepsin L, legumain, cathepsin B, and cathepsin H. Indeed, the last two enzymes, which fragment polypeptides (endopeptidase action) and then attack the fragments at either the C-terminal end, in the case of cathepsin B (carboxypeptidase action), or at the amino terminus, in the case of cathepsin H (aminopeptidase action), are functionally well equipped to fulfill a digestive role.

Antigen-Ii Processing

In the major histocompatibility complex (MHC) class II antigen-presenting cells, such as dendritic cells, macrophages, and B lymphocytes, the lysosomal or endocytic localization of some cysteine proteases has allowed them to participate in antigen presentation to T cells. In this process, the antigen is endocytosed and fragmented into peptides of between 13 and 26 amino acids in length. In order to allow the peptides thus generated to bind to the MHC complexes for presentation at the cell surface, the invariant chain Ii must be cleaved in order to remove it from the peptide-binding groove. Cathepsin S has been known for some time to be highly expressed in antigen-presenting cells and recently the use of selective cathepsin S inhibitors and the generation of cathepsin S-null mice has demonstrated an important, but not solitary, role for this enzyme in Ii processing.

It is likely that a number of endosomal proteases are involved in antigen processing and also that the protease involved is dependent on the nature of the antigen. In some cases at least, legumain appears to play an important role.

Bone Turnover

Bone is continually being broken down and replenished. This is important in calcium homeostasis, in which soluble calcium is provided by the hydrolysis of the mineral fraction of bone. At the same time, the organic component of bone, consisting largely of type I collagen, is also removed. Although a normal physiological process, under some circumstances bone resorption can outstrip synthesis. This can lead to the condition known as osteoporosis or brittle bone disease, which largely affects postmenopausal women. Other situations in which bone resorption is outside normal homeostatic control include bone metastases and some rare genetic diseases. The process of bone resorption is mediated largely by the multinucleated cell type known as an osteoclast. During periods of active resorption, osteoclasts sitting on bone surfaces generate a ruffled membrane, effectively sealing off the area immediately beneath the cell into which proteolytic enzymes and acid are secreted to remove the organic and mineral components, respectively. Both cysteine proteases and matrix metalloproteinases have been implicated in the hydrolysis of the organic component of bone, and it is likely that the relative contributions played by these different enzymes depend on the type of bone, with cysteine proteases playing a dominant role in the resorption of long bone.

The discovery that pycnodysostosis, an autosomal recessive disease leading to short stature and bone fragility, was due to a deficiency in cathepsin K activity, provided the first indication that this cysteine protease played a major role in bone resorption. Laboratory experiments have demonstrated this enzyme's efficiency at cleaving type I collagen, and consequently it has become a major drug target for the treatment of bone-resorbing diseases.

Other cysteine proteases are likely to be involved in bone resorption. For instance, legumain acts as an inhibitor of bone resorption by inhibiting the formation of multinucleated osteoclasts from their mononuclear precursors. The precise mechanism is not known, but it is not linked to the catalytic activity of the enzyme, and

in fact the active component is the C-terminal peptide that is removed upon generation of full catalytic activity.

Thyroglobulin Processing

The distribution of cathepsin K is quite restricted, being found predominantly in the ovary and in the osteoclasts, the bone-degrading cells. The other site where cathepsin K is highly expressed, alongside the more ubiquitously distributed cathepsins B and L, is in the thyroid follicles, which are the site of storage of thyroglobulin, the precursor of the thyroid hormones. It appears from experiments using single- and double-knockout mice that all three of these cysteine proteases are involved in thyroid hormone generation from thyroglobulin. All are found in the lumen of thyroid follicles, where cathepsin L appears to be involved in both the solubilization of cross-linked thyroglobulin and subsequent generation of thyroid hormones. In contrast, cathepsin B may be primarily involved in thyroglobulin solubilization and cathepsin K in thyroid hormone generation.

Apoptosis

The importance of programmed cell death to developmental processes has been recognized for many years. The discovery that the proapoptotic *ced-3* gene of *Caenorhabditis elegans* encodes a protease homologous to the mammalian cysteine protease interleukin-1β-converting enzyme (ICE), together with the demonstration that ICE induces apoptosis in mammals, ignited a great deal of renewed interest in the field, due in large part to the desire of the pharmaceutical industry to control the process. This article is too short to do justice to such a large area of research, which has been the subject of a number of good reviews (see Further Reading). Briefly, the proteases most intricately involved in the process of apoptosis are the caspases (including ICE), all of which have acute specificity for the cleavage of aspartyl bonds and which function in a cascade reaction. Upstream caspases activate downstream caspases, which cleave proteins whose functions are essential to cell survival. One of the initiators of this cascade event is the occupation of cell surface death receptors of the tumor necrosis factor receptor 1 family, which triggers the activation of caspase 8. Alternatively, the formation of a complex with cytochrome c and Apaf-1 in response to DNA damage leads to the activation of caspase 9. Both of these initiating caspases then activate the downstream executioner caspases, such as caspase 3. In cell killing by cytotoxic T cells or NK cells, this pathway is highjacked in the target cell through the ability of the killing cell's serine proteinase, granzyme B, to activate caspases.

It has become increasingly clear that, under some circumstances, cysteine proteases other than caspases are involved in apoptosis. For instance, cathepsin B may be involved in death receptor-mediated apoptosis of tumor cells if downstream caspases are inhibited. This process is expedited by tumor necrosis factor- and caspase 8-induced increases in cytosolic cathepsin B and subsequent release from mitochondria of cytochrome c.

Pathology

Cysteine proteases have been implicated in a wide range of pathologies, including cancer, osteoporosis, and arthritis. Here we concentrate on their involvement in two other pathological situations that may be less fully appreciated.

Allergenic Proteinases

Proteases represent a disproportionately high number of allergens. Examples include the major allergen from the house dust mite (a cysteine protease that is the product of the *Der p*1 gene) and many plant cysteine proteases such as actinidain, bromelain, papain, and glycyl endopeptidase. The normal route for the generation of atopy involves the initiation of a Th2 lymphocyte phenotype and enhanced IgE responses by B cells. Although the mechanisms by which cysteine (and other) proteases favor a switch to a Th2-like response are not completely elucidated, a link with the catalytic activity of these enzymes has been made. The mechanisms may be many and varied and include the cleavage (and activation?) of IgE and IL-2 receptors and disruption of epithelial tight junctions, thus enhancing access by allergens to immune cells. However, a systematic analysis of potential molecular targets for these enzymes has not been undertaken.

Parasitic Proteinases

Many parasites contain cysteine proteases in their phagocytic vacuoles, where they are involved in the digestion of engulfed material to be used in satisfying the nutritional requirements of the organism. As such, these enzymes are potential therapeutic targets. Examples include *Entamoeba histolytica*, a causative agent of amoebic dysentery; trypanosomatids that cause African sleeping sickness and Chagas' disease; schistosomal organisms and the plasmodial parasites that are the causative agents of malaria; and a number of parasitic helminths. In the case of plasmodial parasites, the cysteine proteases are known to be instrumental in the degradation of host hemoglobin, the principal source of amino acids for the parasite, because enzyme inhibition blocks hemoglobin degradation and parasite development. In a mouse model of the human disease, an orally administered inhibitor of the enzyme produced a 40%

cure rate, and a delayed progression of the disease in the remaining animals. New treatments for this and other parasitic diseases that kill millions every year are badly needed, due to increasing resistance to currently available drugs.

Glossary

endocytosis The taking in by a cell of soluble or membrane-bound material from outside the cell. In the case of eukaryotic cells, endocytosed material passes into the endosome, a membrane-limited organelle that can fuse with lysosomes to allow digestion of the contents.

homeostasis The normal balance of a healthy living organism, in which the status quo is maintained by regulatory mechanisms such as feedback control. In protein turnover, it is the balance between protein synthesis and protein breakdown.

hydrolase An enzyme that breaks peptide, ester, or glycoside bonds by the addition of water. In the case of proteases, water is split, and the resulting oxygen is added to the newly formed carboxyl terminus while the two hydrogens are added to the new amino terminus formed by the breaking of the peptide bond.

protease An enzyme that cleaves proteins or peptides (also called proteinase, peptidase, or proteolytic enzyme).

specificity Susceptibility of an amino acid sequence of a peptide or protein to cleavage by a particular protease. Most proteases possess specificity for the cleavage of particular sequences. For instance, caspases cleave immediately after aspartic acid residues (they cleave aspartyl bonds); most lysosomal cysteine proteases cleave the second peptide bond on the carboxyl side of a hydrophobic residue, the exception being legumain, which cleaves asparaginyl bonds. Specificity is conferred by the structure of the substrate-binding groove on the protease.

Biography

David J. Buttle is Reader in Matrix Biology in the Division of Genomic Medicine at the University of Sheffield, U.K. His principal research interests are the turnover of extracellular matrix proteins by proteases and how this relates to various diseases such as arthritis, multiple sclerosis, and cancer. He received a Ph.D. from the Council for National Academic Awards, U.K., before receiving postdoctoral training at the Strangeways Research Laboratory, Cambridge, U.K.

John S. Mort is a Principal Investigator at the Shriners Hospital for Children and an Associate Professor in the Departments of Surgery and Medicine at McGill University in Montreal, Canada. His research program aims to determine the role of specific proteolytic enzymes in connective tissue remodeling during growth and development and in its destruction in arthritis. He received his Ph.D. from McMaster University, Hamilton, Canada, and his postdoctoral training at the University of Western Ontario.

Cytochrome b_6f Complex

Günter A. Hauska and Thomas Schödl
Universität Regensburg, Regensburg, Germany

The cytochrome b_6f-complex connects oxygen evolution by photosystem II, with NADPH production by photosystem I (PSI), in the photosynthetic electron transport (ET) chain of plants, algae, and cyanobacteria. More specifically, it reoxidizes plastoquinol, which has been produced in the membrane by PSII with electrons coming from water, at the expense of plastocyanin or cyt *c*, the electron donors to PSI. It belongs to the family of the cytochrome *bc*-complexes, which function at central position in many eukaryotic and prokaryotic ET chains. They all oxidize quinol in a proton translocating redox reaction, which is best described by the so-called Q-cycle. The resulting transmembrane electrochemical proton gradient drives ATP synthesis in a rotatory mechanism of the H^+-translocating F1Fo-ATP synthases. The scenario holds for respiration and photosynthesis, from higher organisms down to bacteria and archaea.

Quinol oxidation is the rate-limiting step in these ET chains ($\tau \sim$ ms), and therefore a key point for regulation. Plastoquinol oxidation by the cyt b_6f-complex in oxygenic photosynthesis, for example, controls the distribution of light quanta to the two photosystems, via a protein kinase, which by phosphorylation determines the association of chlorophyll antenna proteins with the reaction centers.

Crystal structures of the cytochrome b_6f-complex at atomic resolution have recently been obtained for the prokaryotic cyanobacterium *Mastigogladus laminosus* as well as for the eukaryotic green alga *Chlamydomonas reinhardtii*. They largely resemble the dimeric structures for the cytochrome bc_1-complex from mitochondria, but also reveal some striking differences. In addition to the four redox centers – two hemes *b*, one heme *c*, and a high potential 2Fe2S-cluster per monomeric complex – which are shared with the cyt bc_1-complex, the cyt b_6f-complex per monomer contains one chlorophyll *a*, one carotenoid, and most surprisingly, an extra heme.

Discovery and Isolation

Cytochromes b_6 and f were discovered in leaves by Robin Hill in the middle of last century.

The reduction of cyt f by red light absorbed in PSII and its reoxidation by far-red light absorbed by PSI led to the formulation of the "Z-scheme" of photosynthetic ET in chloroplasts, with the two light reactions acting in series, connected by cyt f.

The first evidence for a complex between these two cytochromes was provided by Nelson and Neumann (Tel-Aviv) in 1972, who recognized that a particle isolated from chloroplasts contained redox centers similar to the cyt bc_1-complex from mitochondria – heme b, heme c, and nonheme iron. A little later Wood and Bendall described a plastoquinol–plastocyanin oxidoreductase activity solubilized from chloroplasts. Both observations were combined by Hurt and Hauska, who succeeded in the isolation of the complex with a well-defined composition in functionally active form from spinach chloroplasts. In addition to plastoquinol–plastocyanin oxidoreductase activity, the isolate catalyzed oxidant-induced reduction of cyt b_6, a signature of the Q-cycle mechanism. Furthermore, during the redox reaction it transcolated protons across the membrane in an electrogenic way, after incorporation into lipid vesicles.

The isolation procedure involved four steps – removal of peripheral proteins, selective solubilization by a mild, nonionic detergent, ammonium sulfate precipitation, and sucrose density gradient centrifugation. These procedures have been modified repeatedly, resulting in improved isolates with turnover numbers up to $500\ s^{-1}$, from spinach as well as from other organisms, but in principle the strategy is followed until today.

Composition and Structure

The cyt b_6f-complex consists of four major polypeptides with two pairs of redox centers which differ by 300–400 mV in the redox potentials under standard conditions. The pair with the higher redox potentials is represented by a heme c (+340 mV) covalently bound to cyt f, and by the 2Fe2S-cluster (+300 mV) of the Rieske FeS–protein. The pair with the lower potentials are the two hemes b on cyt b_6 (−50 and −150 mV). The fourth polypeptide (subunit IV) lacks a redox center. According to a nomenclature for cyanobacteria, cyt f, cyt b_6, the Rieske FeS–protein, and subunit IV are also known as

PetA, PetB, PetC, and PetD, respectively (Pet standing for photosynthetic electron transport), and are coded by the corresponding *pet* genes.

The folding of these subunits in the thylakoid membrane is depicted in Figure 2. They correspond to the central components in the cyt bc_1-complex of mitochondria and bacteria. Cyt c_1 (~33 kDa) resembles cyt *f*, the Rieske FeS–protein (some 20 kDa) occurs in both systems, and the N-terminal part of cyt *b* (~42 kDa) is equivalent to cyt b_6 (24 kDa), while its C-terminal part corresponds to subunit IV (17 kDa).

Several bacterial cyt bc_1-complexes contain just these central components, cyt c_1, cyt *b* and the Rieske FeS–protein, while the eukaryotic bc_1-complexes in mitochondria contain 7–8 "supernumerary" subunits, which do not occur in the cyt b_6f-complex. On the other hand four small hydrophobic polypeptides (3.2–4.2 kDa) have been identified in the cyt b_6f-complex only. These are PetG, PetL, PetM, and PetN, each consisting of little more than a transmembrane helix (Figure 2). In the crystal structure they are found as a transmembrane four-helix bundle, distal to the symmetry axis of the dimer (Figure 3).

Cytochrome *f*

Mature cyt *f* is a 31 kDa protein built from ~290 amino acids. It holds the heme *c* covalently bound to the pentapeptide CxxCH in an elongated, peripheral domain, largely of β-sheet structure. This domain is exposed to the intrathylakoid surface, which becomes positively charged during illumination (p-side, s. Figure 1), and is anchored by a C-terminal transmembrane helix. The fifth ligand to the heme iron is an N-atom of a histidine, while the sixth ligand is exceptional for a *c*-type cytochrome: it is the free α-amino group of the N-terminal tyrosine (Figure 2).

Cytochrome b_6 + Subunit IV

These two subunits are integral membrane proteins, spanning the membrane seven times together. Cyt b_6 (24 kDa, 215 amino acids) contains four hydrophobic helices, the second and fourth holding the two hemes *b* by four H-residues in transmembrane arrangement (Figure 2). These histidines are strictly conserved in all cyt *bc*-complexes. Subunit IV (17 kDa, 160 amino acids) comprises three transmembrane helices. These correspond to helices 5–7 in cyt *b* (42 kDa) from bc_1-complexes, which spans the membrane 8 times. The eighth helix is missing in subunit IV.

In addition to the two hemes *b*, cyt b_6 contains a third heme, which came as a surprise from the crystal structures (Figure 3). It has escaped spectroscopic detection, because it is a low-spin heme. It is of the *c*′-type, being covalently bound by only one of its vinyl groups to C-37 of cyt b_6, which is conserved in all b_6f-complexes. This covalent binding is responsible for the old, but misinterpreted notion that cyt b_6 stains for heme on denaturing SDS-polyacrylamide electrophoresis, in contrast to other cyt's *b*. Noteworthy, this covalently bound heme has been described for the b_6f-type complex of the respiratory, Gram-positive bacterium *Bacillus subtilis* by Yu and LeBrun in 1998 already, without wide recognition, however. It may be involved in ferredoxin–plastoquinone reduction, as an additional entry of electrons into the cyt b_6f-complex.

The hydrophobic region of cyt b_6 and subunit IV furthermore binds a chlorophyll *a* and a carotenoid (Figure 3).

The Rieske FeS–Protein

This protein with a 2Fe2S cluster of +300 mV has been discovered by John S. Rieske in mitochondria in 1964. The unusually high redox potential for a FeS–protein results from "softer" ligation of one Fe to the N-atoms

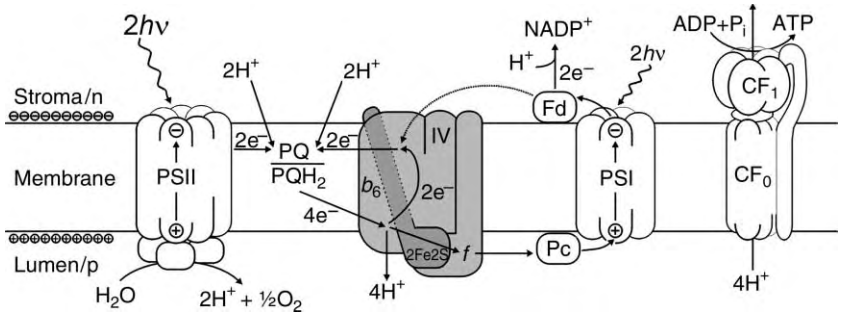

FIGURE 1 The cytochrome b_6f-complex in the chloroplast membrane. The transfer of two electron equivalents from PSII to PSI, and the accompanying proton transfer reactions are shown, indicating the bifurcation of the reduction equivalents from plastoquinol in the Q-cycle of the cyt b_6f-complex. Abbreviations: b_6, cyt b_6; *f*, cyt *f*; 2Fe2S, FeS-cluster of the Rieske protein; IV, subunit IV; PQ, plastoquinone; PC, plastocyanin; Fd, ferredoxin; CF1CFo, H^+-translocating ATP synthase; "p" and "n" denote the positively and negatively charged membrane surfaces; the dotted arrow indicates cyclic electron flow around photosytem I.

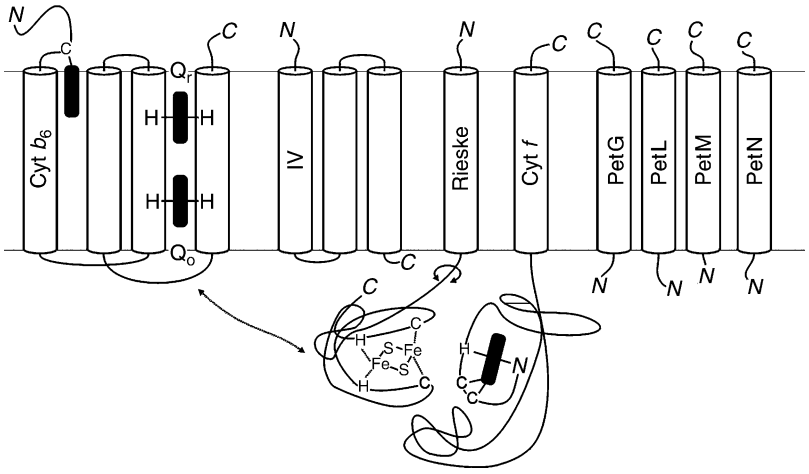

FIGURE 2 Folding of the protein subunits in the cytochrome b_6f-complex across the thylakoid membrane. The solid and dotted double-headed arrows indicate the domain movement of the Rieske FeS–protein by rotation at the "hinge" region. Q_o and Q_r denote the sites of plastoquinol oxidation and plastoquinone reduction, respectively. Italic Ns and Cs stand for N and C termini. Further explanations are given in the text.

of two H-residues, instead of S-atoms of C-residues (Figure 2). The protein of the cyt b_6f-complex consists of 179 amino acids (20 kDa). The two cluster binding peptides are CTHLGC and CPCHGSQY, containing a histidine and two cysteins each. The first cystein in each peptide ligates the other Fe-atom, while the second two cysteins form a stabilizing S–S bond. H-bonds from S and Y in the second peptide stabilize the reduced form of the cluster, additionally increasing the redox potential by some 60 mV per H-bond. Rieske proteins of lower redox potentials occur in menaquinol oxidizing organisms, and carry non-H-bonding residues at these positions.

Like the heme c carrying part of cyt f, the cluster carrying domain of the Rieske FeS–protein is exposed to the p-surface (Figures 1 and 2), and is tied to the membrane by a single transmembrane helix, at the N terminus. Noteworthy, like in the crystal structures of the cyt bc_1-complexes, the Rieske FeS–protein cross-connects the dimer of the cyt b_6f-complex, the

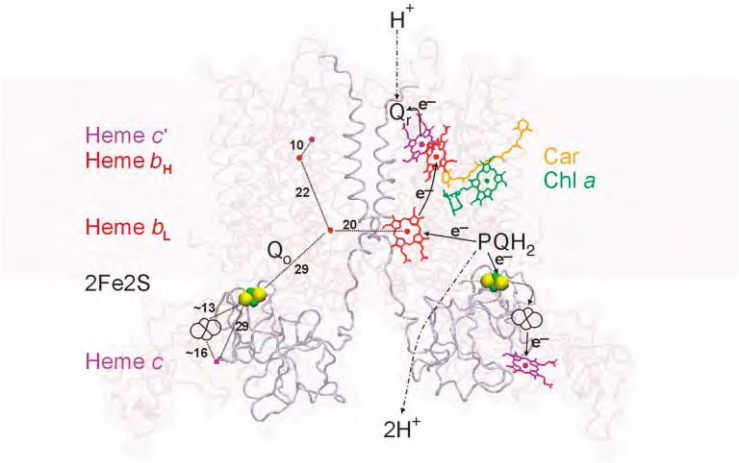

FIGURE 3 Distances, electron and proton transfer in the crystal structure of the dimeric cytochrome b_6f-complex. The figure was constructed from the coordinates for the complex of *Mastigogladus laminosus* submitted to the PDB, accession code 1UM3. The dimeric structure is not totally symmetric, while the one from *Chlamydomonas rheinhardtii* is (PDB accession code 1Q90). Further discrepancies between the two structures are under debate (Daniel Picot, personal communication). In the figure the dimeric structure is depicted in the membrane with its peripheral surface contours and the Cα-backbone in gray. The backbone of the Rieske FeS–protein which cross connects the dimer is emphasized in darker gray. The 2Fe2S cluster is depicted on both halves, the irons in green and the sulfurs in yellow. Its movement to the position closer to the heme c of cyt f is indicated. The positions of the four hemes are shown with the porphyrin rings on the right, and as the central irons on the left. The distances between the metal centers in numbers of Å are given on the left half, while the right includes the electron and proton transfer steps plus the bound molecules of chlorophyll a (Chl a) and carotenoid (Car). Abbreviations: b_H and b_L, high and low potential heme b in cyt b_6; Q_o and Q_r, sites of plastoquinol oxidation and plastoquinone reduction.

FeS-domain being associated with cyt *f* of one-half and the hydrophobic helix with the other (Figure 3). Whether the dimeric structure bears on the function is an unsettled question still. The FeS-domain is linked to the transmembrane helix by a flexible, G-rich "hinge" region, which by rotation allows for the movement of the FeS-domain during the redox cycle. This movement has been documented in oriented samples by polarized EPR, and is indicated by double-headed arrows in Figure 2. The two positions of the FeS-center have been detected in the crystal structure of the mitochondrial cyt bc_1-complex by analyzing preparations with and without the specific inhibitor stigmatellin, which locks the conformation into the form with the FeS-center closer to heme b_L of cyt b_6, at the Qo-site. Only this position of the FeS-center is seen in the structures of cyt b_6f-complex, since the tridecyl derivative of stigmatellin was used to obtain ordered crystals. The second position close to the heme of cyt *f* has been modeled into the cyanobacterial structure, however, and is indicated in Figure 3, which depicts further features of the overall structure. Noteworthy, an electron density close to the heme c' at the Qr-site has been interpreted as bound plastoquinone in the cyanobacterial structure, which has not been identified in the structure for the eukaryotic alga.

Plastoquinol Oxidation – Q-Cycle and Fes-Domain Movement

In 1960, Britton Chance discovered oxidant-induced reduction of cyt *b* during oxygen pulses of anaerobic mitochondria. A decade later Marten Wikström explained this phenomenon as a "pull–push" effect of ubiquinol oxidation in the cyt bc_1-complex, which involves the reactive semiquinone intermediate. Accordingly, Peter Mitchell proposed the Q-cycle mechanism in 1975, which has been reformulated by Antony Crofts, Bernie Trumpower, and others.

The observation of oxidant-induced reduction of cyt b_6 in the isolated cyt b_6f-complex, with pulses of ferricyanide in the presence of excess plastoquinol, was of key importance for acceptance of an operating Q-cycle also in chloroplasts, because the earlier detection in membrane preparations was complicated by reduction of cyt b_6 in cyclic ET around PSI. Quinol oxidation at the Q_o-site is the rate-determining step in ET not only because of second order kinetics, but also because it involves the movement of the 2Fe2S-cluster carrying, peripheral domain in the Rieske protein. The Q-cycle mechanism, as indicated in Figures 1 and 3, comprises the following:

1. Two quinone/quinol interaction sites with different semiquinone stability, and accessible from the aqueous space on opposite membrane surfaces, with two pairs of redox centers at two different redox potential levels.
2. At the Q_o-site the Rieske FeS-center (+300 mV) oxidizes plastoquinol.
3. The resulting instable semiquinone anion is highly reducing (redox potential of semiquinone anion/plastoquinone ~ − 150 mV), and for kinetic reasons does not deliver its electron to the FeS-center but to nearby low-potential heme *b* (− 150 mV) of cyt b_6. This bifurcation is the rate-determining step ($\tau \sim$ ms) of the whole cycle, and causes the oxidant-induced reduction of cyt *b*. It is responsible for the transition from 2e- to 1e-transfer in the electron transport chains of photosynthesis and respiration.
4. Furthermore, this step is linked to the movement of the 2Fe2S-cluster towards the heme *c* of cyt *f* (Figures 2 and 3), close enough for efficient electron transfer. At the same time the oxidized plastoquinone is replaced by plastoquinol from the quinol/quinone pool.
5. The electron from low-potential heme *b* moves across the membrane to the high-potential heme *b* (− 50 mV), and from there to a plastoquinone molecule at the quinone reduction site (Q_r-site), which allows for the electron uptake by stabilizing the resulting semiquinone anion.
6. This semiquinone anion receives a second electron coming from the Q_o-site across the membrane via the two heme *b*, takes up two protons from the n-surface and leaves the site as plastoquinol in exchange for plastoquinone.

An alternative view to the Q-cycle is the "semiquinone cycle," in which the instable semiquinone at the Q_o-site changes into the stable semiquinone at the Q_r-site, either by movement or by conformational dynamics.

In summary, the Q-cycle transports four protons across the membrane per two electrons passing from plastoquinol through the cyt b_6f-complex to plastocyanin. Together with the liberation of two protons in water oxidation inside the thylakoids (p-side), and proton uptake by reduction of CO_2 via $NADP^+$ outside, a total of six protons are translocated across the chloroplast membrane per 2e if the Q-cycle operates (Figure 1). Evidence for a down-regulation to $4H^+/2e$, i.e., a shut down of the Q-cycle at high-energy pressure across the chloroplast membrane has been provided.

One of the two electrons at the bifurcation point reduces cyt b_6, branching off through the membrane. It contributes the "slow phase" to the charge separation across the chloroplast membrane, in addition to the fast phases in the two RCs. These phases are known from the "carotenoid shift," an electrochromic effect on the absorption of carotenoids.

Several inhibitors of electron transport through the cyt b_6f-complex are in use, most of them interfering with quinol oxidation at the Q_o-site. Among them are the antibiotics stigmatellin and myxothiazol, and the quinone analogues DBMIB (2,5-bromo-3-methyl-6-isopropyl-p-benzoquinone) and UHDBT (5-undecyl-6-hydroxy-4,7-dioxobenzothiazole). As mentioned above, the tridecyl derivative of stigmatellin TDS was used to obtain stable crystals. Antimycin A, a Q_r-site inhibitor in cyt bc_1-complexes, and which was valuable in elucidating the Q-cycle mechanism, because it stimulates oxidant-induced reduction of cyt b by blocking its reoxidation with quinone, unfortunately is inefficient in the cyt b_6f-complex. Possibly the additional heme c' at the Q_r-site does not allow the binding of antimycin A. However, MOA-stilbene (β-methoxacrylate-stilbene) acts on the Q_r-site in the cyt b_6f-complex, like antimycin A in the cyt bc_1-complex. Heptyl- or nonyl-4-hydroxyquinoline N-oxides (HQNO and NQNO) block the quinol/quinone interaction at both sites, with a higher affinity for the Q_r-site.

Oxidation of plastoquinol and the coherent movement of the Rieske FeS–protein are rate determining in photosynthetic electron flow, and therefore are linked to regulatory phenomena, like the optimization of the light distribution to the two photosystems via activation of LHCII-kinase (state transitions), but also in light regulation of gene expression.

In the dark and in low light, under aerobic conditions, the chloroplasts are in state 1, with the plastoquinone pool largely oxidized and the outer chlorophyll antenna LHCII associated with PSII for transfer of excitation energy. At high light pressure PSII reduces plastoquinone, and the resulting plastoquinol, via a reduced state of the cyt b_6f-complex, activates a specific kinase which phosphorylates LHCII and causes it to move to PS1. Preferential excitation of PS1 (state 2) reoxidizes plastoquinol leading to deactivation of the LHCII-kinase, deposphorylation of LHCII-P by a phosphatase, and the movement of LHCII back to PSII. This way the distribution of the light quanta between the two photosystems is optimally balanced. LHCII-kinase has been found associated with the cyt b_6f-complex.

Noteworthy, the electron flow through the cyt b_6f-complex *in vivo* can be measured in detail by single turnover laser flash photolysis, or by chlorophyll fluorescence induction (Kautsky-effect) with pulsed light.

Genes, Biogenesis, and Phylogeny

In cyanobacteria, the genes for the major subunits of the cyt b_6f-complex are organized in two transcription units, *petCA* for the Rieske FeS–protein and cyt *f*, and *petBD* for cyt b_6 and subunit IV. The genes for the four small subunits PetG, PetL, PetM, and PetN occur in isolated loci. In eukaryotic plants and algae the genes for the Rieske FeS–protein, *petC*, and for one of the small subunits, *petM*, were moved to the nucleus, while the others remained on the chloroplast genome. In vascular plants *petBD* and *petA* were combined with other genes in transcription units, while in green algae like *Chlamydomonas* these genes have been further rearranged and are transcribed independently.

The nuclear genes *petC* and *petM* acquired N-terminal extensions for signal peptides to recognize the machinery for the uptake of the preproteins into chloroplasts. There they are processed by signal peptidases to the mature proteins during insertion into the thylakoid membrane and assembly with the complex. Since the major part of Rieske FeS–protein faces the intrathylakoid surface (p-side), it has to pass the chloroplast envelope as well as the thylakoid membrane on the path from cytoplasmic ribosomes. Thus it is processed in two steps.

Also cyt *f* faces the p-side and has to pass the membrane. Its plastidal gene *petA*, which is transcribed on stromal ribosomes, also carries an N-terminal extension which targets it across the thylakoid membrane where it is processed. The insertion of cyt *f* and of the Rieske FeS–protein into the complex use different pathways. Cyt *f* follows the secA-route known from bacterial secretion, while the assembly of the Rieske FeS–protein is energized by the proton gradient across the membrane (ΔpH-route). The insertion of the hydrophobic proteins cyt b_6 and subunit IV into the membrane does not require a signal peptide and may follow yet another route. Interestingly cyt *f* controls the stability and assembly of the Rieske FeS–protein and of the other subunits in the cyt b_6f-complex, via a signal in its C terminus which is located on the stromal surface (n-side, see Figure 2). The biosynthesis of 2Fe2S-cluster in the Rieske FeS–protein, and the covalent binding of heme *c* in cyt *f* as well as of the heme c' in cyt b_6 are enzymatic processes governed by several nuclear genes. The insertion of the hemes *b* into cyt b_6 may occur spontaneously.

In many bacteria the genes of the related cyt bc_1-complex, for the Rieske FeS–protein, cyt *b*, and cyt c_1 are joined in the tricistronic *fbc*-operon, while in eukaryotes only the gene for cyt *b* remained in mitochondria, the others were transferred to the nucleus where they were furnished with targeting signal peptides.

The Rieske FeS–protein and cyt *b* in the different cyt *bc*-complexes originate from common ancestors, and since they occur in bacteria as well as in archaea, they appear phylogenetically very old. On the other hand cyt *f* and its *c*-type cyt counterparts have various different ancestors. A "cyt b_6f-complex" without a cyt *f* has been characterized in Gram-positive bacteria, in

respiratory *Bacilli* and in photosynthetic *Heliobacteria*, a notion which is based on the characteristics of the cyt *b*-complement. These are:

1. the splitting into cyt b_6 and subunit IV,
2. 14 instead of 13 amino acid residues between the two histidine ligands of the heme *b* in the fourth transmembrane helix,
3. the loss of the eighth transmembrane helix from subunit IV, and
4. the acquirement of the extra heme c', bound to C-37 of cyt b_6.

Interestingly the cyt *b*-complement from the *bc*-complex from green sulfur bacteria fulfills only the second and third of these criteria, but it is not split, and presumably does not contain the extra heme since C-37 is not conserved. Thus the cyt b_6f-complex has evolved on the path from the common ancestor of green sulfur bacteria (*Chlorobiaceae*) and Gram-positive bacteria (*Firmicutes*), via cyanobacteria to chloroplasts. The addition of a carotenoid and of a chlorophyll *a* molecule should have occurred after the branching of the cyt b_6f-complexes into photosynthetic and respiratory lines.

Glossary

archaea The third domain of life next to eubacteria and eukaryotes, formerly called archaebacteria.

carotenoid shift A bathochromic shift of carotenoid absorption in response to an electric field (Stark effect) across the membranes of photosynthetic organisms.

chlorophyll fluorescence induction The intensity transient of chlorophyll fluorescence in chloroplasts after onset of illumination (Kautsky effect); the initial rise reflects the reduction of plastoquinone by photosystem II, the difference between maximal and actual fluorescence is related to the reoxidation of plastoquinol by the cyt b_6f-complex.

cyclic electron transport Electron transport around photosystem I via plastoquinone and the cyt b_6f-complex which provides extra ATP.

LHCII-kinase An enzyme that phosphorylates LHCII which in that state moves to photosystem I; it is activated by plastoquinol via the reduced state of the cyt b_6f-complex.

light harvesting complex II (LHCII) Also known as chlorophyll *a/b* binding protein (cab-protein), which constitutes the outer antenna of photosystem II.

photosystem The total of pigments assembled around a reaction center.

Q-cycle A mechanism of proton translocating quinol oxidation by cyt *bc*-complexes in respiratory and photosynthetic electron transport, first formulated by Peter Mitchell in 1975.

Q_o-site and Q_r-site The sites for quinol oxidation and quinone reduction in cyt *bc*-complexes are synonymous to Q_p and Q_n, the sites accessible form the positively and negatively charged membrane surface, respectively. Frequently the pair Q_o/Q_i, instead of Q_o/Q_r or Q_p/Q_n is in use, indicating the sites outside and inside the inner mitochondrial and bacterial membrane. Since the sidedness of the thylakoid membrane is turned around the Q_i-denotation is not appropriate for the cyt b_6f-complex.

thylakoid Coined by Wilhelm Menke to denominate the structure of the inner membrane system of the chloroplast which in cross-section appears to be built from stacked "little bags," but their inner space is connected in the third dimension.

Z-scheme Electron transport chain of oxygenic photosynthesis pictured in the redox potential scale, first formulated by Robin Hill and Fay Bendall in 1960.

Biography

Günter Hauska is a Professor of Cell Biology and Plant Physiology at the Institute of Botany, in the Department of Biology at the University of Regensburg, Germany. He obtained his Ph.D. in Chemistry at the

University of Vienna in 1967. Subsequently he served as Postdoctoral Fellow in the Biochemistry Department of the Cornell University, before qualifying as Dozent for Biochemistry at the Ruhr-Universität in Bochum, Germany. His research interest is in energy transduction by membrane protein complexes of electron transport chains, especially in quinol oxidation by cytochrome *bc*-complexes and in photosynthetic reaction centers. In recent years he turned to flavoproteins. He is a member of the German Society for Biochemistry and Molecular Biology.

Thomas Schödl graduated in chemistry at the University of Regensburg and finished his Ph.D. in Biochemistry. He is studying the structure and redox reactions of flavoproteins, in particular of the sulfide quinone reductases from bacteria and eukaryotes.

Cytochrome bc_1 Complex (Respiratory Chain Complex III)

Bernard L. Trumpower
Dartmouth Medical School, Hanover, New Hampshire, USA

The cytochrome bc_1 complex (ubiquinol:cytochrome *c* oxidoreductase complex, E.C. 1.10.2.2) is an energy-transducing, electron transfer enzyme located in the inner mitochondrial membrane of oxygen utilizing eukaryotic cells, where it participates in cell respiration. A functionally similar but structurally simpler version of the bc_1 complex is located in the plasma membrane of many, but not all, bacteria, where it takes part in respiration, denitrification, nitrogen fixation, and cyclic photosynthetic electron transfer, depending on the species. In all of these organisms the bc_1 complex oxidizes a membrane-localized quinol and reduces a water-soluble, *c*-type cytochrome and links this redox reaction to translocation of protons across the membrane in which the bc_1 complex resides. The bc_1 complexes from mitochondria of several species have been crystallized and the mechanism of the enzyme is generally well understood, although some questions remain outstanding.

Function of the bc_1 Complex

The cytochrome bc_1 complex participates in respiration in oxygen utilizing cells and also participates in electron transfer in numerous bacteria that utilize alternative terminal-electron acceptors in addition to oxygen. The functional relationship of the bc_1 complex to other redox enzymes in these linked electron-transfer systems is illustrated in Figure 1. In mitochondria the bc_1 complex is a confluence point for reducing equivalents from the various dehydrogenases and it is essential for mitochondrial respiration, since there is no alternative route to oxidize ubiquinol by molecular oxygen. Bacteria such as *Paracoccus denitrificans* that have a bc_1 complex usually have alternative mechanisms to oxidize ubiquinol or otherwise bypass the bc_1 complex. Consequently, the enzyme is not essential in these organisms. Hydroxyquinone analogues of ubiquinone, such as atovaquone, inhibit the bc_1 complex and are used therapeutically against fungal (e.g., pneumocystis) and parasitic (e.g., malaria) infections, but are ineffective against bacteria in which the enzyme is not essential. In some photosynthetic bacteria, such as *Rhodobacter*, the bc_1 complex is essential for cyclic photosynthetic electron transfer in the absence of a terminal electron acceptor, but is not essential when the cells are growing heterotrophically. In all of these organisms the bc_1 complex is located in the organelle or plasma membrane and converts the energy associated with electron transfer from ubiquinol to cytochrome *c* into an electrochemical proton gradient across the membrane in which the enzyme resides. The resulting protonmotive force is used by the cell for energy-requiring reactions, including ATP synthesis, ion and metabolite transport, and flagellar motion.

Structure, Composition, and Properties of the bc_1 Complex

Protein Subunits

All cytochrome bc_1 complexes contain three protein subunits with redox prosthetic groups, a diheme cytochrome *b* containing a relatively high-potential b_H heme and a lower potential b_L heme, cytochrome c_1, and a Rieske iron–sulfur protein with a 2Fe–2S cluster. In some bacteria, such as *Paracoccus denitrificans* and *Rhodospirillum rubrum*, the bc_1 complex contains only these three subunits. Other bacteria, including the *Rhodobacter*, contain a fourth subunit of unknown function that lacks prosthetic groups. *Rhodobacter* can adapt to grow photosynthetically when this subunit is absent, but the stability of the enzyme is compromised, suggesting at least a structural role.

The cytochrome bc_1 complexes of mitochondria contain as many as seven or eight supernumerary subunits. The enzyme from *Saccharomyces cerevisiae* contains ten subunits, while those from bovine heart and *Schizosaccharomyces pombe* contain 11. The difference between the 10- and 11-subunit enzymes is due to the fact that the 11-subunit enzymes contain one small subunit that is formed when the presequence that targets the Rieske protein to the mitochondria is cleaved from the protein. The cleaved presequence is retained in the

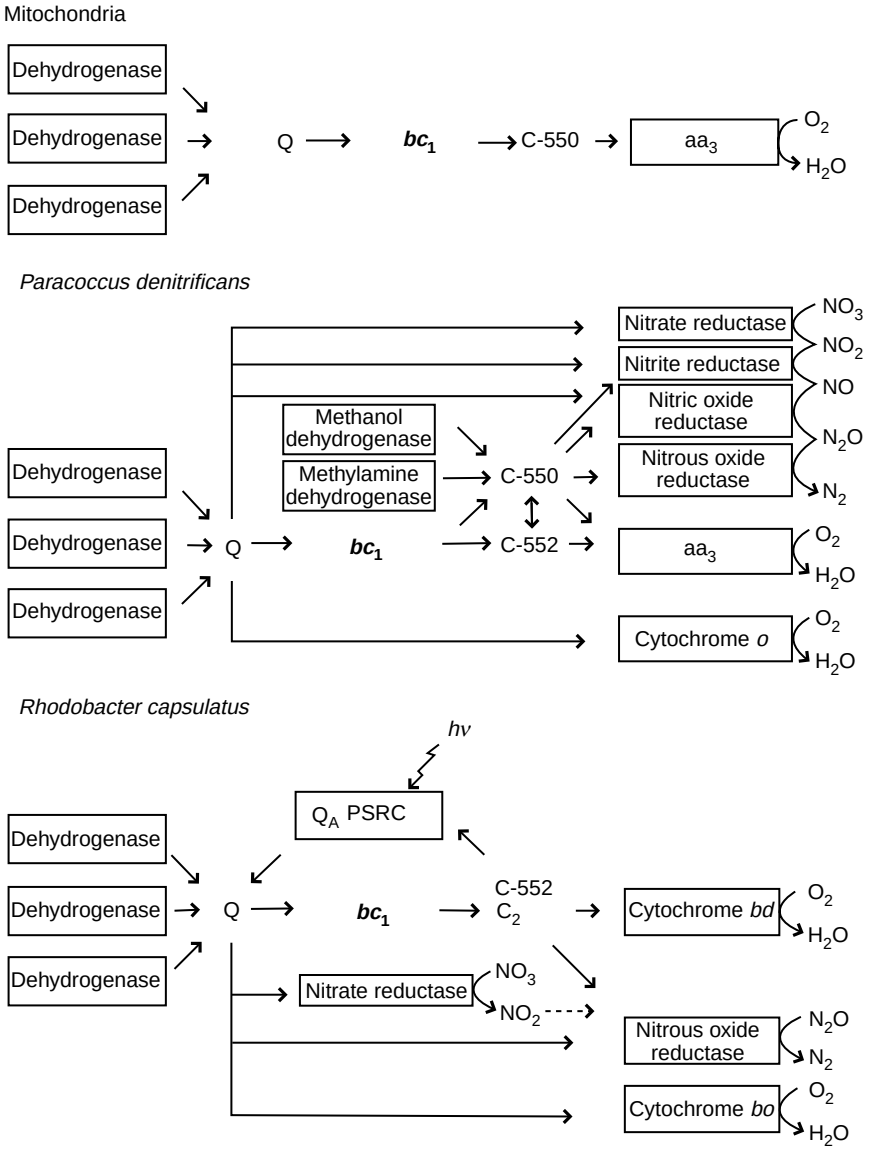

FIGURE 1 Function of the cytochrome bc_1 complex in mitochondria and bacteria. In mitochondria the bc_1 complex oxidizes ubiquinol that is formed by reduction of ubiquinone by various dehydrogenases including glycerol phosphate dehydrogenase, succinate dehydrogenase, NADH dehydrogenase, and ETF dehydrogenase. In bacteria such as *Paracoccus dentrificans*, ubiquinol can be oxidized by various routes that bypass the bc_1 complex, including a terminal oxidase, cytochrome o, which oxidizes ubiquinol directly, without the intervention of cytochrome *c* and cytochrome *c* oxidase. These bacteria can also use alternative terminal electron acceptors, such as nitrate, in which case the bc_1 complex is also not essential for electron transfer from the quinol. In photosynthetic bacteria such as the *Rhodobacter* the bc_1 complex participates in cyclic electron transfer when the bacteria are grown photosynthetically, and is essential under those growth conditions. However, *Rhodobacter* can also grow heterotrophically on a variety of nutrients and can use either oxygen or nitrogen in the form of nitrate and nitrous oxide as terminal electron acceptor. Under these conditions the ubiquinol that is formed by the various dehydrogenases can be oxidized by the bc_1 complex and electrons transferred via the *c* cytochromes to oxygen or nitrous oxide, or electrons from the quinol can bypass the *c*-cytochrome pool and be transferred directly to nitrate, nitrous oxide, or oxygen.

bc_1 complex as an additional subunit. In *Saccharomyces cerevisiae*, the presequence is cleaved from the Rieske protein in two steps and degraded, thus that bc_1 complex contains only 10 subunits.

The functions of the supernumerary subunits in the mitochondrial enzymes are not known. They are not required for the electron transfer and proton translocation activities of the enzyme, since the three-subunit enzyme from *Paracoccus* has the same electron transfer and proton translocation functionality as the mitochondrial enzymes. Possible functions for these nonredox subunits include docking sites for ternary complex formation with the dehydrogenase and oxidase complexes, regulation of half-of-the-sites activity of the

dimeric enzyme, structural stability in the relatively long-lived eukaryotes, and protection against oxygen radicals.

Spectroscopic and Thermodynamic Properties of the bc_1 Complex

The bc_1 complex is visibly red due to the cytochromes. Optical spectra of the yeast enzyme in the visible region of the spectrum are shown in Figure 2. When the enzyme is reduced by dithionite, a difference spectrum of the dithionite reduced versus ferricyanide oxidized enzyme exhibits an absorption maximum at 562 nm due to ferro-cytochrome b and a shoulder at ~553 nm due to ferro-cytochrome c_1. When the enzyme is reduced with ascorbic acid, the reduced versus ferricyanide oxidized difference spectrum consists of only cytochrome c_1, with a maximum at 553 nm (Figure 2B). The extinction coefficient of reduced versus oxidized cytochrome c_1 at 553 nm versus 539 nm is 17.5 $mM^{-1}\,cm^{-1}$, which was obtained from the purified protein. By subtracting the spectrum of c_1 from that of $b+c_1$, it is possible to derive a calculated difference spectrum of the cytochrome b as shown in Figure 2C. The extinction coefficient of reduced versus oxidized cytochrome b at 562 versus 575 nm is 25.6 $mM^{-1}\,cm^{-1}$, which was determined by measuring the fluorescence quenching upon stoichiometric binding of antimycin to the bovine enzyme. This value is an average of the two b hemes. The individual extinction coefficients of the b_H and b_L hemes have not been determined for most bc_1 complexes, but the contribution from the b_H heme at 562 is significantly greater than that from the b_L heme, which has a split absorption maximum with peaks at 564–566 and ~558 nm.

The Rieske iron–sulfur protein is a pale yellow-gold color when isolated from the bc_1 complex in the oxidized form but bleached to colorless when reduced and thus makes no contribution to the optical spectrum of the reduced enzyme. The redox status of the 2Fe–2S cluster is monitored by electron paramagnetic resonance (EPR) spectroscopy since the reduced cluster is paramagnetic. The Rieske cluster exhibits a unique EPR spectrum with peaks at approximately $g_x = 1.76$, $g_y = 1.90$, and $g_z = 2.03$, resulting in $g_{av} = 1.90–1.91$, which is atypical of binuclear iron–sulfur clusters. The unusual EPR spectrum of the Rieske protein is due to bis-histidine coordination of one of the two iron atoms, which was first suggested by spectroscopic studies and confirmed by crystal structures of the enzyme.

The midpoint potentials of the redox centers in the bc_1 complex determine the thermodynamic parameters and in some cases control electron transfer reactions within the enzyme. In *Saccharomyces cerevisiae* the midpoint potentials at pH 7 are as follows: cytochrome c_1, +240 mV; Rieske iron–sulfur cluster, +280 mV; cytochrome b_H, +120 mV; and cytochrome b_L, −30 mV. Although there are species differences in these midpoint potentials it is generally true that the midpoint potential of the Rieske center is ~20–40 mV more positive than that of c_1, and that of the b_L heme is 60–120 mV lower than that of the b_H heme. The midpoint potentials of the b hemes are influenced by the detergents used to purify the enzyme, and may be similarly influenced by bound phospholipids. The midpoint potential at pH 7 of ubiquinone is +90 mV in the membrane, but this value may be altered by preferential binding of either quinone or quinol to reaction sites in the enzyme. These midpoint potentials result in a thermodynamic profile of the bc_1 complex as shown in Figure 3.

Three-Dimensional Structure of the bc_1 Complex

Cytochrome bc_1 complexes from bovine, chicken, and yeast mitochondria have been crystallized and their structures solved to atomic resolution. The yeast enzyme, shown in Figure 4, is the highest resolution structure available at this time. The mitochondrial bc_1

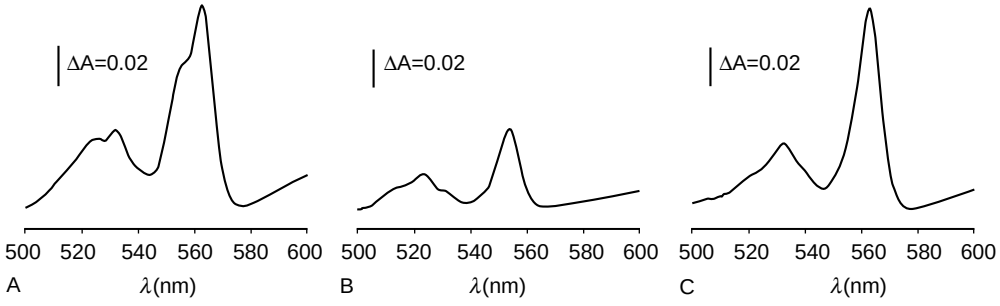

FIGURE 2 Optical spectra of the yeast cytochrome bc_1 complex. Difference spectra of (A) the dithionite reduced versus ferricyanide oxidized enzyme and (B) the ascorbate reduced versus ferricyanide oxidized enzyme. (C) Calculated difference spectrum, obtained by subtracting the spectrum of the ascorbate reduced enzyme from the spectrum of the dithionite reduced enzyme.

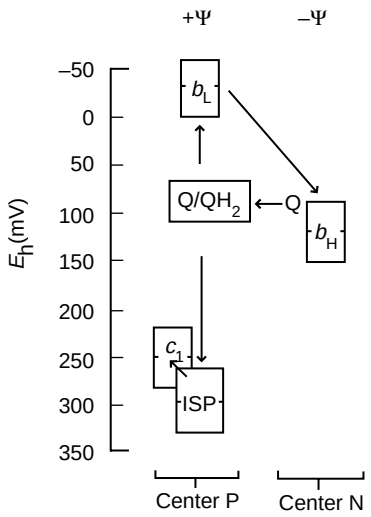

FIGURE 3 Thermodynamic profile of the *Saccharomyces cerevisiae* cytochrome bc_1 complex. The figure illustrates the thermodynamic relationship between the redox components of the cytochrome bc_1 complex. Arrows indicate electron transfer reactions in the enzyme. The redox groups are arranged vertically according to their oxidation–reduction potentials, with the center of the boxes positioned vertically at the midpoint potentials of the redox groups. The open boxes depict the approximate range of potentials spanned by the redox components as their oxidation–reduction status varies in response to changes in rates of electron transfer. The midpoint potentials of the redox components are cytochrome b_L, −30 mV, cytochrome b_H, +120 mV, cytochrome c_1, +240 mV, and Rieske iron–sulfur protein, +280 mV.

complex is a symmetrical, oligomeric dimer, in which the three redox subunits are surrounded by a periphery of nonredox, supernumerary subunits. The dimeric structure of the enzyme was suspected from hydrodynamic measurements and confirmed by the first crystal structure of the bovine enzyme. Although the bacterial enzyme has not yet been crystallized, it will presumably turn out to be a dimeric structure too, but lacking the large number of supernumerary subunits.

One unusual aspect of the dimeric structure is that the iron–sulfur protein spans the dimer. The Rieske protein is anchored in one monomer by a single transmembrane helix, as shown in Figure 4A, while the peripheral domain that contains the 2Fe–2S cluster is located in the other monomer, where it forms part of the ubiquinol oxidation site. Crystal structures of the chicken bc_1 complex in the absence and presence of stigmatellin, an inhibitory ligand, also provided striking evidence that the peripheral domain of the Rieske protein moves back and forth between positions proximal to cytochrome *b* and cytochrome c_1. This suggested that movement of the Rieske protein facilitates electron transfer, which was confirmed by site-directed mutagenesis studies that demonstrated that such movement of the Rieske protein was essential for enzyme activity.

Functionally the enzyme consists of the cytochrome *b* and c_1 subunits from one monomer and the Rieske protein from the other, as shown in Figure 4B. The crystal structures established the location of the sites of ubiquinol oxidation and ubiquinone reduction at topographically separated sites within the enzyme. The structures also confirmed the transmembrane disposition of the *b* hemes, which form a conduit through which electrons are cycled across the membrane in which the enzyme resides. These structural details provided the final confirmatory evidence of the protonmotive Q cycle mechanism of the enzyme.

Mechanism of the Enzyme

The Protonmotive Q Cycle

The bc_1 complex oxidizes ubiquinol and transfers two electrons to two molecules of cytochrome *c*. During this electron transfer reaction two protons are taken up from the mitochondrial matrix or bacterial cytoplasm and four protons are deposited on the other side of the membrane. The mechanism by which the bc_1 complex links the electron transfer and proton translocation reactions is the protonmotive Q cycle, shown in Figure 5. In the Q cycle mechanism proton translocation is the net result of topographically segregated reduction of quinone and reoxidation of quinol on opposite sides of the membrane, with protons being carried across the membrane as hydroxyl hydrogen atoms on the quinol. The sites where quinone is reduced and quinol is oxidized are referred to as center N and center P, respectively, since they are located toward the electronegative and electropositive sides of the membrane. Protons are taken up at center N, carried across the membrane by the quinol, and released at center P.

In the first step of the Q cycle, ubiquinol is oxidized at center P in a reaction that divergently transfers the two electrons from ubiquinol to the Rieske iron–sulfur cluster and the cytochrome b_L heme (reactions 1a–1c in Figure 5). In reaction 2 the reduced Rieske cluster oscillates to within electron transfer distance of cytochrome c_1 and an electron is transferred from the iron–sulfur cluster to the c_1 heme. Two protons are released from center P coincident with ubiquinol oxidation. In reaction 3 an electron is transferred from the b_L to b_H heme, which in turn reduces ubiquinone to ubisemiquinone (reaction 4). Following oxidation of a second ubiquinol at center P and reduction of the *b* cytochromes the b_H heme reduces ubisemiquinone to ubiquinol (reaction 5), accompanied by uptake of two protons at center N.

There is evidence that the mitochondrial bc_1 complex functions by an alternating-sites mechanism, in which binding of ubiquinol in one monomer exerts negative cooperativity on binding of ubiquinol in the other

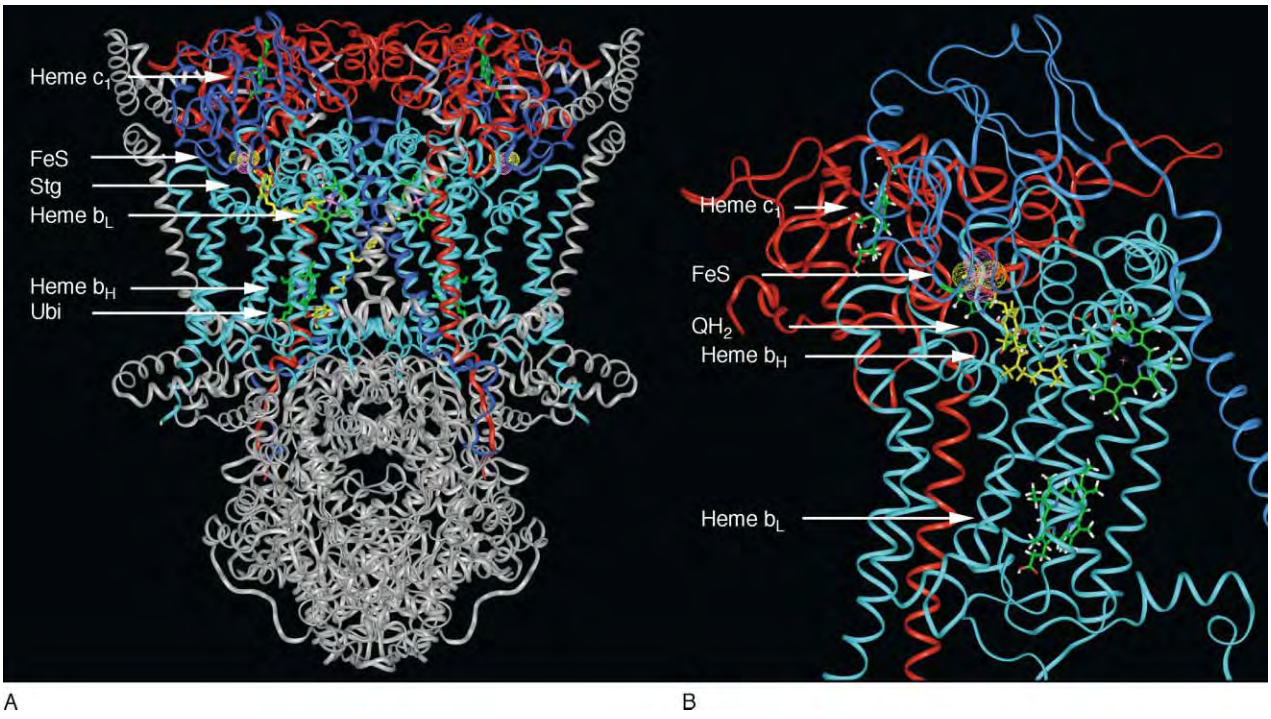

FIGURE 4 Crystal structure of the cytochrome bc_1 complex. The structure in (A) is of the yeast bc_1 complex with stigmatellin bound, resolved to 2.3Å by Hunte and co-workers, and shows all of the subunits of the enzyme dimer, except subunit 10, which is lost during purification. The structure is oriented so that the mitochondrial matrix would be at the bottom and the intermembrane space at the top of the figure. Cytochrome *b* is colored cyan, cytochrome c_1 red, and the Rieske protein blue. The supernumerary subunits are colored gray. The heme groups (heme b_L and heme b_H) are shown as stick structures, colored green. Stigmatellin (Stg) bound at center P in only one monomer is shown as a stick structure, with carbon atoms colored yellow and oxygen atoms red. Ubiquinone (Ubi) bound at center N in only one monomer is also shown as a stick structure, with carbon atoms colored yellow and oxygen atoms red. The iron–sulfur cluster (FeS) is shown with its van der Waals radius, with iron atoms colored purple and sulfur atoms colored yellow. The structure in (B) is of a functional monomer, consisting of cytochrome *b* and cytochrome c_1 from one monomer and the Rieske protein from the other. Ubiquinol (QH_2) containing two isoprenyl groups is hydrogen bonded between His181 of the Rieske protein and Glu272 of cytochrome *b* to form a putative electron-donor complex. An energy-minimized structure of the docked quinol was obtained by replacing stigmatellin in the crystal structure, followed by molecular dynamics and energy minimization calculations. The protein subunits, heme groups, and ubiquinol are colored as in (A).

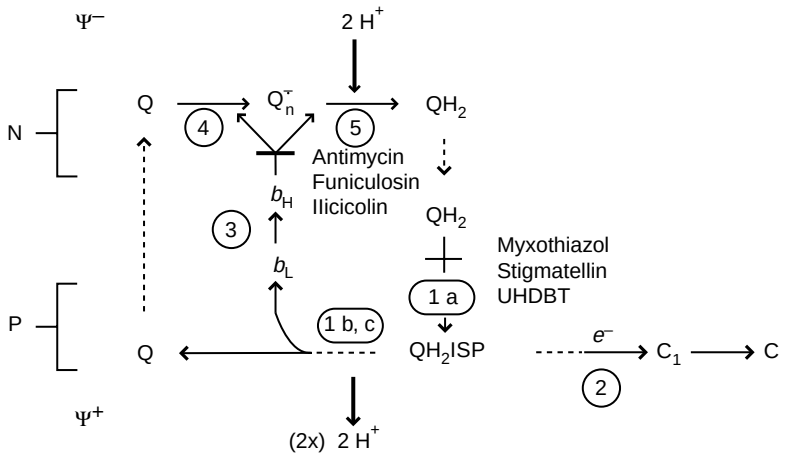
monomer. If the enzyme can be switched from a form in which ubiquinol oxidation alternates between the two monomers to a form where both monomers are simultaneously active, it would provide a mechanism to regulate the activity of the enzyme, perhaps in response to cellular energy needs. Whether such a regulatory mechanism exists and, if so, how it operates, is not known.

Proton Conduction Pathways

In the Q cycle mechanism, protons are carried across the membrane as hydrogen atoms on the hydroxyl groups of ubiquinol. However, the sites where ubiquinol is oxidized at center P and ubiquinone is reduced at center N are not freely accessible to the bulk aqueous phase at the membrane surface. Consequently, the linkage of proton chemistry to electron transfer requires mechanisms for moving protons to and from the aqueous phase and the hydrophobic sites of quinol and quinone redox reactions.

The crystal structures of the bc_1 complex with bound stigmatellin (Figure 4A) show that the inhibitor is hydrogen bonded between His181 (in the yeast numbering system) of the Rieske protein, which is a ligand to the iron-sulfur cluster, and Glu272 of cytochrome *b*. Since stigmatellin presumably mimics an intermediate in ubiquinol oxidation, this suggests that ubiquinol forms an electron-donor complex involving hydrogen bonds between the quinol hydroxyl groups and these two amino acids, as shown in Figure 4B.

When ubiquinol reduces the Rieske protein, an electron is transferred to the iron–sulfur cluster, while a proton from the quinol hydroxyl group protonates the imidazole nitrogen on His181 of the Rieske protein. The Rieske protein acts as a hydrogen carrier and releases the proton to the aqueous phase when it moves proximal to cytochrome c_1 and is oxidized. The second proton from ubiquinol is transferred to Glu272 and then to a propionate of the cytochrome *b* heme as an electron is transferred to the b_L heme. From the crystal structure of the yeast enzyme it appears that this proton can then



(1a) $QH_2 + ISP \rightleftharpoons QH_2ISP$

(1b) $QH_2\ ISP + b_L \rightleftharpoons QH_2ISP\ b_L$

(1c) $QH_2\ ISP\ b_L \rightleftharpoons Q + ISP^-H^+ + b_L^-H^+$

(2) $ISP^-H^+ + c_1 \rightleftharpoons ISP + c_1^- + H^+$

(3) $b_L^-H^+ + b_H \rightleftharpoons b_L + b_H^- + H^+$

FIGURE 5 Mechanism of electron transfer through the cytochrome bc_1 complex. The scheme shows the pathway of electron transfer from ubiquinol to cytochrome *c* through the redox centers of the cytochrome bc_1 complex. The circled numbers designate electron transfer reactions. Dashed arrows designate movement of ubiquinol (QH_2) or ubiquinone (Q) between center P on the positive side of the membrane and center N on the negative side of membrane, and movement of the iron–sulfur protein between cytochrome *b* and cytochrome c_1. Solid black bars indicate sites of inhibition by antimycin, funiculosin, ilicicolin, myxothiazol, UHDBT, and stigmatellin. In reaction 1, ubiquinol oxidation delivers two electrons divergently to the Rieske iron–sulfur cluster and the b_L heme, two protons are released, and the resulting ubiquinone leaves center P. In reaction 2, the reduced Rieske cluster oscillates to within electron transfer distance of cytochrome c_1, resulting in electron transfer from the iron–sulfur cluster to the c_1 heme. In reaction 3, an electron is transferred from the b_L to b_H heme, which in turn reduces ubiquinone to ubisemiquinone (reaction 4). Following oxidation of a second ubiquinol at center P and reduction of the *b* cytochromes the b_H heme reduces ubisemiquinone to ubiquinol (reaction 5), accompanied by uptake of two protons at center N.

access the aqueous surface from the b_L heme via a conserved arginine (Arg79). In this manner two protons are released from center P with minimal charge separation as the two electrons are divergently transferred from the quinol to the high potential and low-potential electron acceptors (Figure 3).

The crystal structure of the yeast enzyme has also revealed pathways for conduction of two protons into center N. One of these pathways, the (CL)/K pathway, involves a conserved lysine and a bound cardiolipin, which may function as a buffer to concentrate protons at the entrance to the pathway. The second proposed proton conduction pathway at center N is referred to as the E/R pathway and involves a conserved glutamate and a conserved arginine. The high resolution of the yeast crystal structure also reveals that one or two bound water molecules may serve as direct proton donors during quinone reduction. Notably, whereas ubiquinol oxidation at center P proceeds with minimal charge separation, ubiquinone reduction at center N begins with substantial charge separation as electrons and protons enter the reaction site from opposite directions, and the redox reaction is accompanied by charge compensation, which enhances the reaction rate.

Inhibitors

There are numerous inhibitors that act on the cytochrome bc_1 complex and that bind specifically to either the ubiquinol oxidation site at center P or the ubiquinone reduction site at center N. These have proven to be especially useful in establishing the mechanism of the enzyme and for selectively blocking electron transfer reactions at either of the two reaction sites in the enzyme to facilitate kinetic analysis. In addition, some of the inhibitors have antifungal and antiparasitic activity.

Antimycin, funiculosin, and ilicicolin H are produced by micro-organisms as defensive toxins and inhibit the bc_1 complex by binding to center N with near stoichiometric affinity. Under conditions of catalytic turnover, they block reduction of ubiquinone by cytochrome *b* by

binding to the ubiquinone reduction pocket at a site proximal to the b_H heme, causing electrons to accumulate in the *b* hemes. Under presteady-state conditions where the enzyme is reduced by ubiquinol they block reduction of the b_H heme by quinol.

Stigmatellin, also produced by a micro-organism, inhibits the bc_1 complex by binding to the ubiquinol oxidation pocket, simultaneously forming hydrogen bonds to the imidazole nitrogen of His181 on the Rieske protein and a carboxyl oxygen of Glu272 on cytochrome *b*. In this manner the inhibitor locks the Rieske protein in a conformation proximal to cytochrome *b*. Stigmatellin raises the midpoint potential and shifts the EPR spectrum of the iron–sulfur cluster, indicative of its interaction with the Rieske protein.

Hydroxyquinones such as UHDBT, a benzoxythiazole (3-undecyl-2-hydroxy-1,4-benzoxythiazole) and atovaquone, a hydroxynaphthoquinone (2-[trans-4-(4′-chlorophenyl) cyclohexyl]-3-hydroxy-1,4 hydroxynaphthoquinone) also bind to the ubiquinol oxidation pocket and form a hydrogen bond to His181 of the Rieske protein. Like stigmatellin these ligands raise the midpoint potential and change the EPR spectrum of the iron–sulfur cluster. However, the hydroxyquinone inhibitors do not hydrogen bond to Glu272 of cytochrome *b*. Instead, the crystal structure of the yeast bc_1 complex with an analogue of UHDBT bound shows Glu272 rotated toward the heme propionate, which suggested the proton conduction pathway described above.

Methoxyacrylates, such as myxothiazol, also bind to the ubiquinol oxidation pocket but do not interact directly with the Rieske protein. These inhibitors bind proximal to the b_L heme and affect its spectral and thermodynamic properties.

Glossary

protonmotive Q cycle The mechanism of electron transfer by which the cytochrome bc_1 complex transfers electrons from ubiquinol to cytochrome *c* and links the electron transfer to proton translocation. The mechanism is so-named, because the enzyme oxidizes ubiquinol on one side of the membrane and re-reduces ubiquinone on the other side in a cyclic manner, thus bringing about transmembrane movement of protons, carried through the membrane as hydrogen's on the quinol hydroxyl groups.

ubiquinone 2,3-dimethoxyl-5-multiprenyl-6-methyl-1,4-benzoquinone, where the multiprenyl group is an isoprenoid side chain consisting of 6–10 isoprenyl groups, is a lipid-soluble benzoquinone that is reduced to quinol by various dehydrogenases and reoxidized to quinone by the cytochrome bc_1 complex.

Biography

Bernard L. Trumpower is a Professor of Biochemistry at Dartmouth Medical School. His principal research interest is the function of the cytochrome bc_1 complex. Dr. Trumpower received his Ph.D. from St. Louis University and did his postdoctoral training at Cornell University with Prof. Efraim Racker. Dr. Trumpower has been an established investigator of the American Heart Association and received a Merit Award from the National Institutes of Health. He has authored more than 100 original research articles on the cytochrome bc_1 complex, and in 1984 he was awarded the Humboldt Prize by the Federal Republic of Germany for his contributions to understanding the enzymology of respiratory enzymes.

Cytochrome *c*

Hans Tuppy and Günther Kreil
University of Vienna, Vienna, Austria

Cytochrome *c* is a heme protein that is present in and can easily be isolated from mitochondria of all eukaryotic organisms. The amino acid sequence of the protein moiety was among the first sequences which could be elucidated. This was the starting point for comparative studies about sequence variations found in cytochrome *c* from a wide range of species. A phylogenetic tree constructed on the basis of this information was found to be biologically significant and became exemplary for subsequent studies on molecular evolution. The function of cytochrome *c* in the respiratory chain as an electron carrier is well established. More recently, an additional role of cytochrome *c* was discovered: its release from mitochondria into the cytosol triggers apoptosis – the programmed cell death.

Introduction

Cytochromes are proteins which contain heme as their prosthetic group and whose principal biological function, in the cells of animals, plants, and microorganisms, is electron transport. The foundations of the knowledge of heme proteins and their roles as electron carriers in cell respiration were laid by David Keilin (1887–1963), ~80 years ago. In the cytochromes, the iron which is coordinately linked with four nitrogens within the prosthetic group and with two additional ligands provided by the protein moiety, can alternate between a reduced Fe^{2+} and an oxidized Fe^{3+} state. Different classes of cytochromes (*a*-type, *b*-type, *c*-type) differ in the nature of their heme prosthetic groups. They can be observed and differentiated spectroscopically, on the basis of characteristic absorption bands. The absorption peaks of reduced cytochrome *c* and other *c*-type cytochromes (such as c_1) are at ~550, 520, 416, and 270 nm. The *b*-type and *a*-type cytochromes absorb visible light at higher wavelengths. In eukaryotic cells, cytochromes of types *a*, *b*, and *c* are found predominantly within mitochondria. In the mitochondrial respiratory chain, cytochrome *c* accepts electrons from complex III, which contains cytochromes *b* and c_1 (bc_1), and transmits them to complex IV (cytochrome oxidase), which has two heme prosthetic groups (aa_3). These respiratory complexes, with their respective cytochromes, are firmly integrated in the inner membrane of the mitochondrion. Cytochrome *c*, by contrast, is only loosely bound in the space between the inner and outer mitochondrial membranes and shuttles between bc_1 and aa_3. As shown by Keilin and others, cytochrome *c* can be easily removed experimentally from and reincorporated into isolated mitochondria, their respiratory capacity thereby being impaired and restored, respectively. It has recently been discovered that the release of cytochrome *c* from mitochondria into the cytoplasm is an important step in programmed cell death. This participation in apoptosis of eukaryotic cells is now considered to be another significant function of cytochrome *c*.

Cytochrome *c* and *c*-type cytochromes occur in all eukaryotic organisms. The comparative analysis of the protein structures of cytochromes isolated from a multitude of different species of organisms has made it possible to establish evolutionary relationships between them. The phylogenetic tree based on the slow changes of the structure of cytochrome *c* in the course of evolution is most impressive and biologically relevant.

The *c*-type cytochromes are also present in prokaryotes, where they may function in a respiratory chain or in photosynthesis. Examples are cytochrome c_2 from *Rhodospirillum rubrum* (purple bacteria) and cytochrome c_{551} from *Pseudomonas aeroginosa* (gram-negative bacteria). These are distantly related to mitochondrial cytochromes *c*; however, a more detailed discussion of these diverse hemoproteins is outside the scope of this article.

Attachment of the Heme Prosthetic Group to Cytochrome *c* Apoprotein

The prosthetic group of *c*-type cytochromes, such as cytochrome *c* and c_1 in mitochondria and cytochrome *f* in chloroplasts, unlike that of *a*- and of *b*-type cytochromes, is covalently linked to the polypeptide moiety. The thiol groups of two cysteinyl residues in a Cys-X-Y-Cys-His peptide motif are attached to two vinyl groups of heme through thioether bonds.

This linkage is resistant to heat and hydrolysis, but can be broken with the help of silver or mercury salts. Thus, the polypeptide moiety of cytochrome *c*, or of heme peptides derived from it by proteolytic cleavage, could be obtained. In eukaryotic cells, the apoprotein of cytochrome *c* is encoded by a nuclear gene, translated on cytoplasmic ribosomes and translocated into the intermembrane space of mitochondria, where an enzyme, cytochrome *c* heme lyase, combines it with heme. An *in vitro* synthesis of a microbial *c*-type cytochrome from its apoprotein and reduced heme has recently been achieved.

Amino Acid Sequence Studies

Cytochrome *c* is a small, water-soluble protein that can easily be isolated and purified from cells and tissues of many different eukaryotic organisms. In proteolytic digests of cytochrome *c*, one fragment containing the covalently linked heme group can be separated from all the other ones. Studies on the amino acid sequence of these heme peptides isolated from cytochromes *c* of diverse origin thus became feasible. It turned out that certain sequence elements, like the one mentioned in the introduction were highly conserved from yeast to mammalian cytochromes *c*.

Expanding on this early work, cytochrome *c* from horse heart was one of the first proteins whose complete amino acid sequence could be determined. It consists of a single polypeptide chain of only 104 residues that could be analyzed even with, by modern standards, rather primitive tools available around 1960. The protein contains many (up to 19) lysine residues, whose positive charges can form ionic bonds with constituents of the inner mitochondrial membrane.

With the horse sequence as a reference, cytochrome *c* isolated from diverse species was subsequently analyzed in quick succession. These included other mammals (human, rhesus monkey, pig, dog, rabbit, whale, and kangoroo), birds (chicken, pigeon, king penguin, turtle), reptiles (rattlesnake, alligator), amphibia (bullfrog), fish (tuna, carp, dogfish) and the chordate pacific lamprey. And with unabated pace, additional sequences were determined for cytochromes *c* from flies, moths, yeasts, Neurospora, and a large variety of plants. By now, we know the sequence of this protein from more than 100 eukaryotic species. As a result of these efforts, cytochrome *c* became the first and still is a standard example for studies on the molecular evolution of proteins. Nuclear genes encoding cytochrome *c* have been analyzed from various species. The mammalian gene contains a small intron in the coding sequence and a larger one upstream of the initiation codon.

The recent progress in the sequencing of whole eukaryotic genomes has also yielded information about the number of cytochrome *c* genes in various species. For example, in the human genome, a single gene for cytochrome *c* is present on chromosome 7, along with 49 pseudogenes located on many different chromosomes. These are mostly processed pseudogenes, which were formed by retro-transcription of an mRNA. In rodents, two cytochrome *c* genes are expressed, one of them exclusively in the testis. This latter gene is still present as a pseudogene in the human genome.

Evolutionary Aspects

Cytochrome *c* is a highly conserved protein, which retained many structural characteristics over the eons of evolution of animals and plants. This makes it an ideal tool for amino acid sequence comparisons over a wide range of species (Figure 1). From the sequence differences, a molecular "pedigree" can be constructed based on the original assumption, now corroborated by many examples, that the longer ago the common

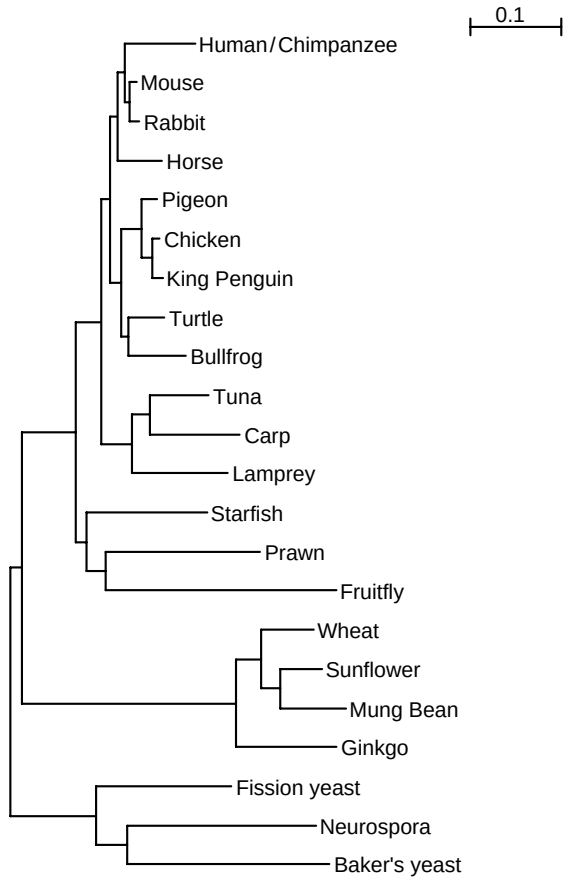

FIGURE 1 Phylogenetic tree constructed from the amino acid sequences of cytochrome *c* using the ClustalW program. The length of the branches corresponds to evolutionary distances (0.1 = 10% amino acid substitutions).

ancestor of two species existed, the more amino acid changes will have accumulated since. As it turned out, the phylogenetic trees constructed on the basis of the sequence of a single protein were surprisingly similar to those derived from comparative anatomy, fossils etc. Moreover, since cytochrome *c* could be extracted from species for which no reliable data were available from other sources, these could now also be included in this analysis.

In this comparison of cytochromes *c* from diverse eukaryotic species, it was found that more than a quarter of the amino acids have been conserved during more than a billion years of evolution. Among these immutable residues are the two cysteines to which the heme is bound via thioether linkages. The central iron of the planar heme is not only bound to four nitrogen atoms of the porphyrin but, in addition, to the side chains of two invariant amino acids of the protein, one being a histidine adjacent to the second cysteine (residue #18 in the vertebrate sequences), the other the sulfur atom of methionine 80, present on opposite sides. Moreover, certain amino acids with hydrophobic side chains, some of which line the crevice where the heme is buried, are also conserved. Surprisingly, it was found that several glycine residues in the sequence were also invariant. Glycine is the smallest amino acid containing only a hydrogen atom where the 19 others have more or less bulky side chains. From the three-dimensional structure, this first puzzling observation could be explained. At these sites, there is simply no space in this tightly folded protein and every other amino acid would presumably prevent proper folding of the polypeptide chain and thus be deleterious. Also, some charged amino acids, mostly lysines, have been conserved. These may be essential for the ionic interaction with two its reaction partners as well as with acidic phospholipids present in the inner mitochondrial membrane.

Three-Dimensional Structure

Using X-ray crystallographic analysis, the three-dimensional structure of tuna cytochrome *c* in its oxidized and reduced forms could be determined. As shown by these studies, the polypeptide chain is tightly wrapped around the heme, which sits in a deep pocket, exposed only on one edge to the solvent. In accordance with the "oil droplet" model of folded proteins, the hydrophobic amino acids are mostly buried inside the protein, some of them surrounding the heme. In the respiratory chain located in the inner membrane of mitochondria, cytochrome *c* shuttles between a reduced ferro-(Fe^{2+}) and ferri-(Fe^{3+}) form. In this redox cycle, the protein changes its conformation, with the reduced form having a more compact structure.

Interactions of Cytochrome *c* in the Respiratory Chain

Cytochrome *c* is loosely bound to the outer surface of the inner mitochondrial membrane. In the respiratory chain, an electron is transferred to cytochrome *c* from cytochrome bc_1. These cytochromes are part of a large, membrane-bound complex, also termed complex III composed of 11 proteins. Subsequently, the electron is delivered to the cytochrome aa_3 of the complex IV, the cytochrome oxidase, which contains 13 proteins. Some of the molecular details of this electron transport has recently also been clarified. In the crystal structure of the yeast cytochrome bc_1 complex with its bound substrate cytochrome *c*, the heme groups of cytochrome c_1 and *c* are in close proximity (see Figure 2). This suggests that the redox process takes place by direct heme-to-heme electron transfer. The same may also be true for the oxidation of cytochrome *c* by cytochrome aa_3.

In both redox reactions, a proton is pumped across the inner membrane. The proton gradient thus formed drives the ATP synthetase motor, which results in the synthesis of ATP.

Cytochrome *c* and Apoptosis

Cells that are damaged or are no longer needed may undergo a form of cell death that is controlled and executed by intracellular programs. One major apoptotic program involves the release of cytochrome *c* from the intermembrane space of mitochondria into the cytosol, together with some other mitochondrial proteins. Once in the cytoplasm, cytochrome *c* combines with an "apoptosis activating factor-1" (Apaf-1) and thus triggers the assembly of a multimeric protein complex, the so-called apoptosome. An inactive proform of a proteolytic enzyme, procaspase-9, is then recruited to the apoptosome and activated. Active caspase-9, in turn, activates other caspases, whose proteolytic actions finally lead to cell death. The crucial role of cytochrome *c* in this process is shown by the fact that microinjection of cytochrome *c* into the cytoplasm suffices to induce apoptosis in several cell lines. In the interaction with Apaf-1, as in the interaction with cytochrome c_1, the exposed heme edge of cytochrome *c* is involved.

When cytochrome *c* molecules are released from the mitochondrion, they have to pass through pores in the outer membrane of the organelle. A group of related proteins, the Bcl-2 family, regulates apoptosis by controlling the permeability of this membrane. Bcl-2 itself and other antiapoptotic proteins are located in the outer mitochondrial membrane and inhibit cytochrome *c* release. Conversely, release of cytochrome *c* is

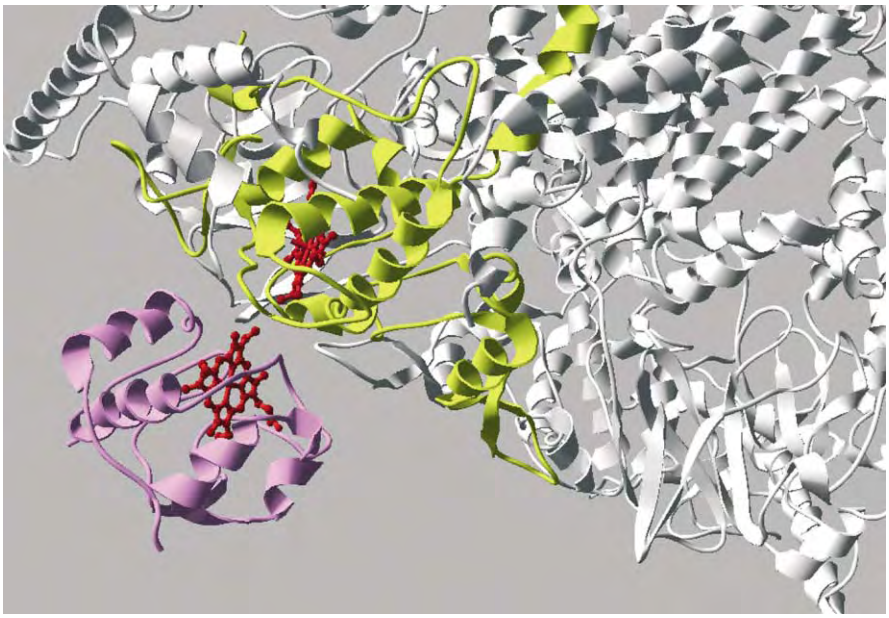

FIGURE 2 Part of the yeast cytochrome bc_1 complex and the bound substrate cytochrome *c* (Protein Data Bank, accession number 1KYO). Cytochrome c_1, yellow; cytochrome *c*, magenta; hemes, red.

triggered by proapoptotic members of the Bcl-2 family, which are induced by a number of stimuli to translocate to the mitochondria. Since one of the functions of apoptosis is to help the multicellular organism get rid of cancer cells, the pro- and antiapoptotic Bcl-2 family members are considered to be oncogenic and antioncogenic proteins, respectively. They control whether cytochrome *c*, besides being a vital mediator of electron transfer in respiration, also gets involved in cell death.

Glossary

apoptosis Also called "programmed cell death," a means for the multicellular organism to eliminate cells that are no longer needed or are damaged.

cytochromes Literally "cell pigments," heme proteins chiefly involved in cell respiration and energy supply.

heme An iron porphyrin complex that is attached (as a "prosthetic group") to protein moieties in the red blood pigment hemoglobin, in the cytochromes and in many other heme proteins.

mitochondria Intracellular organelles, the main site of oxidative metabolism which supplies the cell with utilizable energy in the form of ATP. In the course of cellular respiration, elementary oxygen is taken up by mitochondria and reduced to water. The electrons required for reduction are transmitted to oxygen via the respiratory chain, one of the electron transporters being cytochrome *c*.

Cytochrome Oxidases, Bacterial

Peter Brzezinski and Pia Ädelroth
Stockholm University, Stockholm, Sweden

Bacterial cytochrome *c* oxidases are integral membrane proteins that catalyze the four-electron reduction of dioxygen (O_2) to water and oxidation of different types of water-soluble or membrane-anchored cytochromes *c* (cyt.*c*). The oxygen-reducing site of the enzymes consists of a heme-copper center, which is buried within the protein. Hence, cytochrome *c* oxidases belong to the super-family of heme-copper oxidases, a class of enzymes that also includes the quinol oxidases, which use different types of lipid-soluble quinols (QH_2) instead of cytochrome *c* as their electron donor. The heme-copper oxidases are also often termed *respiratory oxidases* or *terminal oxidases*, terms that refer to the enzymes being the last components of the respiratory chains of aerobic organisms. However, not all terminal oxidases belong to the heme–copper oxidase superfamily. One example is the group of so-called alternative oxidases (e.g., in plants), which do not contain any heme groups.

Chemical Process

In the cytochrome *c* oxidases the protons used for O_2 reduction to water (substrate protons) are taken up from the inner (cytosol) side of the membrane, while cytochrome *c* reacts on the opposite, outer (periplasm) side of the membrane. In the quinol oxidases, the quinol binds from the core of the membrane, and upon oxidation, the protons are released to the periplasm. Thus, the reaction catalyzed by the heme-copper oxidases has a direction not only in time (c.f. any chemical reaction), but also in space, which is referred to as *vectorial chemistry*. The charge distribution across the membrane is such that there are more positive charges on the outer side than on the inner side. Hence, the outer and inner sides are referred to as the positive (*P*) and negative (*N*) sides, respectively:

cytochrome *c* oxidases

$$4\text{cyt.}c_P^{2+} + O_2 + 4H_N^+ \rightarrow 4\text{cyt.}c_P^{3+} + 2H_2O$$

quinol oxidases

$$2QH_2 + O_2 + 4H_N^+ \rightarrow 2Q + 2H_2O + 4H_P^+,$$

where the subscripts *N* and *P* refer to the negative and positive sides, respectively. In both cases outlined above, a net of four positive charges are generated on the *P*-side, while four positive charges are consumed on the *N*-side. Consequently, the chemical reactions catalyzed by heme-copper oxidases are arranged topographically in such a way that they result in a charge separation corresponding to the net transfer of one positive charge from the *N*-side to the *P*-side of the membrane per electron transferred to O_2. In addition, for most heme-copper oxidases characterized to date, part of the free energy released in the catalytic reaction is also used to pump (translocate) protons from the *N*-side to the *P*-side of the membrane, with an average stoichiometry of one proton per electron (see Figure 1 and more detailed discussion below). Hence, on average, two charges are transferred across the inner membrane per electron transferred to oxygen. As suggested by Peter Mitchell and formulated in the Chemiosmotic theory, this transmembrane proton and voltage gradient generated in part by the heme-copper oxidases is used, for example, for synthesis of ATP by the ATP synthase.

Structures

The bacterial heme–copper oxidases consist of several (in many cases four) subunits, located in the (inner) cell membrane of the bacterium. The minimal functional unit of the heme-copper oxidases is the subunit (SU) I–II complex (see also below). The heme–copper oxidase family is defined by the presence in SU I of six conserved histidine residues that coordinate three redox-active metal sites: (1) a six-coordinated heme group which has two axial His ligands and in which the iron ion is in a low-spin state; (2) a five-coordinated heme group with one axial His ligand and in which the iron ion generally is found in the high-spin state; and (3) a copper ion (Cu_B) which is bound by three His ligands. The SU I scaffold, which holds the redox centers, comprises at least 12 transmembrane helices, which span the membrane. The five-coordinated heme is usually denoted with a subscript 3, e.g., heme a_3. In the examples and discussion

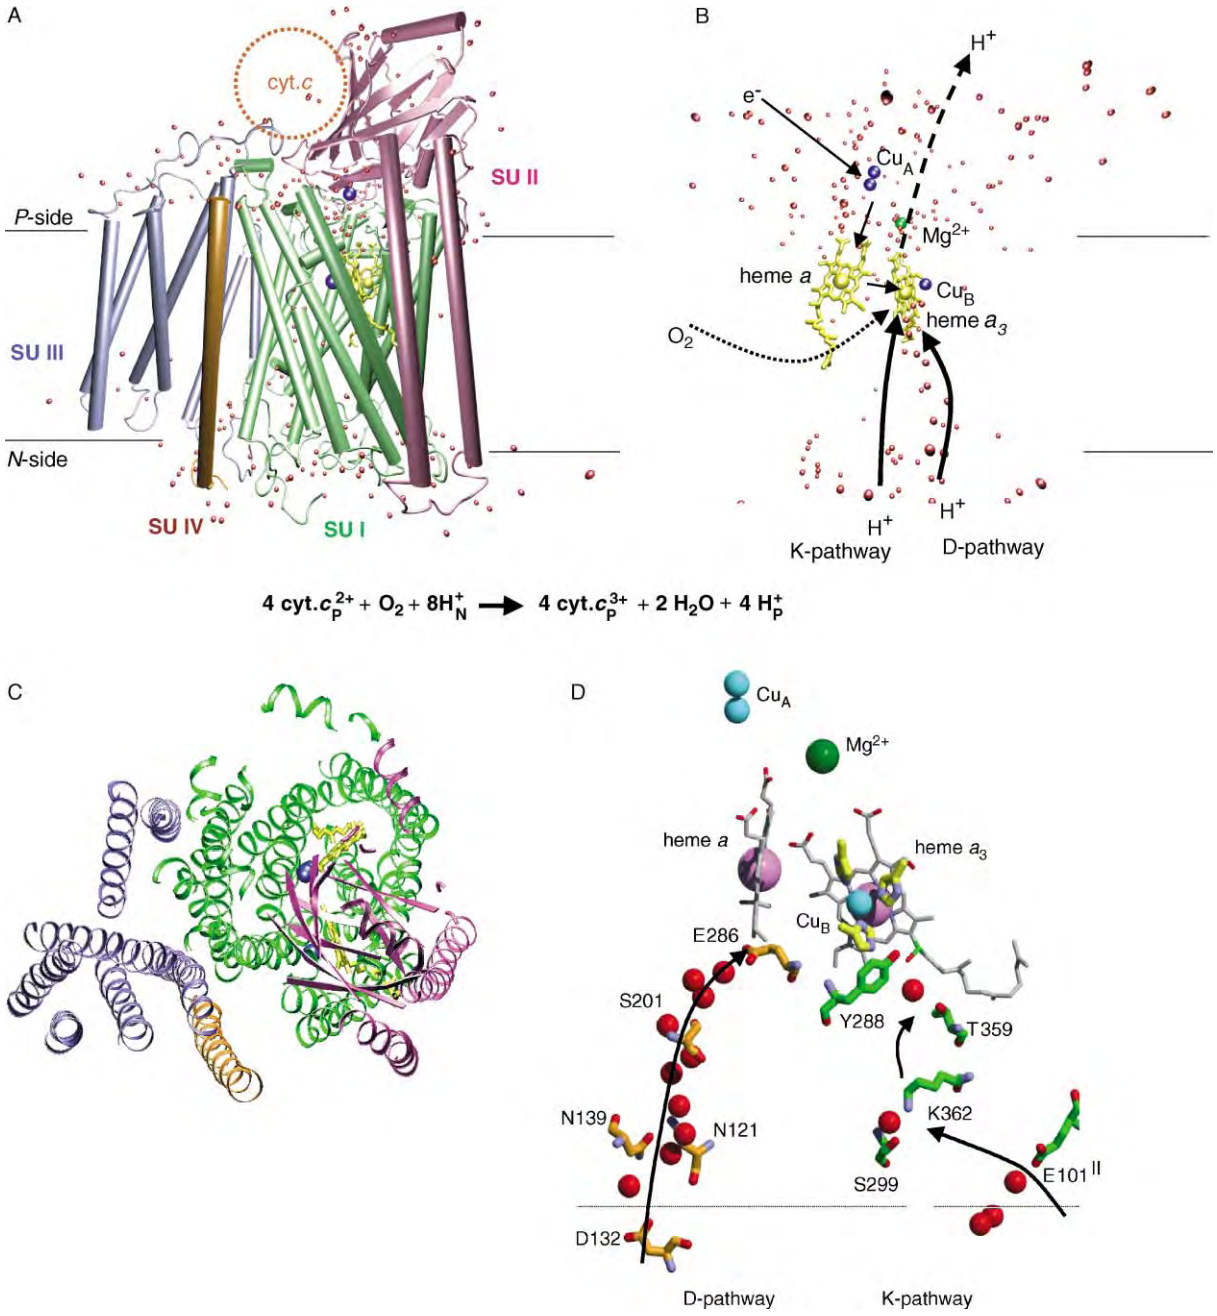

FIGURE 1 (A) The overall structure of the *R. sphaeroides* cytochrome aa_3 (cytochrome *c* oxidase). Subunits I, II, III, and IV are shown in different colors as indicated. The heme groups are shown in yellow, the copper ions in blue, and a redox inactive Mg^{2+} ion in green. Three redox active sites, heme *a*, and the catalytic site consisting of heme a_3 and Cu_B are found in SU I. The Cu_A center is found in SU II. A likely location of the cytochrome *c* binding site is indicated. Water molecules resolved in the structure are shown as red spheres. (B) Only the cofactors are shown together with the water molecules resolved in the structure. Substrate and pumped protons (thick arrows) are taken up from the inner, cytosol side (*N*-side) and the pumped protons (dashed arrow) are released on the outer, periplasm side (*P*-side), as shown. e^- is the electron from cyto *c* (thin arrows). (C) Top view of the enzyme. (D) The redox-active cofactors (and the Mg^{2+} ion) and proton-transfer pathways of cytochrome *c* oxidase. The overall reaction catalyzed by cytochrome c oxidase is described by the reaction formula, where the subscripts *P* and *N* refer to the two sides of the membrane. Subunits I–III of the *R. sphaeroides*, *P. denitrificans*, and the mitochondrial enzymes are highly homologous and their overall structures are very similar.

below, we call the two hemes of the enzyme hemes *a* and a_3, respectively.

Unlike the six-coordinated heme, heme a_3 binds ligands such as O_2, CO, and CN^-. Heme a_3 and Cu_B are collectively called the binuclear center, which is the catalytic site at which O_2 is reduced to water. The heme groups may be of different types, such as heme *a*, *b*, or *o*, where the two hemes in SU I may be of the same or of different types. Heme–copper oxidases are also often given a name that indicates the types of hemes present, e.g., cytochrome aa_3. Many bacteria have several types of oxidases, which are expressed to various degrees

depending on the environmental conditions (e.g., the O_2 concentration). The X-ray structures of heme–copper oxidases that have been determined to date are summarized in Table I.

A common feature of most (but not all) cytochrome *c* oxidases is a copper center (Cu_A) bound in SU II, which is the primary electron acceptor from cytochrome *c*. Hence, the binding site for the water-soluble cytochrome *c* is located near Cu_A (see Figure 1). The Cu_A center is composed of two copper ions coordinated by two –SH groups of two Cys residues (among other ligands), which resembles the [2Fe–2S] centers of iron–sulfur proteins. The Cu_A center can accept and donate one electron switching between the formal charges $[Cu^{1+}–Cu^{1+}]$ and $[Cu^{1.5+}–Cu^{1.5+}]$ in the reduced and oxidized form, respectively. Many cytochrome *c* oxidases that do not have the Cu_A site instead have a cytochrome *c* subunit that protrudes into the inter-membrane space and acts as the primary electron acceptor. In the ubiquinol oxidase from *E. coli*, the ubiquinol binding site was suggested from an analysis of the three-dimensional structure and from experiments using site-directed mutagenesis to be found in the membrane-spanning part of SU I at a cluster of polar residues exposed to the interior of the lipid bilayer.

Subunit III does not contain any redox-active cofactors. Even though the enzyme with SU III removed displays O_2-reduction activity and pumps protons (although with a stoichiometry of less than one proton per electron), this form of the enzyme becomes inactivated after a limited number of reaction cycles. Consequently, SU III is important for the stability of the protein.

Proton-Transfer Pathways

As seen in Figure 1, the O_2-reducing site is located in the membrane-spanning part of the enzyme. Therefore, proton-transfer pathways, leading from the protein surface on the *N*-side to the binuclear center, are needed. Such pathways are typically composed of polar and protonatable amino-acid residues as well as of water molecules forming a hydrogen-bonded chain. The detailed composition of these pathways varies in the bacterial heme–copper oxidases. Two pathways have been identified from an analysis of the three-dimensional structures of heme–copper oxidases determined to date, from a comparison of the amino-acid residue sequences of a large number of other heme–copper oxidases, and from the combined use of site-directed mutagenesis and functional studies. These pathways are found in SU I and are named the D- and K-pathways, after residues Asp(D)132 and Lys(K)-362, respectively. We use the *R. sphaeroides* cytochrome aa_3 amino-acid residue numbering because the structure shown in Figure 1 is from that enzyme. Both pathways start at the inner-side surface and lead to the catalytic site (Figures 1B and 1D). A common feature of a large number of oxidases is a Glu residue in the D-pathway, E(I-286) in the *R. sphaeroides* cytochrome aa_3, located about 25Å from D(I-132) and about 10Å from the binuclear center. In heme–copper oxidases in which the Glu is not conserved, other protonatable residues are found at about the same location in space.

Oxygen Binding and Reduction

Even though the reduction of O_2 to water is a highly exergonic reaction, the O_2 molecule is kinetically stabilized against reduction due to two factors. First, the one-electron reduction of O_2 to form the superoxide radical $O_2^{\cdot-}$ is associated with a positive free energy change, which imposes a thermodynamic barrier in the initial step of the reduction process. Second, in the ground electronic state, O_2 has two unpaired electrons (triplet state), which imposes spin restrictions on many of its reactions. The heme copper oxidases overcome

these problems by binding O_2 to the heme a_3 iron in the high-spin state and by providing a second electron donor, Cu_B, in the immediate vicinity. The rates at which bacterial oxidases catalyze the O_2 reduction are remarkably rapid with turnover numbers of up to several hundred O_2 molecules per second. The rapid uptake of O_2 may be facilitated by hydrophobic channels leading from the membrane core to the catalytic site, as suggested from analyses of the crystal structures of heme–copper oxidases.

The mechanism of the O_2-reduction has been primarily investigated in detail in cytochromes aa_3 from *R. sphaeroides*, *P. denitrificans*, the closely related mitochondrial enzyme, as well as in cytochrome bo_3 from *E. coli*. The reaction sequence is most likely the same for all oxidases, but the mechanism described below has been identified primarily from studies of these enzymes.

Initially, the electrons are transferred one at a time to the binuclear center. When both heme a_3 and Cu_B are reduced (i.e., $Fe^{2+}_{a_3}$ and Cu^{+}_{B}, state **R** in Figure 2), O_2 binds to heme a_3 (the state is called **A**). After binding of O_2 the O–O bond is cleaved, which results in formation of a ferryl group ($Fe^{4+}_{a_3}{=}O$, see Figure 2), where one electron and a proton are donated by an internal group, presumably a highly conserved Tyr at the catalytic site, which would form a radical. Even though the binuclear center is in a two-electron reduced state, formally four electrons are donated to O_2 in this reaction because two electrons are donated by Fe_{a_3}($Fe^{2+}_{a_3} \rightarrow Fe^{4+}_{a_3}$), one by Cu_B($Cu^{+}_{B} \rightarrow Cu^{2+}_{B}$ and one by the Tyr. For historical reasons, this state is called "peroxy" and denoted **P**.

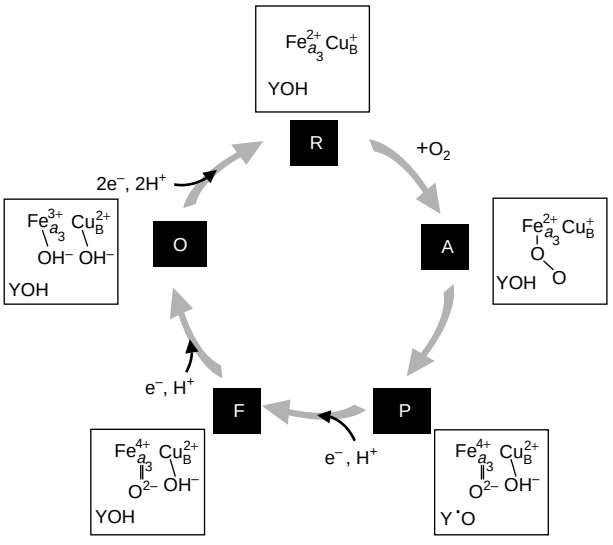

FIGURE 2 The reaction cycle of cytochrome *c* oxidase. State **O** is the oxidized enzyme. The two-electron-reduced catalytic site (state **R**) binds O_2 (forming state **A**). In the first step of O_2 reduction, a ferryl state is formed (**P**), where one electron and one proton are transferred from a Tyr residue at the catalytic site. The transfer of the third electron to the catalytic site is accompanied by proton uptake from the bulk *N*-side solution and the formation of state **F**. In the next step, the fourth electron is transferred to the binuclear center associated with proton uptake from the bulk *N*-side solution.

The transfer of the third electron to the binuclear center is associated with proton uptake from the inside bulk solution. The intermediate that is formed is called "ferryl" and is denoted **F** (Figure 2). It is assumed to have the same chemical structure as **P**, except for the additional electron and proton at the binuclear center, which are presumably transferred to the Tyr radical. The transfer of the next, forth electron to the binuclear center is also associated with proton uptake from the inside bulk solution and results in formation of the oxidized binuclear center, denoted **O**.

Proton Pumping

In 1977, Mårten Wikström showed that in addition to the charge separation associated with the O_2 reduction reaction, cytochrome *c* oxidase also releases protons to the *P*-side of the membrane. In other words, the enzyme is a proton pump, which translocates one proton from the *N*-side to the *P*-side of the membrane per electron transferred to O_2. Consequently, since there is no proton carrier in the enzyme that can bodily move protons across the membrane, there must be a specific mechanism by which the enzyme uses the free energy from reduction of O_2 to translocate protons across the membrane. This function must be reflected in specific structural elements of the molecular machine. The molecular mechanism by which heme–copper oxidases pump protons is not known. The general view is that during the process the enzyme must provide an alternating access of protons to the two sides of the membrane and have this alteration strictly coupled to specific transitions of the catalytic cycle. Such changes in the accessibility for protons to the two sides of the membrane are likely to be achieved by breakage and formation of hydrogen bonds in the proton-transfer pathways, for example, through local rearrangements of amino-acid residue side chains. It has been shown that the **R** → **P** transition is not associated with proton pumping, while the **P** → **F** and **F** → **O** transitions are associated with the translocation of one proton in each step. The definite assignment of other reaction steps in which proton translocation occurs and conditions under which this takes place is at present not definitely settled.

As indicated above, in the initial step of the reaction, the O_2 molecule is formally reduced by four electrons (to form state **P**, Figure 2). An advantage of such a four-electron reduction of O_2 in a single step is that it prevents accumulation of potentially harmful, partly reduced O_2 intermediates. However, since the formation of **P** is not associated with proton translocation, this mechanism

requires that the free energy available from the O_2--reduction reaction is conserved within the enzyme, for example by the formation of high-pK_a internal proton acceptors; and the free energy can be used for proton translocation in the following steps of the reaction.

Some Experimental Techniques Used to Study Heme–Copper Oxidases

Present knowledge about the O_2-reduction mechanism is derived from the use of a large number of experimental techniques. One of these is the "flow-flash" technique, pioneered by Quentin Gibson and Colin Greenwood. The enzyme reduced with 2–4 reduction equivalents and with CO bound to heme a_3 is mixed with an O_2 solution after which the CO ligand is flashed off by means of pulsed illumination, which initiates the reaction of the enzyme with O_2. The application of this technique has made it possible to observe, with microsecond time resolution, the transitions between different states. The progress of the reaction is followed, e.g., by observing absorbance changes of the redox sites, by measuring voltage changes that originate from the movement of charges in enzyme reconstituted in lipid vesicles, or by using time-resolved resonance-Raman spectroscopy to obtain information about the structure of the oxygen intermediates. In addition, Fourier Transform Infrared Difference spectroscopy is used to identify specific residues that undergo changes in their protonation state and/or hydrogen-bonding patterns, and Electron Paramagnetic Resonance spectroscopy is used to explore the electronic configuration and the chemical environment of the redox centers. The use of the techniques discussed above, combined with the use of site-directed mutagenesis, has provided important insights into the catalytic mechanism.

Biography

Peter Brzezinski is Professor of Biochemistry at the Department of Biochemistry and Biophysics at Stockholm University in Stockholm, Sweden. He specializes in the field of bioenergetics, and his principal research interests are mechanisms of electron- and proton-transfer reactions in biological systems, in particular in membrane-bound proteins. He holds a Ph.D. in physics from Chalmers University of Technology in Göteborg, Sweden and received his postdoctoral training at the University of California, San Diego.

Cytochrome P-450

Rita Bernhardt
Saarland University, Saarbrücken, Germany

Cytochromes P-450 are ubiquitously distributed multicatalysts, which were discovered approximately 50 years ago. They possess a high degree of complexity and display a broad field of activity. Although already more than 2500 different P450 forms have been described, new forms are constantly being found, opening up new research fields. They are the key enzymes responsible for the metabolism of many drugs, carcinogens, alkaloids, pesticides, and other important xenobiotics. Moreover, they are involved in a variety of physiological processes such as steroid hormone, eicosanoid, vitamin D, and bile acid biosynthesis. Cytochromes P-450 are hemoproteins that use molecular oxygen to catalyze various reactions. They get the electrons necessary for oxygen activation and substrate hydroxylation from NADH or NADPH, in general via the action of electron-transferring proteins. Most cytochromes P-450 are membrane-bound. Many of them are inducible, but some are constitutively expressed. Defects in some of the cytochromes P-450 lead to pathological effects, such as congenital adrenal hyperplasia and hypertension, and adverse drug effects.

Cytochrome P-450—General Aspects

There are two general classes of enzymes involved in oxygen metabolism: oxidases, transferring electrons from a substrate to oxygen, and oxygenases, transferring oxygen to a substrate after reductive splitting of molecular oxygen. Oxygenases can be divided into dioxygenases and monooxygenases. Monooxygenases (mixed-function oxidases) catalyze the incorporation of a single atom of molecular oxygen into a substrate with the concomitant reduction of the other atom to water. The monooxygenases are divided into two classes, the internal and the external monooxygenases. Internal monooxygenases extract two reducing equivalents from the substrate to reduce one atom of dioxygen to water, whereas external monooxygenases use an external reductant. Cytochromes P-450 are external monooxygenases. Initially the microsomal drug and xenobiotic-metabolizing enzymes were referred to as mixed-function oxidases, but in more recent years the term monooxygenase has become the more accepted one.

Cytochromes P-450 got their name from their character as a hemoprotein and from their unusual spectral properties, displaying a typical absorption maximum of the reduced CO-bound complex at 450 nm (Figure 1)—cytochrome stands for a hemoprotein, P for pigment, and 450 reflects the absorption peak of the CO complex at 450 nm. The ability of reduced P450 to produce an absorption peak at 450 nm upon CO binding is still used for the estimation of P450 content. The red shift of approximately 30 nm observed in cytochromes P-450 means that the distribution of electron density at the heme is significantly perturbed compared to other cytochromes. It has been documented that it is the thiolate sulfur that causes this effect by means of a direct bond to the iron. The Soret band (named after its discoverer) describes the absorption band of hemoproteins at approximately 380–420 nm.

Cytochrome P-450 systems catalyze the following reaction:

$$RH + O_2 + NAD(P)H + H^+ \rightarrow ROH + H_2O + NAD(P)^+$$

They catalyze reactions as diverse as hydroxylation; N-, O-, and S-dealkylation; sulfoxidation; epoxidation; deamination; desulfuration; dehalogenation; peroxidation; and N-oxide reduction. Their substrates include fatty acids, steroids, and prostaglandins, as well as a multitude of foreign compounds such as drugs, anesthetics, organic solvents, ethanol, alkylaryl hydrocarbon products, pesticides, and carcinogens. This diversity of catalyzed reactions and acceptable substrates has attracted researchers from diverse fields to the study of cytochrome P-450 systems (Figure 2). In addition to pharmacologists and toxicologists, endocrinologists, physiologists, microbiologists, organic chemists, plant biologists, and environmental scientists also are working on diverse aspects of P450 function and regulation.

It is obvious that this diversity of substrates and catalyzed reactions cannot be managed by only a few different isoforms. In the human genome alone 57 different P450 genes have been found, and in total more than 3000 different isoforms have been characterized

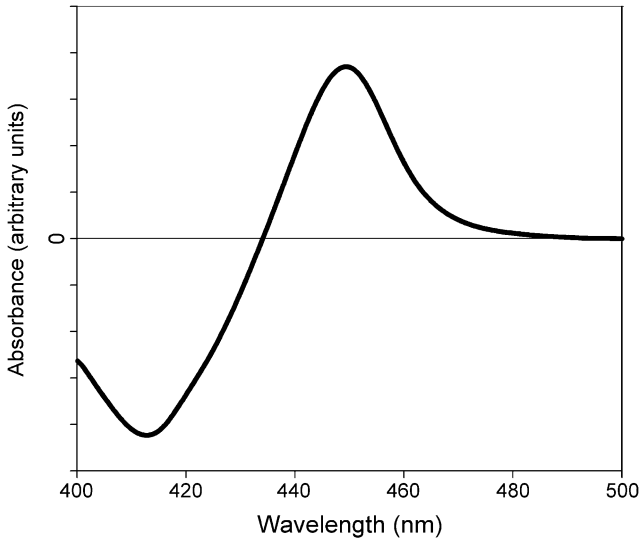

FIGURE 1 CO-difference spectrum of reduced versus oxidized cytochrome P-450 (CYP106A2).

(D. Nelson lists the available P450 sequences identified so far on his website). This superfamily of proteins (and their respective genes) is divided into families, subfamilies, and finally into individual members according to similarities in primary structure. A new nomenclature has been introduced in which CYP and a series of numbers and letters are used to characterize each P450 as a hemoprotein. For example, in CYP1A1, for cytochrome P4501A1 (previously called P450c), the first arabic number defines the gene family, the following letter defines the subfamily, and the second number defines the individual enzyme. Members of the same gene family are defined as usually having $<40\%$ sequence identity to a P450 protein from any other family. Mammalian sequences within the same subfamily are always $>55\%$ identical. The numbers of individual P450 enzymes in different species differ, the highest numbers observed so far being in plants.

Structural Organization of Cytochrome P-450 Systems

As already mentioned, cytochromes P-450 belong to the external monooxygenases. This means that they need an external electron donor to transfer the electrons necessary for oxygen activation and the following substrate hydroxylation. Two main classes of cytochromes P-450 can be defined with respect to their electron-supporting system, although other subclasses also occur: the microsomal type and the mitochondrial/bacterial type (Figure 3).

Microsomal cytochromes P-450 are membrane-bound and accept electrons from a microsomal NADPH–cytochrome P-450 reductase, containing flavin adenine dinucleotide (FAD) and falvin mononucleotide (FMN). All drug- and xenobiotica-metabolizing cytochromes P-450 isolated so far belong to this class. In addition, CYP102 (P450BM-3) isolated from *Bacillus megaterium* was shown to belong to this class. This P450 system consists of a polypeptide chain with two different domains, one containing the hemoprotein and the other containing a flavoprotein with FAD and FMN. Most of the other bacterial cytochromes P-450 belong to

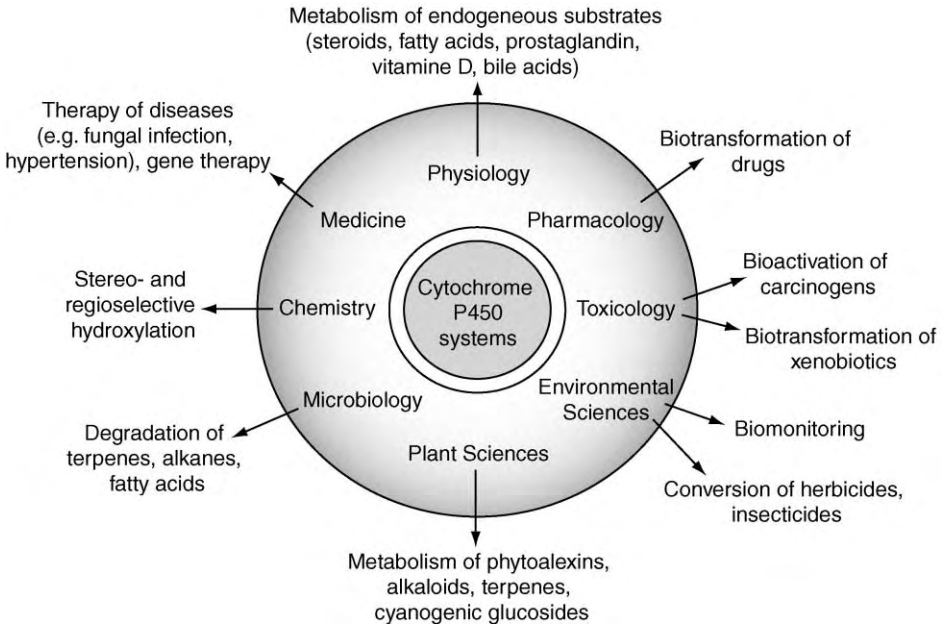

FIGURE 2 Cytochrome P-450 research and application fields.

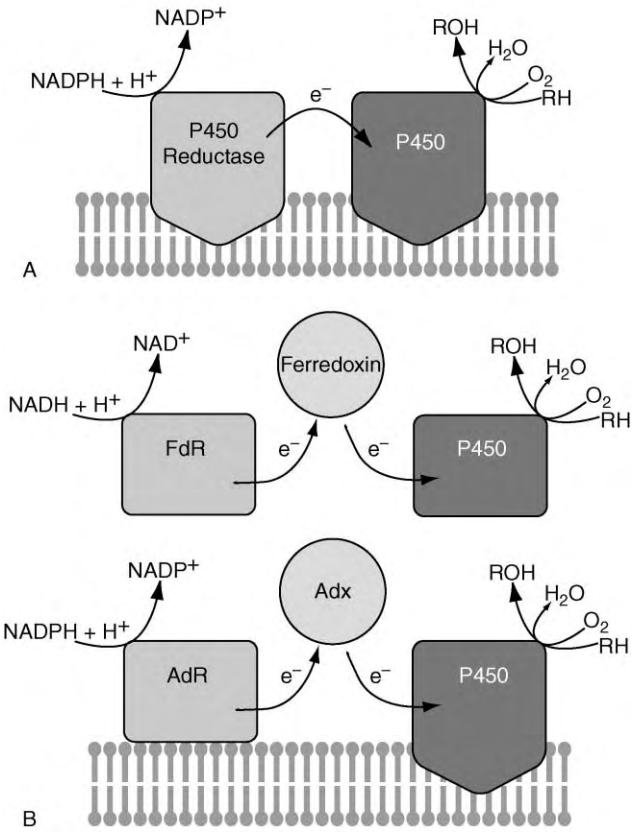

FIGURE 3 Model for the organization of cytochrome P-450 systems. (A) Microsomal type. (B) Mitochondrial/bacterial type.

the second class. They are soluble and obtain the electrons necessary for the reaction mechanism from an NADH-dependent FAD-containing reductase via an iron–sulfur protein of the [2Fe–2S] type.

Mitochondrial cytochromes P450, which are involved e.g., in the side-chain cleavage of cholesterol, the 11β-hydroxylation of deoxycortisol, and the production of aldosterone, also belong to the second class. These cytochromes P-450 are localized in the inner mitochondrial membrane, where the [2Fe–2S] protein, called adrenodoxin in the case of adrenal steroid hydroxylase systems, is a soluble protein of the matrix. The FAD-containing reductase, adrenodoxin reductase, is associated with the inner mitochondrial membrane.

The interaction of the cytochromes P-450 with their corresponding electron donors is a necessary prerequisite of the catalytic cycle. Its specificity guarantees a sufficient reaction rate of catalysis and likewise a discrimination between the different potential donors and acceptors of electrons to protect the system from shunt reactions.

Because many different isoenzymes in liver microsomes have to interact with only one type of reductase, the binding site for reductase is very similar or identical on various cytochromes P450. Salt bridges are responsible for the recognition of reductase by the cytochromes P-450 and for the correct orientation of the proteins to one another. In addition to microsomal reductase, some microsomal cytochromes P-450 are able to accept the second electron from cytochrome b_5. cytochrome b_5 has also been shown to exert a differential stimulatory action, depending on the form of cytochrome P-450 and the substrate metabolized.

In mitochondrial steroid hydroxylases and in the camphor hydroxylating bacterial cytochrome P-450 (CYP101) system, a charge–pair interaction mechanism has been demonstrated by chemical modification, site-directed mutagenesis studies, and structural data of electron-transfer complexes. Like microsomal reductase, the mitochondrial ferredoxin has been shown to deliver electrons to different cytochromes P450. From the available data, a shuttle model is favored, in which the oxidized ferredoxin interacts first with the ferredoxin reductase to undergo reduction, with the formation of a Fe^{3+}–Fe^{2+} iron–sulfur cluster. It dissociates from the reductase and then interacts with the respective cytochrome P450, to which it delivers this electron before going back to the reductase, and transfers the second electron to the cytochrome P450. The mechanism of electron transfer between the components of the different cytochrome P-450 systems, one of the fundamental problems in life sciences, is not well understood.

Reaction Cycle

The generally accepted mechanism of cytochrome P450-dependent substrate conversion is depicted in the overall scheme presented in Figure 4. The first step of the reaction cycle is the formation of the substrate–enzyme complex. Substrate binding induces structural changes in the cytochrome P-450 that may result not only in a

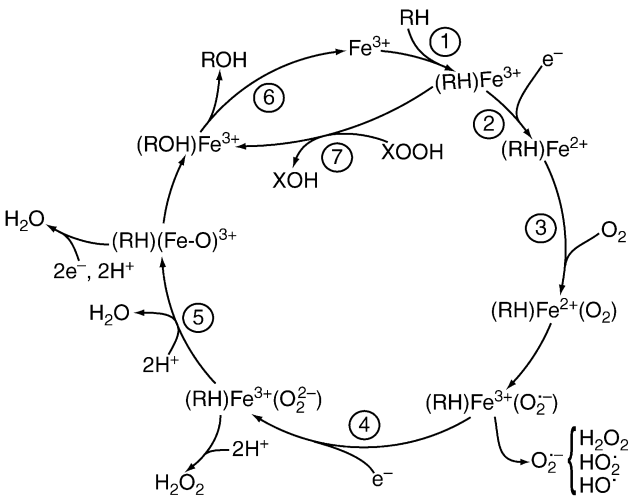

FIGURE 4 Reaction cycle of cytochromes P450.

spin shift, but also in changes of the redox potential and in changed binding affinities between interacting components of the cytochrome P-450 system. The second step of the reaction cycle is the introduction of the first electron, either by NADPH-dependent reductase or via a ferredoxin (see Figure 3). Iron (3+) is reduced to iron (2+). Although in some cytochromes P450 the substrate binding is a prerequisite for electron transfer, this is not a universal requirement. In the third step of the reaction cycle, the hemoprotein reduced by one electron binds the dioxygen molecule. As shown in Figure 4, from this complex a superoxide anion radical can be released. Step 4 of the reaction cycle is the introduction of the second electron. In some instances, another microsomal hemoprotein, cytochrome b_5, can facilitate catalysis by providing the second electron. From the $(RH)Fe^{3+}(O_2^{2-})$ complex, hydrogen peroxide can be split off. The structure of the activated oxygen complex and the precise mechanism of oxygen cleavage are not fully understood yet. Step 5 in the reaction cycle is the removal of the terminal oxygen atom from the dioxygen ligand, that is, the cleavage of the dioxygen bond. Heterolysis of the oxygen–oxygen bond also results in the formation of a putative oxyferryl species. Heterolytic cleavage in P450cam (CYP101), where most of the mechanistic studies have been performed, was shown to be facilitated by hydrogen bonding of the ferric hydroperoxide via a water molecule to a highly conserved threonine residue (Thr252 in CYP101), which is involved in a proton transfer network that promotes oxygen cleavage. The introduction of two electrons and two protons to the putative oxyferryl species may lead to the formation of water. Finally, in step 6 the hydroxylated product dissociates and the cycle can start again. Interestingly, in many but not all cytochromes P450 a shunt reaction can proceed (step 7), in which the substrate can be hydroxylated directly by peroxides such as hydrogen peroxide, cumene hydroperoxide, and *tert*-butyl hydroperoxide without the necessity of an interaction with an electron-donating system. Taken together, cytochromes P-450 do not catalyze just monooxygenase, but also oxidase and peroxidase reactions. Variations of this scheme for the reaction mechanism of cytochromes P-450 occur with different cytochrome P-450 systems such as thromboxane and prostacyclin synthase, nitric oxide reductase (CYP55A1), and others.

Regulation of Cytochrome P-450 Systems

The regulation of enzyme systems is possible at different levels. When considering cytochrome P-450 systems, the complexity of the reaction cycle, the organization within membrane systems for most of the cytochromes P450, and their organ- and tissue-specific expression imply various possible ways for regulatory mechanisms to work. Interaction between these mechanisms then leads to the tuned response of these enzyme systems to endogenous and exogenous signals in terms of acute and long-term reactivities of cytochromes P450.

First it is possible to regulate cytochromes P-450 on the level of the organism. Some of the cytochromes P-450 are expressed in age-, tissue-, and sex-dependent manners. These differences in the expression pattern are governed by sex or other hormones. There are also clearly developmental influences on the expression and function of various cytochrome P-450 systems.

Cellular regulation of cytochromes P-450 is extremely complex and can occur on at least two different levels, enzyme induction and post-translational modification of enzymes. The induction of drug-metabolizing enzymes was noted in the early 1950s. Since then specific inducers for various cytochrome P-450 families and subfamilies have been identified. It can be demonstrated that the inductor functions by enhancing the rate of mRNA synthesis of a special cytochrome P450. In some cases, receptors (the best-studied system currently is the aryl hydrocarbon, Ah, receptor) are involved in mediating the effect of the inducer. Not all cytochromes P450 are, however, inducible; some of them are constitutively expressed.

After the biosynthesis of cytochromes P450, the enzymes might be subject to post-translational modifications to exert a short-term control of activity. One of the most common types of post-translational modifications in eukaryotic organisms is protein phosphorylation, which has been demonstrated for several steroid hydroxylases such as the microsomal CYP7 and the mitochondrial CYP11A1 and also for the drug-metabolizing microsomal CYP2B4.

Because nearly all the cytochromes P-450 are bound to membranes, they can be regulated also at that level. Exclusions are most of the bacterial cytochromes P450, such as CYP101, CYP102, and CYP108, which are soluble. The composition of the membrane (e.g., protein–lipid as well as lipid-mediated protein–protein interactions) exert a functional control on cytochromes P450. Lipids appear to function in at least three ways—they (1) stabilize and induce a functionally active conformation of cytochromes P-450 and the corresponding electron-transfer systems, (2) modulate the electron transfer, and (3) mediate interactions between cytochromes P-450 and the electron-donor systems.

Finally, cytochromes P-450 can be regulated at the molecular level. This includes regulation of the activities by changes of the primary sequence (e.g., by polymorphisms), the spin equilibrium, protein–electron donor interactions, and protein–protein interactions.

Important Functions of Cytochrome P-450 Systems

Cytochromes P-450 and Drug Metabolism

Cytochromes P-450 are able to perform the biotransformation of an enormous variety of substrates. Taking into account all drugs metabolized by enzymes, cytochromes P-450 are responsible for more than two-thirds of these reactions. The most important cytochrome P-450 form for biotransformation in humans is CYP3A4; it is involved in the metabolism of more than one-half of the known drugs and xenobiotics, such as nifedipine, cyclosporin, erythromycin, gestodene, and aflatoxins. This variety of substrates makes CYP3A4 one of the most important enzymes for drug metabolism. The fact that a single cytochrome P-450 is responsible for the metabolism of many different drugs may lead to competition among various drugs for the same enzyme and thus to drug–drug interactions, resulting in higher plasma levels of the less successful (i.e., displaying a lower affinity for the particular cytochrome P450) substrate and even to fatal side effects of the drug treatment.

Another fact complicating drug treatment is the presence of genetic polymorphisms in some of the drug-metabolizing enzymes. It has been shown that 5–10% of Caucasians suffer from a decreased ability to metabolize certain drugs such as debrisoquine and bufuralol (i.e., they are poor metabolizers), due to the presence of nonfunctional alleles of CYP2D6 in these individuals. A smaller portion of patients metabolize the corresponding drugs extremely rapidly (i.e., they are extensive metabolizers), due to having multiple copies of this gene. These pharmacogenetic effects are being studied in many laboratories and will certainly lead to personalized pharmacotherapy.

Physiological Role of Cytochromes P450

In addition to being involved in drug metabolism and xenobiotica degradation, cytochromes P-450 also play a pivotal role in various physiological processes in humans. They are central in the biosynthesis of steroid hormones (sex hormones, glucocorticoids, and mineralocorticoids), vitamin D, fatty acids, bile acids, and eicosanoids. Some severe defects are connected to mutations in cytochrome P-450 genes, such as congenital adrenal hyperplasia, which is mostly due to a steroid 21-hydroxylase (CYP21) deficiency. In addition, human essential hypertension can be caused by the overproduction of aldosterone produced by CYP11B2. More recently, products of cytochrome P-450 reactions such as oxysterols and the endothelium-derived hyperpolarizing factor (EDHF) have been found to play important roles in cellular cholesterol homeostasis, inhibition of cellular proliferation, gene regulation, endothelium-dependent dilation, and enhanced endothelial cell proliferation.

Cytochrome P-450 Diversity

Cytochromes P-450 are found in all kingdoms—eubacteria, archaebacteria, fungi, plants, fish, insects, and vertebrates. More than 250 different forms have been found in the plant *Arabidopsis thaliana*. It was shown that plant cytochromes P450 play a role in the metabolism of a variety of secondary metabolites, in plant–insect interaction, in herbicide metabolism, and in other vital functions. Due to the diversity of catalyzed reactions it can be anticipated that plant cytochromes P450 will offer a broad field for future applications.

Biography

Rita Bernhardt is a Full Professor at the Saarland University and Head of the Institute of Biochemistry. Her principal research interests are cytochrome P-450 systems. She holds a Ph.D. from Moscow State Lomonossov University and received her postdoctoral training at the Central Institute of Molecular Biology of the Academy of Sciences of the GDR in Berlin–Buch, the University of Illinois at Urbana-Champaign, and the University of Sendai, Japan. She uses a variety of biochemical, biophysical, and engineering techniques to study cytochrome P-450 system functions and improve their catalytic efficiency and stability, with special attention to the structure, function, and regulation of mitochondrial steroid hydroxylase systems.

Cytokines

Andrea L. Wurster and Michael J. Grusby
Harvard School of Public Health, Boston, Massachusetts, USA

Cytokines are a diverse set of small, secreted proteins that help direct many critical aspects of an immune response. Cytokines are rapidly produced in response to foreign antigen exposure and can promote the expansion, activation, recruitment, and differentiation of the responding cell types. However, cytokine expression and signaling must be tightly regulated because dysregulated cytokine responses can lead to pathological conditions such as autoimmunity and asthma.

General Features of Cytokines

Nomenclature

Cytokines have been referred to by a number of labels depending on the cell types that produce them or their functional properties. For example, cytokines that are derived primarily from mononuclear cells such as macrophages have been referred to as monokines while the cytokines produced by activated T lymphocytes are termed lymphokines. Cytokines that specifically regulate the migration of other cells are called chemokines in reference to their chemotactic properties. Historically cytokines were also referred to as interleukins since in a general sense they are being produced by and acting on leukocytes. It is the term interleukin that spawned a universal numerical nomenclature for cataloguing newly identified and characterized cytokines (i.e., IL-4). Sequence comparisons between previously identified cytokines and the recently completed mouse and human genome databases have resulted in a rapid increase in the discovery of new cytokines with the most recently reported being IL-29.

Pleotropism and Redundancy

With so many cytokines now known to exist, an added complexity to their biology is that most cytokines are pleiotropic. This refers to the notion that cytokines do not just act on one particular cell type but can have wide effects on a number of cell types within the immune system as well as on cell types outside of the immune system. A clinically relevant example is the cytokine IL-13. IL-13 is a T cell derived cytokine whose effects on B lymphocytes and monocytes (up-regulation of MHC class II and inhibition of inflammatory cytokine production) have been well described. However, IL-13 has also been shown to be critically involved in the pathogenesis of allergic asthma and is thought to mediate its effects by its actions on epithelial and smooth muscle cells in the lung.

Cytokines are also redundant in nature. This means that many (but not all) biological properties originally described for one cytokine can also be ascribed to others. For instance, when IL-2 was originally discovered it was thought to be the primary T cell growth hormone. Subsequently it has been found that a number of other cytokines can also promote T cell expansion, including IL-4. This redundancy is borne out in genetic knockout experiments of individual cytokines often resulting in mice with subtle defects in their immune responses suggesting that the loss of a particular cytokine can be compensated for by the action of another.

Regulated Expression

The expression of cytokines is also highly regulated. Cytokine gene transcription usually occurs rapidly after an inducing stimulus. The rapid increase in cytokine gene mRNA results in a burst of cytokine protein secretion into the surrounding milieu and can act directly on the cell that produced it or on neighboring cells. For example, T lymphocytes produce large amounts of IL-2 within minutes of encountering antigenic peptides which functions to promote their own expansion. Likewise, when a phagocytic monocyte encounters bacterial lipids it rapidly produces the cytokine TNF resulting in recruitment and activation of additional inflammatory leukocytes. This rapid increase in transcription is usually transient and is extinguished rapidly resulting in a self-limited event. The transitory nature of the cytokine response is imperative since, in the case of TNF, high levels and sustained cytokine production can cause systemic problems such as cachexia and septic shock.

Cytokine expression is not only highly regulated temporally but can also be restricted in a cell type specific manner. For example, CD4+ T helper cells can be divided into two distinct subsets based precisely on

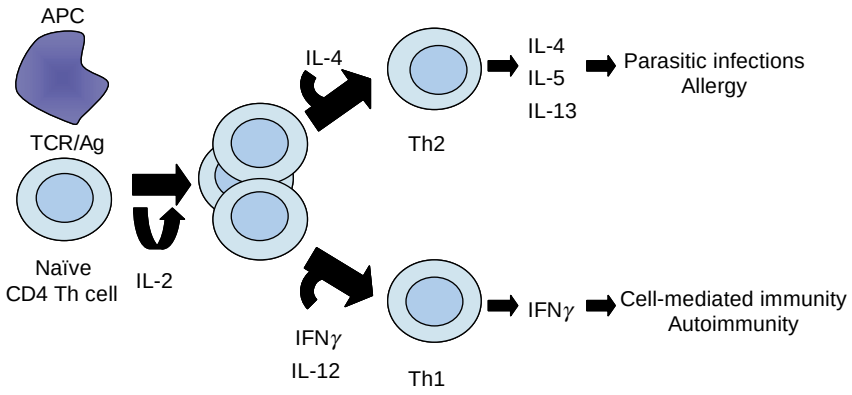

FIGURE 1 T helper cell differentiation. Th cells can differentiate into functionally different subsets depending on the cytokines they are exposed to during antigen activation. Developing Th cells that are exposed to IL-4 differentiate into Th2 cells capable of producing IL-4, IL-5, and IL-13. Th2 cells are important for the clearance of parasitic infections but can also contribute to the pathogenesis of asthma. Th cells that develop in the presence of IFNγ and IL-12 ultimately become IFNγ-producing Th1 cells and play an important role in the clearance of intracellular bacteria but can also contribute to the development of autoimmunity.

their cytokine expression profiles (Figure 1). These individual subsets carry out very different roles in an immune response in part due to the cytokines they produce. T helper type 1(Th1) cells are characterized by the production IFNγ, a cytokine involved in the activation of macrophages to kill phagocytosed microbes. Not surprisingly, Th1 cells are heavily involved in the clearance of intracellular bacteria. Alternatively, T helper type 2 (Th2) cells are characterized by their production of IL-4, IL-5, and IL-13 which directly promote the production of the IgE antibody isotype and stimulate eosinophils. These downstream responses are critical for the clearance of helminthic parasites.

The Role of Cytokines in Immune Responses

It is clear from the discussion above that cytokines can promote a variety of effects on a number of cell types resulting in a wide range of outcomes. Ultimately, the specific expression of and response to cytokines helps orchestrate a tightly regulated immune response.

Cytokines and the Innate Immune Response

Innate immunity is characterized by the initial recognition that a foreign pathogen, such as a virus or bacteria, is in the host. Cytokines play an important role in alerting and activating the immune system to an infection.

Cytokine Response to Bacterial Infection

The cytokine TNF plays an important role in the initial inflammatory response to bacteria especially in the recruitment of leukocytes to the site of infection (Figure 2). When a mononuclear phagocyte, such as a macrophage, encounters gram-negative bacteria it recognizes a product of the cell wall called LPS. LPS binds to a cell surface receptor on the macrophage called CD14 and stimulates the rapid production of TNF. The local presence of TNF serves to recruit other cells, neutrophils and monocytes, to the site of infection. TNF does this by stimulating the expression of adhesion molecules on the surrounding endothelial cells, which capture the leukocytes as they pass by the activated endothelium. TNF also stimulates the production of chemokines from the activated endothelial cells, which further serves to increase recruitment and activation of leukocytes and ultimately results in their transmigration through the vessel wall directly to the infection site. Another cytokine, IL-1, is also produced by macrophages after bacterial exposure and promotes similar inflammatory responses.

Macrophages also respond to bacterial products by producing IL-12 (Figure 2). IL-12 is an important activator of IFNγ production from NK cells and T cells. This IFNγ then feeds back onto the macrophages by enhancing their microbicidal functions to destroy phagocytosed bacteria. IL-12 also directly increases the cytolytic activity of NK cells themselves. Mice made genetically deficient for functional IL-12 have defects in their IFNγ production and NK cell function.

Cytokine Response to Viral Infection

The cytokines IFN-α and IFN-β, also known as type I IFNs, are important mediators of the innate immune

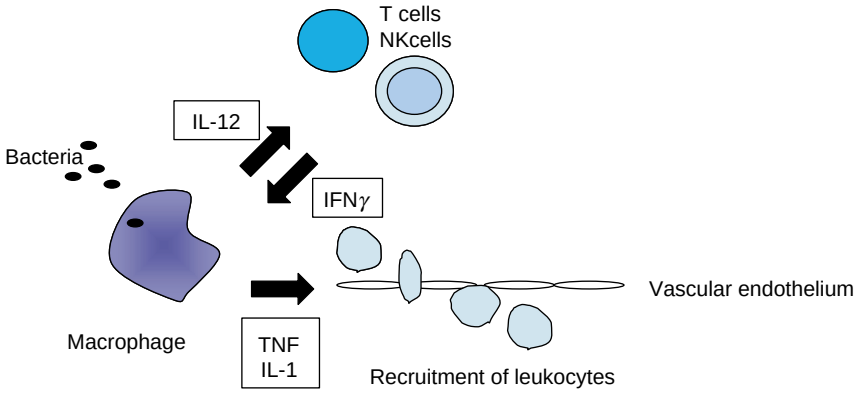

FIGURE 2 Cytokine response to a bacterial infection. Macrophage activation by exposure to bacterial products results in TNF and IL-1 secretion. TNF and IL-1 activate nearby vascular endothelial cells to permit recruitment of leukocytes to the infection site. Activated macrophages also produce IL-12 leading to increased IFNγ production from NK and T cells. IFNγ feeds back on the macrophage to increase the phagocytic potential and microbicidal properties of the macrophage.

response to a viral infection. When a cell is infected with a virus, or exposed to double-stranded RNA molecules that mimic viral replication, production of type I IFNs is dramatically induced. The expression of type I IFNs has a number of consequences in the control of a viral infection. First, exposure to type I IFNs induces the expression of enzymes that directly interfere with viral replication and this helps to protect neighboring cells from becoming infected. Also, type I IFNs act to increase class I MHC expression ultimately resulting in enhanced CTL responses to infected cells. Additionally, type I IFNs directly boost the lytic activity of NK cells.

Cytokines and the Adaptive Immune Response

The adaptive immune response is characterized by the specific activation and expansion of antigen-specific lymphocytes in response to a pathogen as well as immunological memory. Cytokines play a critical role in the proliferation of activated lymphocytes and promoting their differentiation into distinct effector subsets and the induction of memory. Here are just a few examples.

IL-2

As mentioned above, IL-2 has been described chiefly as a T cell growth factor, although it is now recognized that IL-2 plays important roles in several aspects of the adaptive immune response. When a T cell recognizes foreign peptide antigen, IL-2 is produced within minutes and then acts in an autocrine fashion to promote the expansion of that T cell clone. IL-2 also stimulates the proliferation and lytic activity of NK cells. However, IL-2 plays an important role in negatively regulating or terminating an inappropriate T cell response as well. When a cell is repeatedly stimulated with antigen, such as the case with autoantigens, IL-2 exposure renders the cells sensitive to a process called activation induced cell death (AICD) and promotes their elimination. Mice that are deficient for IL-2 or IL-2 receptor subunits develop autoimmunity suggesting an important role for IL-2 in regulating inappropriate T cell responses.

IFNγ

As mentioned, IFNγ plays an important role in activating macrophages during the innate immune response as the downstream target of bacterially stimulated IL-12. However, IFNγ also directly influences the function of antigen-specific lymphocytes during an immune response. For example, IFNγ, along with IL-12, directly promotes the differentiation of CD4+ T cells to become IFNγ-producing Th1 effector cells (Figure 1). As discussed earlier, this T cell subset is critical for the clearance of intracellular bacteria. IFNγ also acts directly on B lymphocytes to promote the production of the specific IgG subclass, IgG2a. This IgG subclass binds to Fcγ receptors on macrophages and promotes phagocytosis of microbes. IFNγ also has indirect effects on T cell function through the up-regulation of MHC molecules on antigen presenting cells, which ultimately increases the opportunity for antigen recognition by the T cell.

IL-4

IL-4 is a cytokine that acts in many ways as an antagonist to the actions of IFNγ described previously. As opposed to the Th1-promoting properties of IFNγ, IL-4 directly promotes the differentiation of CD4+ T cells to become IL-4-producing Th2 cells and inhibits the ability of IFNγ to promote Th1 differentiation (Figure 1). As described, Th2 cells are critical for the clearance of

parasitic infections. IL-4 also promotes the production of the IgE immuno-globulin isotype, which is important for mast cell-mediated immune responses, and inhibits class switching to the IFNγ-stimulated IgG2a. IL-4 has also been shown to inhibit the ability of IFNγ to activate macrophages but promotes MHC class II expression on antigen presenting cells.

Regulatory Cytokines

Most of the features of cytokines described here thus far have involved stimulating the proliferation, differentiation, or microbicidal potential of a responding cell. Recently it has become apparent that certain cytokines have a more regulatory nature. Two of the cytokines that have garnered increased interest recently are TGF-β and IL-10. TGF-β generally inhibits the proliferation and activation of lymphocytes and macrophages. TGF-β also stimulates the production of the immunoglobulin isotype IgA, which plays an important role in mucosal immunity. IL-10 has been described primarily as an inhibitor of macrophage function. Exposure of a macrophage to IL-10 results in decreased IL-12 and TNF production and decreased MHC expression. This decrease in macrophage function then in turn leads to decreased T lymphocyte responses as well. Mice that are deficient for IL-10 develop severe inflammatory bowel disease suggestive of uncontrolled macrophage activation. The expression of these regulatory cytokines have been ascribed to certain T cell subsets (T-regs) thought to be important for specifically suppressing immune responses to autoantigens and preventing the inappropriate activation of bystander lymphocytes.

Cytokines and Immunopathology

As important as cytokines are in orchestrating an immune response, dysregulated cytokine production can have serious and deleterious results. For example, the tissue destruction associated with autoimmune diseases such as type 1 diabetes and rheumatoid arthritis is strongly associated with elevated expression of proinflammatory cytokines such as IFNγ and TNF. Additionally, the airway hyper-responsiveness associated with allergic asthma has been causally linked with the Th2 cytokine IL-13. The notion of a relationship between dysregulated cytokine expression and disease has resulted in clinical applications. In particular, anti-TNF therapies have been effective in treating autoimmune disorders such as rheumatoid arthritis

Cytokine Receptors and Signaling

Cytokines mediate their biological effect through the binding of specific receptors on target cell surfaces. These receptors then convert an external signal (binding of the cytokine to the receptor) to an intracellular biochemical signal, usually resulting in new gene transcription. Cytokine receptors are transmembrane proteins where binding of the cytokine occurs in the extracellular region and interaction with signaling proteins occurs in the cytoplasm.

Cytokine Receptor Classes

Classification of cytokine receptors is based on structural homologies in the cytokine-binding regions. There are five families of cytokine receptors: type I cytokine receptors (IL-2 and IL-4), type II cytokine receptors (type I IFNs and IL-10), Ig superfamily receptors (IL-1), TNF receptors, and serpentine receptors (chemokines).

Cytokine Receptor Expression

Like the highly regulated expression of cytokines described above, expression of the cytokine receptors themselves is also highly regulated and can influence the cellular response to the cytokine. For example, the IL-2 receptor is composed of three polypeptide chains; α, β, and γ. In order for the T cell to maximally respond to IL-2 all three receptor chains must be expressed. When a T cell is specifically activated by antigen, the expression of the α-chain is induced and the cell is capable of expanding to the IL-2 it produces. This provides a link between the antigen specific activation of the T cell and the ability of that cell to subsequently respond to IL-2 ensuring that antigen specific T cells are preferentially and appropriately expanded during an immune response.

JAK/STAT Signaling

The best-defined signaling pathway utilized by type I and type II cytokine receptors involves the activation of Janus kinases (JAKs) and transcription factors called signal transducers and activators of transcription (STATs) (Figure 3). The JAK/STAT signaling pathway provides a direct link between cytokine binding at the cell surface to changes in gene expression at the level of new gene transcription. The general scheme consists of inactive JAK kinases bound specifically to the cytokine receptor cytoplasmic tail. Upon cytokine binding, the receptor chains are brought together and induce the activation of the JAKs through transphosphorylation. The JAKs also phosphorylate specific tyrosine residues on the cytoplasmic portion of the cytokine receptor, serving as a docking site for specific STAT proteins. The STAT proteins are also then phosphorylated, dimerize, and migrate to the nucleus. The dimerized STAT proteins are able to bind to specific DNA sequences in

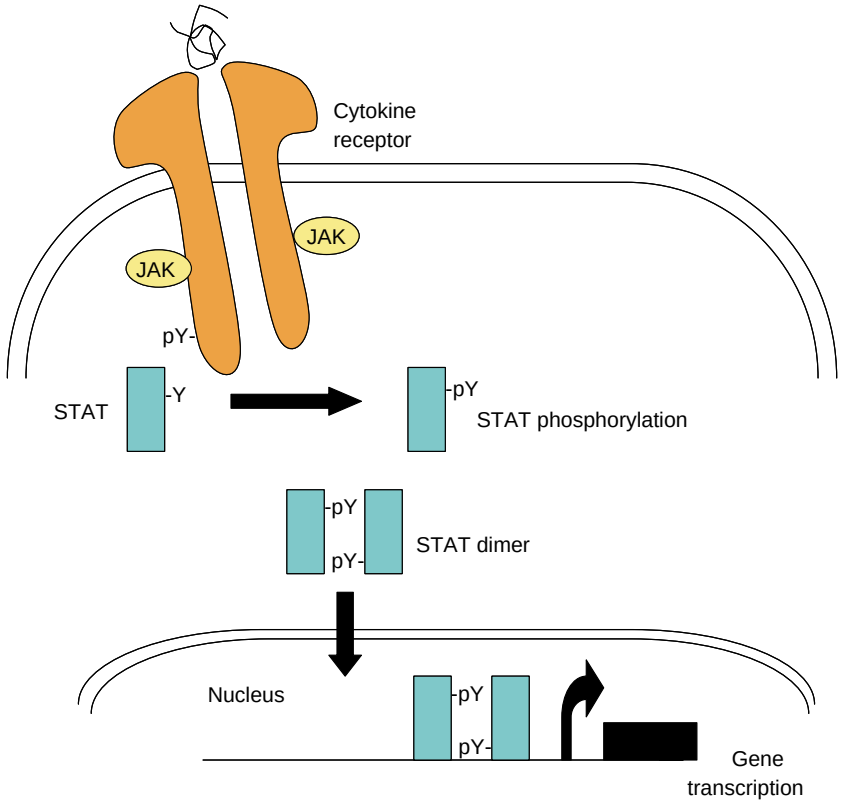

FIGURE 3 JAK/STAT signaling pathway. The activation of the JAKs after cytokine stimulation results in the tyrosine phosphorylation of the cytoplasmic tail of the cytokine receptor and recruitment of the STAT protein. The STAT protein is also tyrosine phosphorylated, forms dimers and migrates to the nucleus to activate the transcription of cytokine responsive genes.

the promoters of cytokine inducible genes and activate the transcription of those genes directly. Different cytokine receptors bind to unique JAK and STAT combinations resulting in specific outcomes to cytokine exposure.

Negative Regulation of Cytokine Signaling

Unopposed cytokine signaling can lead to a number of immune disorders so several regulatory mechanisms are in place to turn off JAK/STAT signaling after cytokine exposure. First, a family of cytoplasmic proteins called suppressor of cytokine signaling (SOCS) can directly interfere with JAK activity or with STAT binding to the cytokine receptor. The expression of the SOCS genes themselves is directly activated by the cytokine-induced STATs, consequently forming a classic negative feedback loop. SOCS1-deficient mice die within a few weeks of birth due to uncontrolled IFNγ responses suggesting a critical role for SOCS proteins in regulating cytokine signaling. JAK and STAT activity can also be negatively regulated by protein tyrosine phosphatases, which return the JAK and STAT proteins to their unphosphorylated, inactive states. STATs are also negatively regulated by their interaction with members of the PIAS protein family. The PIAS proteins in general act to inhibit the ability of STAT proteins to stimulate gene transcription.

Glossary

adaptive immunity Immunity mediated by lymphocytes after exposure to foreign pathogen. Characterized by exquisite specificity for antigen and the formation of a memory immune response.

innate immunity The initial and rapid response to invading microbes. The cell types involved include macrophages, NK cells, and neutrophils. The mechanism for response exists before infection and does not result in immunological memory.

JAK/STAT pathway Intracellular signaling pathway induced by triggering of type I and type II cytokine receptors. Involves activation of specific kinases (JAKs), recruitment, and phosphorylation of transcription factors (STATs) and their subsequent

translocation as active dimers to the nucleus to activate gene transcription of cytokine responsive genes.

macrophage A phagocytic cell that plays important roles in both adaptive and innate immune responses. Activated macrophages engulf and kill invading microorganisms, secrete cytokines, and present antigen to T helper cells.

T helper (Th) cell CD4+ T cell subset that mediates cell-mediated responses in the adaptive immune system. Th cells are divided into two distinct subsets (Th1 and Th2) depending on the cytokines they secrete.

Cytokinesis

Masanori Mishima and Michael Glotzer
Research Institute for Molecular Pathology, Vienna, Austria

During cell division the chromosomes are equally segregated to the two poles of the mitotic spindle and the resulting two sets of chromosomes are sequestered into separate cells by a process known as cytokinesis. Cytokinesis must be controlled in both space and time so that the resulting daughter cells each contain a complete copy of the genetic material and other cellular organelles.

Making the Plans: Various Strategies for Coordinating Nuclear and Cytoplasmic Division

Diverse biological constraints dictate that cytokinesis is performed in different ways in various organisms. For example, the presence or absence of a cell wall greatly influences the nature of the cytokinetic process. In plant cells, which have cell walls, the daughter cells are separated by the cell plate, which is formed in the center of the cell by vesicle transport and fusion. In animal cells, the cleavage furrow is generated by constriction of a contractile ring containing actin and myosin II as key components.

A second feature which appears to differ among different cell types is the means by which the division plane is coordinated with nuclear division. For example, in plants and yeast, the division plane is established before mitosis and chromosome segregation is coordinated with this pre-existing spatial determinant. In contrast, in animal cells, the position of the division plane is established by the mitotic spindle in anaphase.

On the other hand, recent data indicate that different modes of cytokinesis rely on common molecular mechanisms. In yeast, cell-wall synthesis had been thought to be the major mechanism of cytokinesis. However, ingression of cell membrane by the constriction of actin ring is now known also to be important. Conversely, in animal cells, although the dominant factor in cell division is constriction of the contractile ring, vesicle trafficking has recently been demonstrated to contribute to this process. A comparison of the molecules required for cytokinesis in various organisms reveals that although some proteins, such as myosin and profilin, are generally required for cytokinesis in all species analyzed thus far, other proteins that are essential in one system are sometimes not even present in other systems (Table I). Thus, the different modes of cytokinesis in various systems may reflect varying degrees of reliance on common basic processes.

Identification and characterization of the molecular machines responsible for cytokinesis has advanced greatly because of the use of genetic analysis in model organisms including yeast, flies, and worms. It is anticipated that the use of RNA-mediated gene silencing (RNAi) will significantly enhance the understanding of cytokinesis in mammalian cells. The proteins involved in cytokinesis conserved among model organisms are summarized in Table I. The mechanism of cytokinesis in animal cells is the primary focus of this article (Figure 1).

Making the Plans: Coordinating Nuclear and Cytoplasmic Division in Animal Cells

In animal cells, the mitotic spindle provides the spatial cue for division. Micromanipulation experiments indicate that microtubules are the critical factor within the spindle; the chromosomes are dispensible. Although it was long thought that microtubules provide a positive signal for cleavage furrow formation, recent evidence suggests that microtubules may generally inhibit cortical contractility and that a local minimum of microtubule density may direct cleavage furrow positioning. However, the underlying molecular mechanism has not been determined.

Since the critical factor required for contractile ring formation is RhoA, a simple, speculative model that could account for cleavage furrow formation is that high microtubule density inhibits RhoA activation and that sites where microtubule density reaches a local minimum induce activation of the small GTPase, RhoA. Like other small GTPases, the activity of RhoA is controlled by guanine nucleotide exchange factors (GEFs) and GTPase activating proteins (GAPs).

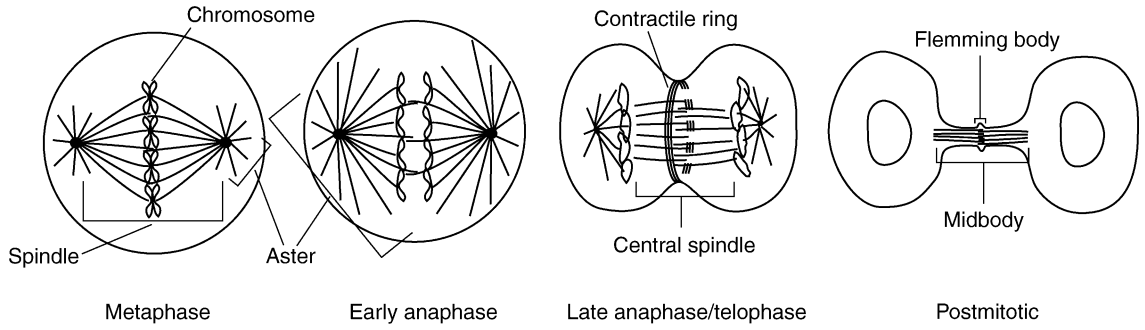

FIGURE 1 The stages of cytokinesis and a guide to the cellular structures involved.

There is strong evidence that a specific GEF regulates cytokinesis. This protein, known as Pebble in flies or ECT2 in mammalian cells, is a multidomain protein whose loss of function parallels that of depletion of RhoA. However, it is not clear if the mitotic spindle generates local activation of RhoA by inducing high GEF activity at regions of low microtubule density. Alternatively RhoA could be activated globally, but other regulatory processes could inhibit the biological function of RhoA where microtubule density is high.

Assembling the Parts 1: Building the Contractile Ring

A number of direct effectors of RhoA have been described and shown to be involved in cytokinesis, including Rho kinase and members of the formin family (Figure 2). Formin family members are auto-inhibitory proteins which are activated by binding of active RhoA. Formins are found concentrated at the contractile ring. They bind to an actin-binding protein, profilin, via a proline-rich sequence. Recently, formin proteins have been shown to have actin-polymerizing activity; this activity is further accelerated by profilin. Thus, formins could contribute to the formation of contractile ring by directing actin polymerization. There is functional evidence for a requirement for formin proteins in cytokinesis in mammals, flies, worms, budding yeast, and fission yeast; so far there is no evidence that formins are required for cytokinesis in plants or *Dictyostelium*.

Like formins, Rho kinase (ROCK) also localizes to the cleavage furrow. One substrate of this kinase is the activation site of the regulatory light chain of myosin II. ROCK also phosphorylates and inactivates the myosin-binding subunit of myosin phosphatase (MBS). Both pathways lead to the activation of myosin-II. In *C. elegans*, mutation of the ROCK orthologue, LET-502, causes defects in cytokinesis. However, these defects can be suppressed by mutation of MBS MEL-11. Thus, ROCK is an important player in cytokinesis, though perhaps it plays an accessory role rather than an essential one.

The contractile ring is a highly dynamic structure. Inhibition of actin polymerization during furrow ingression blocks propagation of the cleavage furrow. Conversely, depolymerization of actin filament in concert with the progression of the constriction is also important for cytokinesis. Indeed, actin depolymerizing factor is required for normal cytokinesis. Moreover, there are indications that inactivation of RhoA is required for completion of cytokinesis, since the CYK-4 RhoGAP is required for completion of cytokinesis.

Assembling the Parts 2: Building the Central Spindle

The central spindle, or spindle midzone, is a barrel-like structure of microtubules formed between the segregating chromosomes during anaphase. The plus ends of nonkinetochore spindle microtubules are bundled to form antiparallel arrays in the spindle midzone. As the cleavage furrow ingresses, these microtubules become compacted. Finally, they form a structure called the midbody with completely constricted contractile ring overlaid by the still continuous cell membrane.

The importance of the central spindle on the promotion and completion (in some systems, initiation) of cytokinesis has been shown by micromanipulation and genetic analysis. For example, depletion or inactivation of *C. elegans* ZEN-4, a kinesin-like molecule that concentrates on the central spindle prevents formation of this structure in early embryos. Contractile ring formation and furrow ingression nevertheless occur. However, the furrow fails to complete and it ultimately regresses. In *Drosophila*, the central spindle seems to be required for early steps in cytokinesis since furrow ingression is not observed in embryos that have mutations in the pavarotti locus (Pav is the orthologue of *zen-4*).

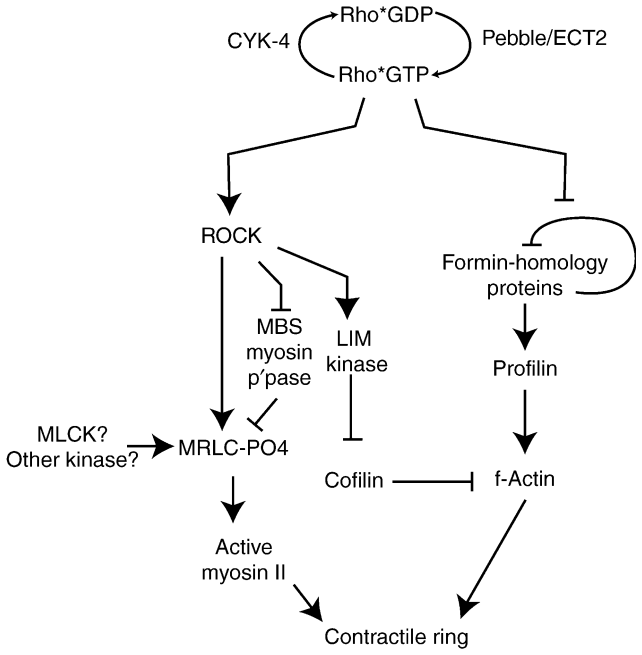

FIGURE 2 The biochemical pathways through which RhoA regulates contractile ring formation.

A RhoGAP, CYK-4, colocalizes with ZEN-4 to the central spindle and midbody. Like ZEN-4, CYK-4 involved the formation of central spindle. CYK-4 forms a stoichiometric complex with ZEN-4 both *in vivo* and *in vitro*. A mutation in the CYK-4 binding domain of ZEN-4 can suppress the embryonic lethality caused by a mutation on the ZEN-4 binding domain of CYK-4, indicating the importance of complex formation for the *in vivo* function of these molecules. This complex is probably directly involved in assembling the central spindle since purified, recombinant CYK-4/ZEN-4 complex has microtubule bundling activity (Figure 3).

Human orthologues of CYK-4 and ZEN-4, HsCYK-4/MgcRacGAP and MKLP-1/CHO1, respectively, also form a similar protein complex. Depletion of HsCYK-4 by RNAi causes cytokinesis defects. Overexpression of MgcRacGAP mutant lacking MKLP-1 binding region or with mutation in the RhoGAP domain inhibits cytokinesis. Overexpression of MKLP-1 with a mutation in the motor domain causes an abnormal central spindle, loss of midbody material, and multinuclear cells. Thus, a protein complex, centralspindlin, containing orthologues of CYK-4 and ZEN-4 has an evolutionary conserved role in the formation and function of central spindle/midbody.

Another molecule, PRC1, is also important for the formation of central spindle. It too has microtubule bundling activity *in vitro*. Antibody injection or depletion by RNAi causes abnormal central spindle and inhibits cytokinesis. In metaphase, PRC1 is phosphorylated by cyclin-dependent kinase 1 (CDK1). This phosphorylation is thought to negatively regulate the protein because a mutant lacking the phosphorylation sites causes abnormal bundling of microtubules in the metaphase spindle. PRC1 contains a conserved central region. Other proteins that have this conserved domain are also implicated in organizing the anaphase spindle, e.g., budding yeast Ase1. In this context it is notable that the centralspindlin complex is not present in yeast. There is no evidence that the anaphase spindle participates in cytokinesis in budding or fission yeast.

Although the mechanism of formation of central spindle has been gradually revealed, the function of the central spindle in cytokinesis remains unclear. There are at least three possibilities.

1. It could be involved in the determination of cleavage site by modulating the distribution of microtubules in the mitotic apparatus during anaphase.
2. It could serve to localize factors that regulate the assembly and/or disassembly of the contractile ring.
3. Like the phragmoplast in plants, it could function to direct vesicle traffic along the ordered microtubule bundles.

These possibilities are not mutually exclusive, although the relative importance might vary among cell types.

Pushing the Envelope: Membrane Fusion

Geometrical considerations require that during cytokinesis, if the total volume of the daughter cells is equivalent to that of the parental cell, the surface area of the cells must increase. Indeed, evidence has accumulated suggesting that vesicle traffic plays an important role in cytokinesis. In *Xenopus*, Zebrafish, and sea urchin embryos, insertion of new cell membrane into cleavage furrow by exocytosis has been observed.

The machinery responsible for this membrane insertion has begun to emerge. Specific syntaxins, rabs, and Golgi proteins have been implicated in cytokinesis and/or cellularization in *Drosophila*, *C. elegans*, and sea urchin embryos. Specific Golgi proteins, such as Lava Lamp, which interacts both with actin and microtubules, are required for cellularization. A lipid kinase, phosphatidylinositol 4-kinase, is required for cytokinesis in spermatocytes (the cell-type specificity may result from genetic redundancy in other cell types).

There are other interesting observations from the point of view of lipid membrane and cytokinesis. Phosphatidylethanolamine (PE) appears on the outer leaflet of cell membrane of cleavage furrow while it is usually enriched in the inner leaflet. A multivalent

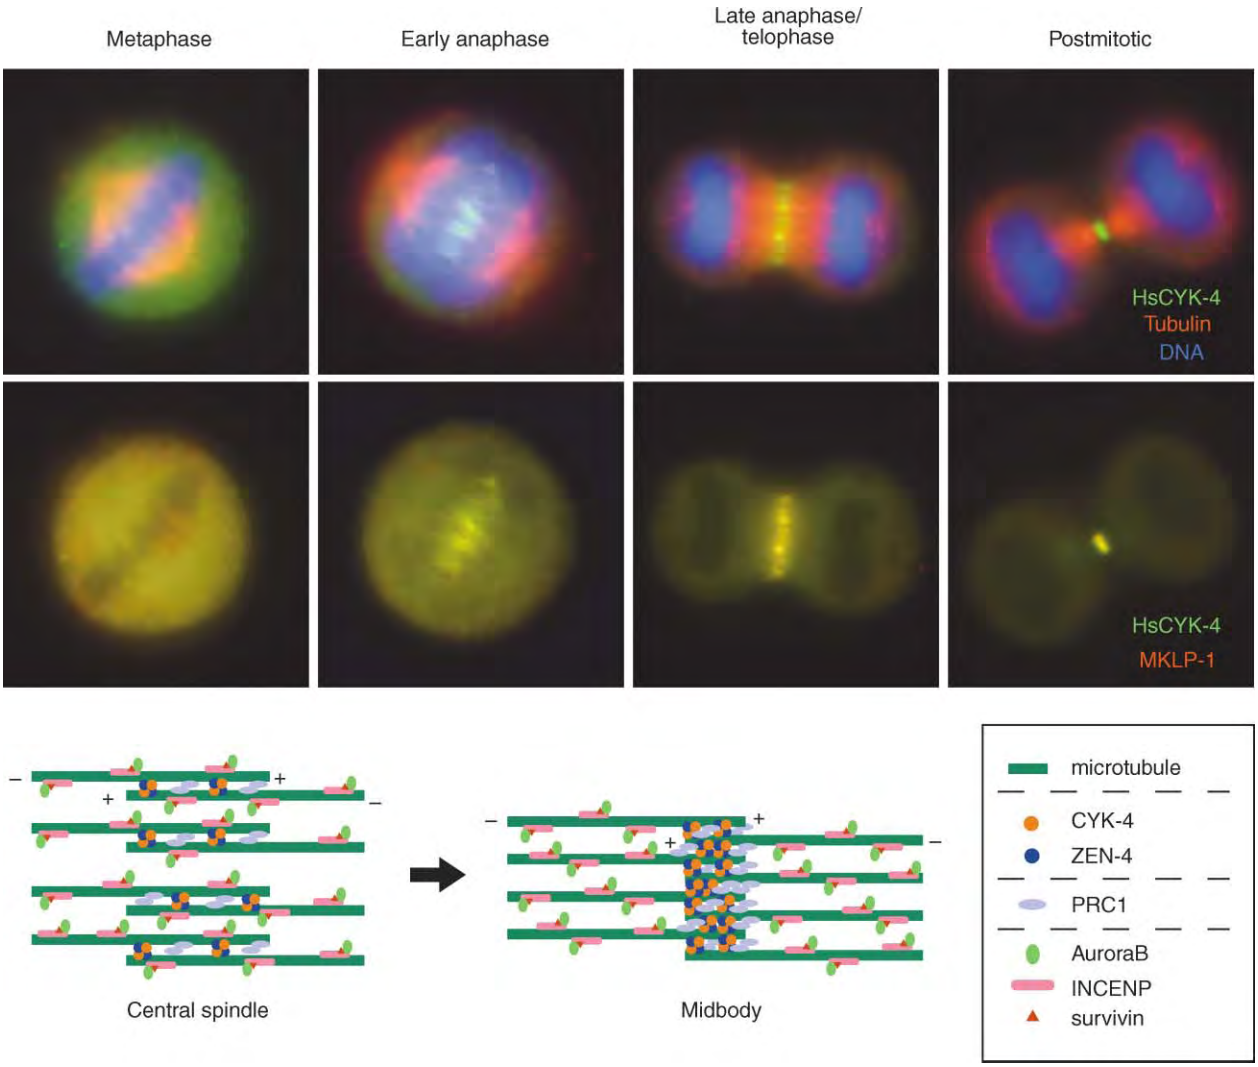

FIGURE 3 The localization of the centralspindlin components MKLP1/HsCYK-4 during the process of cytokinesis. A schematic drawing depicting the assembly of the central spindle.

PE-binding peptide inhibits depolymerization of actin filament at midbody stage, and prevents completion of cytokinesis. Likewise, a sphingolipid, psychosine, causes defect of cytokinesis in some cells.

Getting the Timing Right

In anaphase, activation of anaphase-promoting complex (APC) induces segregation of chromosomes and exit from mitosis by catalyzing the proteolytic destruction of securin and cyclins. Because cytokinesis occurs once per cell cycle and it is coupled to the exit from mitosis, there must be some connection between the cell-cycle engine and cytokinesis. That this is indeed the case is indicated by the fact that a nondegradable mutant of cyclin B prevents assembly of the central spindle and inhibits cytokinesis in mammalian cells, *Drosophila* and sea urchin embryos. This suggests that CDK1/cyclin B negatively regulates cytokinesis. This may be in part due to the regulation of microtubule dynamics. If the spindle is displaced to the vicinity of the cell cortex, furrow ingression can occur in the presence of high levels of CDK1/cyclin B.

CDK1/cyclin B may also regulate central spindle assembly via PRC1, since its function appears to be negatively regulated by CDK1. The RhoGEF, Ect2/Pebble, may also be negatively regulated by CDK1/cyclin B. In addition, cyclic activation of myosin-II in *Drosophila* embryos is indirectly regulated by CDK1 activity.

A conserved signaling cascade called the mitotic exit network (MEN) (budding yeast) or the septation initiation network (SIN) (fission yeast) has been

characterized in detail. At the end of the cascade, a protein phosphatase (Cdc14 in budding yeast and Flp1/Clp1 in fission yeast) is activated. In budding yeast, activation of Cdc14 leads to the activation of APC–Cdh1 through the dephosphorylation of Cdh1. In *S. pombe*, Flp1/Clp1 is involved in the regulation of the timing of septum formation and entry into M-phase. Although their roles are apparently different, antagonism of CDK1 activity could be a common function between Cdc14 and Flp1/Clp1. There are orthologues of Cdc14 in animal cells; however, the conservation of the MEN or SIN cascade is less clear. In mammalian cells, inhibition of Cdc14 causes several mitotic defects including abnormal separation of centrosomes and failure of the completion of cytokinesis. In nematodes, CeCDC-14 localizes to central spindle and its depletion by RNAi causes a similar phenotype to depletion of ZEN-4. Perhaps one conserved role of CeCDC-14 is to relieve the inhibition of cytokinesis by CDK1, though the critical targets may be different in different systems.

Finishing the Job

Daughter cells typically enter G_1 phase connected to each other by the midbody. How they are finally separated (abscission) is not clear, although there is evidence that the midbody and vesicle traffic are involved. Interestingly, it has been observed that the abscission is delayed while the mother centriole, which is loosely connected to the daughter centriole, comes close to the midbody. It has been observed that the timing of abscission correlates with the moment at which the mother centriole moves away from the midbody.

Cytokinin

Thomas Schmülling
Free University of Berlin, Berlin, Germany

Cytokinins are plant-specific chemical messengers (hormones) that play a central role in the regulation of the plant cell cycle and numerous developmental processes. Cytokinins were discovered by F. Skoog, C. Miller, and co-workers during the 1950s as factors that promote cell division (cytokinesis). The first cytokinin discovered was an adenine (aminopurine) derivative named kinetin (6-furfuryl-aminopurine), which was isolated as a DNA degradation product. The first common natural cytokinin identified was purified from immature maize kernels and named zeatin. Several other cytokinins with related structures are known today. Cytokinins are present in all plant tissues. They are abundant in the root tip, shoot apex, and immature seeds. Their endogenous concentration is in the low nM range. Typically, several types of cytokinins and their modified forms are present in a given tissue. Cytokinins can act over long distances or in the direct vicinity of the cytokinin producing cells (paracrine signaling). Cytokinins may act also on the cell that produced them (autocrine signaling). Cytokinins are also produced by cyanobacteria, some plant pathogenic bacteria (e.g., *Agrobacterium tumefaciens*, *Pseudomonas savastanoi*, *Rhodococcus fascians*) and the slime-mold *Dictyostelium discoideum*.

Cytokinin Structures

Naturally occuring cytokinins are adenine derivatives with a side chain at the N^6-position (Figure 1). The structure and conformation of the N^6-attached side chain can markedly influence the biological activity of the cytokinin. Depending on the structure of the N^6-substituent, cytokinins are classified as isoprenoid or aromatic cytokinins. The biological activities of both classes are qualitatively similar but they may differ quantitatively in different processes. Isoprenoid cytokinins are the most abundant class. They are either isopentenyl (iP)-type cytokinins, having an isopentenyl N^6-side chain, or zeatin-type cytokinins, having a hydroxylated isopentenyl N^6-side chain. The side chain of a zeatin-type cytokinin occurs in either *cis* or *trans* configuration, depending on which of the two methyl groups is hydroxylated. The *cis* form is usually much less active. Reduction of the double bond in the side chain leads to dihydrozeatin. Aromatic cytokinins have an aromatic benzyl group at N^6. They occur more rarely and much less is known about them. Because of their greater stability, aromatic cytokinins are often used in tissue culture, an example is benzyladenine. In addition, there are the structurally unrelated phenylurea-type cytokinins (e.g., diphenylurea, thidiazuron), a class of synthetic cytokinins. These cytokinins are highly active but do not occur naturally.

Cytokinin Biosynthesis and Metabolism

The rate of *de novo* synthesis, metabolic interconversion, and breakdown are, together with transport processes, relevant to the regulation of cytokinin homeostasis in cells. Cytokinin metabolism includes mainly conversions among cytokinin bases, ribosides, ribotides, side-chain modification, conjugation and conjugate-hydrolyzing reactions, and cytokinin degradation.

Biosynthesis

The initial and rate-limiting step of biosynthesis of isoprenoid-type cytokinins is the transfer of the isopentenyl moiety from dimethylallyl pyrophosphate (DMAPP) to AMP, ADP or ATP. The reaction is catalyzed by DMAPP::AMP/ADP/ATP isopentenyltransferases (IPT). ADP and ATP are the preferred substrates of most of the known plant IPT enzymes, while bacterial enzymes prefer AMP. The reaction leads to the formation of isopentenyl-AMP, -ADP and -ATP, which are the precursor molecules of biologically active cytokinins. The isopentenyl side chain is subsequently hydroxylated to form zeatin-type cytokinins (Figure 1). An alternative pathway, in which an already hydroxylated side chain is directly added to the N^6-position of the adenine moiety, may exist. IPT enzymes are encoded in *Arabidopsis* by a small gene family with seven members (*AtIPT1*, *AtIPT3–AtIPT8*). *AtIPT* genes are expressed in specific tissues of the root and shoot (e.g., vasculature), indicating that cytokinin synthesis

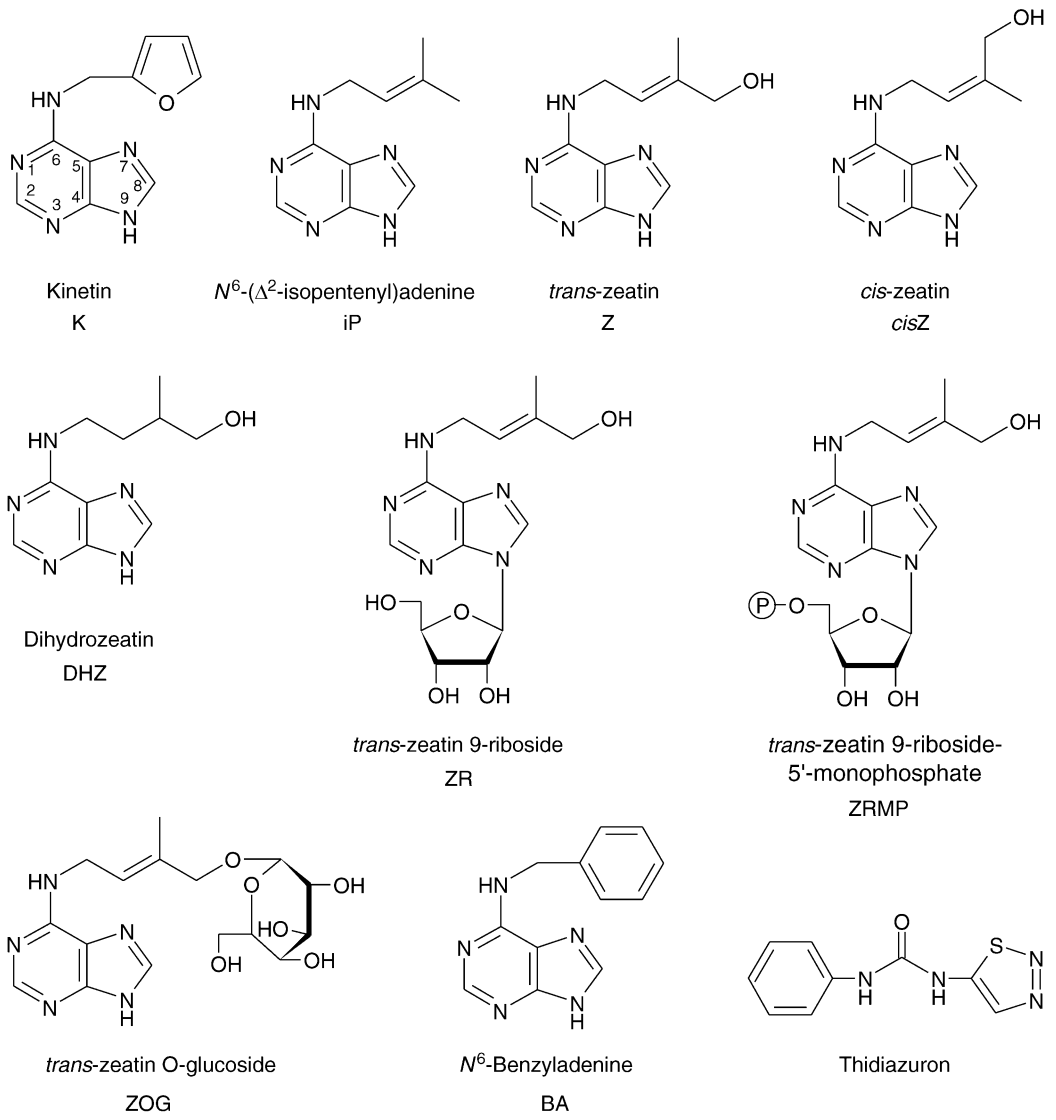

FIGURE 1 Chemical structures of some naturally occurring and synthetic cytokinins. Common names and abbreviations are indicated below the structures. The numbering of purine ring atoms is shown for kinetin.

occurs in all major organs. Another possible source of cytokinins is tRNA, since tRNAs of most organisms contain isopentenylated adenine and other structural derivatives with cytokinin activity. However, it is generally assumed that tRNAs play only a minor role, if any, as a cytokinin source.

Interconversion

A characteristic feature of cytokinin metabolism is the rapid metabolic interconversion of base, ribosides, and ribotides. The biologically most active form of cytokinins is the base. Attachment of ribose or ribose-5′-phosphate to the N^9 atom of the adenine ring leads to the formation of ribosides and ribotides, respectively, which do have lower activities (Figure 1). Interconversion of cytokinins is presumably an important mechanism to regulate the concentration of active compounds. Cytokinin ribosides are probably relevant as a transport form. The interconversions may be catalyzed by the same enzymes that metabolize adenine, adenosine, and AMP. The conversion between the *cis*- and *trans*-isomers of zeatin is catalyzed by the enzyme *cis–trans* zeatin isomerase. Zeatin is converted to dihydrozeatin by a NADPH-dependent zeatin reductase.

Conjugation

Cytokinins can be stably or transiently inactivated by glycosylation of the purine ring or of the side chain. The purine ring can be glycosylated at the N^3-, N^7-, and N^9-positions. In addition, the N^6-side chain group can

form *O*-glycosyl conjugates if it bears a hydroxyl-group. Most often, glucose is the conjugated sugar molecule, more rarely xylose is attached. N^7- and N^9-conjugates are biologically inactive and extremely stable. Thus, they are irreversibly inactivated cytokinins. N^3- and *O*-conjugates are biologically inactive but can be readily hydrolyzed. They are believed to be transient storage forms of cytokinins. Glycosyl conjugation is considered to be important in the regulation of cytokinin activity levels, at least in some tissues and species. Several genes coding for cytokinin glycosyltransferases and glycosidases have been identified. Some conjugates of cytokinins and amino acids (alanine) have been described as well.

Catabolism

Cytokinins are irreversibly degraded in a single enzymatic step by oxidative cleavage of the N^6-side chain. The reaction is catalyzed by cytokinin oxidases/dehydrogenases (CKX), which contain FAD as a cofactor. The reaction products are adenine and an aldehyde. The preferred substrates of CKX are isopentenyladenine, zeatin, and their corresponding ribosides. Ribotides, *O*-glucosides, dihydrozeatin, and aromatic cytokinins are not degraded by CKX. The *Arabidopsis* genome contains seven *AtCKX* genes, which are preferentially expressed in zones of active cell division and growth. The corresponding enzymes are located in the endoplasmatic reticulum, in the apoplast, and in the vacuole.

Cytokinin Transport

Cytokinins are transported from roots to shoots in the xylem, and in the opposite direction in the phloem. Transported cytokinins may have a role in coordinating root and shoot development, for example, by carrying information about nutrient availability. Multiple cellular importers and exporters are required to allow efficient mobilization and targeted translocation of cytokinins, but very little is known about cytokinin transporters. Transport studies indicate that a common H^+-coupled high-affinity purine transport system transports cytokinins.

Cytokinin Signaling

The mechanism of cytokinin signaling is just beginning to emerge. The cytokinin signal is perceived and transduced by a multistep phosphorelay system through a complex form of the two-component system (TCS) pathway. The TCS is common among prokaryotes and lower eukaryotes, among the higher eukaryotes it is unique to plants. In this signaling system, a membrane-located receptor kinase with an extracellular ligand-recognition domain (sensor) dimerizes upon binding a ligand and autophosphorylates a histidine within its cytoplasmic transmitter domain. The phosphoryl group is first transferred to an aspartate residue within the receiver domain at the C terminus of the receptor and from there to a His-containing phosphotransmitter (Hpt), which ultimately phosphorylates and thus activates a response regulator (RR) at a central Asp residue (see Figure 2).

Signal Perception

Cytokinin receptors are histidine kinases consisting of an extracellular sensing domain, a cytoplasmic histidine kinase transmitter and receiver domains. Three cytokinin receptors (CRE1/WOL/AHK4, AHK2, AHK3) have been identified in *Arabidopsis*. They all share a ~270 amino acid long extracellular cyclases/histidine kinases associated sensing extracellular (CHASE) domain, which presumably recognizes cytokinin. This domain might have been acquired by plants through lateral gene transfer from cyanobacteria. Loss-of-function mutants of CRE1/WOL/AHK4 lack the phloem in their primary roots, indicating a role for cytokinins in embryo development.

Signal Transduction

Current knowledge suggests that downstream signaling components of the cytokinin signal-transduction pathway in *Arabidopsis* consist of five Hpt and 22 response regulators of the A- or B-type. Hpts transmit the signal from the receptor, which is presumably localized in the plasma membrane, to B-type RRs, which are in the nucleus. B-type RRs consist of an N-terminal receiver domain and a C-terminal output domain, containing a DNA recognition motif called GARP, which is distantly related to the Myb repeat. The DNA motif optimal for binding is 5′-(A/G)GAT(T/C)-3′. Activated B-type ARRs transcribe primary response genes of cytokinins. Some of the known primary response genes, which are rapidly and specifically up-regulated by cytokinins, code for type A response regulators. Type A RRs resemble type B RRs but lack the C-terminal DNA binding and activation domain. Type A RRs fulfill at least two different functions. On the one hand, they exert a negative feedback regulation of the cytokinin signaling pathway through protein–protein interaction. On the other hand, they mediate the cytokinin-dependent modulation of other pathways, e.g., light signaling. A-Type response regulators can be

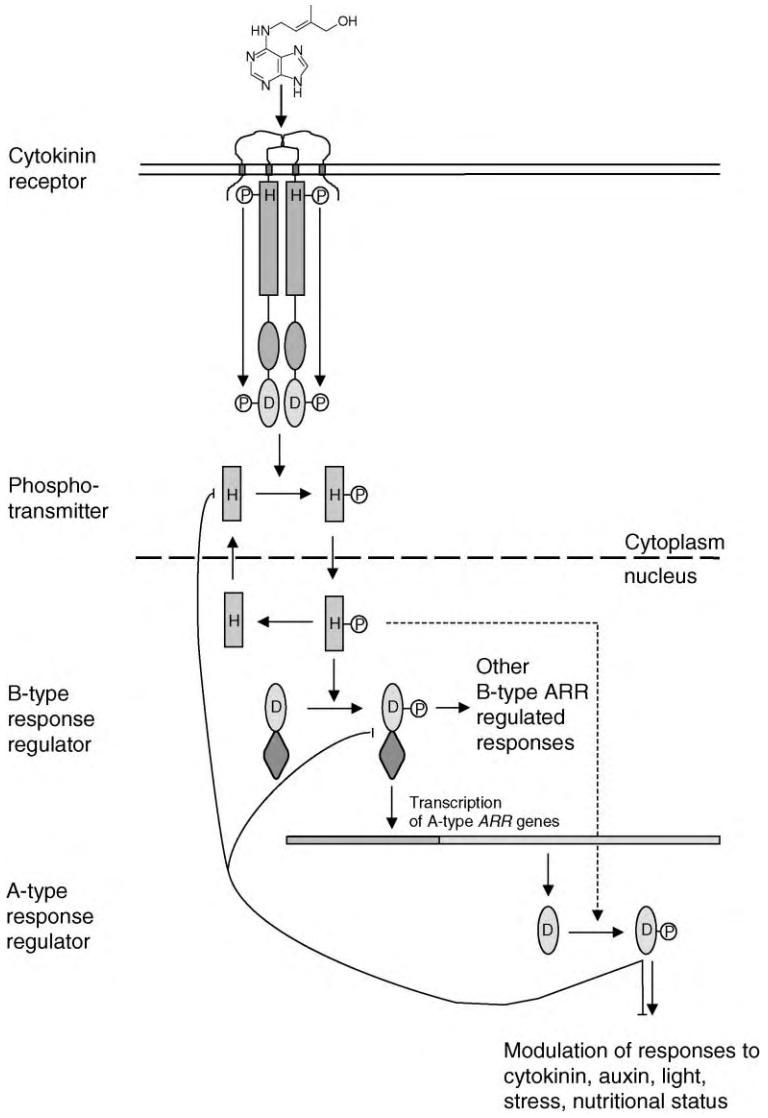

FIGURE 2 A model for cytokinin signal transduction via a His-to-Asp phosphorelay. The structure of CRE1/WOL/AHK4 is shown as an example. Ligand binding induces receptor dimerization and autophosphorylation. Transfer of the phosphoryl group by activated receptors activates histidine phosphotransmitter proteins (Hpts), which transport the signal from the cytoplasm to B-type RRs in the nucleus. B-Type response regulators transcribe target genes, among them A-type *RR* genes. A-Type response regulators may down-regulate the primary cytokinin signal response via a negative feedback loop, modulate downstream activities of cytokinins in a positive or negative fashion, or modulate other signaling pathways through protein–protein interaction. A more complex regulation than shown in the model may exist. D, aspartate residue; H, histidine residue; P, phosphoryl group.

positive or negative regulators, depending on the individual response regulator and the output reaction analyzed.

Cytokinin Functions

Cell Cycle

Cytokinins are required for cell division during embryogenesis in the shoot apical meristem, young leaves, the cambium, and cultured plant cells. In contrast, they have a negative regulatory role in the root meristem. Cytokinin controls the exit of dividing cells from this meristem. Changes in cytokinin levels occur during the cell cycle of cultured cells, the level being highest during the late S and before the M phase. Cytokinins have been functionally linked to all stages of the cell cycle but their mechanism of action has only been partially elucidated. Cytokinin up-regulates expression of the D-type cyclin gene *CycD3*, which is important in regulating the G1/S-transition of the cell cycle. Cytokinin increases the number of replication origins during S-phase and it may also play a role in regulating G2/M transition.

Plant Development and Growth

Cytokinin participates in regulating numerous aspects of plant development throughout the life cycle. These include seed germination, cotyledon expansion, chloroplast differentiation, de-etiolation, differentiation of vascular tissue, apical dominance (shoot branching), root elongation and branching, nutritional signaling, regulation of sink strength, the transition from the vegetative to the reproductive growth phase, flower and fruit development, leaf senescence, and plant–pathogen interactions. A role for the hormone in vascular morphogenesis during embryonic development is firmly established. During post-embryonic development cytokinins are required to maintain meristem activity and leaf development in the plant shoot. Local exogenous cytokinin application to the shoot leads to premature growth of lateral buds, retarded leaf senescence, partial photomorphogenesis in the dark, increased sink strength and an altered vasculature. In contrast to their stimulatory activities in the shoot, cytokinins have a negative regulatory role in the control of root elongation and branching. Additionally, cytokinin regulates important physiological parameters that determine biomass formation and distribution via central genes of primary metabolite pathways, including invertases, hexose transporters, and key genes of phosphate and nitrogen metabolism and signaling (e.g., nitrate reductase). Changes in cytokinin levels are generally positively correlated with levels of mineral nutrients, especially nitrogenous nutrients. Cytokinin levels are decreased by water stress. *In vitro*, the ratio of cytokinin to auxin determines the differentiation of cultured plant tissues to either shoots or roots. A high cytokinin to auxin ratio promotes shoot formation, a low ratio promotes root formation. Owing to their stimulatory effect on plant regeneration, cytokinins are widely used in plant tissue culture.

Pathogenicity

Cytokinins are produced by several plant pathogenic bacteria and play a role in pathogenicity. One such pathogen is *Agrobacterium tumefaciens*, the causative agent of the crown gall disease. During the infection process, *A. tumefaciens* transfers a small stretch of DNA, the T-DNA, to the host plant, where it becomes integrated in the nuclear genome. The T-DNA harbors an *IPT* gene, which is expressed in the host cell and causes cytokinin overproduction. This leads, together with an enhanced auxin content, to tumorous cell proliferation. Other cytokinin-synthesizing pathogens are *Pseudomonas syringae*, which induces gall formation and *Rhodococcus fascians*, which causes fasciation and a growth abnormality called witch's broom disease. The root-nodule forming and nitrogen-fixing plant symbiont *Rhizobium spec.* is also known to produce cytokinin.

Biotechnology

Practical use of cytokinin in agriculture is currently limited. Modulation of the endogenous cytokinin content of plants or interfering with cytokinin signaling has a high potential for biotechnological applications in agriculture. Plants with increased cytokinin content are more branched and senesce later. Moreover, cytokinins alter sink–source relations, a promising approach to improve yield attributes. Plants with reduced cytokinin content develop a larger root system. An improved root system means improved acquisition of minerals and water, factors which are often limiting for plant growth.

Biography

Thomas Schmülling is a Professor of Genetics and Chair of Developmental Biology of Plants at the Free University of Berlin. His principal research field is the biology of cytokinins. He studied biology at the University of Cologne, accomplished his doctoral thesis at the Max Planck Institute for Plant Breeding and has been an Assistant Professor at the University of Tübingen. He has made contributions to the understanding of *Agrobacterium rhizogenes* T-DNA genes and cytokinin metabolism and signaling. His laboratory was the first to generate cytokinin-deficient plants by means of genetic engineering.

Desmosomes and Hemidesmosomes

Rachel L. Dusek, Jonathan C. R. Jones and Kathleen J. Green
Northwestern University Feinberg School of Medicine, Chicago, Illinois, USA

Desmosomes and hemidesmosomes are cell junctions important for maintaining adherence within epithelial tissues, a function reflected in the Greek root *desmo*, meaning "bound." Desmosomes facilitate adhesion between adjacent epithelial cells, whereas hemidesmosomes (named for their ultrastructural resemblance to half a desmosome) mediate adhesion between basal cells of epithelial tissues and the substratum. These junctions are functionally alike in their ability to couple the intermediate filament (IF) cytoskeleton to sites of cell–cell or cell–substratum contact at the plasma membrane. However, these organelles differ dramatically in their molecular composition and specialized functions.

The Desmosome

Desmosomes are prominent in tissues that are subjected to mechanical stress. Found most abundantly in epithelial tissues, desmosomes are also present in the myocardium, brain meninges, and follicular dendritic cells of the lymph nodes. These specialized anchoring junctions function to mediate intercellular adhesion and maintain tissue integrity by connecting sites of cell–cell contact to the highly tensile intermediate filament (IF) cytoskeleton.

Desmosome Ultrastructure

Ultrastructurally, the desmosome appears as a symmetrical, highly organized, electron-dense structure that connects neighboring cells (Figure 1A). The plasma membranes of adjacent cells are separated by an ~30-nm space containing an electron-dense midline, composed of the extracellular portion of the transmembrane desmosomal components. Just internal to the plasma membrane is an electron-dense outer plaque containing the intracellular desmosomal components. Interior to this region is a less-dense, IF-rich fibrillar inner plaque.

Structure and Molecular Components of the Desmosome

The basic blueprint of a desmosome comprises molecular components that fall into three main gene families: desmosomal cadherins, armadillo family members, and plakins. Several studies suggest that these molecules are arranged linearly in this order from the cell surface inward and function together to indirectly tether the IF cytoskeleton to the cell membrane. Lateral interactions between these proteins occur as well and enhance the strength of the junction. Nonadhesive functions have also been proposed for several of these molecules. The best characterized desmosomal components (Figure 1B) are discussed in detail here. However, minor components, including pinin and desmocalmin/keratocalmin, have also been described.

Desmosomal Cadherins

Two types of glycosylated, type I transmembrane adhesive cadherin proteins are found in the desmosome, desmogleins (Dsgs), and desmocollins (Dscs). Different genes encode four isoforms of the Dsgs (1–4) and three isoforms of the Dscs (1–3), which are expressed differentially in various cell types and in a differentiation-specific manner in complex stratified epithelia. The Dsc isoforms are further subdivided into two types, a longer "a" form and a shorter "b" form. Like classical cadherins, both Dsgs and Dscs have a highly conserved calcium-binding extracellular domain, membrane-spanning region, and catenin-binding intracellular cadherin segment (ICS) (not present in Dsc b), whereas Dsgs contain additional unique cytoplasmic subdomains of unknown function. Dsgs and Dscs are thought to function primarily in mediating homo- and heterophilic calcium-dependent adhesion across the membranes of adjacent cells. Severe blistering of the skin or lesions on the hands and feet are consequences of genetic, autoimmune, and bacterial diseases that compromise the adhesive function of these molecules (Table I).

Armadillo Family Members

Proteins with homology to the *Drosophila* segment polarity protein armadillo are important structural components of the desmosome, linking the desmosomal cadherins at the plasma membrane with intracellular cytoskeleton components. These proteins contain

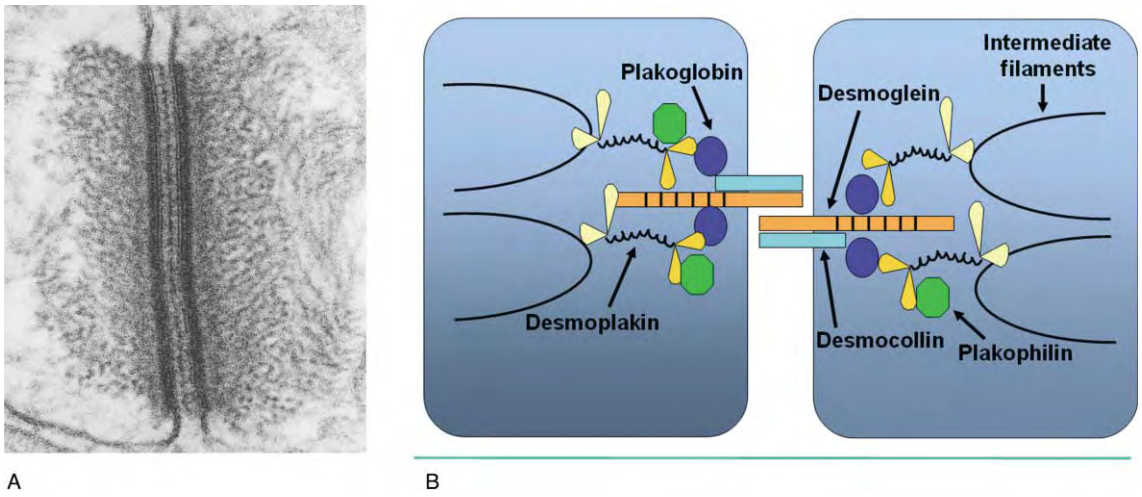

FIGURE 1 Molecular composition and structure of the desmosome. (A) Desmosome ultrastructure is shown in this electron micrograph of bovine tongue epidermis. Reprinted from *Biophysical Chemistry*, Vol. 50, A. P. Kowalczyk, A.P., *et al*., Structure and function of desmosomal transmembrane core and plaque molecules, pp. 97–112, copyright 1994 with permission from Elsevier Science. (B) Desmosomal proteins, their interactions, and their approximate position within the organelle are depicted in this schematic diagram of the desmosome.

a 42-amino-acid repeated motif called the arm repeat, which is thought to mediate protein–protein interactions. Plakoglobin (Pg) is one armadillo protein whose presence in both adherens junctions and desmosomes is selectively regulated. In the desmosome, it binds directly to the cytoplasmic tail of the desmosomal cadherins and to the obligate desmosomal protein, desmoplakin (DP). Pg's adhesive importance is reflected by one genetic disease in which the disruption of its function results in cardiomyopathy, keratoderma, and wooly hair (Table I). In addition to its adhesive role, Pg is also thought to function in a variety of signal transduction pathways.

The plakophilins (PKP1–3) are another group of armadillo family members that contribute to desmosomal adhesion. These proteins have a specific tissue distribution and are differentially expressed in complex stratified epithelia. PKPs are found both in the desmosome and in the nucleus. In the desmosome, PKPs interact cytoplasmically with the desmosomal cadherins, as well as with DP and IFs. The role of PKPs in desmosome assembly and IF attachment is not entirely clear; however, PKP1 is known to enhance the recruitment of DP to the plasma membrane and to facilitate lateral clustering of plaque components. Genetic mutations in both PKP1 alleles negate the protein's function and result in excessive skin fragility (Table I).

Plakins

Although desmosomes consist of various components in different tissues, DP, the most abundant protein in the desmosomal plaque, is an obligate desmosomal constituent. DP is the primary plakin family member found in the desmosome, although other less-abundant plakins include envoplakin, periplakin, and plectin. Structurally, the DP molecule consists of two globular ends connected by a coiled-coil rod whose size is modulated by alternative splicing of the transcript to produce two variants (I and II). The rod domain mediates DP self-dimerization. DP also directly associates with Pg and PKPs through its amino (N) terminus and with IFs through its carboxyl (C) terminus. In addition, direct association of DP with desmosomal cadherin tails has been noted. DP is required for desmosome assembly, linking the IF cytoskeleton to the plasma membrane and anchoring IFs in the plaque. The importance of DP in maintaining epithelial tissue integrity is emphasized by severe keratodermas, sometimes associated with heart defects, affecting patients with genetic diseases in which DP function is compromised by haploinsufficiency, protein truncation, or point mutations (Table I).

Desmosome Assembly and Maintenance

The regulation of the assembly and disassembly of cell–cell junctions is important for normal tissue homeostasis and during junction-remodeling processes such as development or wound healing. One crucial factor controlling desmosome assembly appears to be the prerequisite formation of adherens junctions, perhaps to bring adjacent membranes close together and permit the interaction and clustering of desmosomal molecules. In cultured cells, desmosome assembly occurs in

TABLE I

Human Diseases Associated with Desmosomal Components

Mutated gene/target antigen	Phenotype
Genetic diseases	
Plakoglobin	*Naxos disease*: Autosomal recessive arrythmogenic right ventricular cardiomyopathy (ARVC) combined with striate palmoplantar keratoderma (SPPK) and woolly hair
Plakophilin 1	Autosomal recessive ectodermal dysplasia with a skin fragility syndrome, hair loss, reduced sweating, and nail dystrophy
Desmoglein 1	*Striate palmoplantar keratoderma (SPPK)*: Lesions of the palms and soles exacerbated by mechanical trauma
Desmoglein 4	*Autosomal recessive hypotrichosis* (LAH): Loss of hair on scalp, chest, arms, legs, and face due to hair follicle abnormalities
Desmoplakin (haploinsufficiency)	*Striate palmoplantar keratoderma (SPPK)*: Lesions of the palms and soles exacerbated by mechanical trauma
Desmoplakin (N-terminal missense mutation)	Autosomal dominant arrythmogenic right ventricular cardiomyopathy (ARVD/C)
Desmoplakin (C-terminal missense mutation)	Autosomal dominant arrhythmogenic right ventricular cardiomyopathy (ARVD/C); wooly hair and lesions on the palms of hands and soles of feet
Desmoplakin (C-terminal truncation)	Autosomal recessive left ventricular cardiomyopathy with SPPK and woolly hair
Desmoplakin (compound heterozygosities)	*Palmoplantar keratoderma*: One missense mutation in the N-terminus and one nonsense mutation resulting in a C-terminal deletion; alopecia, hyperkeratosis, acantholysis, and keratin retraction
Autoimmune diseases	
Desmoglein 3	*Pemphigus vulgaris*: Blistering of the oral cavity caused by circulating autoantibodies directed against desmoglein 3; presence of antibodies against both desmoglein 3 and 1 cause the mucocutaneous form with blisters also in the deep epidermis
Desmoglein 1	*Pemphigus foliaceus*: Blistering of the superficial epidermis caused by circulating autoantibodies directed against desmoglein 1
Desmocollin 1, Desmoglein 1, Desmoglein 3	*IgA pemphigus*: Intraepidermal blistering with different forms characterized by circulating autoantibodies against desmocollin 1, desmoglein 1, or desmoglein 3
Plakin family members and desmogleins	*Paraneoplastic pemphigus*: Severe blistering of the skin and mucous membranes caused by circulating autoantibodies against plakin family proteins, desmoglein 1 and desmoglein 3; occurs mainly in patients suffering from malignant lymphomas and thymomas

response to cell–cell contact in a calcium-dependent manner. In low-calcium conditions, newly synthesized desmosomal components are unstable. During assembly, desmosomal cadherins and Pg are delivered together in vesicles to the plasma membrane. Subsequently, DP and IFs are added to the assembling junction. Upon association with the IF cytoskeleton, desmosomal components become stabilized, insoluble, and lose their calcium dependence. The assembly and maintenance of desmosomes is regulated in part by post-translational modification of protein components. Specifically, serine/threonine and tyrosine phosphorylation of several desmosomal components regulates desmosomal assembly and maintenance by modulating the ability of desmosomal proteins to interact with one another.

Desmosome Function

Far from static spot welds, desmosomes are malleable and dynamic structures that respond to extra- and intracellular signals to adapt their functions in cell–cell adhesion, morphogenesis, and signal transduction.

Cell–Cell Adhesive Function

Although desmosomal cadherins were long assumed to function in calcium-dependent cell–cell adhesion, until recently there was a lack of direct evidence demonstrating that ectopically expressed desmosomal proteins promote adhesion in normally nonadherent cells. Evidence now suggests that both Dscs and Dsgs, along with the associated protein Pg, are required for adhesion and that they may interact heterophilically. The existence of autoimmune, genetic, and bacterial diseases that affect the function of desmosomal cadherins and result in compromised epidermal integrity (Table I) support the idea that desmosomes function in intercellular adhesion. Intercellular adhesion may also be disrupted by human diseases that perturb the structure of the desmosomal plaque (Table I). Cell culture models have demonstrated that IF attachment to the desmosome core is a critical aspect in the regulation of desmosome-mediated intercellular adhesion. This is especially important in tissues such as the heart, in which intercellular adhesive defects can have grave consequences.

Morphogenetic Function

Desmosome-mediated intercellular adhesion may be intimately involved in many morphogenetic events. For example, because severe developmental abnormalities lead to embryonic lethality in DP-null mice, desmosomes are thought to play a critical role in maintaining tissue integrity during normal embryogenesis and development. In addition, the importance of desmosomal adhesion in the normal patterning of epithelial cells is demonstrated by the fact that peptide inhibition of desmosomal adhesion can disrupt mammary epithelial cell morphogenesis and positioning.

Signaling Function

Desmosomes may also have a signaling function. A role in outside-in signaling is evidenced by the fact that the ligation of the extracellular domain of Dsg3 by pemphigus vulgaris (PV) antibodies can modulate the intracellular calcium concentration and phospholipid metabolism in keratinocytes. In cultured cells, such ligation results in serine phosphorylation of Dsg3 and its reported dissociation from Pg. Pg-null keratinocytes were used to demonstrate that PV antibody ligation of Dsg3 leads to a Pg-dependent keratin retraction, which may contribute to the epidermal-blistering characteristic of this disease. Intracellular signals can also be propagated by desmosomes. Pg, whether in a desmosomal or nondesmosomal pool, is thought to be the best candidate protein for this process. Although Pg can be found in different junction types, the metabolic stability and cellular localization of Pg are tightly regulated, allowing it to function in cell–cell adhesion, transcriptional activation, proliferation, and programmed cell death.

The Hemidesmosome

Hemidesmosomes are specialized junctions that connect basal epithelial cells to the basement membrane and underlying extracellular matrix. Hemidesmosomes promote the integrity and strength of epithelial tissues by indirectly connecting the intracellular keratin IF cytoskeleton to extracellular matrix proteins.

Hemidesmosome Ultrastructure

The ultrastructure of the hemidesmosome (Figure 2A) includes an electron-dense cytoplasmic triangular plaque, which makes up an inner IF-rich region closest to the cell cytoplasm and a perimembrane plaque containing the cytoplasmic tails of the transmembrane hemidesmosome components. Just adjacent and external to the basal cell membrane is a sub-basal dense plate and thin extracellular anchoring filaments that extend from the plate into the specialized extracellular matrix of the basement membrane.

Structure and Molecular Components of the Hemidesmosome

The major hemidesmosomal components together connect the basal epithelial cell cytoskeleton to the extracellular matrix (Figure 2B). Hemidesmosomal proteins are arranged such that IFs are anchored to the plaque at multiple points, reenforcing the connection to the substratum.

$\alpha 6\beta 4$ Integrin

The $\alpha 6\beta 4$ integrin is the principal factor connecting IFs to the extracellular matrix and, as such, is essential for hemidesmosome formation and the maintenance of epithelial cell attachment to the basement membrane. The $\alpha 6$ integrin can dimerize with $\beta 1$ integrin, but prefers to interact noncovalently with $\beta 4$ integrin. The $\beta 4$ integrin has an unusually long cytoplasmic tail, important for the specialized functions of this molecule. The $\alpha 6\beta 4$ integrin pair is expressed predominantly in epithelial tissues, Schwann cells, and endothelial cells. In complex stratified epithelia, $\alpha 6\beta 4$ integrin is oriented in a polarized fashion on the basal surface of the basal cell layer. The association of the $\alpha 6$ and $\beta 4$ subunits generates a functional transmembrane receptor whose extracellular domain binds to laminin-5, an abundant protein in the extracellular matrix. The interaction of

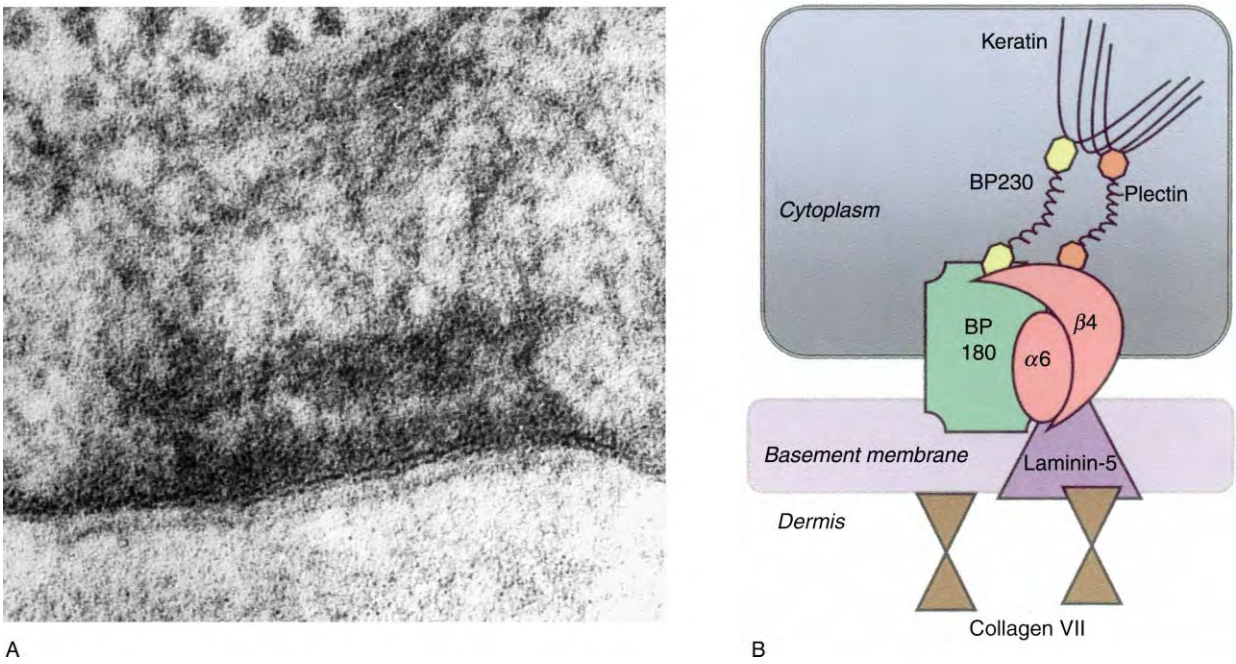

FIGURE 2 Molecular composition and structure of the hemidesmosome. (A) Hemidesmosome ultrastructure is shown in this electron micrograph of bovine tongue epidermis. Reproduced from Is the hemidesmosome a half desmosome? An immunological comparison of mammalian desmosomes and hemidesmosomes, J. C. R. Jones *et al.*, *Cell Motility and the Cytoskeleton*, Vol. 6, pp. 560–569, Copyright (1986). Reprinted by permission of Wiley-Liss, Inc., subsidiary of John Wiley & Sons, Inc. (B) Hemidesmosomal proteins, their interactions, and their approximate position within the organelle are depicted in this schematic diagram of the hemidesmosome.

$\alpha 6\beta 4$ integrin with laminin-5 is thought to be the structural center of the hemidesmosome, as well as the primary channel for the transduction of hemidesmosome-mediated signaling cascades. The $\beta 4$ subunit interacts with another hemidesmosomal protein, plectin, to anchor the IF cytoskeleton to the hemidesmosome core. This interaction is thought to stabilize the association of $\alpha 6\beta 4$ integrin with laminin-5 to enhance adhesion strength.

BP180

Bullous pemphigoid antigen II (BP180) is a 180-kDa type II transmembrane protein component of the hemidesmosome, so named because it is recognized by autoantibodies from the serum of patients with the severe blistering disease bullous pemphigoid (Table II). A member of the collagen family, BP180 is a trimer that contains collagen-like repeats in its C-terminal extracellular domain. These repeats organize into a triple helical coiled-coil arrangement thought to contribute to the structure of anchoring filaments. BP180 interacts with $\beta 4$ integrin in the cytoplasm through its N-terminal domain and binds directly to $\alpha 6$ integrin via its C-terminal extracellular domain, an interaction essential for hemidesmosome formation and stabilization. BP180 is also known to interact with actinin family members and codistributes at sites of cell–cell contact with adherens junction proteins, suggesting a potential role for this molecule in mediating cross-talk between cell–substrate and cell–cell junctions.

BP230

Bullous pemphigoid antigen 230 (BP230) is a 230-kDa cytoplasmic plaque component of the hemidesmosome and a plakin family member. BP230 is known to interact with IFs through its C-terminus. BP230 and BP180 directly interact through their N-terminal domains. BP230 is thought to link the keratin IFs to BP180 and the hemidesmosomal plaque. BP230-null mice have poorly formed hemidesmosomes with few filament attachments.

Plectin

Plectin, a 500-kDa plakin family member, is particularly important for hemidesmosome function in epithelial tissues and as a cytoplasmic cytoskeletal linker in other tissues, but has also been reported in less abundance in desmosomes. Plectin's importance for hemidesmosome stability and tissue integrity is emphasized in patients with genetic mutations in the plectin gene who suffer from severe skin blistering and

TABLE II

Human Diseases Associated with Hemidesmosomal Components

Mutated gene/target antigen	Phenotype
Genetic diseases	
Laminin 5	*Herlitz or Non-Herlitz junctional epidermolysis bullosa (JEB)*: Autosomal recessive severe blistering at the dermal–epidermal junction often coincident with early mortality (Herlitz); less severe form (non-Herlitz) often includes lifelong blistering, loss of hair and nails, and dental abnormalities
β4 Integrin (missense mutation in cytoplasmic tail)	*Non-Herlitz junctional epidermolysis bullosa (JEB)*: Autosomal recessive severe life-long blistering at the dermal–epidermal junction, together with hair, nail, and teeth defects
α6 or β4 Integrin	*Junctional epidermolysis bullosa with pyloric atresia (JEB-PA)*: Mucocutaneous blistering associated with congenital intestinal abnormalities
Collagen VII	*Dystrophic epidermolysis bullosa (DEB)*: The most severe form of epidermolysis bullosa characterized by deep blistering in dermis due to disruption of anchoring fibril stability
BP180	*Non-Herlitz JEB/generalized atrophic benign epidermolysis bullosa (GABEB)*: Autosomal recessive generalized skin blistering, nail dystrophy, enamel hypoplasia, and hair loss
Plectin	*Epidermolysis bullosa with muscular dystrophy (EB-MD)*: Skin blistering noted from birth with late-onset, progressive muscle weakness
Autoimmune diseases	
Laminin-5 and BP180	*Cicatricial pemphigoid*: Chronic subepithelial blistering of mucous membranes and occasionally the skin caused by circulating autoantibodies against laminin-5 or BP180
α6 and β4 Integrin	*Ocular cicatricial pemphigoid*: Subepithelial blistering that mainly affects conjunctiva and other mucous membranes caused by circulating autoantibodies against α6 and β4 integrin
Collagen VII	*Epidermolysis bullosa acquisita*: Minor skin trauma induces severe blistering below the dermal–epidermal junction caused by circulating autoantibodies against collagen VII
BP180 and BP230	*Bullous pemphigoid*: Generalized large subepidermal blisters caused by circulating autoantibodies against BP180 and BP230

muscular dystrophy (Table II). Plectin can interact with itself, with IFs, and with multiple domains of the β4 integrin tail. Plectin has been proposed to cluster $\alpha6\beta4$ molecules at the basal cell surface, a potentially critical step in the formation of hemidesmosomes. In addition, plectin is required for the ligand-independent assembly of hemidesmosomes. However, the primary role for plectin (like BP230) is to link the IF system to the hemidesmosome plaque, stabilizing the junction by connecting the IF cytoskeleton to the hemidesmosome core at multiple points.

CD151

CD151, a member of the tetraspan family, is a potential hemidesmosome component. By immunoelectron microscopy, CD151 appears concentrated at hemidesmosomes in an $\alpha6\beta4$ integrin-dependent manner. Although CD151 associates with $\alpha6\beta4$ integrin and may help stabilize and organize the hemidesmosome, the exact nature of CD151 as a hemidesmosomal component requires further investigation.

Laminin-5

Laminin-5 is a member of the laminin family of large heterotrimeric glycoproteins, which are major constituents of extracellular matrices. Highly expressed in many types of epithelia, laminin-5 is specifically composed of subunits $\alpha3$, $\beta3$, and $\gamma2$, which interact in a noncovalent fashion to form a cross-shaped structure. Laminin-5 is necessary for the firm attachment of basal epithelial cells to the subepithelial basement membrane by linking the hemidesmosome to the underlying tissue. In the hemidesmosome, laminin-5 binds to $\alpha6\beta4$ integrin to mediate cell–substrate attachment. However, laminin-5 is also known to mediate epithelial cell attachment through the nonhemidesmosomal integrin $\alpha3\beta1$. Laminin-5 strongly attaches epithelial cells to the extracellular matrix by interacting with other basement

membrane proteins, including collagen type VII. Laminin-5 can also organize together with BP180 into anchoring filaments thought to extend from the sub-basal dense plate of the hemidesmosome to the deep extracellular matrix. Genetic or autoimmune diseases involving laminin-5 are characterized by complete separation of the epidermis from the dermis (Table II) and further support an important role for laminin-5 in the attachment of basal epithelial cells to the underlying basement membrane.

Hemidesmosome Assembly and Maintenance

The nucleation and assembly of hemidesmosomes is dependent on the $\alpha6\beta4$ integrin pair and its phosphorylation state. The $\beta4$ integrin tail is believed to play important roles in the initiation of hemidesmosome assembly by inducing early clustering of the $\alpha6\beta4$ integrin pair and recruiting BP180, BP230, and plectin to the nucleation site. The $\alpha3\beta1$ integrin pair is also suspected to be an initiator of hemidesmosome assembly, perhaps by preconfiguring the basement membrane into a conformation conducive for stable hemidesmosome formation.

The BP antigens are also thought to be important players in regulating hemidesmosome assembly. Patients with mutations in the BP180 gene have normal $\alpha6\beta4$ integrin and laminin-5 localization but absent or underdeveloped hemidesmosomes. Also, the overexpression of BP230 in cells alters the localization of endogenous BP180, suggesting a role for BP230 in initiating the early interaction of some hemidesmosome proteins prior to junctional incorporation. Laminin-5 also contributes to the regulation and maintenance of hemidesmosomes. Laminin-5 itself is capable of and essential for initiating the formation of hemidesmosome junctions. Hemidesmosome induction, however, is related to the enzymatic cleavage of the $\alpha3$ laminin-5 subunit. The processing of laminin-5 promotes hemidesmosome formation and discourages motility. For adhesion, laminin-5 appears to initially interact with $\alpha3\beta1$ integrin to mediate the attachment of the epithelial cells to the extracellular matrix. Ligation is then transferred to $\alpha6\beta4$ integrin for long-term stable adhesion. The interaction of laminin-5 with $\alpha6\beta4$ integrin induces the formation of the hemidesmosome core.

Hemidesmosome Function

Hemidesmosomes were long thought to be inert adhesive structures with primary importance in maintaining and stabilizing epithelial cell attachment to the underlying basement membrane. However, recent evidence suggests that these structures also exhibit dynamic characteristics that may facilitate tissue-remodeling processes during development and wound healing, as well as permitting rapid responses to biological signals.

Cell–Substrate Adhesive Function

A structural function for hemidesmosomes in initiating and maintaining adhesion between basal epithelial cells and the extracellular matrix is well accepted today, in part because of evidence from autoimmune and genetic human skin diseases that result in epithelial cell-basement membrane separation and severe blister formation (Table II). Other evidence supporting this structural role comes from the noted absence of hemidesmosomes in cells closing wounds and in invasive epithelial tumor cells. Thus, hemidesmosomes appear necessary for stable anchorage of cells to the basement membrane, but may not be required in motile cells.

Morphogenetic Function

The role that hemidesmosomes play in morphogenetic events such as breast epithelial tubule formation indicates the relative dynamic nature of these structures *in vivo*. Indeed, perturbation of the microfilament cytoskeletal architecture in cultured cells results in a redistribution of IF-tethered hemidesmosomes to the cell periphery, highlighting the dynamic nature of the hemidesmosome plaque and its ability to move laterally within the cell membrane.

Transmembrane Signaling Function

Hemidesmosomes are also critical signaling centers competent to transduce both outside-in and inside-out signaling events to regulate such cellular activities as gene expression, cell proliferation, and differentiation. Outside-in signaling during ligation of $\alpha6\beta4$ integrin by laminin-5 is known to regulate cell-cycle progression via the Ras/mitogen-activated protein kinase (MAPK) pathway. Although not fully understood, $\alpha6\beta4$ integrin has also been reported to regulate cell survival. Signal transduction through $\alpha6\beta4$ integrin can modulate cell motility characteristics, particularly through phosphorylation of the $\alpha6\beta4$ integrin pair. Inside-out signaling involving $\alpha6\beta4$ integrin is supported by the dephosphorylation of an 80-kDa membrane-bound protein following the disruption of the $\alpha6\beta4$ integrin–laminin-5 interaction, suggesting that signals inside the cell may contribute to the ligation of $\alpha6\beta4$ integrin by laminin-5.

Conclusion

Despite their ultrastructural and functional similarity as adhesive junctions, desmosomes and hemidesmosomes

are unique structures. Significant progress has been made thus far in the fields of desmosome and hemidesmosome research. The structural organization of these junctions has been examined. Molecular components that make up these junctions have been identified. Protein–protein interactions that contribute to the normal function of these organelles have been characterized. Future studies in these fields will probably focus on further examining the dynamic nature of desmosomes and hemidesmosomes, identifying potential nonadhesive functions for the protein components of these junctional complexes, and investigating junction-mediated signaling cascades and their regulation.

Biography

Rachel L. Dusek is a Ph.D. candidate in the Cancer Biology track of the Integrated Graduate Program and is secondarily affiliated with the Departments of Pathology and Dermatology and the R. H. Lurie Comprehensive Cancer Center at Northwestern University Feinberg School of Medicine. Her primary research interest is in the field of cell–cell adhesion, specifically, the potential nonadhesive functions of the desmosome components.

Jonathan C. R. Jones, Ph.D. is a Professor of Cell and Molecular Biology at Northwestern University Feinberg School of Medicine. He is secondarily affiliated with the Pulmonary Division of the Department of Medicine and the Robert H. Lurie Comprehensive Cancer Center of Northwestern University.

Kathleen J. Green, Ph.D. is the Joseph L. Mayberry Professor of Pathology and a Professor of Dermatology at Northwestern University Feinberg School of Medicine and is affiliated with the Robert H. Lurie Comprehensive Cancer Center of Northwestern University.

Detergent Properties

Darrell R. McCaslin
University of Wisconsin, Madison, Wisconsin, USA

A detergent is formed when a hydrophilic group with an affinity for water and a hydrophobic group with an aversion to water are spatially segregated within a molecule's chemical skeleton so as to create a polarity. In aqueous solution, detergents generally exist as a mixture of monomers in equilibrium with a fairly monodisperse population of detergent aggregates known as micelles. In the micelle, the hydrophobic groups are packed together to create a hydrophobic core with the attached hydrophilic groups projecting out from the surface of this core and protecting it from contact with water. As such, detergents have only limited biological functions such as the well-known role in digestion and possibly to some extent in membrane fusion events; however, they play necessary if not essential roles in the isolation, manipulation, and characterization of the constituents of biological membranes.

Chemical Structure of Detergents

The chemical structures of detergents which have been employed in biological studies are quite varied and continues to grow as investigators attempt to develop new entities that will permit the facile isolation of membrane constituents while enhancing their stability once isolated. To reach this goal, various combinations of hydrophobic and hydrophilic groups have been utilized and yield a variety of physical and chemical properties.

Hydrophobic Groups (Tails)

Simple Hydrocarbon Chains

The hydrocarbon chain is the most easily recognized hydrophobic group and when present is often referred to as the molecule's hydrophobic tail (Figure 1). These chains are most often saturated hydrocarbons (Figure 1) and are available in many lengths. The shorter the chain the less well defined the detergent properties tend to be, whereas longer tails become essentially insoluble. Unsaturation and more complex branching structures have been explored as well as chains incorporating phenyl rings. The presence of the ultraviolet light-absorbing phenyl should generally be avoided as it can complicate various spectroscopic techniques.

Ring-Based Hydrocarbons

The naturally occurring bile salts synthesized from cholesterol and utilized in digestive processes are the prototypes for detergents based on ring systems. Figure 1 shows cholic acid, one of the abundant bile salts which is converted to deoxycholate (DOC) by removing the hydroxyl at the arrow. Identifying the spatial segregation of the hydrophilic and hydrophobic groups in these detergents may require careful inspection of their three-dimensional chemical structure. In cholic acid, the carboxyl group is an obvious hydrophilic group, but the effects of the hydroxyl groups located on the rings must also be considered. Viewing the steroid ring nucleus in the molecule as defining a plane, the spatial arrangement of the hydroxyls creates a hydrophilic face on one side and a hydrophobic face on the other side of this plane. The structure of DOC suggests the presence of only a hydrophilic edge along the ring plane, making the whole structure more hydrophobic than cholic acid, which may explain why DOC is generally a more aggressive solubilizer than cholic acid.

Hydrophilic Groups (Headgroups)

Ionic

Positively (e.g., amino) and negatively (e.g., carboxyl) charged groups have been utilized as hydrophilic groups. Single-tailed ionic detergents tend to denature all proteins, with the anionic ones being more aggressive at denaturation than cationic molecules. One of the most familiar examples is the anionic detergent, sodium dodecyl sulfate, $NaDodSO_4$ (Figure 1). It is the denaturing effect of $NaDodSO_4$ on proteins that led to the development of one of the most widely exploited analytical tools of biochemistry, denaturing gel electrophoresis, which permits one to easily assess the number of components present in a sample as well as their approximate molecular weights. Interestingly, it is the monomeric form of the ionic detergent that drives the denaturation process.

The bulk of the lipids which form the basic membrane framework are amphiphiles with two hydrophobic

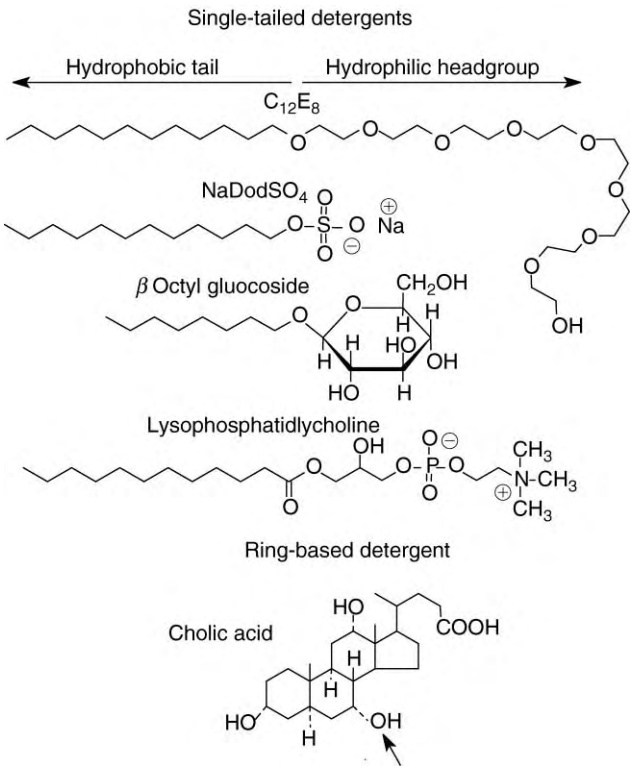

FIGURE 1 Selected chemical structures of detergents. Removal of the hydroxyl near the arrow on cholic acid coverts the molecule to deoxycholic acid.

tails esterified to zwitterionic headgroups (contains both positive and negative charges). While the lipids themselves generally form vesicular structures when dispersed in water, removal of one of the tails creates a detergent such as the lysophosphatidylcholine in Figure 1. Such lysolipids and other zwitterionic detergents (e.g., sulfobetaines) have been used as well as highly dipolar groups (e.g., amine oxide) that lack a formal charge.

Nonionic

Any uncharged group of atoms capable of accepting or donating hydrogen bonds to water can in principle become a nonionic headgroup. The headgroup must be big enough so that the detergent dissolves in solution (as a mixture of monomer and micelles) rather than forming a separate phase. Thus, simple alkyl alcohols tend to phase separate for all but the shortest hydrophobic tails and have no useful detergent properties. Carbohydrate groups are useful headgroups and one of the most frequently encountered is β-octyl glucoside (OG) in Figure 1. Octyl glucoside in the α-anomeric configuration is essentially insoluble, demonstrating how a simple change in chemical structure can dramatically alter detergent properties. More elaborate carbohydrate structures have also been explored.

Commercial applications of detergents have driven the development of a large class of nonionic detergents with polyoxyethylene (POE) headgroups. A chemically homogeneous example is $C_{12}E_8$ (Figure 1), where a 12-C tail (C_{12}) is attached to a polymer with eight repeats of $-CH_2CH_2O-$ (E_8) and terminates with a hydroxyl group. The ether groups of this chain provide sites for hydrogen bonding with water offsetting the hydrophobic nature of the intervening ethylene groups. Most commercially available POE-based detergents have headgroups consisting of a single chain although the length is often heterogeneous; however, highly branched structures have been created by attachment of several POE chains to a central moiety such as sorbitol (e.g., Tweens). The POE chains are subject to peroxidation and breakdown and solutions should only be used when relatively freshly prepared; moreover, when using commercial sources one should be aware that antioxidants are sometimes included.

Connecting Head and Tail

Linkages between the hydrophobic and hydrophilic groups are most often either an ether or ester linkage. The latter can be susceptible to hydrolysis, especially in biological preparations, which in turn could generate an ionic group with denaturing properties.

Detergent Properties

Critical Micelle Concentration (CMC)

The most common concentration-dependent behavior for detergents is illustrated in Figure 2. The monomer concentration increases until the critical micelle concentration (CMC) above which an equilibrium is established between the monomer and an increasing concentration of micelles. The monomer concentration increases very little after reaching the CMC and thus is in effect the highest possible concentration of monomeric detergent. All detergent in excess of the CMC is incorporated into micelles (dashed line in Figure 2). The concentration of micelles increases linearly with total detergent concentration above the CMC, but at a slower rate since a large number of molecules are incorporated into each micelle. Some detergents exhibit more complex behavior, such as secondary association of micelles or even new phases as the total concentration continues to increase.

As illustrated in Figure 2, the CMC is actually a narrow range of concentration over which the formation of micelles becomes dominant. Nonetheless, a single number is usually defined as the CMC and determined by plotting some physical observable whose response differs markedly above and below the CMC against the total

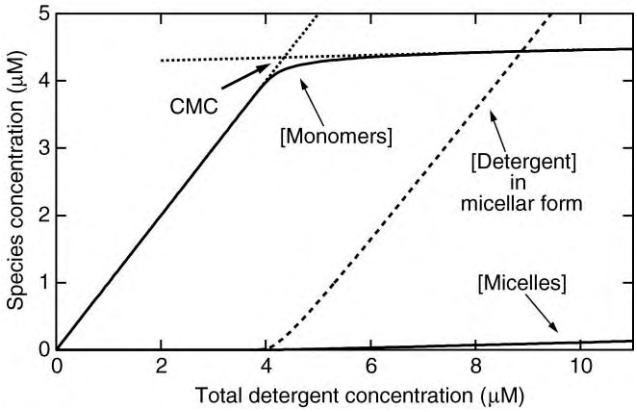

FIGURE 2 Concentration-dependent behavior of a detergent. The calculations are based on the theory of micelle formation developed by Tanford. An aggregation number of 50 was used and the equilibrium constant for micellization was chosen to yield the critical micelle concentration (CMC) indicated.

concentration of detergent. The CMC is then taken as the intersection of lines extrapolated from the nearly linear regions above and below the transition as shown by the dotted lines in Figure 2. Using different observables or concentration ranges for the extrapolation can lead to somewhat different values for the CMC. One of the simplest methods to measure a CMC concentration ranges or for the extrapolation. is by solubilization of heme, which is essentially insoluble below the CMC and increases as the concentration of micelles increases and would be similar to the dashed line in Figure 2.

CMCs range from nanomolar to several millimolar. For single-tailed detergents, the CMC decreases with increasing length of tail and with smaller headgroups. The CMC of nonionics is generally lower than that of ionics with the same length of tail. Ionic headgroups are more susceptible to solution variables than the nonionics. Ionic headgroups that can be titrated are sensitive to pH and may precipitate when the headgroup is in neutral form (both cholic acid and DOC are examples). The CMCs of ionics are also influenced by the type and concentration of counterions present, e.g., using potassium instead of sodium for dodecyl sulfate, results in an insoluble salt. In general, higher salt concentrations will decrease the CMC of an ionic detergent which is a consequence of reducing the headgroup repulsion in the micelle. Even the POE-based nonioncs may be influenced by presence of salts as the ether groups are capable of complexing ions. The solubilization of other components in the micelle (e.g., mixed micelles with lipids) will generally decrease the CMC (i.e., the maximum monomer detergent concentration is decreased). Published values of CMCs are useful guides in experimental design, but should generally be confirmed under the actual experimental conditions.

Aggregation Number

Micelles are formed by self-association of many detergent molecules into a single noncovalent structure. Since the number of molecules in each micelle is somewhat variable, micelle size is characterized by the aggregation number, which is the average number of molecules per micelle and can be determined by standard hydrodynamic methods (e.g., sedimentation equilibrium). The aggregation number is needed to calculate the micelle concentration, which is the total detergent concentration in excess of the CMC divided by the aggregation number.

The CMC transition becomes sharper as the aggregation number increases. The CMC is generally strongly dependent on the size of the hydrophobic moiety, but repulsion between headgroups is the dominant factor for the aggregation number. Thus, nonionics tend to have larger aggregation numbers than ionics of the same tail length. The aggregation number for ionic detergents can be strongly influenced by both the type and concentration of counterions present as well as pH since these factors can dramatically change the electrostatic repulsion between the charged headgroups. Longer hydrophobic tails tend to have larger aggregation numbers. Detergents with high CMCs tend to have more variability in their micelle size distribution. At high concentrations and under certain solution conditions (e.g., elevated temperature) larger structures may be formed which in some cases are new micellar phases and in others simply secondary aggregation of smaller micelles.

Temperature Effects

As a thermodynamic equilibrium, the formation of micelles can be influenced by temperature. At low enough temperatures, solid detergent will exist in equilibrium with monomeric detergent; as the temperature increases, the monomer concentration increases until it reaches the CMC at the critical micelle temperature. Above this temperature, solid detergent will begin to go into solution as micelles. The temperature at which solid, micelles, and monomer at the CMC coexist is called the Kraft point and for most detergents is the same as the critical micelle temperature. An often observed Kraft point, which is near room temperature, is that of sodium dodecyl sulfate and upon cooling one sees precipitation of detergent. A second temperature effect observed at higher temperature, especially with nonionics containing POE, is the cloud point. At this temperature and above the CMC, the solution will turn turbid due to the formation of much larger aggregates. Both the critical micelle temperature and cloud point have been exploited in purification of membrane components.

Micelle Structure

Single-Tailed Detergents

In a micelle, the hydrophobic tails are sequestered into a central core structure with the hydrophilic groups projecting out from the surface of this core into the aqueous surrounding. The tails in the core are not fully extended but are quite flexible, some even lying along the surface of the core rather than within it. The surface of the core should be regarded as having a rippled texture with some tail methylene groups protruding above it. Experimental and theoretical arguments suggest that for most detergent micelles the overall shape is best described as an oblate ellipsoid, although for small aggregation numbers the shape cannot be readily distinguished from spherical. For $C_{12}E_8$ micelles (Figure 1), theoretical calculations constrained by hydrodynamic measurements yield an oblate ellipsoid with dimensions shown in Figure 3. One dimension must be less than the 3.4 nm length of two fully extended 12C chains since the core cannot contain a void. For the same length of tail, the overall dimensions of the micelle will depend on the nature of the headgroup. For POE-based detergents, the headgroup is in a random-coil configuration and consequently occupies a very large region of the space surrounding the core, as illustrated in Figure 3.

Figure 3, while a convenient visualization of micelle structure, cannot convey the highly dynamic processes occurring. Detergent molecules are rapidly exchanged among micelles; whole micelles disappear and reform with slightly different aggregation numbers. The hydrophobic core acts for the most part like a simple liquid hydrocarbon with the tails constantly flexing. POE headgroups occupy a great deal of space around the core and are constantly changing their conformation as well. Finally, it should be obvious that the type and size of headgroup can generate dramatically different chemical environments to which molecules solubilized by detergents are exposed; moreover, the solution composition near a micelle may be quite different from that of the bulk aqueous solution.

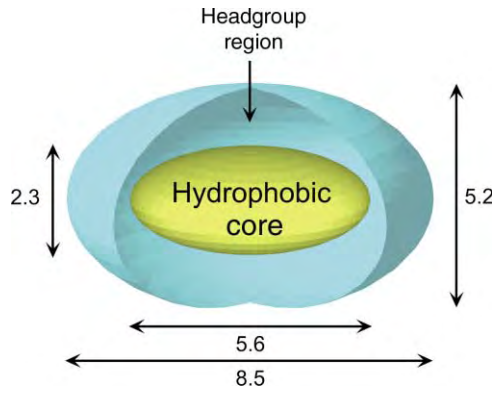

FIGURE 3 Shape of micelles formed by typical single-tailed detergents. The model shown is based on data and calculations for C12E8. The dimensions shown are in nm.

Ring-Based Detergents

Bile salts usually have relatively high CMCs and quite small aggregation numbers (4–10). The small aggregation number does not permit micelles as just described. The micelles are more heterogeneous and are probably best viewed as small assemblies with the hydrophobic surfaces facing each other, presenting their hydrophilic faces to the surrounding solution. The size and shape of these micelles are quite sensitive to the concentration and types of ions, and potentially pH.

Detergents as Tools in Membrane Studies

Membrane Solubilization

Initially when a membrane is exposed to a detergent, monomers partition into the bilayer, so one can imagine that a high CMC might be advantageous (e.g., OG has a very high CMC (>15 mM) and is an efficient solubilizer). As more detergent intercalates into the membrane's bilayer, one reaches a stage where fragmentation occurs, resulting in large mixed micelles containing detergent, lipids, and proteins in various ratios. Continuing to add detergent will eventually disperse the membrane components to the point that any given micelle contains no more than a few lipids, a protein, or the detergent alone. One can apply isolation and enrichment techniques for specific targets to this solubilized mix. The choice of detergent can hinder or help in isolation, e.g., a small aggregation number can facilitate separation of a large protein-containing micelle from those containing only lipid components. It is possible, and perhaps even desirable, to exchange detergents, so that one detergent might be used to speed initial membrane solubilization and another for final isolation of a stable target. It is important to recognize that it is the concentration of micelles that needs to be controlled when one is studying membrane components solubilized by detergents, and generally one should maintain a ratio of several micelles to each solubilized component to avoid the possibility of spurious associations.

Membrane Proteins

A detergent can be found that can reasonably mimic the hydrophobic core of the native membrane. However, the membrane provides a physical constraint to the embedded protein, in that the protein cannot expand

laterally in the plane of the membrane nor can it pull itself through the bilayer; in a detergent solution, such a physical constraint is greatly relaxed and the protein in effect has a much expanded conformational space including conformations where activity will be lost possibly irreversibly. Low CMCs and large aggregation numbers may partially compensate for the loss of the membrane's physical constraints. Moreover, the native environment of the membrane provides a multitude of interactions with a variety of lipid headgroups, tails, and with other proteins and these interactions may differ from one side of the membrane to the other. The roles of these interactions in maintaining an active protein are not well understood and they are radically changed upon solubilization. Studies as a function of micelle concentration should be performed, as there is always a possibility of adventitious interactions, due merely to the fact that too little detergent is present.

Reconstitution of Protein into a Bilayer

Many of the functions of membrane proteins are vectorial in nature, and one must eventually reconstitute the protein into a lipid bilayer where these functions can be probed. Starting with mixed micelles of protein in detergent and lipids in detergent, one must effect a controlled removal of the detergent, permitting the formation of an artificial membrane bearing the protein. This is accomplished largely by trial and error. A high CMC permits the use of dialysis since the monomer should pass through the dialysis membrane. Hydrophobic beads to which the detergent absorbs have also proven effective in reconstitution studies.

Summary

Obviously single-tailed ionic detergents should generally be avoided because of their potential to denature any protein. While zwitterionic headgroups can be identical or at least similar to those of native lipids, to date they have not proven any more useful than others. High CMCs may be appropriate choices for initial solubilization and eventual reconstitution. But long tails and large headgroups (usually accompanied by a low CMC) may enhance stability by restricting the conformational space accessible to the protein in detergent solution. The requirements for efficient solubilization and for the maintenance of activity may to a large extent be antagonistic. The possibility of using one detergent to solubilize and subsequently exchanging into another to enhance stability for isolation and study should always be considered. Finally, there is no perfect detergent for all situations nor are there hard-and-fast rules for choosing a detergent for a specific task. In the end the choice is still largely a matter of trial and error.

Glossary

aggregation number Number of detergent molecules in the average micelle.

CMC (critical micelle concentration) Concentration of detergent in aqueous solution above which micelles begin to form, essentially the maximum concentration of detergent in monomeric form.

detergent A compound having spatially segregated hydrophilic and hydrophobic regions and which, when dissolved in water above the CMC, self-associates to form micelles.

hydrophilic group Structure having an affinity for water with strong favorable noncovalent bonds with water molecules.

hydrophobic group Structure exhibiting an aversion to water and preference for hydrocarbon-type liquids.

micelle Structure formed by the noncovalent and highly cooperative self-association of a detergent molecule so as to form a hydrophobic core from which the hydrophilic groups project into the aqueous surroundings.

Biography

Dr. Darrell R. McCaslin holds a B.S. with Honors in biochemistry from Oklahoma State University and a Ph.D. in physical biochemistry from Duke University. He has held positions at Duke University Medical Center and Rutgers University in Newark. Presently, he is the Director of Operations for the Biophysical Instrument Facility at the University of Wisconsin in Madison. In addition to overseeing the operations of the facility and training investigators in the use of the instrumentation, he collaborates on a variety of characterization problems.

Diabetes

David W. Cooke
The Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

Diabetes mellitus is among the most common chronic diseases, affecting over 6% of the adult population in Western society, and with a prevalence that is rising dramatically worldwide. However, diabetes mellitus is not a single disease, but rather a number of distinct disorders. They share, in common, deficient action of the hormone insulin. This can be due to an absolute deficiency of insulin production and secretion by the β-cells of the pancreatic Islets of Langerhans. However, in many types o diabetes mellitus there is an impaired cellular response to insulin; this insulin resistance imposes a requirement for increased insulin levels to maintain metabolic control. In this case, diabetes mellitus occurs when there is an inability to secrete sufficient insulin to meet this increased demand. The insulin deficiency, whether absolute or relative, leads to a failure to control carbohydrate and lipid metabolism.

Introduction

The defining feature of diabetes mellitus is an abnormal elevation of the blood glucose level. When the degree of hyperglycemia is mild, there may be no symptoms of diabetes. With greater degrees of hyperglycemia, the concentration of glucose in the blood exceeds the ability of the kidneys to completely reabsorb the glucose delivered to it. The resultant loss of glucose in the urine provides an osmotic force that draws increased water into the excreted urine, causing the patient to experience polyuria (increased urination; this glucosuria gives diabetes mellitus its name, which can be translated from the Greek as "sweet urine" – or more directly as "honey siphon". The osmotic diuresis from glucosuria induces polydipsia (increased drinking) in order to prevent dehydration. When uncontrolled, diabetes mellitus puts patients with these diseases at risk of acute metabolic decompensation, particularly when the insulin deficiency is complete, as in type 1 diabetes mellitus. While this decompensation is life threatening, since the introduction of insulin treatment over 80 years ago these events are generally preventable. It is now the long-term complications that all patients with diabetes mellitus are at risk that has become the most significant burden. Due to these long-term complications, diabetes is a leading cause of blindness and end-stage renal disease. In addition, diabetes is associated with accelerated atherosclerotic vascular disease, leading to a risk of myocardial infarction, stroke, and limb amputation that is increased and occurs at a younger age than in those without diabetes.

Etiology

For each type of diabetes mellitus, the relative contribution of a defect in insulin secretion versus a defect in insulin action will vary. For example, the two most common forms of diabetes are type 1, which is due to an isolated deficiency in insulin, and type 2, which is due to varying degrees of insulin resistance and deficient insulin secretion. In addition, some forms of diabetes have a predominantly genetic etiology, such as the autosomal dominantly inherited maturity-onset diabetes of the young (MODY), whereas in other types both genetic and environmental factors are important, exemplified by type 2 diabetes, where the development of obesity is a significant contributor to the cause of insulin resistance that is central to the pathophysiology of this disease.

Type 1 Diabetes Mellitus

Type 1 diabetes accounts for ~5–10% of all cases of diabetes. It typically has its onset in childhood, although it can occur at any age. Type 1 diabetes is due to the destruction of the insulin-producing β-cells of the pancreas, resulting in an absolute deficiency of insulin. In the vast majority of cases, the destruction is due to a cell-mediated autoimmune attack of the β-cells. This process appears to be precipitated by environmental factors in genetically susceptible individuals. While viral infections, dietary components and specific toxins have been suspected, the true identity of the environmental triggers remains unknown. Similarly, while the immune-recognition genes of the HLA locus account for much of the genetic risk, there are other unidentified genes that also contribute to this risk.

In almost all cases of type 1 diabetes, there is ultimately complete destruction of the pancreatic

β-cells. Because of this, these patients are dependent on treatment with exogenous insulin for their survival, as the absence of such treatment leads to rapid metabolic deterioration into diabetic ketoacidosis and death.

Type 2 Diabetes Mellitus

Over 90% of diabetes is due to type 2 diabetes. The prevalence of this disease increases with age; previously it had been uncommon for children or young adults to be diagnosed with this disease. However, there has been a recent dramatic increase in the prevalence of this disease, and with this, significant numbers of children are now being diagnosed with type 2 diabetes. Although much has been learned about the pathophysiology of type 2 diabetes in the past few decades, there remains much to be learnt about the specific details of its cause. What is known is that two defects are present in patients with type 2 diabetes: insulin resistance and defective insulin secretion. Insulin resistance refers to a decreased effectiveness of insulin in activating signals distal to binding of insulin to the insulin receptor. Insulin resistance itself, except in the most extreme situation, will not lead to diabetes, as normal metabolic control can be maintained by a compensatory increase in insulin secretion. When a second defect results in an inability to respond to the requirement for increased insulin secretion imposed by insulin resistance, type 2 diabetes mellitus occurs.

There is strong familial clustering of type 2 diabetes, and the risk for this disease varies considerably across different ethnic populations. These and other findings indicate that there is a strong genetic component to the development of type 2 diabetes. Multiple genes are most likely to be involved, with each individual with diabetes having altered function of multiple gene products. In addition, the relative contribution of insulin resistance versus defective insulin secretion can vary from patient to patient, so that there is likely a subset of altered genes contributing to the development of type 2 diabetes that differs from one person to the next. The genes involved will include those encoding proteins affecting insulin signaling and insulin secretion, those controlling metabolic pathways, and those contributing to the development of obesity.

Environmental factors play a significant role in determining which genetically predisposed individuals will develop type 2 diabetes. Obesity and low levels of physical activity are strongly associated with insulin resistance, and are the factors to which the rising prevalence of type 2 diabetes in industrialized societies are ascribed. In addition, insulin sensitivity (the inverse of insulin resistance) decreases with age, accounting for much of the increased prevalence of this disease with increasing age.

Insulin Resistance

Both central (hepatic) and peripheral (muscle and adipose) defects contribute to the insulin resistance of type 2 and obesity. (Interestingly, experiments in rodents have indicated that resistance in cells not classically characterized as being insulin-responsive, including the brain and pancreatic β-cells, may contribute to the pathophysiology of obesity and type 2 diabetes.) Hepatic insulin resistance results in increased glucose output from the liver, predominantly due to increased gluconeogenesis. Insulin-resistant muscle and adipose cells have diminished insulin-stimulated glucose uptake, and the muscle cells have a marked decrease in glycogen synthesis. These defects, particularly in the muscle, result in decreased disposal of glucose after a meal. In addition, the decreased metabolism of glucose to glycogen leads to increased glycolysis and production of lactate, which circulates to the liver and provides substrate for increased gluconeogenesis. The increased hepatic glucose production contributes most to fasting hyperglycemia, while the decreased glucose disposal into muscle contributes most to postprandial hyperglycemia.

Although the mechanisms remain incompletely understood, a number of factors have been demonstrated to contribute to the insulin resistance of type 2 diabetes, including free fatty acids and other factors secreted by adipocytes, as well as hyperglycemia itself (Figure 1). Free fatty acids impair insulin sensitivity, both in the liver and in muscle, and increased circulating levels of free fatty acids are found in obese and insulin-resistant subjects, due to increased lipolysis in adipocytes. Importantly, intra-abdominal fat tissue has a higher lipolytic rate compared to subcutaneous adipose tissue, and excess intra-abdominal adiposity has a much higher association with insulin resistance than obesity with a more peripheral (subcutaneous) distribution. Abnormal secretion by the adipocyte of a number of other factors (adipokines) has also been implicated in

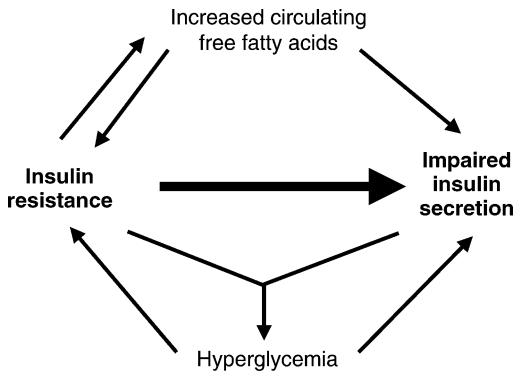

FIGURE 1 Factors contributing to insulin resistance and impaired insulin secretion include the ability for each of them to affect both themselves and each other through direct and indirect mechanisms.

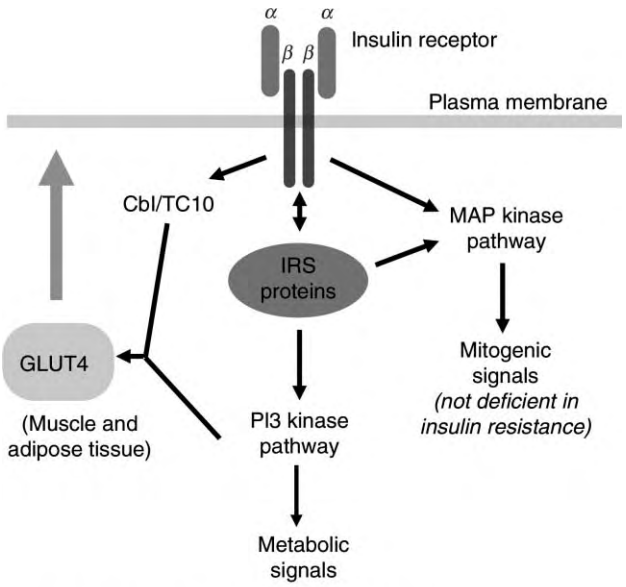
the pathophysiology of insulin resistance, including TNF-α, resistin, adiponectin, and leptin. Hyperglycemia itself causes impaired insulin sensitivity. This may be due to activation of protein kinase C (PKC) by hyperglycemia. Recently, it has also been suggested that hyperglycemia-induced insulin resistance is in some way caused by increased flux of glucose through the glucosamine pathway.

Molecular Mechanisms of Insulin Resistance Insulin is a peptide hormone that binds to a transmembrane-spanning cell surface receptor (Figure 2). The insulin receptor is heterotetrameric in structure, containing two α- and two β-subunits. Insulin binds to the extracellular α-subunit, inducing a conformational change in the transmembrane β-subunit that derepresses intrinsic tyrosine kinase activity contained in the intracellular domain. The activated β-subunit tyrosine kinase activity first trans-phosphorylates the opposite β-subunit of the $\alpha_2\beta_2$ receptor complex. Once autophosphorylated, the insulin receptor is capable of phosphorylating intracellular proteins that propagate the insulin signal within the cell. Proteins of the insulin receptor substrate (IRS) family, the most important of these being IRS-1 and IRS-2, recognize and bind to phosphotyrosine motifs on the activated insulin receptor. Once bound, the IRS proteins are themselves phosphorylated on multiple tyrosine residues by the activated insulin receptor. The IRS proteins do not have intrinsic enzymatic activity, but serve as docking sites to bring other proteins into proximity to the insulin receptor. A signaling cascade is initiated, as proteins recognize and bind to the phosphotyrosine motifs on either the insulin receptor or the IRS proteins. This results in their activation, often through their phosphorylation by the insulin receptor.



Abnormalities found in insulin resistance:

Insulin receptor:
- decreased number (minor)
- decreased insulin-stimulated tyrosine phosphorylation
- increased serine phosphorylation

IRS proteins:
- decreased protein level
- decreased insulin-stimulated tyrosine phosphorylation
- increased serine phosphorylation
- increased frequency of IRS-1 polymorphisms (some populations)

Decreased insulin-stimulated PI3 kinase associated with IRS proteins

GLUT4:
- decreased expression (adipose tissue)
- decreased insulin-stimulated translocation to the plasma membrane (muscle and adipose)

FIGURE 2 Major signaling pathways of insulin action and abnormalities found in insulin resistance.

The downstream components of the insulin-signaling cascade include protein kinases and phosphatases, and lipid kinases. The two pathways that have been investigated in the most detail are the mitogen-activated protein (MAP) kinase and the phosphatidylinositol-3-OH (PI3) kinase pathways. Although the distinction is not absolute, activation of the MAP kinase pathway is most responsible for the mitogenic actions of insulin, while activation of the PI3 kinase pathway is predominantly involved in the metabolic actions of insulin. This is significant, because activation of the MAP kinase pathway by insulin is not reduced in type 2 diabetes, a result that may be involved in the pathogenesis of the long-term complications of insulin resistance and diabetes. A third pathway involves phosphorylation and activation of the Cbl proto-oncogene by the insulin receptor, which results in activation of the G protein TC10. Many of the pathways that are activated by the insulin receptor are also activated by other means, particularly activation of other growth factor receptors. Specificity of the insulin signal is felt to be due to the integration of the multiple pathways activated, as well as to compartmentalization of the components of the cascade. For example, both the PI3 kinase and Cbl/TC10 pathways appear to be necessary for insulin-stimulated glucose uptake into muscle and adipose cells.

Abnormalities of each of the components of the insulin-signaling cascade, from the insulin receptor at the beginning to the enzymes, transcription factors, and other effector proteins at the end, are potential candidates for contributing to the insulin resistance of type 2 diabetes. Indeed, certain polymorphisms in the IRS-1 gene are found more frequently in individuals with diabetes in some populations (the lack of this association in other populations likely underscores the genetic heterogeneity of this disease). For all the other components, however, mutations or significant alterations in expression have either not been found or have been extremely rare. However, there have been clearly

identified abnormalities in insulin signaling that occur in the insulin resistance of type 2 diabetes (Figure 2). Notably, insulin-stimulated tyrosine phosphorylation of the insulin receptor and IRS proteins is decreased in tissues in insulin-resistant subjects. This is often associated with an increase in phosphorylation on serine residues in these proteins, which may inhibit the protein–protein interactions necessary for proper signaling. Potential mechanisms for this include serine-phosphorylation of the insulin receptor by PKC, and stimulation of serine-phosphorylation of IRS-1 by TNF-α; PKC activity is increased in the presence of hyperglycemia, and adipocytes from obese subjects express increased amounts of TNF-α. The increase in free fatty acids present in obesity and insulin resistance may also lead to increased serine phosphorylation of the insulin receptor and IRS proteins.

In order to enter a cell, glucose requires specialized transporters to be present on the cell surface. GLUT4, the insulin-responsive glucose transporter, is sequestered in intracellular vesicles in the basal state. When muscle or adipose cells are stimulated by insulin, these vesicles translocate and fuse with the plasma membrane, and the increase in transporters at the cell surface results in increased glucose uptake. In the insulin resistance of obesity and type 2 diabetes, there is a decrease in the insulin-stimulated translocation of GLUT4. There may also be a decrease in the intrinsic activity of GLUT4 in insulin-resistant states. Finally, in adipocytes (but not muscle cells) there is significantly decreased expression of GLUT4 that contributes to the diminished insulin-stimulated glucose uptake. Although quantitatively adipose tissue contributes only a small fraction to glucose disposal compared to muscle, evidence from animal models with tissue-specific insulin resistance demonstrates that insulin resistance in one tissue can affect insulin sensitivity in other tissues. Thus, insulin resistance in the adipocyte can cause insulin resistance in liver and muscle, most likely through secreted free fatty acids and adipokines.

Insulin Secretory Defect

Insulin secretion increases to compensate for insulin resistance, so that in obese or otherwise insulin-resistant individuals, fasting and meal-stimulated insulin levels are elevated. When insulin secretion fails to fully compensate for the degree of insulin resistance, glucose levels rise, first to those of mild glucose intolerance (glucose levels above normal but below criteria for a diagnosis of diabetes), and then to those of diabetes. Insulin levels early in this progression are still elevated compared to individuals with normal insulin sensitivity, but are not elevated sufficient to maintain normal glucose control. With time, in most patients, the insulin secretory defect continues to worsen, including loss of β-cells, ultimately requiring exogenous insulin treatment to maintain control of blood glucose levels.

As for insulin resistance, the development of impaired insulin secretion is likely due to both genetic and environmental factors. The persistent stimulus imposed by insulin resistance on the β-cell to oversecrete insulin appears to be a key factor contributing to the loss of β-cell function (Figure 1). This may be due in part to the effect of excessive secretion of islet amyloid polypeptide (IAPP), which is cosecreted with insulin; in the islets in the majority of patients with type 2 diabetes there is the accumulation of amyloid, containing IAPP. Another factor is the elevated free fatty acid level present in insulin resistance, which can contribute to the defective insulin secretion, just as it can contribute to insulin resistance. While short-term exposure to lipids increases insulin secretion, long-term exposure impairs β-cell function, and may be responsible for β-cell death by apoptosis. Similarly, prolonged exposure to increased glucose levels imposes a "glucotoxicity" on the β-cell: if glucose levels are normalized in a patient with diabetes, endogenous insulin secretion will improve. Over time, however, this glucotoxicity may lead to irreversible β-cell damage, perhaps through oxidative injury. Finally, insulin resistance of the β-cell may itself lead to impaired β-cell function, as demonstrated in mice carrying genetic defects of insulin signaling in β-cells.

Other Specific Types

Diabetes of types other than type 1 or type 2 make up a small percentage of the cases of diabetes. For a number of these, however, a single gene defect results in the disease, providing potential insight into what may be the underlying cause of the insulin resistance or insulin secretory defect in type 2 diabetes.

Genetic Defects of β-Cell Function

Insulin Gene Mutations in the insulin gene have been described, but are extremely rare causes of diabetes. In the few families where such mutations have been found, the result is very mildly abnormal glucose control, inherited in an autosomal-dominant manner.

Maturity-Onset Diabetes of the Young Maturity-onset diabetes of the young are a group of diabetes types caused by mutations in single genes. Mutations in six genes have been identified, each of which results in deficient insulin secretion. These mutations result in autosomal dominantly inherited forms of diabetes that have an early onset, usually before the age 25. Because these patients retain some insulin secretion, albeit insufficient to prevent hyperglycemia, these patients are, in general, not ketosis prone, and so are not dependent on insulin treatment for survival. In contrast

to type 2 diabetes, obesity and insulin resistance are not a major feature of MODY; the diabetes in these cases is due to the defective insulin secretion. The severity of the insulin deficiency varies for the different genes involved, and consequently the severity of the untreated diabetes can vary from mild, sometimes unrecognized hyperglycemia with little risk of long-term microvascular diabetic complications, to severe hyperglycemia with a very high risk of microvascular complications.

MODY2 is caused by mutations in the gene for glucokinase, which is expressed in highest levels in the pancreatic β-cell and in the liver. In the β-cell, glucokinase catalyzes the phosphorylation of glucose to generate glucose-6-phosphate, the first step in glucose metabolism. Because glucose metabolism is the stimulus for insulin release, glucokinase functions as the glucose sensor in the β-cell as it is rate limiting for glucose entry into the glycolytic pathway. Thus, glucokinase mutations lead to decreased glucose-stimulated insulin secretion. In the liver, glucokinase affects the storage of glucose as glycogen; this defect may contribute to the hyperglycemia in patients with glucokinase mutations. MODY2 is caused by heterozygous mutations of the glucokinase gene; complete glucokinase deficiency due to homozygous mutations lead to more severe neonatal-onset diabetes.

The other genes that have been identified as having mutations that cause MODY are each transcription factors expressed in the pancreatic β-cell: hepatocyte nuclear factor (HNF)-4α (MODY1); TCF1, which encodes HNF-1α (MODY3); insulin promoter factor-1 (IPF1;MODY4); TCF2, which encodes HNF-1β (MODY5); and neurogenic differentiation 1/β-cell E-box transactivator 2 (NeuroD1/BETA2;MODY6). Each of these genes are expressed in the β-cell and regulate expression of the insulin gene and genes for other factors involved in the regulation of insulin signaling; heterozygous mutations lead to β-cell dysfunction sufficient to cause diabetes. IPF-1 and NeuroD1/BETA2 are also involved in pancreatic development, and homozygous mutations of IPF-1 lead to pancreatic agenesis and congenital diabetes mellitus and pancreatic insufficiency.

Mitochondrial DNA Mutations Mutations in the mitochondrial genome can cause diabetes mellitus, the most common involving the mitochondrial $tRNA^{LEU(UUR)}$. Due to the maternal origin of mitochondria, this type of diabetes is maternally inherited. The pancreatic β-cell is rich in mitochondria and has a high rate of oxidative metabolism; the mitochondrial mutations result in a β-cell defect that causes diabetes through deficient insulin secretion. This form of diabetes is frequently associated with neurosensory deafness.

While inherited mitochondrial genome mutations are rare as a cause of diabetes mellitus, they may provide insight into the worsening insulin secretory defect that occurs in type 2 diabetes. The mitochondrial genome consists only of coding sequences, and its repair mechanisms are poor so that it is highly susceptible to mutation. With age, there is an increase in reactive oxygen species generated in mitochondria, and this may be exacerbated in β-cells with a higher rate of oxidative metabolism due to exposure to elevated glucose levels. With a low expression of enzymes that defend against oxidative damage, β-cells are particularly sensitive to oxidative injury. The inherited mitochondrial genome mutations that cause diabetes demonstrate that these mutations can impair insulin secretion, and it is possible that an accumulation of mitochondrial DNA mutations due to oxidative damage contribute to the β-cell dysfunction of type 2 diabetes.

Genetic Defects in Insulin Action

Insulin Receptor Mutations Insulin resistance can be caused by mutations of the insulin receptor, although these are rare as a cause of diabetes. Most of the subjects identified with insulin resistance and insulin receptor mutations have mutations of both alleles. Some cases of mild insulin resistance have been described in which only one allele carries a mutation, acting as a dominant negative inhibitor of the wild-type allele, due to their combination within the heterotetrameric structure of the receptor. The severity of the phenotype with two mutant insulin receptor alleles can vary from insulin resistance with relatively normal glucose control (type A insulin resistance) to a more severe phenotype evident in infancy (Rabson–Mendenhall syndrome and Leprechaunism, which is usually fatal in infancy).

Secondary Diabetes Mellitus

A number of systemic disorders can cause marked insulin resistance, which can lead to secondary diabetes mellitus (although as for type 2 diabetes and as discussed above, there must be some defect in insulin secretion to prevent complete compensation for the insulin resistance by the β-cell). Excess growth hormone, as in acromegaly, excess glucocorticoid, as in Cushing's disease or exogenous glucocorticoid treatment, or excess catecholamines, as in pheochomacytoma, as well as other diseases such as uremia and hepatic cirrhosis can lead to secondary diabetes primarily through their effect on insulin sensitivity. Similarly, diabetes mellitus will occur if a disorder produces sufficient β-cell damage. Examples of this include pancreatitis, cystic fibrosis, pancreatectomy, and hemochromatosis; in addition, somatostatin-secreting tumors can inhibit insulin secretion sufficient to cause diabetes mellitus.

Rarely, patients with autoimmune disease have been identified where antibodies against the insulin receptor

block signaling, leading to an insulin resistant form of diabetes referred to as type B insulin resistance.

Strikingly, just as the excess adipose tissue in obesity leads to insulin resistance, the deficiency of adipose tissue that is found in lipoatrophy/lipodystrophy also causes insulin resistance, often severe. Mice that are genetically engineered to have a paucity of adipose tissue are also markedly insulin resistant, confirming this association. The cause of insulin resistance in syndromes of adipose deficiency is likely due to intrahepatic and intramuscular accumulation of triglyceride, as well as a loss of normal secreted signals from adipocytes.

Gestational Diabetes

Glucose intolerance that is first identified during pregnancy is referred to as gestational diabetes. The importance of this classification is the significant maternal and fetal morbidity related to diabetes during pregnancy, warranting screening for diabetes mellitus in all pregnant women except those at low risk. In some cases gestational diabetes is merely the identification of glucose intolerance that was previously unrecognized until screening is performed during a pregnancy, or to the temporal development of diabetes (type 1 or type 2) during a pregnancy, perhaps accelerated by the pregnant state, but otherwise predestined to develop. In the majority of cases, however, glucose regulation returns to normal after the pregnancy. Pregnancy is characterized by progressively decreasing insulin sensitivity, due to the insulin antagonizing effects of increases in prolactin, human placental lactogen, estrogens, progesterone, and unbound cortisol levels. In the majority of pregnancies, this insulin resistance is compensated for by increased insulin secretion. However, in the 2–5% of pregnancies that develop gestational diabetes mellitus, there is an inadequate compensation. Thus, gestational diabetes represents the same or similar pathophysiologic abnormality of insulin sensitivity and insulin secretion that occurs in type 2 diabetes, with a portion of the insulin resistance being self-limited due to the pregnant state. However, there is also an underlying defect in insulin sensitivity and insulin secretion, and women who have had gestational diabetes are at a substantially increased risk for the future development of type 2 diabetes.

Metabolic Syndrome and Prediabetes

Insulin resistance often precedes the development of diabetes mellitus by many years. In addition, in some people, β-cell dysfunction does not develop, and insulin resistance exists indefinitely without progressing to diabetes. However, insulin resistance is not without significance of its own. The metabolic syndrome (also referred to as syndrome X) is an association of findings that frequently coexist, and includes insulin resistance, obesity (particularly abdominal/visceral rather than peripheral/subcutaneous), hypertension, and a specific form of dyslipidemia: hypertriglyceridemia and decreased high-density lipoprotein (HDL) cholesterol. These subjects are at risk of developing type 2 diabetes if they do not already have it, but more importantly, even in the absence of progression to diabetes, these individuals are at a markedly elevated risk for atherosclerotic vascular disease. The causality of obesity and insulin resistance in this syndrome is supported by the fact that lipid levels and hypertension may both be improved by decreasing insulin resistance through exercise and weight loss.

The diagnosis of diabetes mellitus is based on blood glucose levels that exceed defined levels, either in the fasting state or after a challenge with an ingested glucose load. The cutoffs are based mostly on levels that predict an increased risk for diabetic microvascular complications. Some individuals with insulin resistance will have glucose levels that do not meet criteria for the diagnosis of diabetes, but are above levels considered normal. Some of these subjects with impaired fasting glucose (IFG) or impaired glucose tolerance (IGT) will have glucose levels that revert to normal, or remain "impaired" over time. However, a large percentage will have progressive β-cell dysfunction (or worsening insulin resistance, or both) that results in progression to type 2 diabetes – ~40% in 5–10 years.

Complications

Acute

Ketoacidosis

Diabetic ketoacidosis (DKA) is the life-threatening acute metabolic decompensation in patients with diabetes mellitus. Because the development of DKA is suppressed by even modest insulin action, DKA is generally only a risk for patients with type 1 diabetes. The pathophysiology of DKA is one of acidosis, hyperosmolarity, and dehydration.

Decompensation towards DKA begins with a fall in insulin action, either due to an absolute decline in the insulin level, or due to antagonism of insulin action by cytokines and stress hormones, including catecholamines, cortisol, glucagons, and growth hormone. As insulin action becomes inadequate, serum glucose levels rise; the loss of insulin suppression of gluconeogenesis and glycogenolysis in the liver results in an increase in hepatic glucose output, and the loss of insulin stimulation of glucose uptake in muscle and adipose tissue results in accumulation of the excess glucose in the blood. The loss of insulin suppression results in unrestrained lipolysis in the adipocyte, releasing free

fatty acids and glycerol. Increased protein breakdown in muscle releases amino acids. These metabolites are taken up by the hepatocytes, where the free fatty acids are metabolized to ketoacids (β-hydroxybutyrate and acetoacetic acid), and the glycerol and amino acids serve as substrates for accelerated gluconeogenesis.

The hyperglycemia and ketoacidosis are initially moderated by the loss of glucose and ketoacids in the urine. However, the glucosuria produces an osmotic diuresis, and the ketoacidosis produce an ileus leading to nausea and vomiting that impairs the ability of the patient to drink to maintain their hydration. As dehydration develops, then worsens, the glomerular filtration rate of the kidney falls, and less glucose and ketoacids can be excreted in the urine, resulting in dramatic accumulation of glucose and ketoacids in the blood. The evolving disease stimulates (further) release of stress hormones that antagonize any remaining insulin action, and further exacerbate the hyperglycemia. The acidosis and the hyperosmolarity caused by the extreme hyperglycemia decrease cerebral function and impair the patient's consciousness, further compromising the patient's ability to drink. Without intervention, death is inevitable.

Nonketotic Hyperosmolar, Coma

Patients with type 2 diabetes are not at much risk of developing DKA. They will generally have sufficient insulin action to restrain lipolysis, limiting free fatty acid delivery to the liver and subsequent ketoacid production. However, decompensation similar to that of DKA, but without the excess ketoacid production, can occur in patients with type 2 diabetes. Nonketotic hyperosmolar coma in patients with type 2 diabetes generally occurs when another illness induces a stress response, and there is an impaired ability to maintain hydration with oral fluids. As in DKA, the increase in stress hormones antagonize insulin action, resulting in increased hepatic glucose production and decreased peripheral glucose utilization. The rising hyperglycemia produces a glucosuria-driven osmotic diuresis. Dehydration is a result of an inability of oral fluid intake to compensate for the osmotic diuresis. As in DKA, the dehydration impairs the renal excretion of glucose, allowing the glucose level to continue to rise. The dehydration and hyperosmolarity impair the patient's consciousness, and oral intake falls further. The final situation is one of marked hyperglycemia, hyperosmolarity, and dehydration. As in DKA, the mortality of nonketotic hyperosmolar coma is high.

Chronic

Patients with diabetes will have bothersome symptoms and are at risk of severe acute metabolic decompensation, even if treatment is successful in avoiding these issues, diabetes can lead to long-term complications that develop over years. These complications can be categorized as microvascular, which are unique to patients with diabetes, and macrovascular, which are complications of atherosclerotic vascular disease that also occur in people without diabetes, but occur with higher frequency in those with diabetes. These complications are felt to be due to a failure of treatment to perfectly normalize insulin and glucose levels, as well as to changes produced by insulin resistance in type 2 diabetes.

Macrovascular Disease

As in individuals without diabetes, atherosclerotic changes in medium- and large-sized arteries that either partly or completely occlude the vessel lumen lead to morbidity and mortality due to impaired blood flow to the heart (angina and myocardial infarction), the brain (stroke), or the periphery (claudication and ischemic damage requiring amputation). These complications occur at a higher frequency and develop at younger ages in patients with diabetes; over half of patients with type 2 diabetes die from cardiovascular disease. It is not fully clear how diabetes contributes to the risk of atherosclerotic vascular disease. The factors that have been implicated include lipid abnormalities, hyperglycemia, and increases in prothrombotic and proinflammatory factors. In addition, the coexistence of other atherosclerotic risk factors, most notably hypertension in obese patients with type 2 diabetes, also plays a role.

In patients with type 2 diabetes, the insulin resistance that is a part of the pathophysiology is associated with a specific pattern of lipid abnormality that increases the atherosclerotic risk: decreased high density lipoprotein (HDL) cholesterol concentration, and elevated triglyceride concentration in the serum. In addition, the inadequate insulin action in poorly controlled diabetes of any type leads to inadequate stimulation of lipoprotein lipase activity and to increased lipolysis and elevated free fatty acids. The free fatty acids that are not oxidized to ketones in the liver are re-esterified to triglycerides and secreted as very low-density lipoproteins (VLDL). Thus, poorly controlled diabetes can lead to atherosclerotic risk by increasing triglyceride and VLDL levels; hypertriglyceridemia can exacerbate the risk by depressing HDL levels. Finally, hyperglycemia may contribute to disordered serum lipids by reducing expression of the heparin sulfate proteoglycan perlecan on hepatocytes, leading to increased levels of the atherogenic cholesterol-enriched apolipoprotein B-containing remnant particles.

Endothelial dysfunction is central to the development of atherosclerosis, with decreased production of the vasodilating molecule nitric oxide and increased production of the prothrombotic factor plasminogen

activator inhibitor-1 (PAI-1) two factors implicated in this dysfunction. In diabetes, hyperglycemia inhibits nitric oxide production and increases production of PAI-1. Hyperglycemia may also contribute to macrovascular disease indirectly through microvascular damage to the nutrient blood vessels supplying the walls of the medium- and large-sized arteries.

Another aspect that is likely to play a role in the development of atherosclerosis in type 2 diabetes relates to the pathway-specific insulin resistance that is present. As noted previously, the insulin resistance of type 2 diabetes has less of an effect on the activation of the intracellular mitogen-activated protein (MAP) kinase pathway than the pathway activating phosphatidylinositol-3-kinase. This may lead to increased activation of the MAP kinase pathway by insulin signaling, which also decreases nitric oxide production and increases PAI-1 production. In addition, as the MAP kinase pathway is a mitogenic pathway, the increased MAP kinase signaling can increase proliferation of the vascular smooth muscle cells, contributing to the atherosclerotic process.

Microvascular Disease

The hyperglycemia of diabetes mellitus leads to damage to the microvascular circulation that results in tissue and organ damage, most notably in the retina, kidneys, and nerves. Due to these microvascular complications, diabetes mellitus is a leading cause of blindness, end-stage renal disease, and neuropathy. Increasing degrees of hyperglycemia are the main risk factor for microvascular complications, with the Diabetes Control and Prevention Trial (for type 1 diabetes) and the United Kingdom Prospective Diabetes Study (for type 2) definitively demonstrating a decreased incidence of microvascular complications with treatments that lower the degree of hyperglycemia. Unfortunately, even the best of current therapies do not completely normalize blood glucose levels. The risk of microvascular complications increases with time, with the earliest evidence uncommon prior to a duration of hyperglycemia of 5 years; note, however, that except for typical type 1 diabetes, hyperglycemia may be present for years before the diagnosis of diabetes is made. Finally, as yet undefined genetic factors also play a role in the risk of microvascular disease.

Microvascular disease begins with abnormal blood flow and increased vascular permeability due to decreased activity of vasodilators, increased activity of vasoconstrictors, and overexpression of permeability factors. Irreversible increases in vascular permeability occur with alterations in the extracellular matrix. Ultimately, there is cell loss, and capillary occlusion from deposition of extravasated plasma proteins and the overproduction of extracellular matrix. Microvascular disease affects the glomerulus in the kidney, with the earliest evidence being leakage of albumin into the urine and progressing to loss of glomerular function. Damage to retinal capillaries causes hypoxic-ischemia, edema, new vessel formation, and hemorrhage. It is the development of new vessels, referred to as proliferative retinopathy, that leads to retinal detachment, vitreous hemorrhage, and loss of sight. Diabetic neuropathy includes degeneration of motor, sensory, and autonomic nerves.

While it is clear that hyperglycemia leads to microvascular disease, the precise mechanism for this has not been completely demonstrated. However, four pathologic processes triggered by hyperglycemia have been identified and proposed as causative mechanisms: increases in the polyol and hexosamine pathways, production of advanced glycation end-products (AGEs), and activation of protein kinase C (PKC). *In vivo* studies with inhibitors, either in animal models or in human subjects, have supported a role for each of these pathways (except the recently implicated hexosamine pathway) in microvascular pathology. The relative contribution of each of these proposed mechanisms likely varies across cell types.

While mechanisms exist for hyperglycemia to directly activate each of the four potential microvascular pathogenic pathways, they may also be activated by the hyperglycemia-induced overproduction of superoxide. The increased metabolism of glucose in the presence of hyperglycemia increases the delivery of electron donors from the tricarboxylic acid (TCA) cycle to mitochondria. This can lead to an increase of the proton gradient across the inner mitochondrial membrane, inhibiting the electron transport chain and increasing superoxide production. Because superoxide inhibits the glycolytic enzyme glyceraldehyde 3-phosphate dehydrogenase (GAPDH), precursors (as noted) can accumulate and be diverted into the polyol pathway (glucose), the hexosamine pathway (fructose-6-phosphate), production of DAG (glyceraldehyde-3-phosphate) which activates PKC isoforms, and production of the reactive dicarbonyl methylglyoxal (glyceraldehyde-3-phosphate) which produces AGEs.

Polyol Pathway Hyperglycemia drives an increased intracellular generation of sorbitol through the NADPH-dependent reduction of glucose by aldose reductase. Increased production of sorbitol could alter cellular functions in a number of ways, including increasing intracellular osmotic stress, decreasing myoinositol and taurine (as compensation for the increase in sorbitol in order to prevent or mitigate an increase in osmolarity), or through an increased NADH/NAD^+ ratio (due to NAD^+-dependent oxidation of sorbitol to fructose). However, the most likely mechanism for cellular dysfunction caused by increased flux through the polyol pathway is due to the consumption of NADPH.

This leads to a lack of NADPH available to regenerate reduced glutathione, limiting the ability of the cell to protect itself against oxidative stress.

Hexosamine Pathway The hexosamine pathway generates UDP-*N*-acetylglucosamine (GlcNAc) from glucose to provide substrate for proteoglycan synthesis and for O-linked glycosylation of certain proteins. The activity or function of many proteins, including transcription factors, can be modified by O-linked glycosylation, often in concert with reciprocal modification by phosphorylation. With hyperglycemia, some of the excess glucose is shunted into the hexosamine pathway. As noted previously, increased flux through this pathway may play a role in insulin resistance. In addition, increased generation of UDP-GlcNAc could alter gene expression and cellular function through excess protein glycosylation, contributing to the pathogenesis of microvascular disease.

Advanced Glycation End-Products Glucose will react with free amino groups on proteins in a nonenzymatic reaction to form glycated proteins. This reaction starts with the formation of a Schiff base (aldamine), which then undergoes an internal Amadori rearrangement. The formation of the Schiff base is rapid and reversible, while the Amadori rearrangement is much slower and results in a more stable ketoamine. This process occurs at a rate proportional to the prevailing glucose level that a given protein is exposed to. The glycation of hemoglobin is used clinically to estimate the average blood sugar in patients with diabetes, as the percent of hemoglobin in the glycated A_{1C} form (HbA_{1C}) is proportional to the average glucose level present over ~3 months prior to testing (roughly the red blood cell life span).

Proteins modified irreversibly through nonenzymatic reaction with glucose or glucose-derived compounds are referred to as advanced glycation end-products (AGEs). Most AGEs are not formed through the reaction of proteins directly with glucose but rather with three reactive dicarbonyl compounds that are produced intracellularly from glucose: glyoxal (an auto-oxidation product of glucose), 3-deoxyglucasone (formed from decomposition of the Amadori product of glucose), and methylglyoxal (from fragmentation of glyceraldehyde-3-phosphate and dihydroxyacetone phosphate generated from glycolysis). The reactive dicarbonyls interact with the amino groups of proteins, and can introduce both intra- and intermolecular cross-links. AGE formation may lead to microvascular damage through alteration of the function of both intracellular and extracellular proteins modified in this way. In particular, the modification of extracellular matrix proteins by this process is likely to contribute to abnormal vascular permeability and elasticity. In addition, however, AGEs formed from plasma proteins bind to and activate specific AGE receptors on endothelial cells, mesangial cells, and macrophages, (one such receptor is RAGE, a member of the immunoglobin superfamily). Activation of AGE receptors induces production of cytokines, growth factors, procoagulatory factors, and reactive oxygen species. Induction of vascular endothelial growth factor (VEGF) by AGE receptor activation most likely contributes to the increased permeability of capillary walls present in diabetes.

Activation of PKC Hyperglycemia increases intracellular diacylglycerol (DAG) levels, which is an activator of many of the PKC isoforms. Hyperglycemia may also activate PKC isoforms indirectly by increasing reactive oxygen species from activation of AGE receptors and from increased activity of the polyol pathway. As discussed above, activation of PKC may play a role in hyperglycemia-induced insulin resistance. Mechanisms through which activation of PKC may be involved in the development of microvascular disease include: inhibiting production of the vasodilator nitric oxide; increasing activity of the vasoconstrictor endothelin-1; increasing expression of VEGF, leading to increased cell permeability; and contributing to the accumulation of extracellular matrix protein by inducing expression of TGF-β1, fibronectin, and type IV collagen.

Diabetes Treatment Medications – Mechanisms of Action

Patients with diabetes of any type can be treated with insulin to overcome the relative or absolute insulin deficiency. For patients with type 1 diabetes, the loss of the ability to produce endogenous insulin because of the loss of pancreatic β-cells makes insulin the only treatment option. Similarly, in many patients with type 2 diabetes, the β-cell dysfunction will progress to a degree that insulin treatment is necessary to maintain glycemic control. However, for many patients with type 2 diabetes, a number of treatments may be effective in lowering the degree of hyperglycemia.

Weight Loss and Exercise

For the majority of patients with type 2 diabetes, obesity is a significant contributor to the insulin resistance that underlies their disease. Therefore, in many cases, if the patient is able to lose weight, insulin sensitivity will improve sufficiently to return metabolic control to normal or near normal. In many cases, only modest weight loss can be effective. A sedentary lifestyle also leads to decreased insulin sensitivity. Therefore, exercise

to improve fitness can also improve insulin sensitivity sufficient to ameliorate the diabetic state, an effect that can occur in the absence of weight loss. AMP-activated kinase (AMPK) functions as an intracellular energy sensor. During exercise, activation of AMPK increases glucose uptake into muscle by stimulating GLUT4 translocation to the plasma membrane in a noninsulin receptor dependent pathway. In addition, the exercise-stimulated activation of AMPK may lead to a prolonged increase in insulin sensitivity by increasing expression of GLUT4, and increasing the insulin sensitivity of the liver.

Insulin Secretagogues

Sulfonylureas and the newer meglitinide analogues lower blood sugar levels by stimulating endogenous insulin secretion. They act by binding to the sulfonylurea receptor (SUR) – one component of the β-cell potassium channel, the other being $Kir_{6.2}$. Binding of these agents to SUR results in closure of the potassium channel, mimicking the effect of a glucose-driven increase in the cellular ATP/ADP ratio, and setting in motion the intracellular signal for exocytosis of insulin. Unfortunately, due to the worsening β-cell dysfunction in most patients with type 2 diabetes, insulin secretagogues often become ineffective over time.

Metformin

Metformin is a biguanide compound that works by increasing insulin sensitivity in diabetic patients. Its main effect is on the liver, to decrease excess hepatic glucose production. The underlying mechanism for metformin's action has not been fully determined. However, it appears to function by activating AMPK. By activating AMPK, the hepatocyte shifts from lipogenesis to fatty-acid oxidation. This reduces hepatic triglyceride content, which has been implicated in the cause of insulin resistance. How metformin activates AMP-kinase is uncertain, but may involve inhibition of the mitochondrial electron transport chain.

Thiazolidinediones

Thiazolidinediones (TZDs) are a second class of insulin-sensitizing drugs. In contrast to metformin, however, their primary action is to increase peripheral insulin sensitivity, increasing glucose uptake into fat and muscle. TZDs are ligands for the peroxisome proliferator-activated receptor-γ (PPAR-γ), which is expressed in high levels only in adipose tissue, although low levels of expression are seen in other tissues, including in muscle, liver, and pancreatic β-cells. PPAR-γ is a transcription factor that alters gene expression in a ligand-dependent manner. The importance of PPAR-γ in the pathophysiology of diabetes is highlighted by the fact that individuals homozygous for a common amino acid polymorphism (Pro12Ala) in the *PPAR*γ gene are more insulin resistant and have an increased risk of diabetes than individuals with one Ala12 allele. The ability of PPAR-γ to improve overall carbohydrate control in spite of the fact that adipocytes are responsible for a relatively minor fraction of insulin-stimulated glucose uptake compared to muscle may be due to direct effects of TZDs on muscle. However, it is most likely that TZDs exert their effect by altering gene expression in adipocytes, which leads to improved insulin action in muscle and liver.

α-Glucosidase Inhibitors

Acarbose and miglitol inhibit the intestinal enzyme α-glucosidase. Given with meals, this delays carbohydrate absorption, leading to a requirement for a lower maximal insulin level to dispose of the absorbed carbohydrate. These drugs do not significantly affect fasting glucose levels, and so are generally ineffective as single agent therapy. However, there is accumulating information demonstrating the importance of controlling postprandial hyperglycemia to minimize long-term diabetic complications.

Glossary

β-cell The insulin producing cells in the Islets of Langerhans.

glucose disposal The removal of glucose from the blood, usually in the context of its removal after having been added, as after absorption of a carbohydrate-containing meal.

glucose intolerance The condition where the concentration of glucose in the blood after ingestion of carbohydrate is elevated above normal; may also refer more generally to a condition associated with hyperglycemia.

hyperglycemia An abnormally elevated concentration of glucose in the blood.

kinase An enzyme that modifies a substrate through the addition of a phosphate group.

osmotic diuresis An increase in urine output stimulated by an increase in osmotically active solute in the urine; in diabetes, the solute is glucose.

phosphatase An enzyme that modifies a substrate through the removal of a phosphate group.

prandial Meal associated.

Diacylglycerol Kinases and Phosphatidic Acid Phosphatases

Stephen M. Prescott and Matthew K. Topham
Huntsman Cancer Institute, University of Utah, Salt Lake City, Utah, USA

Diacylglycerol (DAG) is an important lipid that initiates specific intracellular signaling events. The majority of signaling DAG is generated by hydrolysis of phosphatidylinositol-4,5-bisphosphate (PIP_2) by the enzyme phospholipase C (PLC). DAG activates protein kinase C (PKC) isoforms, binds to and activates the RasGRP nucleotide exchange factors, and recruits the chimaerins, which are Rac GTPase activating proteins (GAPs), to membrane compartments. Because DAG can modulate a plethora of signaling events, it is crucial that intracellular DAG levels be tightly regulated. Though DAG can be metabolized in various ways, under most circumstances its major route for metabolism is by its phosphorylation (Figure 1), a reaction that is catalyzed by the diacylglycerol kinases (DGKs).

The Diacylglycerol Kinases

Nine mammalian DGK isoforms have been identified (Figure 2). The heterogeneity of the gene family is similar to the PKC and PLC families, suggesting that the DGKs are not simply lipid biosynthetic enzymes, but that they also have signaling roles, since enzymes involved in biosynthetic pathways usually do not have extended families. One or only a few DGK isoforms have been identified in organisms such as *Caenorhabditis elegans*, *Drosophila melanogaster*, and *Arabidopsis thaliana*, and no DGK gene has been identified in yeast. The structural diversity of DGKs in mammals suggests that they may have roles in processes specific to higher vertebrates.

DGK isoforms are categorized based on shared structural motifs. All DGK isoforms have a catalytic domain that is necessary for kinase activity. In most cases, the catalytic domain is a single motif, but DGKs δ and η have bipartite catalytic domains. All DGKs have at least two cysteine-rich regions homologous to the C1A and C1B motifs of PKCs. In theory, these domains may bind DAG, perhaps localizing DGKs to where DAG accumulates. However, no DGK C1 domain has so far been conclusively shown to bind DAG. Structural predictions suggest that most DGK C1 domains may not bind DAG, and most DGKs tested are unable to bind long-lived DAG-like analogues. Houssa and van Blitterswijk noted that in DGKs, the C1 domain closest to the catalytic domain is highly conserved, including an extended motif of 15 amino acids not present in other C1 domains. Conserved residues in this extended motif have been shown to be critical for DAG kinase activity. Together, these data suggest that DGK C1 domains are structurally different from C1 domains in other proteins and that the different C1 domains of a single DGK isoform may have unique functions. Distinct functions of individual C1 domains remain to be definitively demonstrated.

In addition to the C1 and catalytic domains, other regulatory domains are used to group the DGKs into five subfamilies. Type I DGKs have calcium-binding EF hand motifs and have been shown to be more active in the presence of calcium. Type II DGKs have a pleckstrin homology (PH) domain at their amino termini. This domain in DGKδ has been shown to bind weakly and nonselectively to phosphatidylinositols (PIs). DGKδ also has a sterile alpha motif (SAM domain) at its C-terminus that helps localize it to the endoplasmic reticulum (ER). DGKε, a type III enzyme, has an unusual specificity toward acyl chains of DAG, strongly preferring a specific fatty acid – arachidonate – at the *sn*-2 position. This preference suggests that DGKε may be a component of the biochemical pathway that accounts for the enrichment of phosphatidylinositols with arachidonate. Type IV DGKs have a MARCKS phosphorylation domain and, at their C-termini, four ankyrin repeats. The type V enzyme, DGKθ, has three C1 domains and a PH domain.

Regulation of DGK Activity

Activation of the DGKs is complex and unique for each DGK isotype. In most cases, DGKs must translocate to a membrane compartment to access DAG. In addition, their activity can be modified by appropriate cofactors, and several DAG kinases are also regulated by

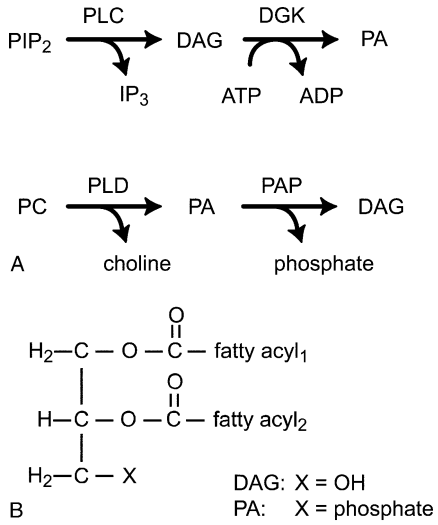

FIGURE 1 (A) Different enzymatic pathways can produce diacylglycerol (DAG) and phosphatidic acid (PA). Phosphatidylinositol-specific PLC enzymes generate DAG that can be phosphorylated by DGKs to produce PA. In another pathway, phospholipase D (PLD) hydrolyzes phosphatidylcholine (PC) – or phosphatidylethanolamine – making PA that can be further hydrolyzed by PAPs to generate DAG. (B) DAG and PA have the same general structure but contain different functional groups attached to the third (*sn*-3) carbon. Depending on their molecular structure, the fatty acyl groups confer different signaling properties to the DAG or PA.

post-translational modifications. Finally, tissue-specific alternative splicing of DGKs β, δ, and ζ, and probably other isotypes, allows additional opportunities for regulation. This complexity permits tissue- or cell-specific regulation of each DGK isotype, depending on the availability of cofactors and the type of stimulus that the cell receives.

DGKα is an example of the contextually dependent differential regulation of DGKs. DGKα translocates to at least two different membrane compartments in T lymphocytes depending upon the agonist used to activate the cells: from the cytosol to a perinuclear region in T cells stimulated with IL-2, and to the plasma membrane upon activation of the T cell antigen receptor. Once at a membrane compartment, the DAG kinase activity of DGKα can be modified by the availability of several cofactors. Calcium is known to bind to EF hand structures and stimulates DGKα activity *in vitro*. Lipids also modify its activity: phosphatidylserine and sphingosine activate DGKα *in vitro* and likely *in vivo* as well. Finally, DGKα can be phosphorylated by several protein kinases including some PKC isoforms and Src kinase, which may enhance its DAG kinase activity.

Like DGKα, other DGK isotypes appear to be sensitively regulated. For example, type II DGKs have a PH domain that may help localize these DGKs, modify their activity, or allow binding to other proteins. The PH domain of the type II DGKδ binds phosphatidylinositols but its DAG kinase activity is not affected by these lipids. In contrast, the activity of DGK types III and IV can be modified by phosphatidylinositols and by phosphatidylserine, sometimes in opposing ways. For example, the type III enzyme, DGKε, is inhibited by, whereas type IV DGKs are activated by, phosphatidylserine. Type IV DGKs are strongly regulated by subcellular translocation. These enzymes have a nuclear localization signal that is regulated by PKC phosphorylation, and there is evidence that the syntrophin family of scaffolding proteins further regulates their subcellular location by anchoring them in the cytoplasm. Finally, DGKθ, a type V DGK, can be regulated through its association with active RhoA, which abolishes its DAG kinase activity and is the only known example of direct regulation of a DGK activity through a protein–protein interaction. Thus, depending on the context of activation, the availability of cofactors, and the activation state of protein kinases, DGKs can be differentially regulated.

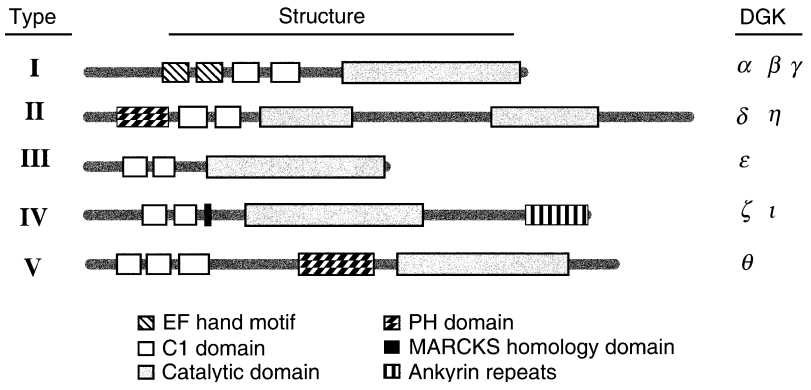

FIGURE 2 The mammalian DGK family. Based on structural motifs, the nine mammalian DGKs are divided into five subtypes. Alternative splicing of some DGK isotypes generates even more structural diversity. Many of the DGKs contain other unique structural domains of unclear significance that are not shown.

Activity of DGKs is Compartmentalized

Evidence suggests that DGK activity is restricted to the area of localized DAG pools generated after activation of receptors. This concept was initially tested in 1994 by Van der Bend *et al.*, who detected DGK activity in cells following receptor activation but could not detect significant DAG kinase activity after treating the cells with exogenous PLC, which caused global, nonspecific DAG generation. Their data suggest that DGKs are active only in spatially restricted compartments following physiologic generation of DAG.

We are only beginning to understand the complexities of spatially restricted DGK function. Several DGKs localize to the cytoskeleton, where they may participate in regulating cytoskeletal dynamics. Investigators have noted that DGK activity associates with a complex of proteins including PI5K, Rac, Rho, Cdc42, and Rho-GDI, all of which regulate cytoskeleton dynamics. Houssa *et al.* showed that RhoA associates with DGKθ – but only when RhoA is in its active form – and that this interaction abolished DGK activity. RhoA appears to bind the catalytic domain of DGKθ, which likely leads to the disruption of DAG kinase activity. DGKζ localizes at the leading edge and cell extensions of glioblastoma cells and can disrupt cell spreading when overexpressed. It and several other DGK isotypes co-immunoprecipitate with Rho family proteins when overexpressed in cells. The physiologic significance of these interactions is not clear, though together, these data suggest that DGKs likely have a role in regulating the cytoskeleton.

In the nucleus, a distinct nuclear phosphatidylinositol cycle is regulated separately from its plasma membrane/cytosolic counterpart. The function of DAG produced in the nucleus has received little attention, but data clearly indicate that in most cases it acts to promote cell growth independently of plasma membrane DAG. For example, some growth factors (e.g., IGF-1) can stimulate a pulse of nuclear DAG without causing a measurable change in extranuclear DAG, and several groups have demonstrated that nuclear DAG fluctuates independently of extranuclear DAG during the cell cycle. Nuclear DAG was shown to peak shortly before S phase, suggesting that it may participate in the G1/S transition. Supporting this conclusion and emphasizing the importance of DAG signaling in the cell cycle, we demonstrated that when a nuclear DGK was overexpressed, cells accumulated at the G0/G1 transition, presumably because the kinase attenuated the nuclear DAG concentration. Within the nucleus, DAG signaling, like its extranuclear counterpart, appears to be compartmentalized. For example, in 1999 D'Stantos *et al.* demonstrated independently fluctuating pools of nuclear diacylglycerol with distinct fatty acid compositions, strongly suggesting the existence of multiple, differentially regulated pools of nuclear DAG.

DGKs are present in nuclei and appear to have prominent and specific roles there. DGKs α, ζ, and ι, translocate to the nucleus, while a fraction of DGKθ is localized there constitutively. Different DGK subtypes are confined to specific, separate compartments within the nucleus, suggesting specificity in their nuclear roles. For example, DGKα associates with the nuclear envelope, while DGKθ and DGKζ are found in discrete regions within the body of the nucleus. Evidence suggests that DGKs likely affect nuclear signaling either by terminating DAG signals or by generating PA. For example, nuclear DGKζ inhibits progression from G1 to S phase of the cell cycle, likely by metabolizing DAG. Conversely, in T lymphocytes, PA generated by nuclear DGKα appears to be necessary for IL-2-mediated progression to S phase of the cell cycle. Thus, DGKα and DGKζ appear to have opposing roles in the nucleus, reflecting the complexity of lipid signaling and DGK activity there.

Coupling of DGKs with Other Signaling Proteins

Recent evidence suggests that in addition to acting locally at sites of DAG pools, DGKs can specifically associate with and regulate signaling proteins that are activated by either DAG or PA. For example, DGKζ associates with and inhibits RasGRP1, a guanine nucleotide-exchange factor for Ras that requires DAG to function. This regulation may be selective: five other DGK isotypes did not significantly inhibit RasGRP1 activity. In *Caenorhabditis elegans*, Nurrish *et al.* found that *dgk-1*, an ortholog of human DGKθ, regulates DAG signaling that is necessary for acetylcholine release. Combined, these data demonstrate that DGK activity is not only targeted at sites of DAG production, but is also specifically directed toward a subset of DAG-activated proteins.

PA as a Signal

The DGK reaction is of special interest because it removes one signaling molecule, DAG, while generating another, phosphatidic acid (PA). PA can stimulate DNA synthesis and is potentially mitogenic. It modulates the activity of several enzymes, including phosphatidylinositol 5-kinases (PI5Ks), PAK1, Ras-GAP, and PKCζ, and it has a prominent role in vesicle trafficking. At the plasma membrane, PA also helps recruit Raf to the Ras signaling complex. Although phospholipase D (PLD)

generates the bulk of signaling PA (Figure 1), DGKs likely also contribute to its intracellular concentration.

The PA species generated by DGK and PLD reactions are distinct from each other by virtue of their initial substrates. Phosphatidylcholine, which is largely composed of saturated and mono-unsaturated fatty acids is the predominant substrate of PLD, while PA produced by DGKs is derived from DAG that is enriched in polyunsaturated fatty acids – particularly arachidonate. There is good evidence that each PA species – saturated and unsaturated – can differentially activate targets. For example, saturated PA species induce MAPK activation to a greater extent than unsaturated PAs; Flores and colleagues presented evidence that the PA produced by DGKα was necessary for stimulated T lymphocytes to progress to S phase of the cell cycle. Thus, DGKs can influence signaling events either by metabolizing DAG or by generating PA.

PA Conversion to DAG by PA Phosphatase

Just as PA can be generated by more than one enzymatic pathway, DAG is also the product of several enzymatic reactions. The PLC reaction is generally thought to be the major route to generate signaling DAG, but some lipid phosphate phosphatases (LPPs) can also produce DAG by dephosphorylating phosphatidic acid (Figure 1). Most LPPs are integral membrane proteins thought to act on extracellular lipids, but some of them are clearly intracellular proteins. Type I LPPs specifically dephosphorylate phosphatidic acid and are also known as PA phosphatases (PAPs). Though their cDNAs have not been cloned and the proteins have not been purified to homogeneity, PAPs are known to be cytosolic proteins that can translocate to membrane compartments. Historically, PAP activity is thought to be coupled with PLD activity to generate DAG. But very little published work supports that this DAG can initiate signaling. Due to the identity of its precursor, DAG generated by PAP activity is composed of predominantly saturated fatty acids, and like PA, the signaling properties of DAG depend on these fatty acid components. Evidence suggests that DAG composed of saturated fatty acids – like that produced by PAP activity – has weak signaling properties compared to unsaturated DAG. Thus, PAPs are not thought to initiate DAG signaling. Instead, PAPs may terminate PA signals that were initiated by phospholipase D. It is possible that PAP activity could couple with DGK activity to regenerate unsaturated DAG that could initiate signaling, but no one has demonstrated that this cycle exists. Thus, PAPs theoretically could contribute to DAG signaling but evidence is lacking that they do so; it is generally agreed that PAP activity is coupled with PLDs and not DGKs.

Conclusions

As evidence accumulates, it is apparent that the structural diversity of DGK isoforms mirrors the range of functions and sites of action of these enzymes. Further studies of the regulation of lipid signaling should reveal additional roles for DGKs and more precise information about their regulation. Phosphatidic acid phosphatases, in contrast, appear to be a less diverse family of enzymes that are coupled to PLD activity.

Glossary

diacylglycerol A lipid composed of a glycerol backbone with fatty acids attached by ester bonds to its first (*sn-1*) and second (*sn-2*) carbons.

fatty acid Monobasic acids containing long hydrocarbon chains that can be either saturated (no double bonds) or unsaturated (one or more double bonds).

phosphatidic acid Diacylglycerol with a phosphate group attached to the third (*sn-3*) carbon of the glycerol backbone.

phosphatidylinositol Phosphatidic acid with an inositol group attached to the phosphate.

phospholipid The major structural lipids of most cellular membranes. They contain one or more phosphate groups and, if derived from glycerol, are known as phosphoglycerides.

Stephen M. Prescott is the Executive Director of the Huntsman Cancer Institute at the University of Utah in Salt Lake City. His research explores the enzymes that generate lipid signals for growth and differentiation, and the role that they play in cancer. Another major area of interest is how inflammation is regulated.

Matthew K. Topham is an Assistant Professor of Internal Medicine at the University of Utah and an Investigator at the Huntsman Cancer Institute. He studies lipid signaling in cancer and is particularly interested in the diacylglycerol kinases and cyclooxygenases.

Disulfide Bond Formation

Hiram F. Gilbert
Baylor College of Medicine, Houston, Texas, USA

Disulfide bond formation is a posttranslational protein modification that introduces a covalent cross-link between the sulfhydryl groups of specific cysteine residues. Biologically, disulfide bonds are most often used to increase the conformational stability of extracellular proteins, but disulfides may also serve catalytic or regulatory roles through their effects on protein structure. Disulfide bonds are formed as the protein folds into its correct biological structure. Elaborate quality control systems in the bacterial periplasm and eukaryotic endoplasmic reticulum assure that correct disulfides are formed as the proper conformation is achieved.

Chemistry of Disulfide Formation as a Posttranslational Modification

Disulfide Formation

Extracellular and secreted proteins often contain many disulfides, with pairs of cysteines linked to each other in a specific configuration in the folded protein (Figure 1). Biochemically, disulfide formation is an oxidation (the loss of electrons). Not all of the cysteines in a protein form disulfides. Disulfides form only when the structure of the protein places two cysteines in the proper spatial location and when an oxidizing agent is available. The chemical reaction is reversible, and high concentrations of a reductant can reverse or prevent disulfide formation.

Disulfide Rearrangements

Through a chemical process called thiol-disulfide exchange, one disulfide may serve as an oxidizing agent to form a disulfide between two different cysteines (Figure 2). If this leads to connecting the cysteines in a different configuration, it is termed disulfide isomerization.

Oxidative Protein Folding

Since many disulfides will be buried in the core of the protein and link cysteines that are not adjacent in sequence, disulfide formation and rearrangements often occur as the protein attains a three-dimensional structure (protein folding). The coupling of disulfide formation and protein folding is termed "oxidative protein folding."

Structure is Linked to Disulfide Formation

In the 1960s, Anfinsen and his colleagues used the reversible nature of disulfide formation to demonstrate that the primary sequence of a protein contains sufficient information to define the final, biologically active structure of a protein. Disulfide bonds stabilize protein structure by organizing and destabilizing the denatured protein relative to the native structure. Usually, both the disulfides and noncovalent interactions (hydrophobic interaction, hydrogen bonds, etc.) are needed to specify the structure of ribonuclease A (RNase). Reducing the disulfides or using urea to disrupt the noncovalent structure causes a loss in biological activity. After removing the urea and including an oxidizing agent to reform the disulfides, the protein spontaneously refolds, forming the correct disulfides and a biologically active structure. However, if disulfide formation is permitted without removing the urea, random disulfides form (scrambled RNase) and there is no regain of biological activity. If disulfide formation is inhibited (by including a reducing agent), the native structure does not form when the urea is removed. Disulfide bonds are essential for forming the native structure but when the noncovalent structure is disrupted by denaturants disulfides are usually not sufficient to specify the tertiary structure.

Disulfide Bond Formation during Protein Folding

Even with two disulfides, there are numerous ways to connect the cysteines (Figure 3), and the problem increases greatly as the number of disulfides to be formed increases. Early in protein folding, disulfide formation tends to be error-prone. Two types of

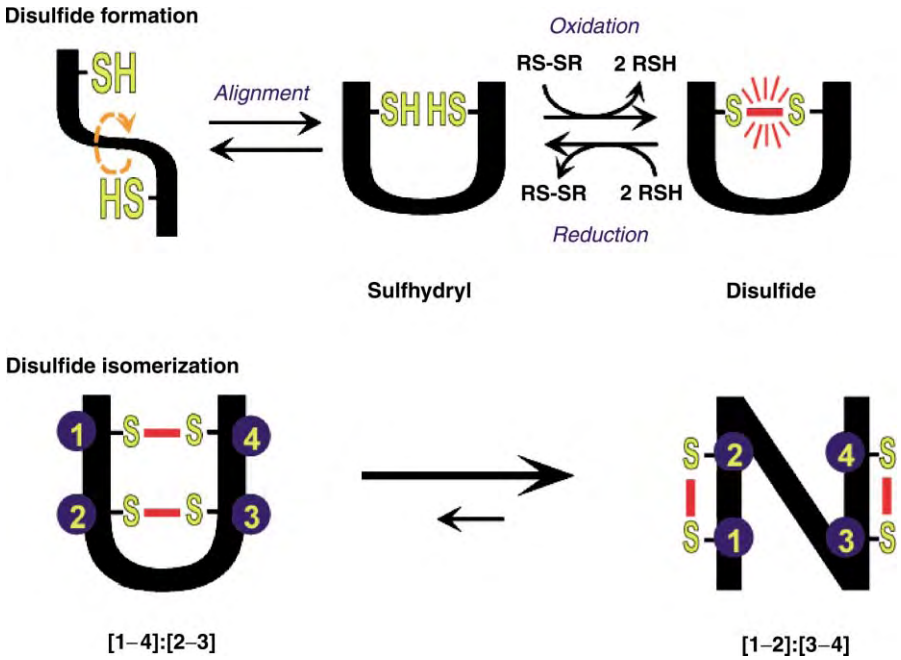

FIGURE 1 Disulfide formation and isomerization. An alignment step is needed to bring two sulfhydryl groups from cysteine residues into close proximity. Disulfide formation represents an oxidation where the electrons from disulfide formation must be transferred to an oxidizing agent. Disulfide isomerization does not formally require a change in the oxidation state of the protein; however, a thiol group is needed to initiate and propagate the change in disulfide connectivity.

error have been found: disulfides may be formed between the wrong pairs of cysteines or the correct cysteines may be paired but in a temporal order that interferes with the assembly of the rest of the structure. In both cases, the incorrect disulfides are replaced with correct ones through disulfide isomerization. In the cases examined so far, many incorrect disulfides accumulate early in oxidative folding. These are slowly replaced by correct disulfides through isomerization which requires the breaking and reforming of disulfide bonds.

Catalysis of Disulfide Formation

Soon after discovering that native proteins can be regenerated from reduced, denatured ones, Anfinsen realized that *in vitro* oxidative folding was often too

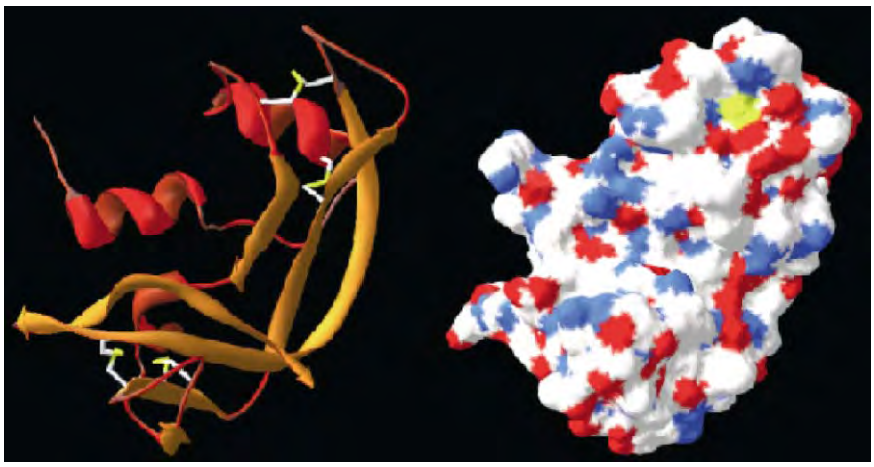

FIGURE 2 Structure of disulfide bonds. (Left) Disulfide bonds cross-link cysteines in various parts of the protein structure. (Right) Some disulfides (yellow) are exposed to solution in the tertiary structure of the protein but others are buried in the core of the protein and not exposed to solution.

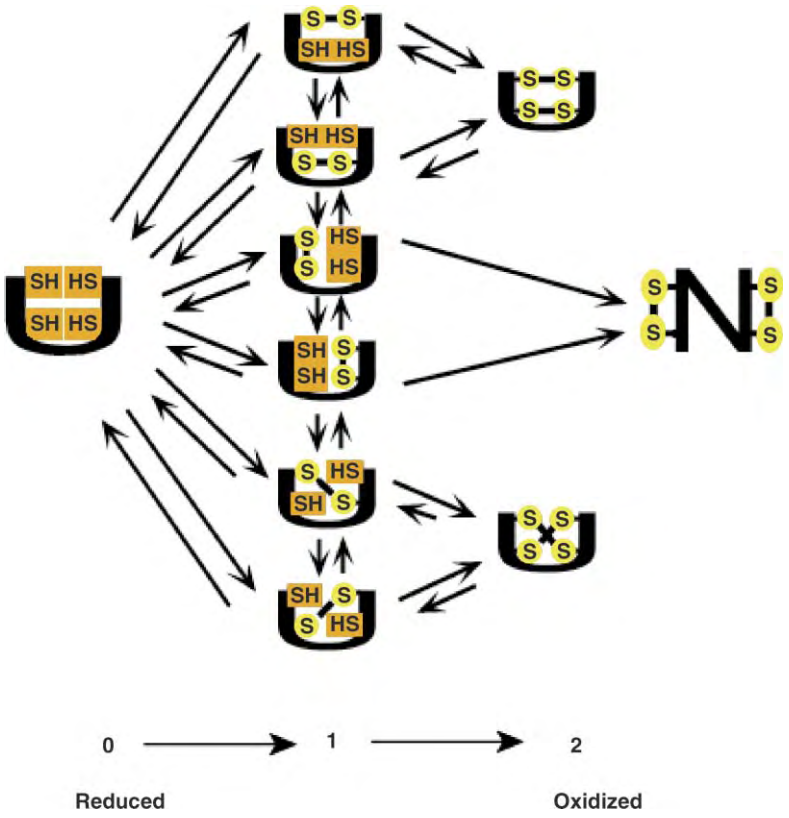

FIGURE 3 Generalized mechanism of oxidative protein folding. The initial stages of oxidative folding are error-prone and often lead to the connection of cysteines that are not connected in the native structure. Different proteins will generate a different population of misoxidized species which are converted to the native structure (N) by disulfide bond isomerization.

slow (hours to days) to be biologically relevant. The resulting search for a biological catalyst for oxidative folding led to the discovery of the first catalyst of protein folding, protein disulfide isomerase (PDI).

Protein Disulfide Isomerase

PDI accelerates the regain of native structure by catalyzing the formation of disulfide bonds and by providing a way to correct mistakes in connecting cysteines. PDI is an enzyme that has both oxidase (disulfide formation) and isomerase (disulfide rearrangement) activities. PDI accelerates thiol/disulfide exchange reactions (Figure 1) with proteins and small-molecule substrates. The final outcome of the reaction will depend on the redox conditions. The catalytic sites are contained in two thioredoxin homology domains located at each end of the PDI molecule. These active sites, both with the sequence CGHC, have the correct redox potential to effectively catalyze oxidation, reduction, and exchange reactions under the redox conditions of the endoplasmic reticulum. PDI interacts with its protein substrates but in a way that does not direct which cysteines are connected in the substrate. The mechanism involves several rounds of making and breaking disulfide bonds until the final structure becomes resistant to further isomerization of its disulfides.

The Thioredoxin Family

Many of the thiol–disulfide exchange reactions of the cell are mediated by members of the thioredoxin family. This large family of proteins is characterized by an active site sequence of CXXC and an α–β secondary structure. The structure greatly affects the redox potential for reducing the active site disulfide. Thioredoxin, the patriarch of the family, is an excellent reducing agent involved in the biosynthesis of deoxyribonucleotides for DNA synthesis and in helping maintain reduced proteins in the cellular cytoplasm. DsbA, a periplasmic oxidase in bacteria is an excellent oxidizing agent that inserts disulfides into secreted proteins. The ease of forming the CXXC disulfide varies by a factor of over 10^5, corresponding to a redox potential difference of more than 0.15 V.

Disulfide Formation in the Cell

Disulfide bond formation state is influenced by the thiol/disulfide redox environment of the cellular compartment where the protein is located. Most disulfides are found in secreted or extracellular proteins where the environment is oxidizing. Generally, the cytoplasm of most cells, bacterial and eukaryotic, is very reducing, due to the high concentration of glutathione (GSH, a tripeptide, γ-glutamylcysteinylglycine) and the low concentration of glutathione disulfide.

Extracellular Proteins

Proteins destined for the extracellular environment acquire disulfides after they are secreted from the cytoplasm during translation. In bacteria, an elaborate system of periplasmic and membrane-bound proteins, comprising the Dsb system, provides the periplasm with oxidizing equivalents to enable disulfide formation and reducing equivalents and catalytic isomerases to correct errors during protein folding (Figure 4). DsbB couples the bacterial electron transport system to disulfide formation, providing a source of oxidizing agent which are delivered directly to folding proteins by DsbA. Reducing equivalents to enable disulfide isomerization are provided by thioredoxin in the cytosol and transferred across the inner bacterial membrane by DsbD to DsbC, the periplasmic isomerase.

A similar system operates in eukaryotic cells, although all the elements of the system have not been found. Extracellular proteins are synthesized on the rough endoplasmic reticulum and translocated into the lumen (inside) during translation. The lumen of the endoplasmic reticulum is a more oxidizing intracellular compartment than the cytoplasm. Oxidizing equivalents are transferred from Ero1 to PDI and then to the folding proteins. The ultimate source of the oxidizing agent is not yet known. Reducing agents of the endoplasmic reticulum enable PDI and other catalysts to correct any errors in pairing cysteines by reducing the incorrect disulfide bond. Reducing agents are provided by glutathione, presumably by importing GSH from the cytoplasm. The endoplasmic reticulum has an elaborate quality control mechanism, which prevents misfolded proteins from exiting the endoplasmic reticulum or directs them to degradation pathways. The error-correction activity of PDI plays a critical role in this system. Depending on the details of the folding mechanism dictated by the primary sequence, different extracellular proteins may use different components of the complex folding and quality control apparatus of the endoplasmic reticulum to gain their correct three-dimensional structure, including the disulfide bonds that stabilize the structures.

Disulfide Formation as a Regulatory Mechanism

Because disulfide bond formation is reversible, disulfide bonds can also regulate biological activity through their ability to stabilize specific protein structures. For example, the bacterial transcription factor, OxyR, senses the redox environment of the aerobic bacterial cell

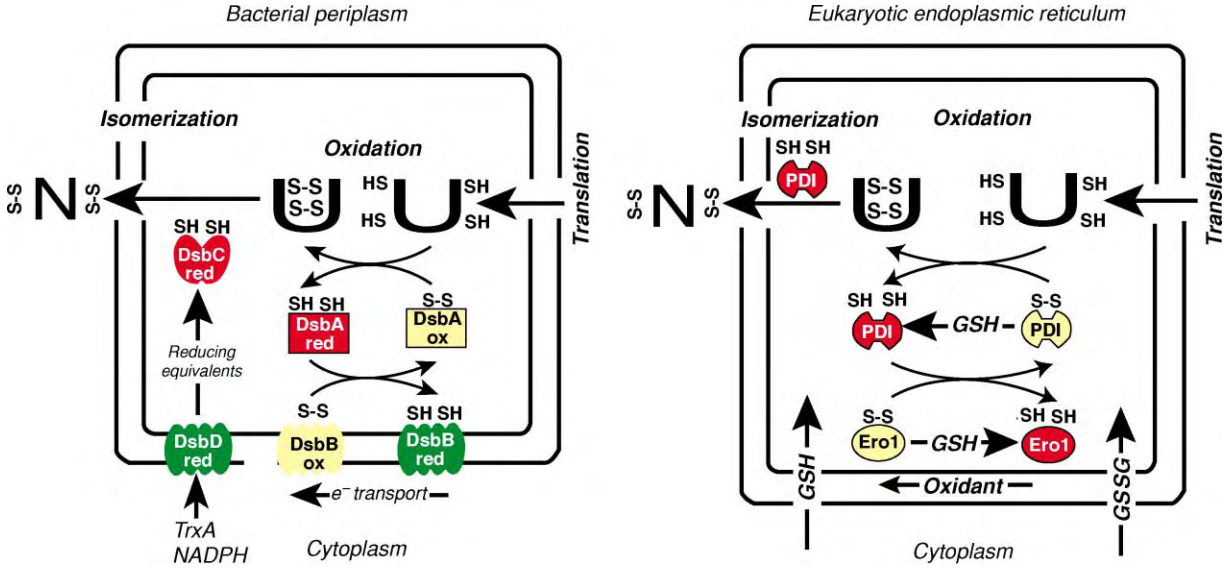

FIGURE 4 Disulfide bond formation in bacterial and eukaryotic cells. In both cells, the major pathways for disulfide formation are located in specialized cellular compartments where the redox state of the environment is maintained in a more oxidized state than the cytosol.

through reversible disulfide bond formation linked to the cellular redox state and oxygen metabolism. Reduced OxyR is inactive as a transcription factor and upon oxidation and disulfide formation, the transcription factor can regulate the transcription of genes involved in the protection of the cell against oxidative stress and reactive oxygen species. Similar mechanisms operate in eukaryotic cells.

Glossary

bacterial periplasm A specialized compartment in between the inner and outer membrane of bacteria. Disulfide formation occurs in this compartment.

disulfide bond A covalent bond between two sulfhydryl groups. In proteins, this bond covalently connects the sulfur atoms of two cysteine residues.

endoplasmic reticulum A specialized compartment of eukaryotic cells in which extracellular proteins are processed for secretion or inclusion in other cellular compartments.

glutathione (GSH) A tripeptide, γ-glutamylcysteinylglycine found at high concentrations in cells. It is the major thiol compound in most cells involved in redox reactions and the protection of cells against reactive oxygen species and toxic compounds.

oxidation Disulfide bond formation (formally, the loss of electrons) oxidation.

oxidative folding The coupling of disulfide formation to the folding of a protein into its correct three-dimensional structure. Disulfides stabilize protein structure and *vice versa*.

protein folding The process by which an unfolded protein gains its three-dimensional structure.

reduction Formally, the gain of electrons. Disulfide bonds are reduced to two thiols.

thiol A sulfhydryl (–SH) group.

DNA Base Excision Repair

Hilde Nilsen and Tomas Lindahl
Cancer Research UK, London Research Institute, London, UK

DNA decomposes spontaneously as a result of chemical modifications inflicted by water and reactive by-products of normal aerobic metabolism. This spontaneous DNA base damage has both mutagenic and cytotoxic consequences. The quantitatively most important classes of such endogenous DNA damage are (1) loss of the purine bases guanine (G) and adenine (A) due to hydrolysis of the *N*-glycosyl bond between the DNA base and the backbone, leaving an abasic (AP) site in the DNA; (2) hydrolytic deamination of cytosine (C) and 5-methylcytosine (5-mC) to generate U:G and T:G base pairs, respectively; (3) formation of base oxidation products by reactive oxygen species, the most studied being 8-hydroxyguanine (8-oxoG) and ring-saturated pyrimidines, such as thymine glycol (Tg); (4) methylation of bases by nuclear methyl donors at reactive nitrogen or oxygen groups, one important product being the cytotoxic residue 3-methyladenine (3-mA); and (5) oxidation of nucleotide precursors resulting in the incorporation of damaged bases into DNA during semiconservative replication, such as the misincorporation of 8-oxodGMP to form 8-oxoG:A base pairs. DNA base excision repair (BER) is the main repair pathway for these lesions, both in the nucleus and in the mitochondria.

Core Base Excision Repair Factors

DNA base excision repair (BER) involves one damage-specific step to identify and release the damaged or, in some cases, mispaired base and a subsequent set of general steps that result in the reinsertion of one or a few nucleotides. There are three major modes of the DNA BER pathway that can be executed by a set of core factors (Figure 1). The choice of pathway is influenced by the initiating DNA glycosylase and the nature of the 3′ and 5′ residues generated during the repair process.

DNA Base Excision

The damaged base is recognized by one of several DNA glycosylases (Table I), which initiate repair by hydrolyzing the *N*-glycosyl bond linking the base and the DNA backbone, leaving an AP site in the DNA. Notwithstanding limited sequence homologies, structural studies of the three-dimensional protein folds have revealed that DNA glycosylases can be divided into two main families. The mammalian members of the smaller family are UNG, TDG, and SMUG1. Members of the larger family are characterized as having a common structural motif and include the OGG1, MYH, NTH, and MBD4 enzymes. In addition, DNA glycosylases are classified as being either monofunctional or bifunctional, with the latter having an associated DNA lyase activity for chain cleavage at AP sites. Several DNA glycosylases can excise the same substrates, but the substrate specificities differ due to architectural diversity of the substrate-binding pockets of the enzymes. Furthermore, variations in biochemical properties, subcellular localization, and regulation suggest that their functions are not entirely overlapping.

Uracil-DNA Glycosylases

Human cells have at least four enzymes that can remove uracil from DNA (UNG, SMUG1, TDG, and MBD4). The UNG and SMUG1 enzymes are unusual in that they can remove uracil from single-stranded DNA as well as from double-stranded DNA. UNG is highly specific for uracil, with a very high turnover number, whereas SMUG1 has broader substrate specificity with lower turnover number. UNG accumulates at sites of active DNA replication in S-phase nuclei via interaction with PCNA and is the main enzyme responsible for post-replicative removal of uracil resulting from dUMP misincorporation. UNG may also be important for the removal of deaminated cytosine residues in single-stranded regions of DNA, in front of the replication fork, or in highly transcribed genes, but the relative contributions of UNG and SMUG1 in the repair of deaminated cytosine residues in general is not clear. In contrast, both TDG and MBD4 require double-stranded DNA as substrates and remove U or T resulting from the deamination of cytosine or 5-methylcytosine (5-mC). MBD4 contains a 5-mCpG binding domain in addition to the DNA glycosylase domain and is probably restricted to repair in a TpG or UpG context, whereas TDG has broader substrate specificity. These are enzymes with very low turnover numbers as a result of strong binding to AP sites.

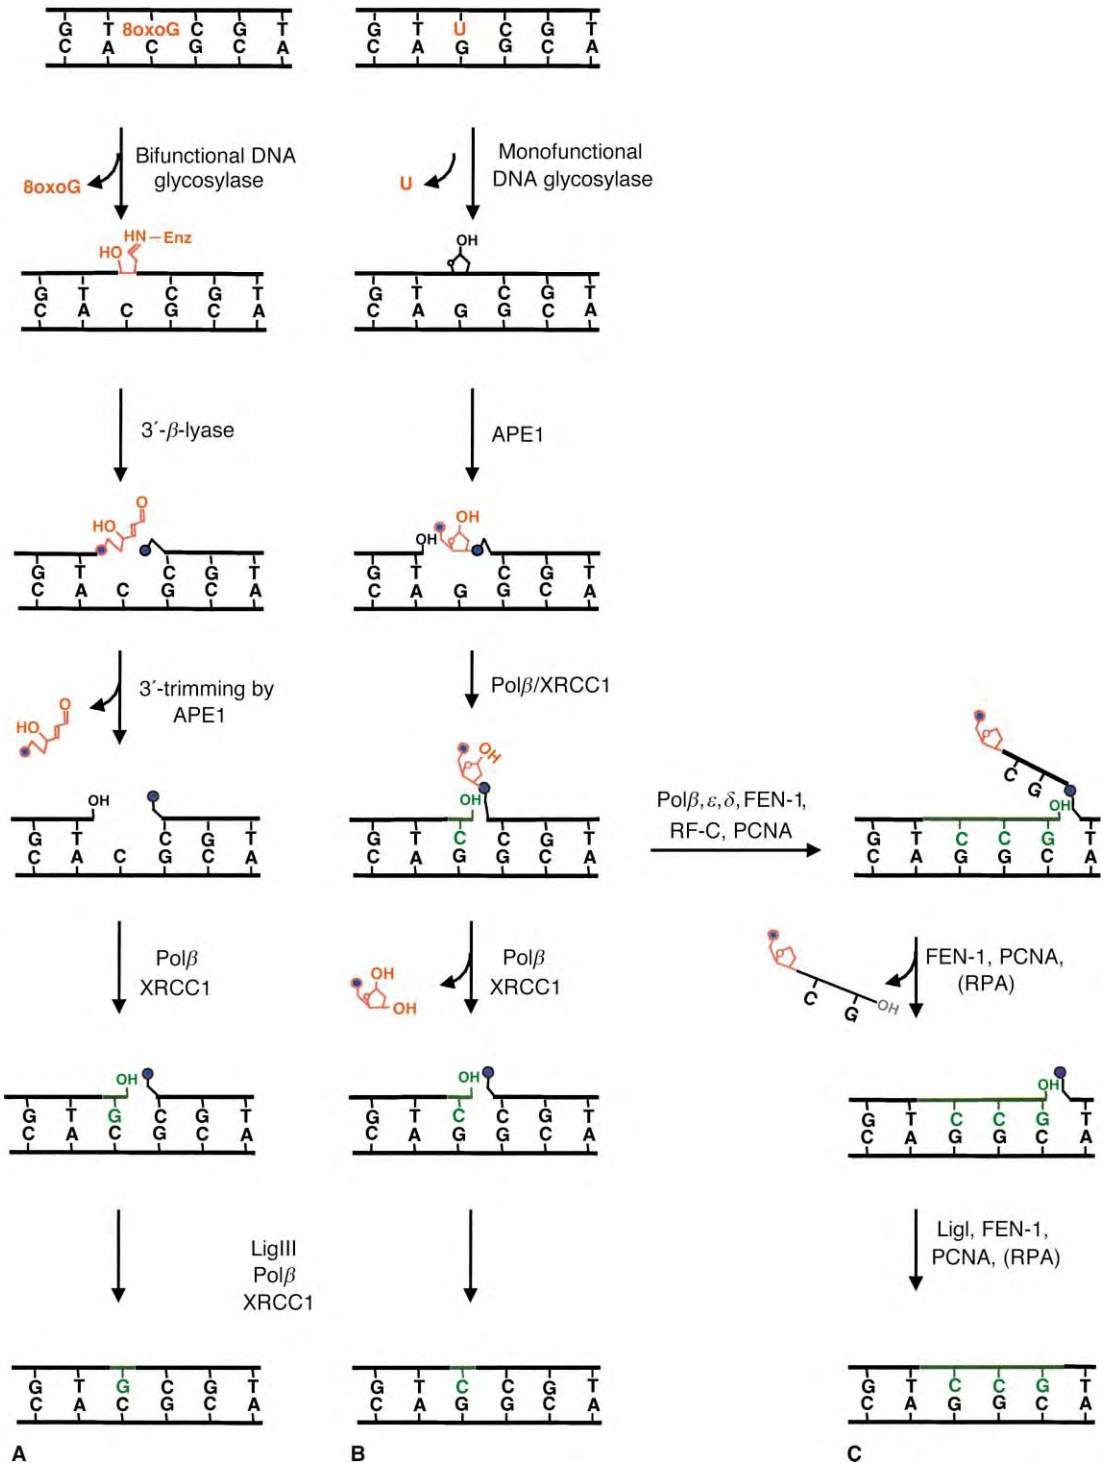

FIGURE 1 DNA base excision repair pathways. (A) One nucleotide gap repair initiated by a bifunctional DNA glycosylase. (B) Short-patch repair is the major mode of repair initiated by a monofunctional DNA glycosylase. (C) Long-patch repair is used when short-patch repair is blocked. Reactive groups in each step are shown in red, phosphate groups are indicated as blue circles, and green blocks represent newly synthesized DNA. Adapted from Krokan, H. TABLE I

Human DNA Glycosylases and their Major Substrates

Enzyme name	Lyase activity	Cellular localization[a]	Major substrates[b]
UNG	No	N/M	U in single- or double-stranded DNA
SMUG1	No	N	U in single- or double-stranded DNA
TDG	No	N	U, T or ethenoC opposite G
MBD4	No	N	U or T opposite G in U/TpG context
MPG	No	N	3-mA
MYH	No	N/M	A opposite 8-oxoG
OGG1	Yes	N/M	8-oxoG opposite C
NTH1	Yes	N/M	Ring-saturated or fragmented pyrimidines
NEIL1	Yes	N	Tg
NEIL2	Yes	N	Oxidation products of C or U
NEIL3	Yes	N	Fragmented or oxidized pyrimidines

[a] The enzyme or specific isoforms of it are sorted to nuclei (N) or mitochondria (M).
[b] Only major substrates are shown. A comprehensive list of substrates for each DNA glycosylase can be found in Wood *et al.* (2001) and a regularly updated version can be found at that article's supplementary Web site.

Methylpurine DNA Glycosylase

Methylpurine DNA glycosylase (MPG, also called 3-alkyladenine DNA glycosylase, AAG) is a monofunctional DNA glycosylase that structurally forms a class of its own. The major substrate for MPG is 3-methyladenine (3-mA) in double-stranded DNA, but the enzyme has an unusually wide substrate binding pocket that can accommodate a wide range of modified purine bases. Interestingly, MPG has a weak, but significant activity toward normal purine bases, illustrating the importance of tight regulation of individual BER enzymes.

DNA Glycosylases for Removal of Oxidized Bases

The repair of oxidized DNA bases is predominantly initiated by bifunctional DNA glycosylases that use an amino group of the enzyme rather than a water molecule as a nucleophile to cleave the *N*-glycosyl bond. Enzyme-catalyzed resolution of the resulting Schiff-base intermediate, referred to as the AP-lyase activity, leads to the incision of the DNA backbone 3′ to the AP site. Several DNA glycosylases specific for oxidized DNA bases have been identified (Table I). Similar to the uracil-DNA glycosylases, they have different but overlapping substrate specificity. Oxidized purines are primarily removed by OGG1, whereas oxidized and fragmented pyrimidines are removed by the NTH1 and NEIL enzymes.

Despite having structural homology to the bifunctional DNA glycosylases, MYH acts as a monofunctional DNA glycosylase when removing unmodified adenine base-paired with 8-hydroxyguanine (8-oxoG). MYH colocalizes, via interaction with PCNA, with replication foci in the S-phase nuclei, where it removes adenine misincorporated opposite 8-oxoG during semi-conservative replication.

Base-Flipping and Release

Despite the lack of sequence homology, DNA glycosylases show structural similarities, which allow base recognition and catalysis to proceed by related mechanisms. Pinching of the DNA backbone followed by intercalation of amino acid side chains into the DNA provides the basis for substrate recognition and catalysis. Consequently, the damaged nucleotide is flipped out of the helix and the scissile bond is exposed upon the stabilization of the base in the substrate-binding pocket. DNA glycosylases then release the damaged base after cleavage of the *N*-glycosyl bond.

Backbone Incision

Following excision of the damaged base, BER can proceed through several routes. Subsequent to base excision by a monofunctional DNA glycosylase, the DNA backbone is incised 5′ of the AP site by AP-endonuclease 1 (APE1), creating a 3′OH group and a 5′-dRP moiety (Figure 1B). Upon resolution of the Schiff-base intermediate formed by a bifunctional DNA glycosylase, the DNA backbone is cleaved 3′ to the damage to give a 5′-phosphate and a blocked, 3′ α, β unsaturated aldehyde or a 3′-phosphate by elimination reactions. Although the NEIL enzyme domains deviate from the OGG1/NTH1 superfamily, they are believed to act by similar mechanisms. The blocked 3′ residue must

be removed to generate a 3′-OH group that is a substrate for DNA polymerases. This is achieved by the 3′ phosphodiesterase activity of APE1, leaving a one nucleotide gap in DNA (Figure 1A).

Base Insertion

DNA polymerase β (Polβ) is the main DNA polymerase involved in BER and comprises a polymerase domain and a dRP-lyase domain. The 3′-OH group is a substrate for the polymerase function of Polβ. Polβ is distributive and will only synthesize a few nucleotides before disengaging. If the 5′-dRP moiety is a substrate for the dRP-lyase activity of Polβ, then one or two nucleotides will be inserted in concert with the removal of the dRP moiety and BER will proceed through the short-patch pathway (Figure 1B). If, however, the dRP moiety is modified, making it a poor substrate for the dRP-lyase activity of Polβ, this polymerase may still incorporate one nucleotide, but BER will then be funneled into the long-patch pathway, which uses DNA replication factors to synthesize a longer repair patch (Figure 1C). In this case, DNA polymerase δ/ε performs strand-displacement synthesis, supported by replication factor C (RF-C) and proliferating cell nuclear antigen (PCNA), and the modified dRP moiety is removed as part of an oligonucleotide released upon Flap endonuclease 1 (FEN1) incision. Finally, because a 1-nucleotide gap in DNA is a poor substrate for the strand-displacement activity of Polβ, a single nucleotide will be inserted when repair is initiated by a bifunctional DNA glycosylase (Figure 1A). Oxidative base lesions frequently occur in clusters, and this pathway might have evolved to prevent the collision between closely spaced repair tracts on different strands, which otherwise could generate double-strand breaks.

Polβ lacks the editing 3′-exonuclease function characteristic of replicative DNA polymerases. Consequently, the accuracy of DNA synthesis by Polβ is relatively low. In the case of BER, the proofreading required is probably performed by a cryptic 3′-exonuclease activity of the APE1 enzyme.

Nick Rejoining

Both DNA ligase III (LigIII) and DNA ligase I participate in BER. Polβ interacts directly with X-ray cross complementing factor 1 (XRCC1). XRCC1 also interacts with LigIII, and this interaction stabilizes LigIII. Polβ, XRCC1, and LigIII form a trimeric complex on substrate DNA, and LigIII is the main nick rejoining activity for short-patch and 1-nucleotide gap repair. DNA ligase I predominantly seals nicks after long-patch repair via direct protein–protein interaction with PCNA.

Pathway Orchestration

One characteristic of the BER pathway is the highly orchestrated manner with which proteins interact sequentially on the DNA substrate, as opposed to the assembly of large preformed nuclear complexes. The DNA glycosylases all remain bound at AP sites, albeit to varying degrees, but are efficiently displaced by APE1. Polβ is in turn recruited through interaction with APE1, and the trimeric complex of DNA Polβ-XRCC1-LigIII ensures that the repair intermediates are protected. There is a progressive bending of the DNA backbone during the repair pathway, starting from a 30° kink when the DNA glycosylase is bound to the substrate, progressing to 45° (APE1-bound), and then becoming almost a 90° bend when the trimeric Polβ-XRCC1-LigIII is bound. Progressive bending and pairwise protein–protein interactions probably aid substrate recognition and give directionality to the pathway without exposure of cytotoxic repair intermediates, such as AP sites and dRP moieties, thus preventing aberrant processing of intermediates and premature activation of cell cycle checkpoints in response to DNA damage.

Base Excision Repair in Chromatin

The organization of DNA into chromatin in eukaryotic cells restricts access for several DNA binding proteins to their substrates and introduces steric constraints that might hamper catalytic reactions on the nucleosome surface. Although BER proceeds more slowly in chromatin than in free DNA, the core BER proteins are apparently able to access DNA on the surface of a nucleosome. Chromatin remodeling might therefore not be a prerequisite for repair of DNA in nucleosomes, but it would presumably facilitate repair in chromatin. Furthermore, mammalian cells might circumvent a need for rapid DNA repair in condensed chromatin by coupling BER to other DNA transactions where the chromatin structure is relaxed. This would ensure efficient repair when speed is of importance, for example, in the cases of UNG and MYH, by targeting the enzymes to sites of active replication.

Base Excision Repair in Mitochondria

Being close to the centers for oxidative metabolism in the cell, mitochondrial DNA is particularly exposed to reactive oxygen species. Several alternatively spliced forms of DNA glycosylases have been identified, and some isoforms are specifically sorted to mitochondria (denoted M in Table I). APE1 is transported to mitochondria and the mitochondrial DNA polymerase

γ has dRP-lyase activity. mtDNA ligase is a processed form of DNA LigIII. Thus, the mitochondria have all the activities required for BER, and BER might be the most important mode of DNA repair in this organelle.

The Cancer Connection

Bacterial and yeast mutants deficient in DNA glycosylases often exhibit elevated spontaneous mutation frequencies. Despite an observed accumulation of DNA base damage in gene-targeted knockout mice, they generally show weaker phenotypes in this regard, presumably because of the high degree of functional overlap among different DNA glycosylases (Table I) and the existence of several efficient and specialized DNA polymerases for translesion synthesis. There are at least four mammalian DNA glycosylases that can remove uracil from DNA and, although Ung-deficient mice accumulate uracil in the genome, they show only a modest increase (less than 50%) in the mutation frequency of a transcriptionally inactive transgene. Nevertheless, the Ung-deficient mice are susceptible to the spontaneous development of B-cell lymphomas. No spontaneous tumor development has been observed in other DNA glycosylase deficient mice, but Mbd4-deficiency accelerates tumor development in a tumor-prone mouse strain. However, human polymorphisms have been identified in most BER genes, and mutations in MYH have been linked convincingly to a higher susceptibility to colorectal cancer.

Base Excision Repair Branching Out

Interestingly, attempts to generate gene-targeted knockout mice for genes downstream of the DNA glycosylases result in embryonic lethality. Similarly, genetic studies with budding yeast have shown that mutants unable to repair AP sites in DNA are not viable. This could be a result of the accumulation of cytotoxic repair intermediates, AP sites or dRP moieties in particular, or a consequence of the involvement of these proteins in other cellular pathways. BER factors associated with the long-patch pathway exert their main function during DNA replication, but other BER factors may also be employed in DNA transactions in addition to classical BER, for example, the involvement of Polβ in meiosis. Mammalian APE1 has an N-terminal domain that allows it to function as a redox factor; this domain is required for redox activation of various spontaneously oxidized transcription factors, such as AP1. Recently, the Ung uracil-DNA glycosylase was shown to be central in the diversification of immunoglobulin genes, a finding that opens up new and exciting prospects for research into the biological significance of DNA BER.

Biography

Dr. Hilde Nilsen is a postdoctoral research fellow at the Cancer Research U.K., London Research Institute. Her research interests are cellular responses to spontaneous DNA damage. She received her Ph.D. from the Norwegian University of Science and Technology in Norway. She has been awarded fellowships from EMBO and the EU Marie Curie program.

Dr. Tomas Lindahl is Director of Research at the Clare Hall Laboratories of the Cancer Research U.K., London Research Institute. His research interests are in DNA repair of spontaneous DNA damage and genome instability. He has an M.D. from the Karolinska Institute, Stockholm. He is a member of EMBO, a fellow of the Royal Society, and a member of the Swedish and Norwegian Academies of Science, and he has published extensively over a period of 30 years.

DNA Damage: Alkylation

Anton B. Guliaev and B. Singer
Lawrence Berkeley National Laboratory, Berkeley, California, USA

Alkylation is the reaction of electrophilic chemical compounds or alkylating agents with the nucleophilic centers in organic macromolecules. Alkylating agents include a large variety of chemicals, some of which are potent mutagens or carcinogens. It is well known that DNA is a key structure that determines development and reproduction of the leaving organisms ranging from simple cells to humans. The sequence and structure of individual nucleotides in DNA are essential for the high degree of fidelity required for generating a "blueprint" during the process of the storing and passing of genetic information from one organism to another. However, DNA is subject to alteration in structure and/or sequence of individual bases. These changes can result in errors during the steps of the DNA replication, recombination, and repair, thus leading to the modification of the molecular structure of genetic material. Most of these modifications can be successfully removed by the DNA repair machinery. However, a significant amount of DNA remains unrepaired, which can lead to mutagenesis.

The common source of the modifications in DNA, particularly the alteration in the nucleotide structure, can be found in the instability of specific chemical bonds of nucleotides under different physiological conditions, such as temperature or pH. Moreover, the DNA structure readily reacts with multiple chemical compounds and physical agents found in the environment. These mutagens and carcinogens can be produced by a variety of chemical reactions, metabolism of other living forms, and they also can be manmade. Modifications of the DNA molecular structure can be characterized as DNA damage. DNA damage is unavoidable and can be divided into two categories: (1) spontaneous, such as formation of mismatches, deamination of bases, loss of base, oxidative damage; (2) environmental, such as ionizing radiation, UV radiation, and chemical agents, including ubiquitous alkylating agents. DNA alkylation, which is a part of the DNA damage, is the reaction of the alkylating agents with the nucleophilic centers, such as oxygen or nitrogen in the DNA base or backbone. The result of the reaction is the formation of the modified DNA bases called *adducts* or formation of the phosphotriesters in the case of the interaction of the agent with the oxygen in the DNA phosphodiester backbone. The adduct together with the opposite base is usually called a *lesion*.

Alkylating Agents and Mechanism of the Reaction with DNA

The first chemical evidence of alkylation damage to DNA was reported in 1962 by the observation of 7-methylguanine as an *in vivo* product of dimethylnitrosamine administered to rats. Since that time, the list of alkylation agents and sites of alkylation has significantly increased, so that now we know that almost all nitrogens and oxygens of nucleotides in DNA can be modified. Alkylating agents include a large number of molecules, which can efficiently react with DNA causing structural modification of the base and phosphate group in DNA. The most common agents are alkyl sulfates, alkyl sulfonates, alkyl halides, dialkyl nitrosamine, alkyl nitrosoureas, acyl nitrosamides, mustards, diazo compounds, lactones, epoxides, etc. (Figure 1). These agents can be divided into two major groups: monofunctional and bifunctional. The monofunctional agents have only one reactive group that is involved in covalent interaction with the single center on DNA. The bifunctional agents have two reactive groups and have the ability to react with two centers on DNA. If the two centers are on the opposite strands of the DNA, the reaction of a bifunctional agent, such as sulfur or nitrogen mustards, can produce an interstrand cross-link. Many of the alkylating agents have a mutagenic effect and are known or suspected carcinogens. The reaction specificity of these compounds is different with different bases. Diazoalkanes react readily with guanosine and thymidine, but only under extreme conditions with adenosine and cytosine. In contrast, alkyl sulfates, alkyl sulfonates, mustards, epoxides, and nitroso compounds alkylate bases in the following order: $G > A > C \gg T$. The rate of ethylation is much slower than that of methylation for all classes of alkylating agents except alkyl iodides, which readily alkylate G, A and C.

The main chemical mechanism of DNA alkylation is a S_N2 and S_N1 type reaction in which the electrophile (alkylating agent) reacts with the electron-rich regions of the base residues and phosphodiester

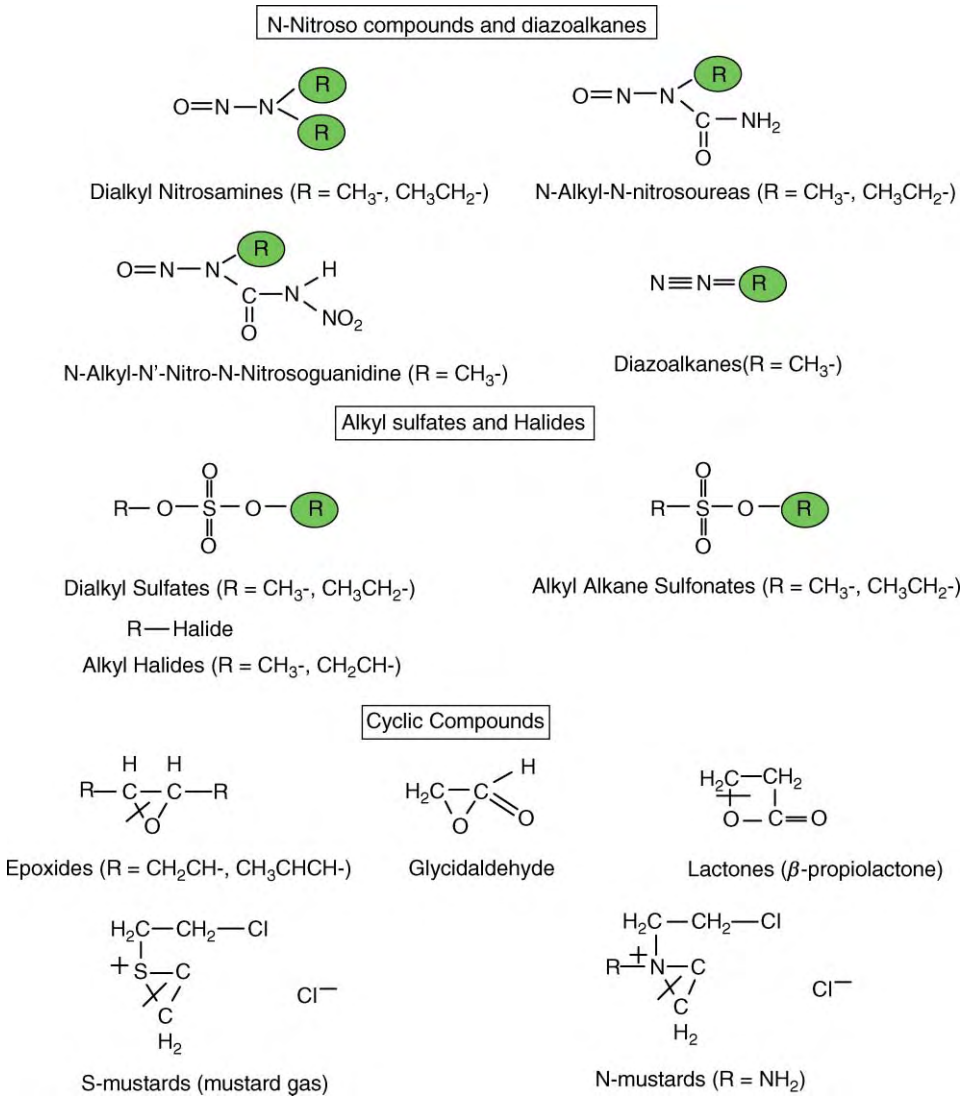

FIGURE 1 Structural formulas of alkylating agents. The alkyl groups are indicated by R. Circled R shows which group of the molecule is being transferred. The opening of the ring for the cyclic compounds is indicated by the line, and the whole molecule acts as a substituent.

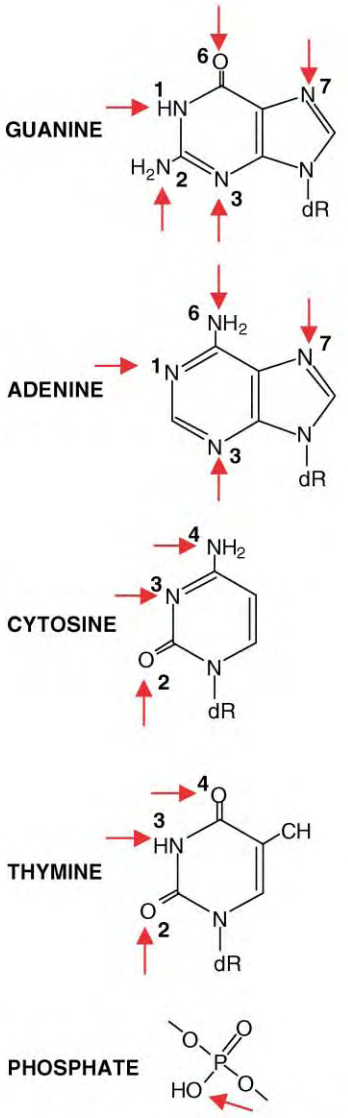
backbone. Figure 2 shows possible sites of alkylation on the DNA bases and the relative reactivity of these sites as measured by the presence of the alkylated base after the reaction with carcinogenic alkylating agents. The ring nitrogens, being more nucleophilic than the oxygens, are known to be more reactive with the alkylating agents. Thus, the N7 of guanine and N3 of adenine are the most reactive. The DNA phosphodiester backbone can also undergo an alkylation reaction through interaction of the agent with the oxygen, which results in the formation of phosphotriesters (Figure 2). However, not all alkylating agents react directly with the DNA bases. Some of them, such as dialkylnitrosamines or vinyl chloride (group of R-halides), must be metabolically activated.

Effect of DNA Conformation on the Alkylation

There are at least two significant differences between alkylation of nucleosides and polynucleotides. One is the presence of the phosphate in the phosphodiester bonds, which can form phosphotriesters, and the other is the effect of secondary structure on the availability of reactive sites. In general, the major sites of alkylation of single-stranded synthetic polynucleotides are the same as those for nucleosides, but the extent of reaction is different. The neighboring base or the overall charge of the nucleotide can affect the nucleophilic potential of the DNA base. For example, if the guanine residue is flanked by another guanine, the negative electrostatic



Adduct \ Carcinogenic alkylating agent	Percentage of total alkylation: DMN MNU SDMH	DEN ENU	MM S

The data presented in the table are available only for the subset of the sites shown.

potential of the N7 position of guanine is enhanced, thus providing a better environment for the electrophilic attack of the alkylating agent. However, the increase of the negative charge of the alkylating moiety diminishes the nucleophilic potential of the base. Steric effects also play an important role in the reaction between the alkylating agents and the nucleophilic sites in DNA. For the normal right-handed (B-form) helix conformation, the access to sites in DNA differs between the major and minor groove. For the guanine residue in the B-form DNA the O6 and N7 atoms are in the major groove, which can be easily accessed by the alkylating agent. In contrast, the relatively reactive N3 of the adenine lies in the minor groove, which is less accessible due to the steric implications of the B-form DNA.

Methods of Identification of Alkyl Derivatives of Nucleic Acids

The initial identification and characterization of the alkylation products can be made using UV absorption

spectroscopy. The nature of the alkyl group introduced to the base does not affect the λ_{max} or λ_{min} significantly. However, the position of the base modification results in the spectral changes that make it possible to distinguish among derivatives. In addition to spectra maxima and minima of the cationic and anionic forms, the shape of the spectra changes significantly depending on the base modification. The characteristic shoulders and alteration in the curve profile can be assigned to a particular adduct. Additional identification can be performed using other methods such as mass spectrometry, nucleic magnetic resonance, and infrared spectroscopy. The detailed description of these methods and their use for identification of alkyl derivatives can be found in the Further Reading.

Cytotoxic and Mutagenic Effects of Alkylation: Methylation

Mutation can be described as a change of one base to another, leading to a change in coding information. The change in the base structure, which is lethal to the cell, can be characterized as a cytotoxic.

Direct alkylation of DNA, particularly methylation, acting through the covalent modification of the base, has the ability to generate miscoding base derivatives and lesions that block replication. The major adducts generated in double-stranded DNA by methylating agents such as methyl methanesulfonate (MMS), dimethylsulfate (DMS) and methyl iodide (MeI)

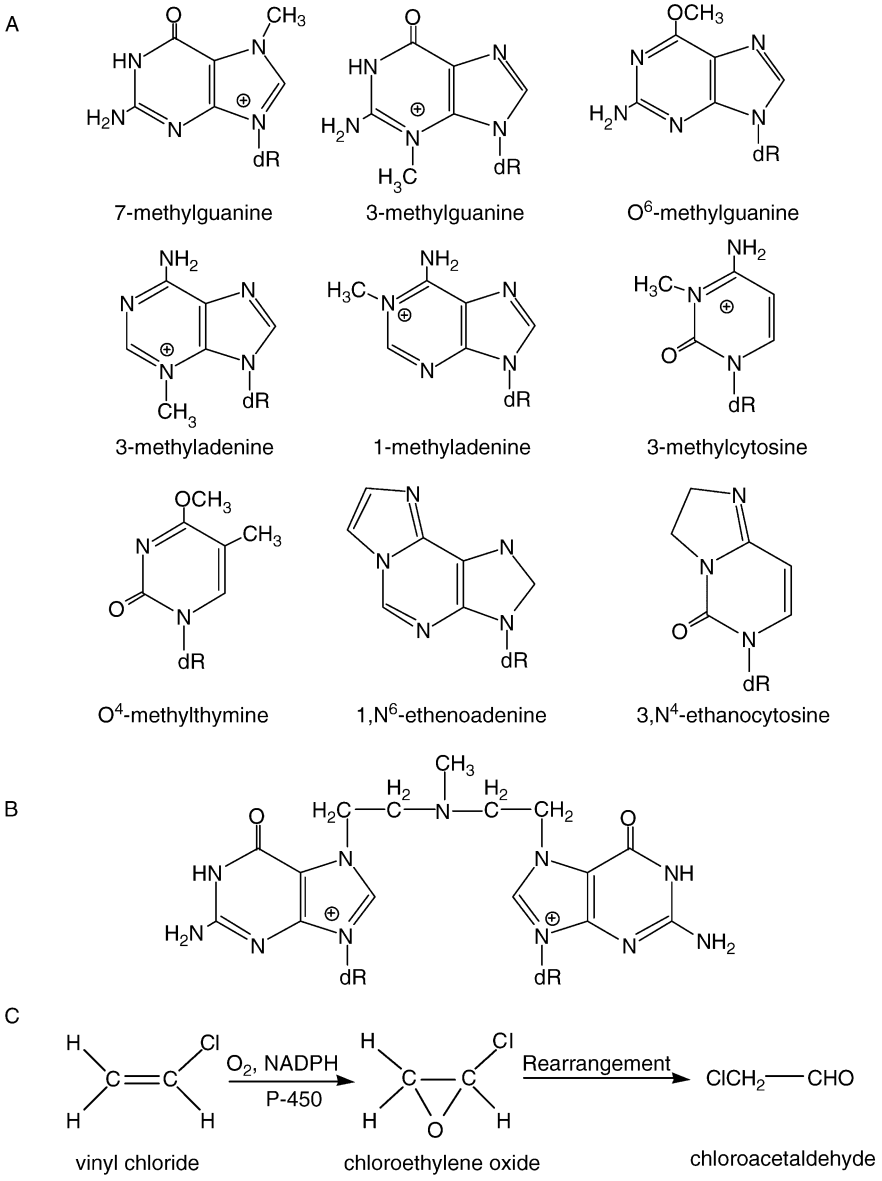

FIGURE 3 (A) Selective structures of the DNA adducts formed by the alkylation reaction. (B) Intrastrand cross-link product of the reaction of nitrogen mustard with N-7 of guanine. (C) Mechanism of the metabolism of vinyl chloride.

are: 7-methylguanine (7-meG), 3-methyladenine (3-meA), 3-methylguanine (3-meG), and O^6-methylguanine (O^6-meG) (Figure 3A). In single stranded DNA, these methylating agents form 1-methyladenine (1-meA) and 3-methylcytosine (3-meC) (Figure 3A). The formation of these adducts in the single-stranded, but not in double-stranded DNA is due to the fact that these modification sites are involved in base-pairing and are therefore protected from alkylation. Adducts 3-meA, 3-meG and 3-meC have the ability to block DNA replication, thus having cytotoxic effects. In contrast, O^6-meG and O^4-methylthymine (O^4-meC) are miscoding base derivatives that mispair during replication thus leading to possible mutations. Environmental mutagens such as 1,2-dimethylhydrazine, diazoquinones, and tert-butylhydroperoxide generate methyl radicals that readily react with the guanine residue to form 8-methylguanine, which also has a high miscoding potential. However, the most common methylation product in DNA, 7-meG, is not mutagenic and basepairs normally in polynucleotides. Most of the adducts produced by methylation can be efficiently removed by a variety of DNA glycosylases through the base excision repair mechanism (BER). This process involves cleavage of a base–sugar bond in order to release the modified base and generate an apurinic/apyrimidinic site that is repaired by endonucleases. This is followed by the action of the DNA polymerase that incorporates the correct base. In contrast, O6-methylguanine is corrected by the direct transfer of the methyl group to a cysteine residue of the methyltransferase repair enzyme. Intrastrand cross-links (Figure 3B), generated by bifunctional alkylating agents, such as nitrogen mustard, represent an important class of DNA damage, since they prevent DNA strand separation, which is crucial to the processes of replication and transcription. The cell has the ability to repair this damage through the mechanism of nucleotide excision repair (NER), which uses multiple enzymes.

The nitroso compounds and hydrocarbons, which are well-known environmental carcinogens, react through a number of metabolic intermediates. However, the most effective direct alkylating agents, such as alkyl sulfates (Figure 1), in turn, are poor carcinogens. In contrast, the metabolically activated alkylating agents are very efficient carcinogens. One of the widely used common chemicals, which is carcinogenic in man and experimental animals, is vinyl chloride (Figure 3C). The industrial use of vinyl chloride is estimated to be about 4×10^9 kg/year in the United States. The exposure to vinyl chloride is generally by inhalation and results in angiosarcoma of the liver or other tumors in the brain, lung, and hematolymphopoietic system in humans. Vinyl chloride is readily metabolized into chloroethylene (CEO) oxide, which rapidly changes to chloroacetaldehyde (CAA) (Figure 3C). Both CEO and CAA are highly mutagenic and carcinogenic and react with the DNA bases to form etheno derivatives (e.g., 1,N^6-ethenoadenine and 3,N^4-ethanocytosine (Figure 3A)). These adducts have a high miscoding potential and also an ability to block DNA replication.

Biography

B. Singer is a Research Professor Emeritus at the Virus Laboratory and Department of Molecular Biology at the University of California, Berkeley; she is currently Senior Scientist at Lawrence Berkeley National Laboratory. She has coauthored the text, "Molecular Biology of Mutagens and Carcinogens," as well as numerous papers on chemistry, molecular biology, and virology. In 1957, together with her husband, H. Fraenkel-Conrat, they discovered that all the genetic information for tobacco mosaic virus was coded by RNA alone. Her current research interests are in the chemical reactions of environmental carcinogens.

Anton B. Guliaev is a Physicist Scientist at Lawrence Berkeley National Laboratory, Berkeley, California.

DNA Glycosylases: Mechanisms

Daniel J. Krosky and James T. Stivers
The Johns Hopkins University School of Medicine, Baltimore, Maryland, USA

The highly accurate replication of an organism's DNA is necessary for it to maintain genetic stability over many generations. Thus, cells need to aggressively repair DNA damage in order to prevent mutations and to eliminate toxic base modifications that can interfere with DNA replication. To this end, cells have evolved several DNA repair pathways geared toward processing different types of DNA lesions. One of these systems, the base excision repair (BER) pathway, recognizes and removes chemically modified DNA bases and replaces them with the correct nucleotides. The first step in BER is catalyzed by a family of functionally related enzymes known as DNA glycosylases that hydrolytically cleave the glycosidic bond between the damaged base and its deoxyribose sugar.

The Biological Function of DNA Glycosylases

DNA bases can be damaged by a variety of mechanisms that include alkylation, deamination, oxidation, and ultraviolet light, each of which produces a different base alteration. Repair of each of these diverse lesions begins with the action of a unique DNA glycosylase (to date, eight have been identified in humans) that is specific for the particular damaged base. This hydrolysis reaction results in a common intermediate, an abasic site, which can be processed by either short- or long-patch repair. In short-patch repair, only the damaged nucleotide is replaced, whereas in long-patch repair, the damaged base and three or four additional nucleotides are excised and replaced.

Types of DNA Glycosylases

Substrate Range and Specificity

The DNA glycosylases have evolved varying degrees of substrate specificity. For example, uracil–DNA glycosylase (UDG) will efficiently cleave uracil that has been misincorporated into DNA, but not thymine, which only differs from uracil by one methyl group. Other DNA glycosylases not only possess high specificity for the cleaved base, but also for the context in which it appears. Examples of these include the bacterial mismatch-specific UDG (MUG), which excises uracil paired with guanine but not with adenine, and the mammalian 8-oxoguanine glycosylase (OGG), which only cleaves the oxidized base 8-oxoguanine when it is opposite cytosine.

In contrast, other DNA glycosylases cleave a relatively wide spectrum of chemically related damaged bases. For instance, *Escherichia coli* 3-methyladenine glycosylase II (AlkA) catalyzes the hydrolysis of a wide range of cationic *N*-alkylated purines, such as 3-methyladenine and 7-methylguanine. In addition, AlkA can cleave undamaged purine bases, although with much lower efficiency than *N*-alkylated purines. Other broad-specificity glycosylases include mammalian methylpurine glycosylase (MPG), which has a substrate range similar to AlkA, and endonuclease III (Endo III), which processes a variety of oxidized pyrimidines (e.g., thymine glycol and 5-hydroxycytosine).

In addition to simply excising damaged DNA bases resulting in an abasic site, a subset of bifunctional DNA glycosylases can subsequently catalyze an elimination reaction in which the 3′-phosphate of the abasic site is expelled. Members of this bifunctional DNA glycosylase family include OGG, Endo III, and pyrimidine dimer DNA glycosylase (PDG). Other enzymes in the base excision repair (BER) pathway then process the resulting repair intermediate, mostly via the short-patch pathway.

Structural Superfamilies of DNA Glycosylases

Even though DNA glycosylases catalyze similar reactions, these enzymes share minimal primary sequence homology with one another. However, X-ray crystallography and nuclear magnetic resonance (NMR) analyses have revealed that many of these proteins share a common fold and have allowed the classification of these proteins into several structural superfamilies. One of these structural superfamilies is defined by the helix-hairpin-helix (HhH) motif, which is found in many non-sequence-specific DNA-binding proteins. This α-helical fold allows these enzymes to make

nonspecific contacts with the DNA phosphodiester backbone, thus permitting sequence-independent excision of their cognate lesions. Other DNA glycosylases, such as UDG, have evolved alternate structural motifs that also result in nonspecific DNA binding and fufill the same function as the HhH domain.

Functional Commonalities of DNA Glycosylases

Base Flipping

Despite differences in substrate specificity, structure, and primary sequence, all DNA glycosylases are functionally related in their ability to extrude DNA bases from the double helix and to catalyze the hydrolysis of the glycosidic bond between the cognate base and the deoxyribose. Extruding a base from duplex DNA, or base flipping, is the process by which an enzyme facilitates the rotation of the DNA phosphodiester backbone such that a base flips from within the double helix to an extrahelical position located within the binding pocket of the enzyme (Figure 1). The most common mode of base flipping occurs when the enzyme flips the damaged base from the DNA double helix. However, some DNA glycosylases use different base-flipping strategies. PDG, which is responsible for cleaving the glycosidic bond of thymine photodimers, flips the adenine that is opposite the target base. *E. coli* MutY, which removes adenine misincorporated opposite to the oxidized base 8-oxoguanine, appears to flip both bases from the duplex.

There are several elements common to the base-flipping mechanisms of DNA glycosylases. First, the enzyme makes extensive nonspecific contacts with the phosphodiester backbone of the DNA (Figure 1). In addition to allowing sequence-independent binding of the DNA glycosylase to DNA, these protein–DNA interactions provide a stable architecture from which the enzyme can distort the DNA. All structural studies of DNA glycosylases bound to DNA have revealed that the DNA is significantly bent at the site of enzyme binding, albeit to differing degrees with different enzymes (Figure 1). Although the exact role of DNA bending is unclear, it may help certain glycosylases locate lesions in DNA. In addition, computational studies have suggested that DNA bending may play an important role in lowering the activation barrier for base flipping, thus providing an explanation for why DNA bending is such a ubiquitous feature of these interactions (Figure 1). Finally, all DNA glycosylases insert a bulky amino acid side chain, such as leucine or phenylalanine, inside the DNA double helix (Figure 1). This group serves as a structural wedge to both push the base out and to act as a barrier to prevent the base from slipping back into the double helix.

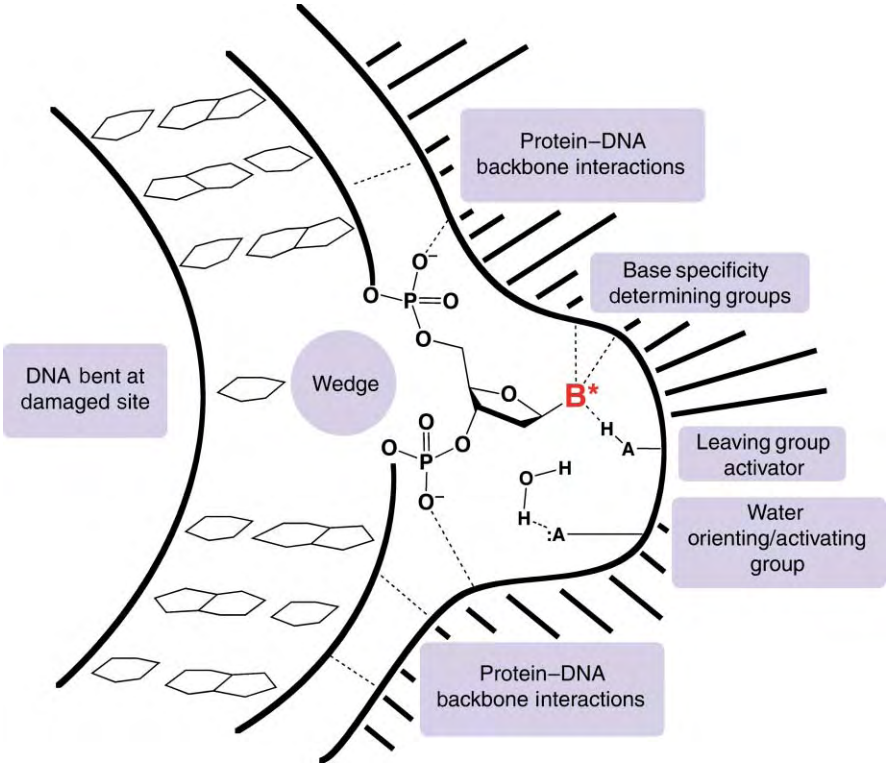

FIGURE 1 Schematic representation of base flipping and other common interactions of DNA glycosylases with DNA. B*, damaged base; (---), hydrogen bond.

Base flipping plays an important role in facilitating base recognition and glycosidic bond cleavage. Extrusion of the base juxtaposes its unique functional groups with complementary groups in the enzyme active site. These specific interactions promote the recognition of the damaged base and largely exclude binding of undamaged bases. Differences in the amino acid residues of the base binding pocket among DNA glycosylases, in part, account for differences in their substrate specificity and catalytic mechanisms (see later discussion). Base flipping also exposes the anomeric carbon (the deoxyribose carbon that is attached to the base) to attack by water in the enzyme active site. Thus, base flipping enables DNA glycosylases to couple damaged base recognition to enzyme catalysis.

Catalytic Strategies for Glycosidic Bond Hydrolysis

At neutral pH and ambient temperature, the glycosidic bond of a deoxynucleotide is a very stable linkage toward hydrolysis ($t_{1/2} = 109$ years for thymidine; $t_{1/2} = 3.9$ years for deoxyadenosine). The stability of this bond stems in part from the poor leaving-group ability of the electron-rich nucleobase, the poor nucleophilicity of water, and the poor electrophilicity of the anomeric carbon. DNA glycosylases have evolved remarkably similar strategies to overcome these chemical problems and remove these lesions rapidly enough to preserve the integrity of the genomic information.

Making the Cognate Nucleobase a Better Leaving Group

Most neutral deoxynucleotide bases are poor leaving groups because they cannot effectively stabilize the developing negative charge that forms on the base during the reaction. Some DNA glycosylases stabilize this negative charge by donating specific hydrogen bonds from active-site residues to acceptors on the base (Figure 1). This type of catalysis has been most clearly shown for UDG, in which an unusually strong hydrogen bond from a histidine residue in the enzyme active site stabilizes the uracil anion leaving group. In other cases, leaving group departure may be facilitated by the full transfer of a proton from an active site donor to a proton-accepting atom on the nucleobase, as has been suggested for MutY.

N-alkylated purines (i.e., 3-methyladenine and 7-methylguanine) are unique in that they are positively charged and electron-deficient; therefore, they are excellent leaving groups in the absence of any enzymatic activation. Accordingly, DNA glycosylases use different types of catalytic interventions to affect the hydrolysis of these labile bases. For example, the cationic base binding site of AlkA lacks the constellation of highly specific hydrogen-bonding groups that line the active sites of DNA glycosylases that recognize neutral damaged bases. Instead, its active site is rich in aromatic amino acids, such as tryptophan and tyrosine, that allow AlkA to bind purine bases of varying shape and account for the promiscuous activity of this enzyme. The unique chemical character of the AlkA active site may facilitate damaged-base recognition by forming favorable stacking interactions between the cationic *N*-alkylpurine and the aromatic side chains. Alternatively, positioning the cationic damaged base in a hydrophobic active site may serve to lower the activation barrier by electrostatic destabilization of the charged ground state. These key questions are still under active investigation.

The Nature of the Transition State

The rupture of the glycosidic bond in DNA can proceed through two limiting routes (Figure 2). In the first route (Figure 2A), the attack of water is coincident with departure of the leaving base, resulting in a concerted transition state. In a concerted reaction, the anomeric carbon is relatively electron rich, and little negative charge has built up on the leaving nucleobase. In the second route (Figure 2B), the bond between the anomeric carbon and the nucleobase is completely broken before the new bond with water forms, and the reaction proceeds via a stepwise mechanism with a discrete intermediate. Thus, in a stepwise reaction, the anomeric carbon is electron poor and has a significant positive charge, and the bonding electrons have migrated fully onto the leaving-group nucleobase.

Although comprehensive mechanistic studies for most DNA glycosylases have not been performed, it appears that these enzymes may catalyze their reactions using mechanisms in which the glycosidic bond is mostly broken and the new bond between water and the deoxyribose is only partially formed. In support of these electronic features, custom oligonucleotides containing a positively charged deoxyribose analogue that mimics the electron-deficient anomeric carbon at the transition state are potent inhibitors of several DNA glycosylases, including UDG and AlkA (Figure 2C). Such inhibitors of DNA glycosylases may someday find use in increasing the efficacy of anticancer agents that modify the bases of DNA by disabling the repair pathways that reverse the effects of these chemotherapeutics.

One way in which DNA glycosylases stabilize stepwise reactions is by surrounding the positively charged deoxyribose with negatively charged groups. For example, UDG engulfs the cationic deoxyribose intermediate with a negatively charged aspartate residue, DNA phosphodiester groups, and the uracil anion leaving group.

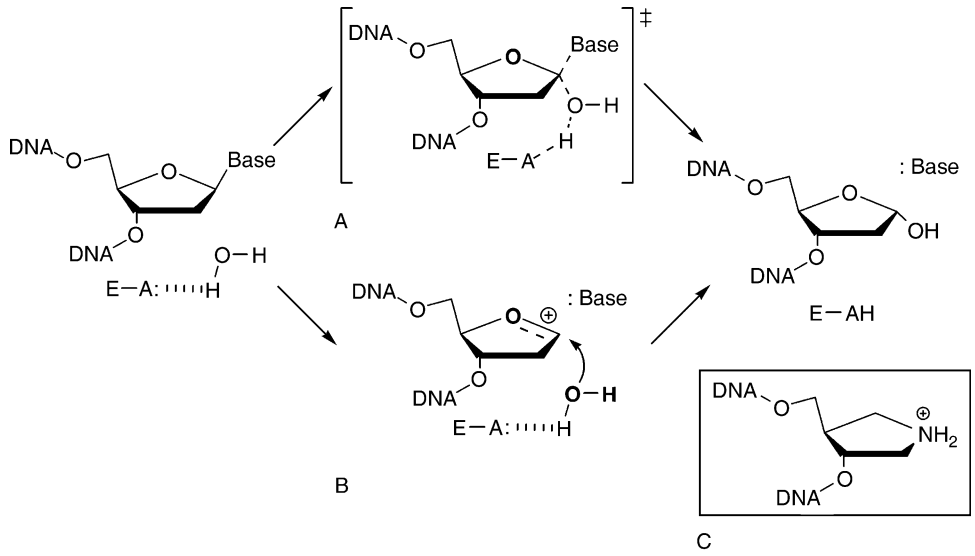

FIGURE 2 Two limiting reaction pathways for DNA glycosylases. (A) Concerted pathway; (B) stepwise pathway; (C) DNA glycosylase inhibitor based on the cationic deoxyribose intermediate of the stepwise reaction.

Helping Water Attack the Anomeric Carbon

Most DNA glycosylases possess a polar amino acid near the anomeric carbon of the target deoxyribose that can accept a hydrogen bond or proton from the attacking water (i.e., aspartate, glutamate, or asparagine) (Figure 1). Depending on the mechanism, this group may simply orient the water close to the anomeric carbon or, alternatively, may actively facilitate its attack by deprotonation. In concerted reactions, when there is significant bond formation between the attacking water and the anomeric carbon in the transition state, the activation barrier is lessened by partial or full deprotonation of the water. For stepwise reactions, the water needs only to be oriented close to the positively charged anomeric carbon because such species are highly reactive even with poor nucleophiles such as water (Figure 2B).

DNA Base Excision Repair

Glossary

abasic site A deoxyribose residue in DNA that lacks a base.

base flipping The process by which an enzyme extrudes a base from within the DNA double helix into an extrahelical position inside the active site of the enzyme.

DNA glycosylase A family of functionally related enzymes that catalyze the hydrolytic cleavage of a damaged base from DNA.

glycosidic bond The bond connecting the anomeric carbon of the deoxyribose to the nitrogen on the purine or pyrimidine base.

transition state The highest potential energy species in the overall transformation of reactants to products. The difference in energy between the reactants and the transition state (the activation barrier) determines the rate of reaction.

Biography

Daniel J. Krosky is currently a graduate student at the Johns Hopkins University School of Medicine, studying the energetics of base flipping by uracil DNA glycosylase. Prior to attending Johns Hopkins University, he was a Senior Research Associate at AstraZeneca R&D, Boston, developing novel antibacterial agents.

James T. Stivers is an Associate Professor in the Department of Pharmacology and Molecular Sciences at Johns Hopkins Medical School. His research focuses on understanding the nature of enzyme catalysis and inhibition for a number of enzymes involved in DNA repair and recombination. He obtained his Ph.D. in biochemistry from Johns Hopkins University in 1992. He received postdoctoral training in heteronuclear NMR and enzymology in the laboratory of Professor Albert Mildvan at Johns Hopkins Medical School.

DNA Helicases: Dimeric Enzyme Action

Timothy M. Lohman
Washington University School of Medicine, St. Louis, Missouri, USA

DNA helicases are a class of motor proteins that function to generate the transient single-stranded DNA required as intermediates in DNA and RNA metabolism. These enzymes couple the energy obtained from the binding and hydrolysis of nucleoside 5′-triphosphates (NTP) to perform the work of DNA duplex unwinding (strand separation) and translocation of the helicase along the linear DNA filament. Helicases function in a variety of processes including DNA replication, DNA repair, recombination, and bacterial conjugation, and are components of eukaryotic transcription complexes. Mutations in enzymes with helicase activity result in a variety of human genetic diseases. This article focuses on the *Escherichia coli* Rep and UvrD helicases, both members of the SF1 helicase superfamily.

Function

The *Escherichia coli* Rep helicase is involved in replication, most likely playing a role in replication restart. Rep was first identified as being required for replication of bacteriophage ϕX174. Rep in complex with the phage ϕX174 gene A protein is highly processive, being able to unwind the entire genome ($>$6000 bp). However, in the absence of this accessory protein, Rep unwinds DNA with significantly lower processivity. *E. coli* UvrD, also known as helicase II, is involved in nucleotide excision repair and methyl-directed mismatch repair of DNA, as well as in plasmid replication. In the absence of accessory proteins, the unwinding processivity of UvrD is also relatively low. However, UvrD must be able to unwind at least 1000 bp processively during methyl-directed mismatch repair. Therefore, the processivity of each of these helicases can be increased through interactions with accessory proteins.

Most DNA helicases show a preference for unwinding duplex DNA possessing a ss-DNA flanking region or "tail" *in vitro*, and generally display a defined "polarity of unwinding" with respect to the backbone polarity of the ss-DNA tail that flanks the duplex DNA. Helicases that initiate unwinding more efficiently on DNA substrates with a 3′-ss-DNA tail are referred to as "3′–5′ helicases," whereas those that prefer DNA substrates possessing a 5′-ss DNA tail are referred to as "5′–3′ helicases." The *E. coli* Rep, UvrD and *B. stearothermophilus* PcrA helicases are 3′–5′ helicases, whereas the phage T4 Dda protein is a 5′–3′ helicase. These results suggest that a 3′–5′ helicase translocates in that direction along ss-DNA and this appears to be the case. At high-protein concentrations, *E. coli* UvrD can also initiate DNA unwinding at a nick *in vitro*, which is the biologically important site for initiation of unwinding in its roles in methyl-directed mismatch repair and excision repair.

Helicases are allosteric enzymes, many of which function as oligomeric assemblies. The class of hexameric DNA helicases exemplifies such oligomerization. The general importance of oligomerization for the function of SF1 helicases is less clear and is the subject of current study. Although there is evidence that a monomer of the phage T4 Dda helicase, an SF1 helicase, displays limited helicase activity *in vitro*, monomers of *E. coli* Rep and UvrD do not display helicase activity *in vitro*, but must dimerize in order to unwind DNA *in vitro*. The role of this dimerization may be to activate the enzyme and to provide the functional enzyme with multiple DNA-binding sites that are important for increasing the processivity of DNA unwinding.

Structural Features of SF1 DNA Helicases

Primary Structures

Helicases have been classified into families and superfamilies (SF1, SF2, SF3, F4, and F5) based on conserved amino acid sequence patterns. The SF1 superfamily (containing *E. coli* Rep and UvrD) is defined by seven conserved regions of primary structure, referred to as "helicase motifs." The only regions of sequence similarity that are shared uniformly among all of the helicase families are motifs I and II, which correspond to the

"Walker A" and "B" boxes that form part of the nucleoside-5′-triphosphate-binding site. The presence of these two motifs is necessary but not sufficient for a protein to have helicase activity. The remaining conserved regions of the SF1 helicases are involved in binding of nucleoside-5′-triphosphate and/or DNA.

Crystal Structures of SF1 Helicases

Crystal structures have been solved for three SF1 DNA helicases, *B. stearothermophilus* PcrA, *E. coli* Rep, and *E. coli* UvrD. The apo form of PcrA as well as PcrA in complex with ADP, was solved at 2.5 and 2.9Å resolution, respectively. Structures of *E. coli* Rep bound to ss-DNA ($dT(pT)_{15}$) and Rep bound to ss-DNA and ADP were solved at 3.0 and 3.2Å, respectively. Structures of PcrA in complex with a 3′-ss-ds DNA junction, both in the presence and absence of the nonhydrolyzable ATP analogue, AMPPNP, were solved at 3.3 and 2.9Å, respectively.

The Rep (673 amino acids), PcrA (675 amino acids), and UvrD (720 amino acids) proteins are structurally homologous; a structure of the Rep-ss-DNA-ADP ternary complex is shown schematically in Figure 1. These SF1 proteins consist of two domains (1 and 2), separated by a cleft; domains 1 and 2 are further composed of subdomains 1A, 2A, 1B, and 2B (Figures 1 and 2). Subdomains 1A and 2A are composed of central

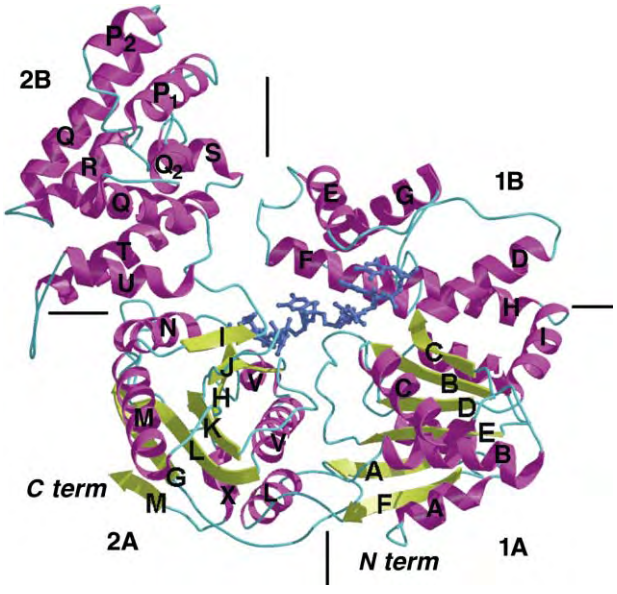

FIGURE 1 Structure of the *E. coli* Rep monomer bound to a single-stranded DNA (6 nucleotides shown in blue). Subdomains 1A, 1B, 2A, and 2B are indicated. The 3′ end of the ss-DNA resides near domain 1. Reprinted from Korolev, S., Hsieh, J., Gauss, G. H., Lohman, T. M., and Waksman, G. (1997). Major domain swiveling revealed by the crystal structures of complexes of *E. coli* Rep helicase bound to single-stranded DNA and ADP. *Cell* **90**, 635–647.

β-sheets flanked by α-helical regions and are homologous to each other as well as to the nucleoside-5′-triphosphate-binding domain of the *E. coli* RecA protein. Subdomains 1A and 2A both contain large insertions which form the α-helical 1B and 2B domains.

The crystal structures of *E. coli* Rep and *B. stearothermophilus* PcrA in conjunction with mutagenesis studies on several helicases indicate that amino acid residues in the seven conserved SF1 "helicase motifs," I–VI and IA are involved in either nucleotide and/or DNA binding. As shown in Figure 2, motifs I, IA, II, and III are contained within domain 1A, motifs V and VI are contained within domain 2A, whereas domain IV is found at the cleft formed between domains 1A and 2A. In general, ADP interacts with residues in motifs I and IV, whereas ATP interacts with residues within or near all of the motifs, with the apparent exception of motif IA.

Rep binds ss-DNA with a defined orientation with respect to the polarity of the sugar-phosphate backbone. In the crystal structures, the 3′–5′ direction runs from domain 1 to domain 2 across the cleft between the two domains, with the 3′ end of the ss-DNA located in a groove formed between subdomains 1A and 1B.

Several of the "helicase motifs" appear to be involved in the transmission of information between the ATP and ss-DNA-binding sites within a Rep monomer. Motif V residues are also likely to be involved in both ss-DNA binding as well as ATP binding through interactions with the γ-phosphate. Motif VI interacts directly with the γ-phosphate of ATP, as well as with motif IV. The above summary considers only interactions that occur within a single monomer or subunit. However, since oligomerization of both Rep and UvrD is functionally important for helicase activity *in vitro*, important allosteric interactions also occur between subunits of a Rep dimer.

"Open" and "Closed" Conformations

The asymmetric unit of the Rep-ssDNA crystal structure shows two molecules of Rep bound to a single molecule of $dT(pT)_{15}$. The conformations of the two Rep monomers are strikingly different with respect to the orientation of the 2B subdomain relative to the other three subdomains. These two conformations, referred to as "closed" and "open," respectively, differ by a ~130° rotation of the 2B subdomain about a hinge region connecting it to the 2A subdomain. It has been speculated that the 2B subdomain might be part of the interface between subunits within the Rep dimer, while others have suggested that the 2B subdomain forms part of the duplex DNA-binding site in the closed form of the PcrA monomer and plays a role in

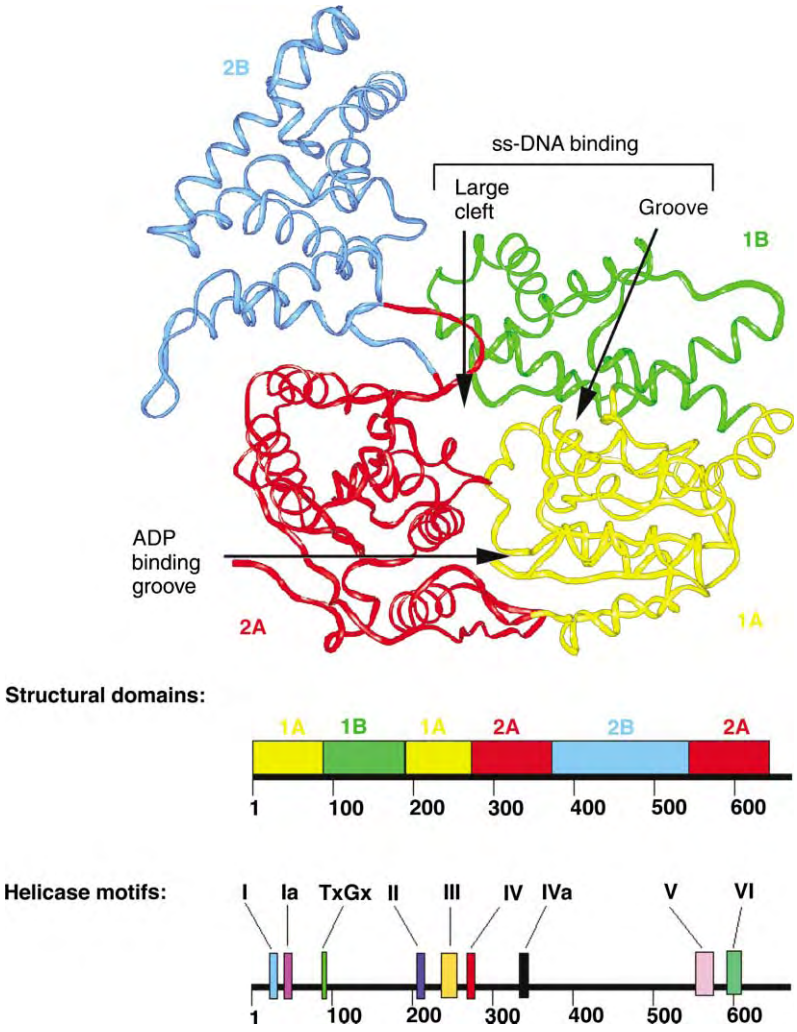

FIGURE 2 The domain structure of *E. coli* Rep monomer. The positions of the subdomains and the helicase motifs within the primary structure of Rep are also shown. The color scheme for the individual motifs corresponds to that shown in Figure 1. Modified from Korolev, S., Hsieh, J., Gauss, G. H., Lohman, T. M., and Waksman, G. (1997). Major domain swiveling revealed by the crystal structures of complexes of *E. coli* Rep helicase bound to single-stranded DNA and ADP. *Cell* **90**, 635–647.

duplex DNA stabilization. The essential nature of the 2B subdomain in Rep was tested by making a *rep* gene construct in which the coding region for the entire 2B domain was deleted and replaced by three glycines. The resulting RepΔ2B protein retains helicase activity *in vitro* and can also support ϕX174 phage replication *in vivo*, thus ruling out models invoking an essential role for the 2B domain in the helicase activity of Rep. In fact, a monomer of the RepΔ2B protein displays limited helicase activity *in vitro* in stark contrast to a wild-type Rep monomer which displays no helicase activity *in vitro*. This indicates that individual Rep monomers do possess all that is needed to unwind duplex DNA. However, the 2B subdomain appears to be inhibiting helicase activity of the monomer, and thus may have a regulatory function. This inhibition is relieved upon formation of a Rep or UvrD dimer.

Single-Stranded DNA Translocation by Monomers of SF1 Helicases

Recent studies have demonstrated that monomers of *B. stearothermophilus* PcrA can indeed translocate with biased directionality (3′–5′) along ss-DNA in an ATP-dependent reaction. In fact, monomers of *E. coli* Rep and UvrD, which are structural homologues of PcrA, also have been shown to be able to translocate along ss-DNA with biased (3′–5′) directionality. However, since monomers of Rep and UvrD are unable to unwind duplex DNA *in vitro*, it is clear that ss-DNA translocation alone is insufficient for DNA helicase activity for these helicases, and that dimerization is required.

DNA Unwinding by *E. coli* Rep and UvrD Helicases

Rep and UvrD Monomers are Unable to Unwind Duplex DNA and Protein Oligomerization is Required for Helicase Activity *in vitro*

Single-turnover DNA-unwinding studies indicate that Rep monomers are unable to unwind DNA *in vitro* and that Rep oligomerization is required for initiation of DNA helicase activity *in vitro*. Single-molecule fluorescence techniques have shown that a monomer of Rep uses ATP hydrolysis to translocate toward the ss/dsDNA junction, but then displays futile ATP-dependent conformational fluctuations, followed by dissociation of the monomer. DNA unwinding is initiated only if a functional oligomeric helicase is formed. Significantly, partial dissociation of the oligomeric helicase during unwinding leaves an inactive Rep monomer, resulting in a stalled complex. This stalled complex can be resolved in two ways. Dissociation of the remaining bound monomer leads to rewinding of the DNA duplex; however, re-initiation of unwinding can occur upon re-formation of the functional helicase by binding of additional Rep protein. These results show that a Rep monomer is unable to sustain DNA unwinding after the active Rep oligomeric complex disassembles. This also suggests that the low unwinding processivity observed for Rep DNA unwinding *in vitro* may be due to the relative instability of the functional dimer.

Initiation of DNA unwinding *in vitro* also requires a dimeric UvrD complex in which one subunit is bound to the ss/ds-DNA junction, while the second subunit is bound to the 3′ ss-DNA tail. Since the assay used in these UvrD studies relies on complete unwinding of an 18 base pair duplex, these results cannot exclude the possibility that monomers might unwind a short stretch of DNA duplex; however, processive unwinding of an 18 bp duplex requires UvrD oligomerization. Therefore, simple unidirectional translocation of a UvrD or Rep monomer along ss-DNA is not sufficient for helicase activity, and thus do not support "passive" models of DNA unwinding which assume that a translocating enzyme can unwind a duplex by simply taking advantage of the thermal fluctuations at the ss–ds DNA junction that result in transient fraying of the duplex end.

Kinetic Estimate of the DNA Unwinding "Step-Size" for *E. coli* UvrD Helicase

A kinetic approach indicates that UvrD unwinds 4–5 bp in each step (called the kinetic step size). This indicates that a rate-limiting step is repeated during the unwinding cycle and the unwinding "step-size" of 4–5 bp represents the number of base pairs unwound between two successive rate-limiting steps. It is not yet known how this kinetic step-size is related to a mechanical step size. Similar experiments performed with *E. coli* RecBCD helicase yield a step size of 3.9 ± 1.3 bp. A value of ~ 6 bp per step has also been estimated for the vaccinia NPH-II helicase. The similarities among these step sizes suggest mechanistic similarities, although this remains to be determined.

Mechanisms for DNA Unwinding and Translocation by SF1 Helicases

Whereas it seems likely that SF1 helicases may share some features of their unwinding mechanisms, it is still too early to conclude whether a single mechanism applies to all SF1 helicases. In fact, there are clear differences among some of the SF1 helicases studied to date. Although *E. coli* Rep and UvrD must oligomerize to function as helicases *in vitro*, a monomer of the phage T4 Dda helicase possesses limited unwinding activity *in vitro*. It is therefore possible that some SF1 helicases function as monomers to unwind short stretches of duplex nucleic acids, while oligomerization may be necessary to activate some SF1 helicases or to enhance their processivity. Of course, interaction of a helicase with an accessory protein may also modify the need for the helicase to oligomerize by providing a second DNA-binding site.

Most proposed mechanisms for DNA unwinding and helicase translocation assume the functional helicase to possess at least two DNA-binding sites. Differences in current models for DNA unwinding center on three aspects: (1) whether translocation of the helicase along ss-DNA is sufficient for helicase activity or whether the helicase also interacts directly with the duplex DNA; (2) whether the two DNA-binding sites are contained within a single polypeptide; and (3) whether the same DNA-binding site remains as the lead site (inch-worm model) or whether multiple sites alternate as the lead subunit ("rolling" or "hand-over-hand" models).

Active Versus Passive Mechanisms of DNA Unwinding

One operational distinction among DNA unwinding models is whether the helicase participates directly in destabilizing the duplex DNA (active mechanism), or whether the helicase interacts solely with the ss-DNA and waits for transient fluctuations in the duplex to form a ss-DNA region (end fraying) onto which the helicase can then translocate (passive mechanism).

"Active" mechanisms would generally involve direct binding of the helicase to the duplex DNA (or the duplex–ss DNA junction), in addition to the ss-DNA, although a "torsional" mechanism is possible in which binding of the helicase to both single strands might unwind the duplex without direct duplex interactions.

Tests of a "passive" mechanism of unwinding have been made for *E. coli* Rep and UvrD helicases using non-natural DNA substrates in which a region of the ss-DNA adjacent to the duplex was reversed in its backbone polarity or replaced by polyethylene glycol. The segments of polyethylene glycol or reversed polarity ss–DNA would prevent a helicase from translocating up to the ss–ds DNA junction, thus a helicase operating by a "passive" mechanism would not be expected to unwind such DNA substrates. However, Rep and UvrD can unwind such DNA molecules, ruling out a passive mechanism for these helicases.

Dimeric, Subunit Switching Models

Active, "Rolling" or "Hand-Over-Hand" Models for a Dimeric Helicase

An "active, rolling" mechanism (Figure 3A) has been proposed for how a Rep dimer might unwind DNA and translocate along the DNA filament. In this model, the individual subunits alternate as the lead subunit, which binds to duplex DNA, followed by unwinding. However, all of the evidence upon which this model was based is also consistent with a "dimeric inch-worm" model shown schematically in Figure 3B.

Dimeric Inch-Worm Models

The only difference between the "rolling" and "dimeric, inch-worm" models is that the same subunit remains as the lead subunit in the "dimeric inch-worm" model. In fact, recent evidence with both Rep and UvrD favors a "dimeric, inch-worm" model rather than a "rolling" or "hand-over-hand" model. Based on the fact that monomers of Rep and UvrD are able to translocate along ss-DNA with biased (3′–5′) directionality, it seems most likely that in a "dimeric inch-worm" model, the trailing subunit of the dimer might maintain continuous contact with the 3′ ss-DNA, possibly providing the motor component of the helicase, whereas the leading subunit would interact with the ss–ds DNA junction. However, such details are still speculative and need to be tested.

Monomeric Inch-Worm Models

It has been proposed that that a PcrA monomer unwinds DNA by an inch-worm mechanism. Support for the monomeric inch-worm model proposed for PcrA comes from the fact that PcrA monomers are able to translocate along ss-DNA with biased (3′–5′) directionality. However, both Rep and UvrD monomers also possess this ability, yet cannot unwind DNA *in vitro*.

Summary

It is now clear that monomers of SF1 helicases are able to translocate along ss-DNA with biased directionality in an ATP-dependent reaction. These monomers must use some sort of inch-worm mechanism for this translocation. However, monomers of *E. coli* Rep and UvrD are not able to initiate DNA unwinding *in vitro*, despite the fact that these monomers can translocate along ss-DNA with directional bias. Therefore, the ability to translocate with unidirectional bias along ss-DNA is not sufficient for a protein to have helicase activity. In fact, to date, only the phage T4 Dda and a deletion mutant of *E. coli* Rep (RepΔ2B) have been shown to unwind DNA *in vitro* as monomers, and these do so with low processivity. The 2B subdomain of Rep is not required for its helicase activity *in vitro*; in fact, this domain inhibits the ability of a Rep monomer to unwind

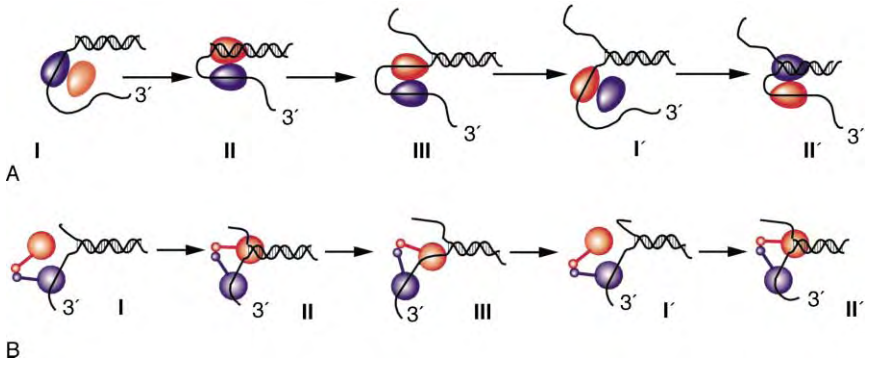

FIGURE 3 Models for DNA unwinding and translocation by a dimeric helicase. (A) Active, "rolling" or "hand-over-hand" model, and (B) dimeric "inch-worm" model.

DNA *in vitro*. Both *E. coli* Rep and UvrD are required to dimerize in order to initiate DNA unwinding *in vitro*, thus the inhibition of helicase activity by the 2B subdomain of Rep appears to be relieved through Rep oligomerization.

Glossary

helicase An enzyme that utilizes nucleoside 5′-triphosphates to separate the two strands of the DNA double helix in order to form the single-stranded DNA intermediates that are required for DNA metabolism (i.e., replication, recombination, and repair).

kinetic step size The average number of base pairs unwound between successive, repeated rate-limiting steps in the DNA unwinding cycle.

processivity A measure of the average number of base pairs that can be unwound by a helicase before it dissociates from the DNA.

Biography

Timothy M. Lohman is the Marvin A. Brennecke Professor of Biological Chemistry and a member of the Department of Biochemistry and Molecular Biophysics at Washington University School of Medicine, St. Louis, MO. His principal research interests are in the study of energetics and kinetic mechanisms of protein–DNA interactions, focusing on helicases and SSB proteins. He holds a Ph.D. in Physical Chemistry from the University of Wisconsin, Madison and did postdoctoral research at the University of California, San Diego and the University of Oregon.

DNA Helicases: Hexameric Enzyme Action

Smita S. Patel
Robert Wood Johnson Medical School, Piscataway, New Jersey, USA

Helicases are molecular motor proteins that use the energy of nucleoside triphosphate (NTP) hydrolysis to unidirectionally translocate along nucleic acid while separating the double-strand (ds) DNA strands, removing secondary structures in RNA, and displacing proteins bound to nucleic acids. Helicases are integral parts of the cellular machinery involved in DNA and RNA metabolic processes. Thus, it is not surprising that helicases and helicase-related proteins constitute more than 2% of the eukaryotic genome. Mutations in human genes coding for helicases result in several diseases that result in cancer and premature aging. Helicases also play a key role in viral life cycles such as viral genome replication and genome packaging/unpackaging. Viral helicases are therefore attractive targets for antiviral therapy. The topic of helicase structure, function, and mechanisms has been widely discussed in the literature. Oligomeric state divides helicases into two groups: ring (hexameric) helicases and all other. In this article, we start by discussing general mechanisms of translocation and strand separation of nucleic acid by helicases, which is followed by a discussion of the mechanisms of ring helicases.

Nucleic Acid Strand Separation Activity of Helicases

A long stretch of ds DNA or RNA is unwound by the helicase in a step-wise manner as shown in Figure 1. In each step, the helicase translocates and separates the duplex strands.

Most helicases require a stretch of single-stranded (ss) nucleic acid of a specific polarity adjacent to the duplex region to initiate strand separation. Helicases that require a 3′ ss tail to initiate strand separation are assumed to translocate in the 3′ to 5′ direction, and *vice versa*. Some helicases including hexameric ring helicases like T7 phage gp4 helicase, T4 phage gp41 helicase, and bacterial DnaB helicase require both 5′ and 3′ non-complementary tails to initiate strand separation, in which case it is difficult to determine the directionality of translocation using this assay.

Nucleic acid strand separation is commonly measured using short duplexes that contain a labeled strand of nucleic acid. Helicase is mixed with the substrate and MgNTP is added to initiate the reaction. This is a discontinuous assay, and after various reaction times, sodium dodecylsulfate (SDS) and ethylenediaminetetraacetic acid (EDTA) are added to stop the reaction. It is assumed that partially separated strands reanneal and only the completely separated strands are observed as products by native polyacrylamide gel electrophoresis. Alternatively, strand separation is measured in real time by using fluorescently labeled nucleic acids. This can be measured in ensemble reactions by the stopped flow method by monitoring fluorescence change or loss of fluorescence resonance energy transfer (FRET) as the strands are separated or by using FRET in single molecule experiments.

Multiple enzymatic activities are required for the helicase function, including NTPase, translocation, and strand separation. All helicases hydrolyze NTP, commonly ATP, both in the absence and in the presence of nucleic acid. The NTPase activity in the absence of nucleic acid is low and is stimulated many fold in the presence of nucleic acid. The stimulated NTPase activity is coupled to strand separation and unidirectional translocation of the helicase along nucleic acid. It is believed that as the helicase cycles through different NTP ligation states, the reactions of NTP binding, hydrolysis and product release induce conformational changes in the helicase's nucleic acid binding site. These conformational changes alter the affinity of the helicase for the substrate and/or to perform a power stroke to somehow drive unidirectional translocation and strand separation.

The helicase activity can be broadly divided into two reactions: unidirectional translocation and strand separation, both of which are fueled by the NTPase activity of the helicase. Several studies indicate that helicases translocate unidirectionally along ss DNA and that unidirectional translocation does not require the presence of the ss/ds DNA junction. Thus, it is likely that unidirectional translocation along nucleic acid is

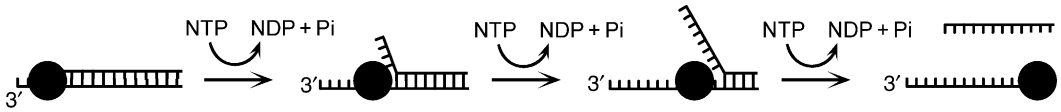

FIGURE 1 Helicase separating the strands of nucleic acid in the 3′–5′direction. The helicase (black circle) initiates strand separation by binding to the 3′-tail, translocating along a strand of the ss/ds nucleic acid substrate, and separating the strands of the substrate as it hydrolyzes NTP to NDP and phosphate (Pi).

the basic activity of helicases that also facilitates the strand separation process. A number of mechanisms of strand separation and NTPase-coupled translocation have been proposed from studies of different helicases. Some of the differences in the proposed mechanisms result from the different biochemical properties of the helicases, such as the protein oligomeric state, the interactions with ss versus ds substrates, and the effect of the nucleotide ligation state of the helicase on its substrate binding properties. Thus, it might appear that there are several ways to separate the strands of nucleic acid; although, it is likely that as detailed studies are carried out, a general mechanism of translocation and strand separation by helicases will emerge.

Mechanisms of Unidirectional Translocation

Stepping Model

It is commonly believed that translocation requires at least two nucleic acid binding sites that independently bind and release nucleic acid as the helicase goes through the NTPase cycle. Such stepping models have been discussed widely and proposed for helicases such as PcrA, Rep, and UvrD. The two nucleic acid binding sites move with respect to each other in response to the conformational changes induced by NTP binding, hydrolysis, and product release at the NTP binding site of the helicase. In an oligomeric helicase, the NTPase activity of each subunit controls the conformation of the nucleic acid binding site; thus, coordinated NTPase activity leads to coordinated binding and release of the helicase from nucleic acid. Several helicases including PcrA, HCV helicase, and T4 DdaA are active as monomers. A monomeric helicase with one nucleic binding site cannot use the stepping mechanism described above. The monomer of PcrA has been proposed to contain two DNA binding sites that coordinate DNA binding and release. In this case, the two DNA binding sites on a monomer are controlled by one nucleotide binding site.

Brownian Motor Model

An alternative model of translocation integrates Brownian motion into a molecular motor. Such a Brownian motor mechanism has been proposed for motors such as kinesin, myosin, and ion pumps. A Brownian motor uses thermal fluctuations from its surroundings and the NTPase reaction to achieve unidirectional movement. Brownian motor model can be applied to monomeric helicases with one nucleic acid binding site, although it predicts limited processivity of translocation and strand separation. The helicase holds on to the ss nucleic acid only via one binding site, and therefore it is more likely to dissociate during the weak binding sliding phase. A dimeric helicase with two and a hexameric helicase with six nucleic acid binding sites can use a Brownian motor mechanism and translocate with a greater efficiency. This is especially true if the helicase subunits coordinate their NTPase cycles and take turns binding and hydrolyzing NTP. In fact, a coordinated dimer or hexamer should appear as if it is stepping, because its subunits are taking turn moving forward.

Figure 2 shows a mechanism in which we suppose that in the absence of NTP the helicase is tightly bound to the nucleic acid and hence is in its lowest energy state unable to move along the substrate. When NTP binds to the helicase, it causes a conformational change in its nucleic acid binding site, resulting in a weakening of the nucleic acid binding affinity. In this weak binding state, the helicase's binding free energy is constant along the nucleic acid length (Figure 2, dotted line), which allows the helicase to slide along randomly in either direction influenced by thermal fluctuations, this is Brownian motion (Figure 2, position 4). It is important that the random movement of the helicase lasts only for a short time, and this is achieved by rapid NTP hydrolysis. After NTP hydrolysis, the tight rebinding to the nucleic acid is associated with a forward movement of the helicase along the direction of translocation. The forward movement of the helicase occurs along a decreasing energy slope and can be considered a power stroke. The forward movement does not require specific interactions with the ss/ds junction; hence, it can provide unidirectional movement along ss nucleic acid. If Brownian motion moves the helicase backward, a forward power stroke while rebinding to the nucleic acid will bring the helicase back to the same position it started, without net movement (position 3). The helicase molecules that diffuse in the forward direction (position 5) will end up one step forward from their original position upon tight

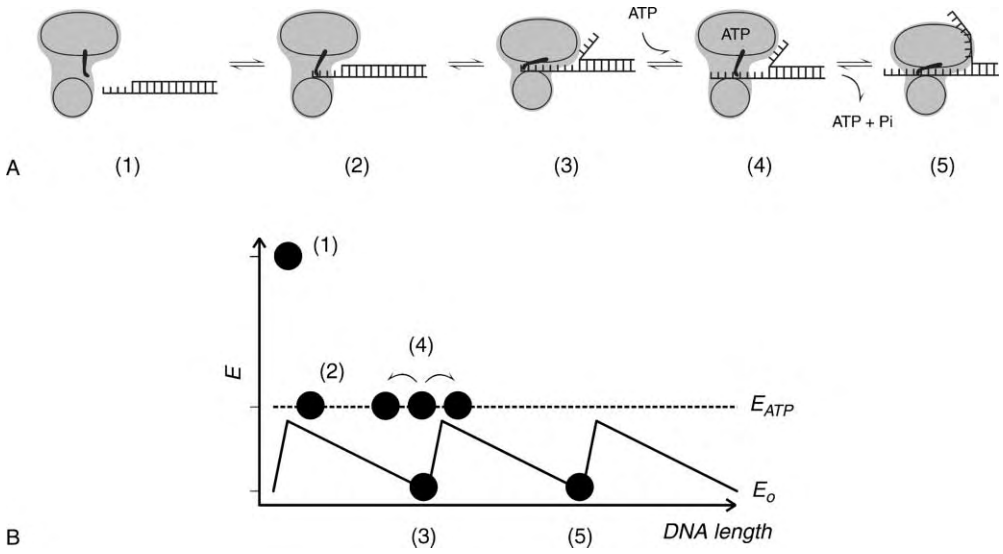

FIGURE 2 Translocation of the helicase by a Brownian motor mechanism. (A) Transition of the helicase from a weakly nucleic-acid-bound state (helicase-ss nucleic acid-ATP state, (2)) to a tightly nucleic acid-bound state (helicase-ss nucleic acid state, (3)) is coupled to unidirectional movement. (B) Helicase binding free energy (E) along the length of ss nucleic acid. The helicase–nucleic acid complex has an asymmetric saw tooth profile along the length of ss nucleic acid, E_o (solid line) in the nucleotide-free state and a flat energy profile in the ATP-bound state, E_{ATP} (dotted line). The helicase position on ss nucleic acid is represented by gray circles: (1) free helicase; (2) helicase bound to ss nucleic acid weakly; (3) helicase bound to ss nucleic acid tightly; (4) helicase bound weakly to ss nucleic acid that can diffuse in either direction; (5) rebinding of the helicase from position (4) results in a net forward movement.

rebinding to the nucleic acid. A helicase can move forward even against a moderate external force (such as strand separation) as long as a significant fraction of the helicase can diffuse forward to position 5. Repeated binding and release of the helicase catalyzed by NTPase cycles results in a net unidirectional translocation of the helicase. This mechanism may be considered a combination of power stroke and Brownian ratchet.

The efficiency of a motor is defined as the fraction of productive steps per round of NTP hydrolysis. Several factors affect the efficiency of a Brownian motor. The greater the asymmetry of the saw tooth energy profile, the greater the efficiency of the motor. The steeper energy profile will increase the fraction of helicase molecules that reach position 5. The efficiency is also highly dependent on the rate of NTP hydrolysis, which determines the lifetime of the weakly bound state (Figure 2, position 4). If NTP hydrolysis is too fast, the lifetime of the weakly bound state will be too short and most molecules will end up in the same position they started with no net directed motion. If NTP hydrolysis is too slow, the molecules will have time to spread broadly in both directions with no net directed motion.

Mechanisms of Nucleic Acid Strand Separation

Separating the strands of a duplex nucleic acid involves breaking the hydrogen bonds that hold the base pair (bp) together. At physiological temperature, nucleic acid bps open and close spontaneously. The rates of spontaneous bp opening as measured by imino proton exchange range from 30 s^{-1} for internal bp to 1000 s^{-1} for bp at the ss/ds junction. Individual bps open at a fast rate but the equilibrium for this reaction is toward bp formation. Therefore, bp closing is fast and it poses a kinetic barrier against the movement of helicase at the ss/ds nucleic acid junction.

At physiological temperatures, nucleic acid strand separation is a thermodynamically unfavorable process. In order to make the process thermodynamically favorable, the helicase must stabilize the transition state and/or stabilize the open bps. This can be accomplished either actively or passively. In an active mechanism, the helicase increases the rate of bp opening. If the helicase separates the nucleic acid strands by the passive mechanism, by definition, it does not change the rate of bp opening. A helicase can increase the rate of strand separation by lowering the transition state energy by binding to an intermediate such as a distorted duplex region or the ss/ds nucleic acid junction. Interaction of the helicase with ds nucleic acid has been viewed as an indication of an active mechanism of strand separation. Another way to actively disrupt bps is by unidirectional translocation or by a wedge mechanism. In this mechanism, the helicase translocates unidirectionally along ss nucleic acid and along its way it is able to capture base-pairs generated by thermal fluctuation. Helicases have been shown to move unidirectionally

along ss nucleic acid. Helicases have also been shown to displace proteins on their path and break the streptavidin–biotin linkage at the end of ssDNA without specifically interacting with them. Unidirectional translocation could be the driving force for strand separation and a basic property of helicases, making helicases similar to motor proteins that move on filaments.

Step-Size of the Helicase

The physical step-size of a helicase is the number of bases it travels in a single cycle during unidirectional translocation; its measurement provides critical insights into the mechanism of translocation. Methods for measuring the physical step-size of a helicase directly have been reported, and there is a need to develop methods to quantitatively measure the stepping motion of the helicase. Kinetic step-size of a helicase can be measured by globally fitting the single turnover kinetics of strand separation of duplexes of various lengths. This method assumes that all species have identical stepping properties. In cases where multiple populations with different stepping rates exist, the kinetics will exaggerate the estimation of step-size. In the case of a helicase whose ATPase cycles are tightly coupled to movement, the step-size can also be obtained by measuring the coupling ratio, which is the number of bases the helicase can travel per NTP hydrolyzed.

Hexameric Helicases

Hexameric ring helicases are found in all organisms including bacteriophage, viruses, bacteria, and eukaryotes. These helicases are often integral parts of protein complexes that catalyze nucleic acid replication, recombination, and transcription (Figure 3).

Ring Structure

In most helicases, six identical polypeptides assemble into a hexameric ring. Eukaryotic minichromosome maintenance (MCM) helicases on the other hand assemble into a heterohexamer of Mcm2–7 proteins with a unique arrangement of the six subunits. The three-dimensional structure of ring helicases from various organisms has been characterized extensively by electron microscopy and image analysis. These studies show that the ring structure is conserved from bacteriophage to viruses and from prokaryotes to eukaryotes as shown in Figure 4. The six subunits are arranged in a toroidal shape. On an average, the outer diameter of the ring is approximately 12 nm and the diameter of the central channel is approximately

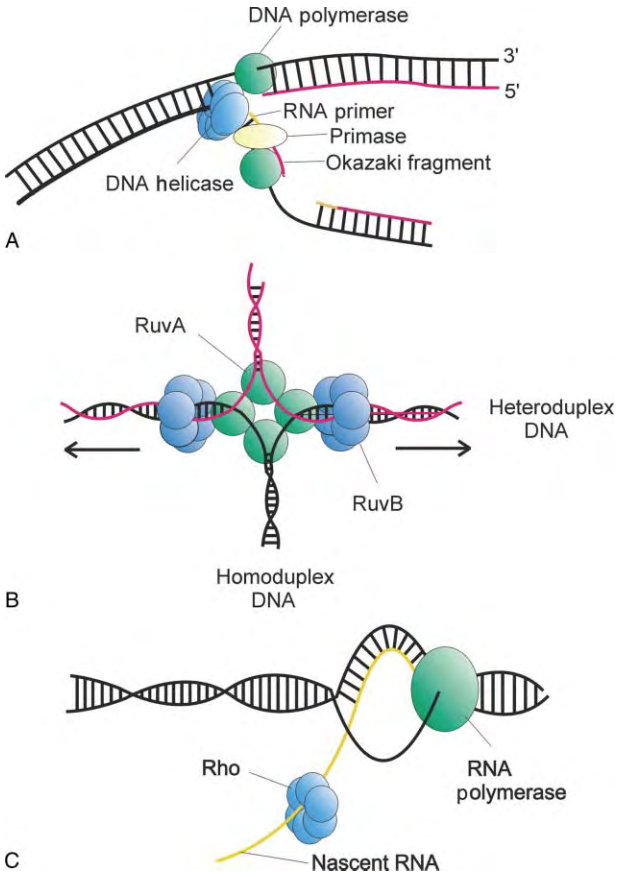

FIGURE 3 Functions of ring helicases in (A) DNA replication, (B) recombination, and (C) transcription.

2 nm. The central channel is therefore wide enough to accommodate duplex DNA or RNA.

Crystal structures of ring helicases including RepA, RuvB, Rho, and fragments of T7 gp4 and SV40 Large T antigen provide atomic details of the subunit interface and the NTP binding site (Figure 5A). The crystallized RepA helicase ring in the absence of NTP has a sixfold symmetry, Rho ring was open, and the T7 gp4 ring with four NTPs bound has a twofold symmetry. The structure of the N-terminal fragment of archaea MCM protein reveals a double hexamer arrangement. The major subunit–subunit contact in RepA and T7 gp4 is between an N-terminal loop (in RepA) or the linker region between the helicase and primase domains (in T7 gp4) contacting helices between H1a and H2 of a neighboring subunit.

The structure of ring helicases shows that most of the helicase-conserved motifs including H1, H1a, H2, and H3 appear at the subunit interface, where they participate in NTP binding (Figure 5). Thus, NTP bound at the interface interacts with residues from adjacent subunits. A critical arginine (Arg 522 in T7 gp4) is found in hexameric helicases that come from a neighboring subunit and is within hydrogen bonding distance of the

gamma phosphate of NTP bound at the interface, as shown in Figure 5B. This residue is important for catalyzing NTP hydrolysis and is implicated in transducing conformational changes between subunits of the hexamer.

Nucleic Acid Binding in the Central Channel

Detailed structural information is not available for the helicase nucleic acid binding site. Electron microscopy studies of ring helicases and biochemical studies indicate that nucleic acid binds in the central channel. Since the nucleic acid is confined within the central channel, its dissociation would require subunit–subunit disruption. This mode of nucleic acid binding is believed to confer processivity in translocation and strand separation activities of the hexameric helicases.

Processivity is the measure of the number of bases translocated or bp unwound before the helicase dissociates from the nucleic acid. Processivity, *P*, can be obtained from the measured stepping rate and the dissociation rate of the helicase. High processivity of translocation distinguishes the ring helicases from helicases such as *E. coli* UvrD, PcrA, and hepatitis C virus (HCV) helicases that do not assemble into rings.

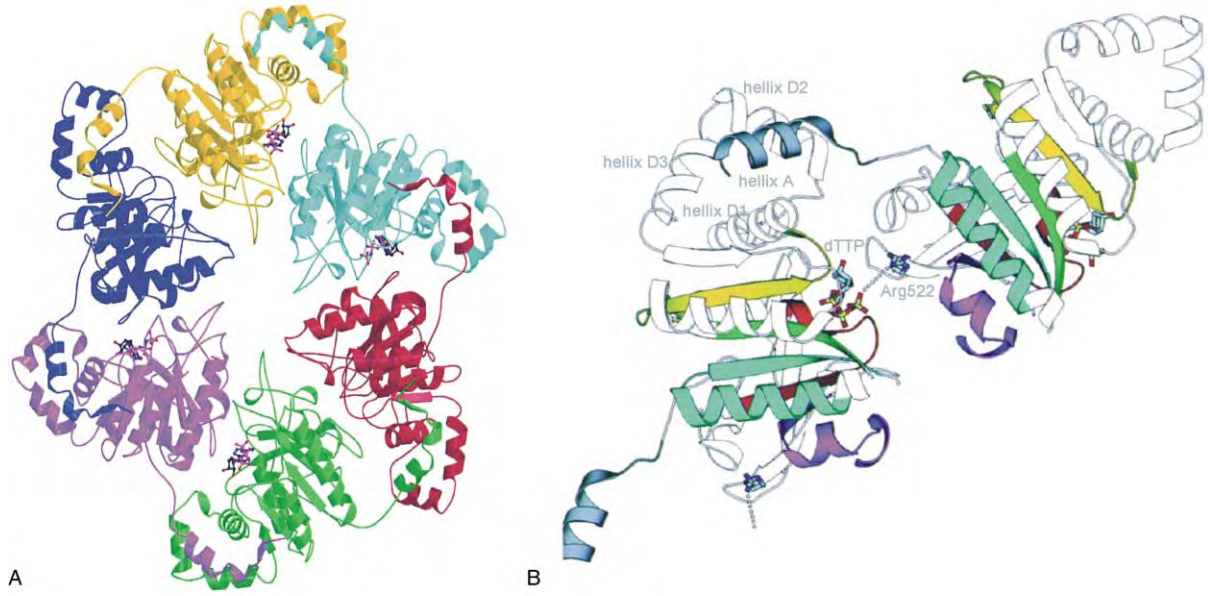

FIGURE 5 Crystal structure of the helicase domain of T7 gp4 protein. (A) Model of a closed ring shaped hexamer with four adenosine 5′-(β,γ-imido)triphosphates (ADPNP) bound at the subunit interfaces. (B) Arginine 522 (arginine-finger) contacting the nucleotide at the subunit interface.

Exceptions include RecBCD that may not encircle the DNA but shows a high processivity. The average processivity of ssDNA translocation by T7 gp4 hexamer on the other hand is $P = 0.99997$, a number close to one, which indicates that the probability of T7 helicase dissociating from ssDNA during translocation is very small. The processivity of T7 gp4 is only moderate because it is translocating and separating the strands of ds DNA, indicating that the association of T7 gp4 helicase with T7 DNA polymerase is necessary to achieve the high processivity observed during DNA replication. High processivity has been observed also for T4 gp41 and *E. coli* DnaB helicase in the replication complex.

How does the ring helicase bind nucleic acid in the central channel? The individual subunits can assemble around the nucleic acid, or the ring can open to accommodate the nucleic acid. Most helicases appear to use the ring-opening mechanism and they require a loader to efficiently bind nucleic acid. The loader is either part of the helicase or a separate protein or set of proteins that interact with the helicase. The primase site of T7 gp4 faces the outer surface of the ring and is proposed to play a role in loading the DNA into the central channel. Similarly, RNA wraps around the N-terminal domain of *E. coli* Rho protein, which plays a role in loading the RNA into the central channel. SV40 large T antigen and papilloma virus E1 contains origin binding domains that assist in DNA loading. In other ring helicases, accessory proteins are required to load the nucleic acid efficiently into the central channel. *E. coli* DnaB requires DnaC, T4 gp41 requires gp59, and MCM 2–7 helicase complex requires Cdc6 in addition to the single-stranded DNA binding proteins and origin recognition complex proteins to load at the replication origins.

Mechanism and Role of NTP Hydrolysis

The role of NTPase activity in ring helicases is similar to that of other helicases, in that NTP acts as a molecular switch. For example, T7 gp4 binds ssDNA in the presence of deoxythymidine (β, γ, methylene)triphosphate (dTMP-PCP), a nonhydrolyzable analog of dTTP with a K_d around 10 nM, and dTTP hydrolysis and Pi release leads to weakening of the interactions with ssDNA. Thus, dTTP binding and Pi release promote DNA binding and release events.

A negative cooperativity in nucleotide binding is observed in most hexameric helicases. A hexamer may bind only three nucleotides or show three high affinity and three low affinity nucleotide binding sites. T7 gp4 binds 3–4 nucleotides tightly in the presence or absence of Mg(II) ion. *E. coli* DnaB and Rho proteins have three high affinity and three low affinity nucleotide binding sites.

All six subunit interfaces of the hexamer can potentially bind and hydrolyze NTP. However, it has been proposed in T7 gp4 *E. coli* Rho as well as in MCM proteins that three subunits may have a regulatory role similar to that of the F_1-ATPase protein. Several possible mechanisms of NTP hydrolysis by ring helicases have

been discussed. The most appealing mechanism is sequential NTP hydrolysis by three or six of the hexameric subunits. Such a mechanism of NTP hydrolysis at three sites has been proposed based on pre-steady-state kinetic experiments in Rho protein with RNA and in T7 gp4 protein in the absence of ssDNA.

Translocation along Single-Stranded and Double-Stranded Nucleic Acid

Hexameric helicases such as T7 gp4 and T4 gp41 have been shown to translocate unidirectionally along ssDNA. T4 gp41 was able to displace streptavidin complexed to biotin placed at the 3′-end but not the 5′-end, suggesting that it translocates in the 5′–3′ direction. Similarly, utilization of primase sites on ssDNA was used to show that T7 gp4 translocates in the 5′–3′ direction. The DNA-dependent NTPase rate of these helicases also shows a dependence on ssDNA length that can be interpreted as unidirectional translocation along DNA. The translocation rate on ssDNA was measured for T7 gp4 as 130 base/s (at 18°C), and while translocating, gp4 hydrolyzes dTTP at a rate of 50 s^{-1}. This indicates that the energy from hydrolysis of one dTTP on average leads to translocation of the helicase along three bases of ssDNA. T7 gp4 helicase therefore translocates with a minimal step-size of three bases along ssDNA. RuvB helicase binds and translocates on dsDNA, catalyzing Holliday junction migration. Recently, *E. coli* DnaB and T7 gp4 helicases have been shown to migrate on dsDNA, but the rate of translocation has not been determined.

Translocation along nucleic acid by hexameric helicases appears to require functional subunits. Mutant poisoning experiments show that substitution of one or two of the hexamer subunits with a mutant inhibits the helicase and nucleic acid-dependent NTPase activity. Pre-steady-state NTPase kinetic experiments have indicated that the subunits of the ring act in a cooperative manner. The crystal structure of T7 gp4 fragment reveals that three adjacent subunits are in different conformational state (Figure 5A). Based on the structure, it was proposed that the hexamer subunits interact sequentially with the DNA during translocation. The stepping mechanism consisting of sequential NTP hydrolysis by the hexameric subunits coupled to sequential binding and release of nucleic acid is an attractive mechanism, but it requires more experimental evidence. An alternative mechanism of translocation to that discussed above is the Brownian motor mechanism that cannot be ruled out for hexameric helicases.

Binding and Strand Separation at the Fork Junction

Ring helicases encircle either the ss nucleic acid or the ds nucleic acid at the fork junction, as shown in Figure 3. Helicases involved in DNA replication are believed to encircle one of the ssDNA strands at the fork junction and to exclude the complementary strand from the central channel, as shown in Figure 3A. This mode of DNA binding minimizes immediate reannealing of the DNA strands after they are separated. The RuvB–RuvA complex involved in recombination (shown in Figure 3B) encircles dsDNA to drive Holliday junction movement. Recently, it was shown that when *E. coli* DnaB helicase and T7 gp4 helicase are presented with a substrate that contains only the 5′ ss DNA tail adjacent to the duplex they encircle and translocate along ds DNA and also drive movement of the Holliday junction. Transcription termination factor Rho is believed to translocate along RNA (shown in Figure 3C) to disrupt the transcription complex.

The kinetics of strand separation by helicase alone can be measured as described earlier using a small ds nucleic acid oligomer and by monitoring the release of ss nucleic acid. It was found with T7 gp4 that the rate of translocation along ssDNA is faster than the rate of ds DNA strand separation. Thus, T7 gp4 separates the ds DNA strands with a rate of about 15 bp/s. This rate depends on the concentration of NTP and temperature. Under the same experimental conditions, the rate of translocation along ssDNA is more than six times faster. Thus, dsDNA presents a barrier to the movement of helicase along DNA. The strand separation rate of helicases involved in replication also increases in the presence of the DNA polymerase. The replicative complex consisting of T7 gp4 helicase, gp2.5 protein, and T7 DNA polymerase catalyzes DNA replication at a rate greater than 200 bp/s at 30°C.

Conclusion

A large number of helicases and helicase-like proteins have been identified by genome sequencing efforts. These proteins play essential roles in almost all nucleic acid metabolism processes, and many are known to be associated with human diseases such as cancer and premature aging. Interestingly, many viruses code for their own helicases, which make them unique targets for antiviral therapy. Understanding the structure and mechanisms of helicases is an important means to find the link between the complex human diseases and helicases and to aid in the drug discovery process. From the viewpoint of understanding how helicases work, there is still a lack of a general mechanism that would

explain nucleic acid strand separation and other functions performed by helicases at the molecular level. Despite all the differences in the properties and structures of helicases, it is possible that they function by similar mechanisms. It is likely that unidirectional translocation is a basic activity of all helicases responsible for nucleic acid strand separation and all other functions of helicases. This makes helicases similar to general motor proteins that translocate on lattices, and their mechanism of operation may apply to helicases as well. New methodologies such as analysis of single helicase molecules will allow direct observation of the helicase reaction, and more detailed information from these experiments will provide physical parameters that will reveal how helicases work.

Biography

Smita Patel is a Professor in the Department of Biochemistry at the University of Medicine and Dentistry of New Jersey–Robert Wood Johnson Medical School in Piscataway, New Jersey. Research in her laboratory is focused on understanding the mechanisms of enzymes involved in DNA replication and transcription. She holds a Ph.D. from Tufts University and received postdoctoral training at Pennsylvania State University. Her laboratory is continuing to elucidate the mechanisms of DNA and RNA helicases from phage T7 and hepatitis C virus. In addition, she is interested in understanding the mechanism of transcription and its regulation and has elucidated the kinetic pathway of transcription initiation of a DNA-dependent RNA polymerase and the mechanism of open complex formation using transient state kinetic approaches.

DNA Ligases: Mechanism and Functions

Alan E. Tomkinson and John B. Leppard
University of Texas Health Science Center at San Antonio, Institute of Biotechnology, San Antonio, Texas, USA

DNA ligases are involved in DNA replication, genetic recombination, and DNA repair. These enzymes belong to a larger superfamily of nucleotidyl transferases that also includes RNA ligases and mRNA capping enzymes. Specifically, DNA ligases catalyze phosphodiester bond formation at breaks in the phosphate backbone of duplex DNA. The DNA ligase family can be subdivided into two groups based on cofactor specificity. Prokaryotic enzymes use either nicotinamide adenine dinucleotide (NAD) or adenosine triphosphate (ATP) as a cofactor, whereas viral, archael, and eukaryotic DNA ligases use ATP almost exclusively. DNA ligases share a common core catalytic domain, but the regions flanking the core domain are widely divergent. These unique regions mediate the specific participation of DNA ligases in different DNA transactions.

Reaction Mechanism

DNA ligase activity was first identified in 1967 in five different laboratories. In the years that followed, the Lehman laboratory was primarily responsible for elucidating the three-step reaction catalyzed by the NAD-dependent *Escherichia coli* DNA ligase and the ATP-dependent DNA ligase encoded by bacteriophage T4 that is described in this article.

Adenylation

In the first step, DNA ligase reacts with either nicotinamide adenine dinucleotide (NAD) or ATP to form a covalent enzyme—adenosine monophosphate (-AMP) intermediate (Figure 1). The AMP group is linked via a phosphoramidate bond to a conserved lysine residue that defines the active site of the core catalytic domain (Figure 2A). Formation of the enzyme–AMP intermediate induces a conformational change that is required for the recognition of a nicked DNA substrate in the next step.

AMP–DNA Intermediate

The second step in the reaction involves the transfer of the AMP group to the 5′-phosphate terminus at the nick in duplex DNA (Figure 1). The previous step leaves the enzyme in an open conformation that exposes the DNA binding site. Specific amino acid residues in the enzyme coordinate the AMP group such that an oxygen atom of the 5′-phosphate in the DNA substrate can attack the phosphoryl group of AMP, generating a DNA–AMP intermediate.

Phosphodiester Bond Formation

The third and final step of ligation is catalyzed by the nonadenylated form of DNA ligase. In this reaction, esterification of the 5′-phosphoryl group to the 3′-hydroxyl group completes phosphodiester bond formation with the concomitant release of AMP (Figure 1).

Structure

Gene cloning and, more recently, genome sequencing has led to a rapid growth in the number of DNA ligase genes identified. Alignment of DNA ligase amino acid sequences indicates that these enzymes share a conserved catalytic domain (Figure 2A). Furthermore, a comparison with the catalytic domains of mRNA capping enzymes revealed the presence of six conserved motifs (I, III, IIIa, IV, V, VI) that are characteristic of nucleotidyl transferases. In recent years, our understanding of how the DNA ligase catalytic domain catalyzes DNA joining has been advanced by a combination of approaches that include the use of site-directed mutagenesis to elucidate the role of individual amino acids within the catalytic domain and the determination of the three-dimensional structure of several DNA ligases by X-ray crystallography.

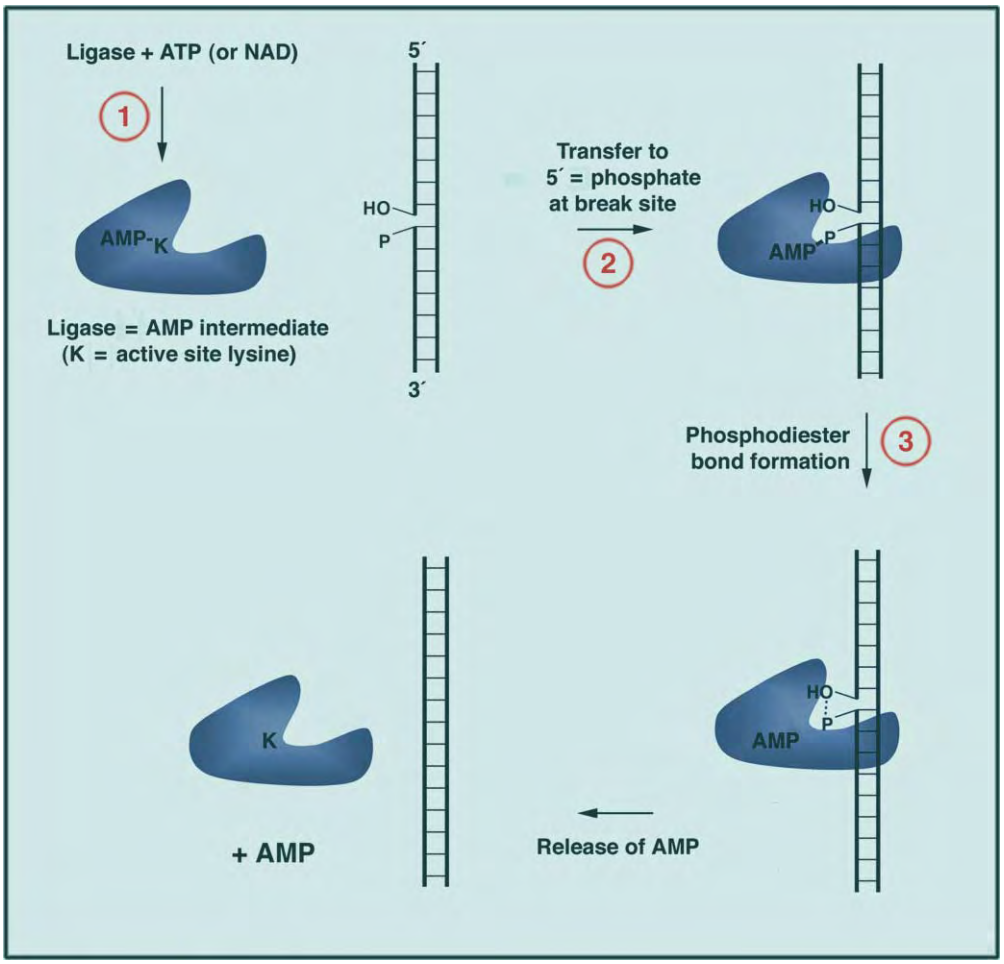

FIGURE 1 Mechanism of phosphodiester bond formation by DNA ligase. Step 1, DNA ligase interacts with ATP or NAD, forming a covalent enzyme–AMP intermediate. Step 2, after nick recognition, the AMP group is transferred to the 5′-phosphate terminus, forming a high-energy phosphate bond. Step 3, DNA ligase catalyzes phosphodiester bond formation, releasing AMP.

Crystal Structures

X-ray crystallographic studies of both NAD- and ATP-dependent DNA ligases have provided important insights into the three-dimensional structure of these enzymes. In 1996, the Wigley laboratory solved the first crystal structure of an ATP-dependent DNA ligase, the bacteriophage T7 DNA ligase, in a complex with ATP. More recently, the structure of the enzyme–AMP intermediate formed by the *Chlorella* virus DNA ligase was determined by the Shuman laboratory. A comparison of these structures revealed a conformational change in the DNA ligase catalytic domain that allows binding to nicked DNA. The structures of the ATP-dependent DNA ligases together with those of NAD-dependent enzymes such as *Thermus filiformis* DNA ligase (Figure 2B) and other members of the nucleotidyl transferase superfamily represent snapshots of this family of enzymes at different stages of the catalytic cycle. Thus, they provide a framework for understanding the dynamic conformational changes that occur when nucleotidyl transferases interact with their nucleotide cofactor and polynucleotide substrate.

Domains Constituting the Core Catalytic Domain

There are two subdomains known as the adenylation domain and the oligomer-binding (OB) fold (Figure 2A) within the DNA ligase catalytic domain. The larger adenylation domain is the minimum region required for formation of an enzyme–AMP intermediate, whereas the OB fold allows the enzyme to bind to DNA and coordinates the ligation event. Residues from motifs I through V line a cleft formed between the two subdomains to generate a positively charged nucleotide-binding pocket. The active-site lysine residue, which is contained within motif I, sits at the bottom of the cleft close to where the adenylation domain and the OB fold are linked. In the nonadenylated form, the enzyme is in an open conformation with the DNA-binding surface of

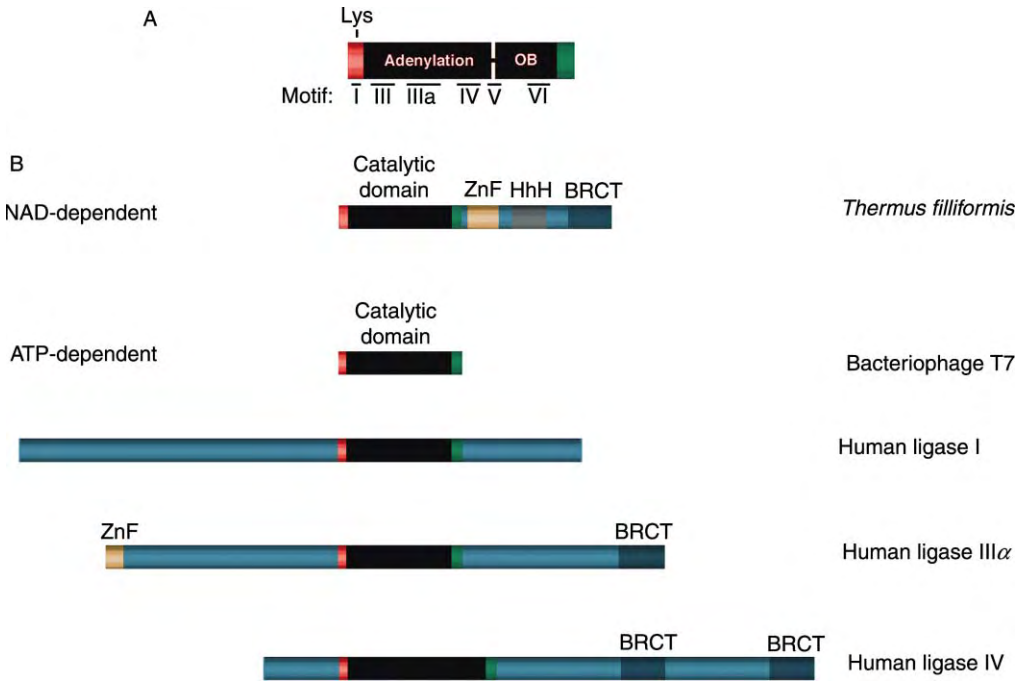

FIGURE 2 (A) Schematic representation of the core catalytic domain shared by all DNA ligases. (B) Comparison of a prokaryotic NAD-dependent DNA ligase (*Thermus filiformis*) and ATP-dependent DNA ligases from virus (bacteriophage T7) and humans (DNA ligases I, IIIα, and IV). BRCT, BRCA1 C-terminus domain; HhH, helix–hairpin–helix domain; Znf, zinc-finger motif.

the OB fold rotated away from the active site, thus preventing nonproductive DNA binding. Upon adenylation, the enzyme undergoes a conformational change such that the DNA binding surface of the OB fold faces in toward the cleft, making the active site accessible.

Other Common Domains of NAD-Dependent DNA Ligases

NAD-dependent DNA ligases are relatively uniform in size (~70 kDa). In addition to the adenylation domain and OB fold, they contain several other common motifs (Figure 2B) that are thought to mediate protein–DNA and protein–protein interactions. The zinc-finger (ZnF) and helix–hairpin–helix (HhH) motifs confer DNA binding activity. The BRCT domain, which was first identified in the breast cancer susceptibility gene 1, is probably involved in protein–protein interactions that recruit the enzyme to its site of action.

Sequences Flanking the Core Catalytic Domain of ATP-Dependent DNA Ligases

Unlike NAD-dependent ligases, ATP-dependent DNA ligases are heterogeneous in size (40–125 kDa) (Figure 2B). The amino acid residues that flank the catalytic domain of ATP-dependent DNA ligases contain a wide variety of sequences that mediate specific protein–protein interactions and protein–DNA interactions (Figure 2B). Intriguingly, recent sequencing studies have identified open reading frames in bacterial genomes whose sequences suggest that ATP-dependent DNA ligase activity may reside in the same polypeptide as nuclease and primase activities.

Biological Functions

The notion that cells may contain more than one species of DNA ligase was based on initial studies in the Lindahl laboratory describing the properties of various species of DNA ligase in mammalian cell extracts. These biochemical studies led to the cloning of three mammalian genes, *LIG1*, *LIG3*, and *LIG4*, that encode DNA ligases (Table I). More recent genome sequencing has led to the identification of additional DNA ligase genes in organisms such as *S. cerevisiae* and *E. coli* that were thought to have only a single DNA ligase gene. Because DNA joining is required to complete DNA replication, DNA repair, and genetic recombination, it appears likely that the multiple species of DNA ligase have evolved to participate in specific DNA transactions. Insights into the biological functions of the various DNA ligases have been obtained by examining the phenotype of DNA ligase-deficient cells and by identifying protein partners of the DNA ligases (Table I).

TABLE I

Mammalian DNA Ligases[a]

Gene	Gene product	Interacting protein	Function
LIG1	DNA ligase I	PCNA, Polβ	DNA replication, BER, NER, recombination
LIG3	DNA ligase IIIα (nuclear)	XRCC1	Single-strand break repair, BER
	DNA ligase IIIα (mitochondrial)	?	Single-strand break repair, BER?
	DNA ligase IIIβ	?	Postmeiotic repair?, meiotic recombination?
LIG4	DNA ligase IV	XRCC4	NHEJ, V(D)J recombination

[a] BER, base excision repair; NER, nucleotide excision repair; NHEJ, nonhomologous end-joining; PCNA, proliferating cell nuclear antigen; XRCC1, XRCC4, X-ray cross complementing factor 1 and factor 4.

DNA Replication

The ability to make a copy of their genetic information is essential for all organisms. During DNA replication, DNA joining events are required to link together DNA intermediates known as Okazaki fragments that are generated by discontinuous DNA synthesis on the lagging strand at the replication fork. As expected, inactivation of genes encoding replication proteins, including the replicative DNA ligase, results in cell lethality. Because DNA replication involves the coordinated actions of many different proteins, it seems reasonable to assume that the DNA ligase involved in DNA replication will interact with one or more of the other replication proteins. In mammalian cells, proliferating cell nuclear antigen (PCNA), a homotrimeric ring-shaped clamp protein that was identified as an accessory factor of the replicative DNA polymerase, specifically interacts with the N-terminal region of DNA ligase I. This interaction is critical for the recruitment of DNA ligase I to the sites of DNA replication and for the efficient joining of Okazaki fragments. A similar protein–protein interaction occurs in *E. coli* between the NAD-dependent DNA ligase and β-clamp, the functional homologue of PCNA, indicating that the interaction between the replicative DNA ligase and the clamp protein is conserved in prokaryotic and eukaryotic DNA replication.

DNA Excision Repair

Exposure to endogenous DNA-damaging agents such as reactive oxygen species and exogenous DNA-damaging agents such as ultraviolet light results in damage to the nitrogenous bases of DNA. In addition, the DNA replication machinery makes errors that result in mispaired or unpaired nucleotides. Damaged and mispaired nucleotides are removed from the genome by excision repair pathways that share three common steps: (1) excision of the damaged or mispaired DNA, (2) gap-filling DNA synthesis using the undamaged strand as template, and (3) DNA ligation to complete the repair.

The pathways for the repair of damaged bases can be divided into two types based on whether the damage is removed as a nitrogenous base, base excision repair (BER), or as a nucleotide, nucleotide excision repair (NER). In mammalian cells, there are two subpathways of BER, long patch and short patch, that appear to involve two different DNA ligases. Short-patch BER events are mostly completed by DNA ligase IIIα in a complex with its partner protein X-ray cross complementing factor 1 (XRCC1), whereas long-patch BER is completed by DNA ligase I. NER events are probably completed by DNA ligase I.

In DNA mismatch repair, specific protein factors recognize the mispaired or unpaired nucleotides and direct the excision proteins to the newly synthesized strand. After the removal of a section of newly synthesized DNA containing the mispaired or unpaired nucleotides, the resultant single-strand gap is filled in by a DNA polymerase and repair is completed by a DNA ligase, presumably DNA ligase I.

Genetic Recombination and Recombinational Repair

Genetic recombination is the major process by which diversity is generated in living organisms. In mammals, exchanges between homologous chromosomes that occur during meiosis contribute to the generation of genetically diverse gametes. It is assumed that DNA ligase I, the replicative DNA ligase, also completes the meiotic recombination events. However, in vertebrates, there is a germ-cell-specific isoform of DNA ligase III, DNA ligase IIIβ, that may also participate in the completion of meiotic recombination. Alternatively, DNA ligase IIIβ may function in DNA transactions in haploid gametes.

Recombination pathways are also critical for the maintenance of genome stability in somatic cells, in particular for the repair of DNA double-strand breaks. This lesion presents a difficult challenge because both strands of the DNA duplex are broken. Recombinational repair pathways can be divided into two types

based on whether they are dependent on DNA sequence homology or not. It is generally assumed that homology-dependent recombinational repair pathways, in particular those involving sister chromatids, are completed by DNA ligase I. In the non-homology-directed repair pathways, the ends of broken DNA molecules are simply brought together by DNA end-bridging factors, processed, and then ligated. Surprisingly, this inaccurate repair pathway, which can result in a wide spectrum of genetic alterations ranging from small deletions to chromosomal translocations, makes a major contribution to the repair of DNA double-strand breaks in mammalian cells. Genetic and biochemical studies have shown that this so-called nonhomologous end-joining (NHEJ) is dependent on DNA ligase IV and its partner protein XRCC4. The same DNA ligase IV/XRCC4 complex is also required for the completion of *** V(D)J recombination, a site-specific recombination mechanism that is required for the rearrangement of immunoglobulin genes to develop a diverse repertoire of antibodies and T-cell receptors.

Mitochondrial DNA Metabolism

The DNA transactions just described occur in the nucleus. However, the eukaryotic organelles, mitochondria and chloroplasts, contain their own genetic information that must be replicated and repaired. Studies in the Campbell laboratory have shown that nuclear and mitochondrial forms of DNA ligase III are generated by translation initiation at different sites within the same open reading frame encoded by DNA ligase IIIα mRNA. Although the yeast *S. cerevisiae* lacks a homologue of the *LIG3* gene, it uses the same mechanism to generate mitochondrial and nuclear forms of the Cdc9 DNA ligase.

Concluding Remarks

Although the basic reaction mechanism catalyzed by DNA ligases was elucidated over 30 years ago, the recent determination of the three-dimensional structure of both NAD- and ATP-dependent DNA ligases has provided exciting new molecular insights into this reaction mechanism. However, structures of DNA ligases interacting with their DNA substrate are needed for a better understanding of the final two steps of the ligation reaction. Because DNA strand breaks are a common intermediate in many different DNA transactions, the study of DNA ligases by genetic and biochemical approaches will continue to provide information about the molecular mechanisms of DNA replication, DNA repair, and genetic recombination. Finally, mutations in DNA ligase genes have been associated with human diseases, highlighting the importance of these enzymes.

Glossary

adenylation The reaction in which DNA ligase interacts with ATP or NAD to form a covalent enzyme–adenylate complex.

motif An amino acid sequence found to be conserved in various proteins.

phosphodiester bond Bond that links deoxynucleotides in DNA, forming the sugar phosphate backbone of the DNA polymer.

phosphoramidate bond The covalent bond formed between a phosphoryl group and an amino group. For DNA ligases, the phosphoryl group of AMP is linked to the amino group of the active-site lysine.

DNA ligases are enzymes that catalyze the formation of phosphodiester bonds at the site of DNA nicks or breaks. They are responsible for maintaining the continuity of DNA, which is of paramount importance for the survival of all organisms. While many different safeguards exist to repair DNA damage and to accurately replicate or recombine DNA, they all share a common, final procedure, the ligation of DNA. The fundamental nature of this process explains why the DNA ligase family of enzymes is represented in all cellular organisms and in a number of DNA virus genomes. High-resolution crystal structures of DNA ligases and important reaction intermediates illuminate the mechanism of covalent catalysis and provide a framework for understanding the results of preceding investigations of ligase biochemistry.

Introduction

The copying and maintenance of the genetic material takes place through the processes of DNA replication, repair, and recombination. In all cases, the final step in these fundamental cellular processes is the sealing of the DNA strands to maintain their fidelity. DNA ligases catalyze the formation of phosphodiester bonds at the site of DNA nicks or breaks via three sequential nucleotidyl transfer steps. In the first step, the enzyme reacts with a high-energy cofactor (ATP or NAD^+) to form a covalent ligase-AMP intermediate with a release of pyrophosphate or nicotinamide mononucleotide. In the second step, the ligase-AMP binds a DNA nick and the AMP moiety is transferred from the enzyme to the 5′ phosphate terminated DNA molecule. The resulting stable DNA adenylate has an inverted 5′–5′ pyrophosphate bridge structure, AppDNA. In the final step, the ligase catalyzes the nucleophillic attack by the 3′ hydroxyl group present on the juxtaposed nucleotide of the discontinuous strand, resulting in closure of the gap between the two polynucleotides and release of AMP.

The ATP-dependent ligases and the GTP-dependent capping enzymes are defining members of the superfamily of the covalent nucleotidyltransferases. The first two steps of DNA ligation are analogous to the steps of GTP-dependent mRNA capping that result in guanylate RNA (GpppRNA). The lysine residue located within a conserved Lys-X-Asp-Gly-X-Arg element (named motif I) is the site of covalent linkage of AMP to the ligase and of GMP to the capping enzyme. In addition to this sequence, the members of this enzyme superfamily share five other conserved regions, referred to as motifs III, IIIa, IV, V, and VI. The numbering corresponds to the position within the primary sequence, with motif I being the most proximal to the protein amino terminus, and motif VI to the carboxy terminus. Mutational analysis of the residues within these motifs has documented their essential role in the catalytic activity of both ligases and capping enzymes.

The multi-step, nucleotidyltransferase reactions are catalyzed by single enzymes, which suggests that these proteins undergo dynamic conformational changes to accommodate the distinct substrates utilized at each step. Crystal structures of a number of ATP- and NAD^+-dependent ligases, as well as the related mRNA capping enzymes, at intermediate steps along the reaction coordinate have provided insights into the catalytic mechanism of the enzymes.

Overall Structure of DNA Ligases

DNA ligases are grouped into two families according to their high-energy cofactor requirements for either ATP or NAD. Those utilizing ATP are more widely distributed and are present in eubacteria, bacteriophages, archaebacteria, eukaryotes, and eukaryotic viruses. They vary in size between the 268 amino acid enzyme of *Haemophilus influenzae* and the larger cellular ligases of vertebrates, which are 912 and 844 amino

acids, respectively, for the human DNA ligase I and IV enzymes. The first reported three-dimensional structure of an ATP-dependent DNA ligase was that of the bacteriophage T7 enzyme, followed by the structure of the eukaryotic DNA ligase from the *Paramecium Bursari Chlorella Virus*, the smallest known (298 residues) eukaryotic ATP-dependent ligase. In addition, the structures of the GTP-dependent mRNA capping enzymes from *Chlorella* virus and *Candida albicans* were also determined. These studies reveal a common molecular architecture of the ligases and capping enzymes, with a large amino-terminal domain (domain 1) and a smaller carboxy-terminal domain (domain 2) separated by a deep cleft. The amino-terminal domain 1 of the *Chlorella* virus ligase consists of two twisted antiparallel β-sheets packing against six α-helices. This domain contains the nucleotide-binding site, which is generated by the spatial approximation of five of the six conserved nucleotidytransferase motifs (I, III, IIIa, IV, and V), and is located between the two β-sheets. The carboxy-terminal domain 2 contains an antiparallel β-sheet and a α-helix and folds into an OB-fold, commonly found in nucleic acid-binding proteins. The sixth nucleotidyltransferase motif (motif VI), which is required for covalent enzyme-nucleotide monophosphate (enzyme-NMP) formation, is located within domain 2 in both the ATP-dependent ligases and the mRNA capping enzymes. The conserved spatial arrangement of critical residues and functional groups in the two enzyme classes suggests a common ancestral protein from which the two enzymatic lineages have descended.

Analysis of the structures presented in Figure 2 demonstrates that the *Chlorella* ligase represents the core catalytic element found in all nucleotidyltransferase enzymes. The sequence alignment of known DNA ligases reveals that in addition to this more conserved core element, most members of this enzyme family contain a variety of amino- and carboxy-terminal sequence motifs and domains, which are likely to mediate interactions with other proteins that participate in DNA replication and repair (illustrated in Figure 1). Mammals encode for four distinct DNA ligases (I, IIIα, IIIβ, and IV). Ligase I contains a proliferating cell nuclear antigen (PCNA) binding motif, which likely functions to coordinate protein-protein interactions at the DNA replication fork. The DNA ligase III gene encodes for two isoforms, IIIα and IIIβ, which are produced by alternative splicing and are found in the nucleus and the mitochondria, respectively. Both ligase III isoforms harbor a putative zinc-finger motif, which could facilitate the DNA-enzyme interactions. In addition, the larger ligase IIIα isoform contains a carboxy-terminal BRCT domain that interacts with XRCC1, a multi-domain protein implicated in base excision-repair. Ligase IV possesses two BRCT domains, and the region between them was shown to bind the repair factor XRCC4 that functions in V(D)J recombination and nonhomologous end joining.

The NAD-dependent DNA ligases are found exclusively in eubacteria, and have a relatively conserved length and sequence. The crystal structures of the NAD-dependent ligase from the thermophilic bacterium *Thermus filiformi* and of the adenylation domain of the *Bacillus stearothermophilus* ligase have been determined. The *T. filiformi* structure documents that the protein contains four discrete domains. Domains 1 and 2 are analogous both in structure and function to

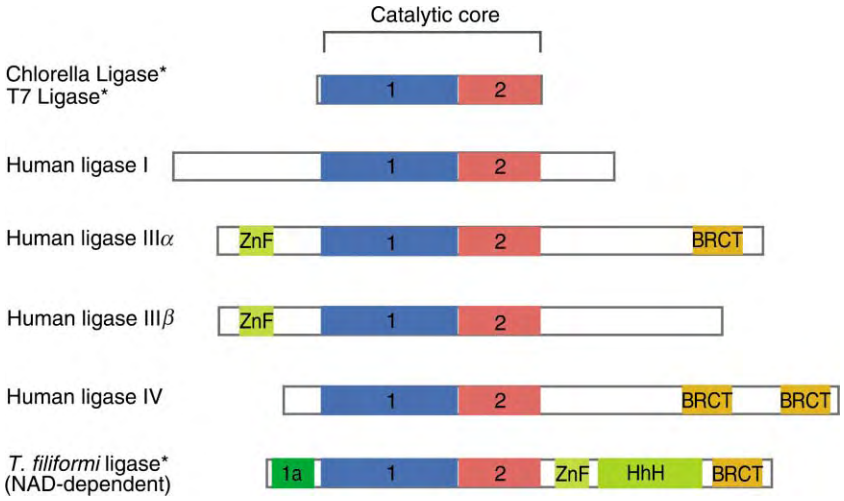

FIGURE 1 Schematic representation of the domain architecture of known DNA ligases. The domains are color-coded. The asterisk indicates that the high-resolution structure is known. The catalytic core consists of two subdomains: 1 (adenylation), blue; and 2 (oligonucleotide-binding or OB), red. In addition to the catalytic core, some DNA ligases contain other domains and/or motifs, such as zinc fingers (ZnF), helix–hairpin–helix (HhH), and BRCT. Many NAD-dependent DNA ligases also have a small amino-terminal helical subdomain (1a).

the two catalytic domains of the ATP-dependent enzymes (Figures 1 and 2). Within this region, the five amino-terminal nucleotidyltransferase motifs adopt nearly identical spatial organization to their ATP-dependent counterparts. Domain 1 of the NAD-dependent DNA ligases contains an additional amino-terminal α-helical subdomain 1a, which may participate in the recognition and binding of the second nicotinamide mononucleotide moiety of NAD^+. Interestingly, domain 2 of the NAD-dependent DNA ligases lacks the motif VI sequence, but still adopts an OB-fold similar to that of the T7 and *Chlorella* ligases. Domain 3 is unique for the NAD-dependent DNA ligase subfamily, and is predicted to be involved in nonsequence-specific DNA binding. It contains a four-cysteine zinc finger and four helix-hairpin-helix (HhH) motifs, which fold around each other to form a compact three-dimensional structure. The carboxy-terminal domain 4 has a BRCT motif similar to those present in mammalian ligases III and IV.

The Nucleotide-Binding Pocket

The structure of the T7 DNA ligase with bound ATP (Figure 2A) reflects the state of the enzyme prior to the first chemical step of nucleotidyl transfer. The ATP is located in a hydrophobic pocket of the active site with the adenosine base adopting a *syn* conformation relative to the sugar (Figure 3A). The active site lysine (Lys-34) in motif I is positioned close to the α-phosphate of the ATP molecule, marking the future site of the covalent AMP-enzyme adduct. Arg-39 in motif I is hydrogen-bonded to the 3′ oxygen of the ribose sugar. Motif III contains two acidic residues, Asp-91 and Glu-93. Asp-91 forms a salt bridge with Arg-39 in motif I, while Glu-93 is hydrogen-bonded to the ribose oxygen at the 2′ position. Two positively charged residues in motif V, Lys-232 and Lys-238, are positioned close to the γ- and β-phosphate groups and stabilize the negative charges on the ATP molecule. The aromatic residue Try-149 in motif IIIa stacks against the purine ring of ATP, positioning the adenine base in an optimal orientation for catalysis. The key residues involved in nucleotide binding are conserved both in the ATP- and in the NAD-dependent DNA ligases (as well as in the capping enzymes) and perform similar catalytic functions as visualized in the corresponding *Chlorella* ligase-AMP and *T. filiformi* ligase-AMP structures, suggesting that the reaction mechanism is conserved throughout evolution.

The *Chlorella* ligase–AMP structure reveals that the adenosine-binding pocket is remodeled upon covalent ligase-adenylate complex formation. In contrast to the *syn* conformation of the ATP adenosine bound in the active site of the T7 ligase, the adenosine nucleoside present in the *Chlorella* ligase–AMP complex is in the *anti* conformation (Figure 4A). As a consequence, the contacts between the enzyme and the ribose oxygen are altered during enzyme-adenylate complex formation. The arginine in motif I forms a hydrogen bond to the ribose 2′ oxygen, rather than the 3′ oxygen, while the glutamate side chain in motif III no longer contacts the ribose sugar, leaving the 3′ oxygen without any direct contacts with the protein. The observation that both the *C. albicans* capping enzyme-GMP and NAD-dependent *T filiformi* ligase-AMP (Figure 3B) intermediates adopt an *anti* conformation suggests that the change in conformation from *syn* to *anti* during enzyme-NMP formation is a general feature of the nucleotidyltransferase superfamily. The wider implication of this structural rearrangement is that the ribose 3′ oxygen is free to directly coordinate the 5′ nucleotide phosphate group of the nucleic acid substrate.

Mechanism of Nucleotidyl Transfer

The first direct evidence for conformational change during the covalent enzyme–NMP complex formation was evinced by crystal structures of two distinct conformations of the *Chlorella* virus mRNA capping enzyme bound to GTP. The two states are referred to as "open" and "closed" capping enzyme-GTP complexes (Figures 2E and 2F). The open conformation corresponds to the enzyme making an initial or transient contact with GTP. The closed complex structure represents the conformation in which the enzyme is stably bound to GTP, and is committed to the nucleotidyl transfer reaction. The two structural forms differ in the relative position of domain 2 with respect to the GTP-binding pocket: in the open complex, the cleft between the domains is wider and as a result the residues within motif VI are unable to make direct contact with GTP. In the closed complex structure, the positively charged amino acids in motif VI make direct contact with the β- and γ-phosphates of GTP, suggesting that these conserved residues function to facilitate the release of pyrophosphate after the formation of the lysyl–NMP

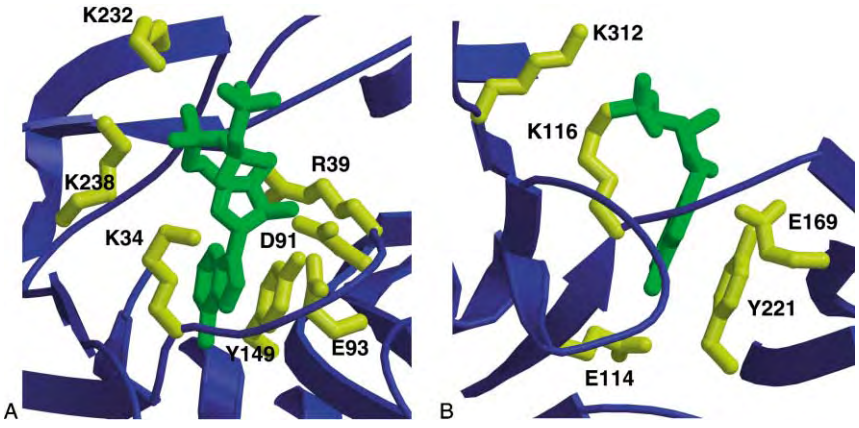

FIGURE 3 The nucleotide-binding pocket of DNA ligases. The ligase adenylation domain (domain 1) is in blue; the side chains of important residues (discussed in the text) are in yellow; and the bound nucleotide is in green. (A) ATP bound in the active site of the bacteriophage T7 DNA ligase. (B) AMP covalently bound to the active-site lysine of the NAD-dependent *T. filiformis* DNA ligase.

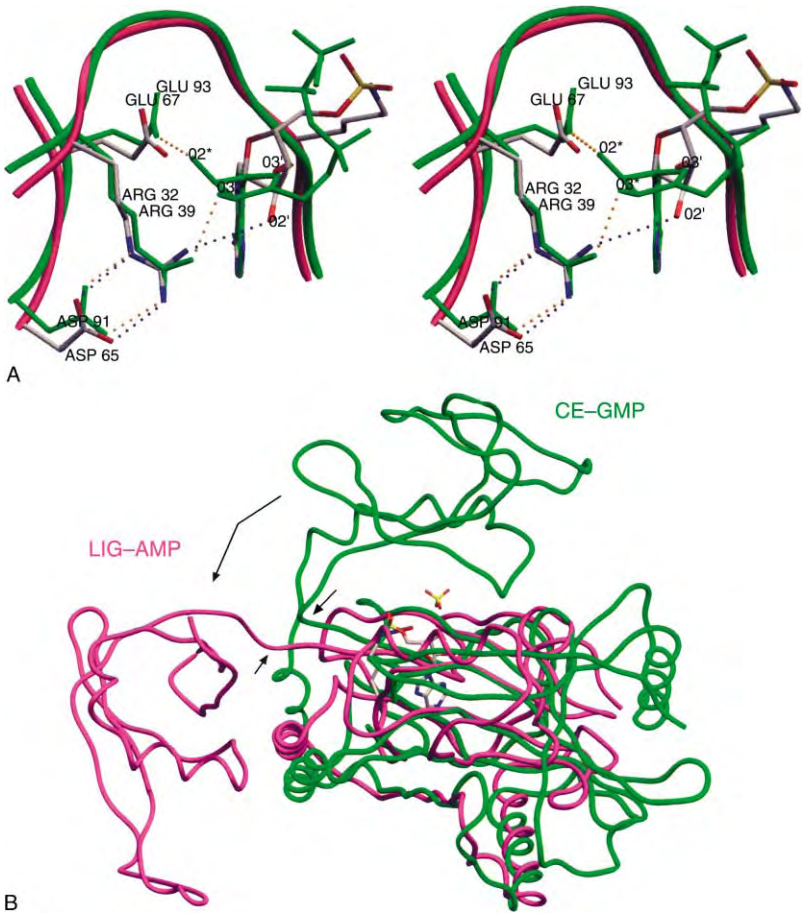

FIGURE 4 Conformational changes in DNA ligases during catalysis. (A) Remodeling of the adenosine-binding pocket after ligase–adenylate formation. Stereoview of the nucleotide-binding pocket of *Chlorella* ligase (purple, with side chains in CPK) highlighting interactions of motif I and III side chains with the ribose sugar of the lysyl-adenylate adduct. The superimposed equivalent structural elements of the T7 ligase–ATP complex are in green. Hydrogen bonds are denoted by dashed lines. (B) Comparison of the *Chlorella* virus ligase (purple) and capping enzyme (green) structures. The structures are superimposed with reference to the nucleotide-binding pocket of domain 1. The lysyl–AMP adduct and the sulfate in the ligase are shown. The guanylate and a sulfate are similarly positioned in the capping enzyme structure. The figure highlights the large movement of domain 2 from the closed state (capping enzyme) to the wide-open conformation (ligase) that exposes a DNA-binding surface. The principal flexion points within the inter-domain linkers (in motif V) are indicated by the short arrows. Reproduced with permission from Odell, M., Sriskanda, V., Shuman, S., and Nikolov, D. B. (2000). Crystal structure of eukaryotic DNA ligase–adenylate illuminates the mechanism of nick sensing and strand joining. *Mol. Cell.* **6**, 1183–1193 with permission from Elsevier.

covalent complex. The requirement of the equivalent motif VI residues in the ATP-dependent ligases for enzyme activity strongly suggests that they undergo a similar conformational change during the first step of the reaction.

While the structure of a ligase bound to DNA has yet to be determined, the ligase-AMP structures of the *Chlorella* virus DNA ligase provide valuable insight into the mechanism of nicked duplex DNA recognition. Occupation of the adenylate binding site is known to be crucial to nick recognition, and in this "DNA-binding-competent" state, domain 2 of the *Chlorella* ligase-AMP complex is pivoted away from domain 1 via a bending in the flexible inter-domain linker region (Figure 4B). The cleft between domains 1 and 2 is substantially wider than in the open complex form of the capping enzyme-GTP complex, and this ligase-adenylate structure is therefore referred to as the "wide-open" complex. The "wide-open" conformation is proposed to expose the DNA-binding surface on domain 1 allowing the 5′ phosphate of the nicked DNA substrate to make direct contact with the adenylation site on the enzyme. Analysis of the surface properties of the *Chlorella* ligase further suggests that the ligase–AMP is ready to bind DNA. In this conformation the electrostatically positive surface of domain 1 favors interaction with the negatively charged phosphodiester backbone of DNA. The relatively flat surface of the ligase molecule (Figure 4B) could allow direct interactions with one face of the DNA double helix. The remodeling of the active site leaves the 3′ oxygen of the ribose sugar free to participate directly in the coordination of

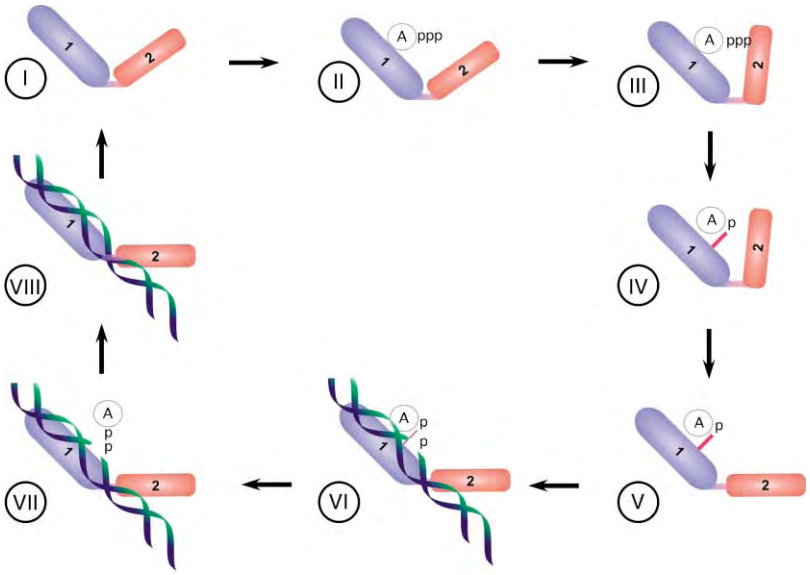

FIGURE 5 Schematic model of ATP-dependent DNA ligation showing the individual catalytic steps and the corresponding conformational changes in the enzyme. Only the catalytic core (domains 1 and 2) of the DNA ligase is shown. See text for details.

the 5′ phosphate of the DNA substrate. This indicates that only catalytically licensed forms of DNA ligases will be able to stably interact with a nicked DNA substrate. The structural data also suggest that domain 2 might not directly participate in the subsequent catalytic events that result in the adenylation of DNA (step 2) and in phosphodiester bond formation (step 3).

A model of ATP-dependent ligation consistent with the known ligase and capping enzyme structures is shown in Figure 5. Specifically, the structural data support a common mechanism of catalysis by nucleotidyltransferases that is carried out through a series of conformational changes induced by substrate binding. In the first step, the energy cofactor, ATP, binds to the open form of enzyme (state I on Figure 5). The binding of this substrate and/or of a divalent cation promotes domain closure, bringing the positively charged residues of the OB-fold into direct contact with the pyrophosphate leaving group (II and III). As a result of the structural rearrangement, the active site lysine is positioned to make an in-line attack on the α-phosphate of the ATP (III). The following formation of the ligase-AMP complex is accompanied by release of pyrophosphate (IV). The ligase undergoes a transition from a "closed" (IV) to a "wide-open" complex (V). This transition is an example of ping-pong kinetics where the active site is initially modified by the first substrate (ATP) to permit recognition of the second substrate (DNA). While structures of DNA ligases in complex with DNA are not yet reported, it is hypothesized that the wide-open complex would allow the nicked duplex DNA to be recognized and bound by the positively charged surface on the nucleotidyltransferse domain 1 (VI) and stabilized by bonding of the 5′ phosphate of DNA by the 3′ oxygen of the NMP sugar moiety, facilitating the transfer of AMP to the 5′-phosphate terminated DNA strand (VII). Once the DNA-adenylate is formed, the enzyme remains bound to the activated nick and catalyzes its sealing via an attack of the 3′ OH on the 5′ adenylated DNA, producing a phosphodiester linkage with the concomitant release of AMP (VIII). It should be emphasized that this model is consistent with ligation of a single nick in an otherwise duplex DNA molecule. The ligation of double-stranded DNA breaks is catalyzed by the mammalian DNA ligase IV, and requires additional proteins to stabilize the free DNA ends. The functional catalytic complex in this case may contain two molecules of DNA ligase, each sealing a single DNA strand.

Glossary

ATP Adenosine triphosphate. An adenosine-containing nucleotide that harbors high-energy phosphate bonds and is used to transport energy to cells for biochemical processes through its hydrolysis.

covalent nucleotidyltransferase Enzyme that reacts with nucleotides and transfers the nucleoside moiety to an acceptor molecule

through the formation of a covalent nucleoside monophosphate (NMP)-enzyme intermediate.

mRNA cap Structure found at 5′ end of the eukaryotic mRNAs, consists of 7-methylguanosine linked to the end of the transcript via a 5′–5′ triphosphate bridge (m7GpppN). The cap structure enhances mRNA stability, splicing of pre-mRNAs, and initiation of protein synthesis.

NAD Nicotinamide adenine dinucleotide (oxidized form). A coenzyme present in all cells that assists enzymes by accepting electrons during metabolic reactions. Acts as an energy donor in bacteria by virtue of a high-energy P–P bond.

Biography

C. Kiong Ho is an Assistant Professor in the Department of Biological Sciences at the State University of New York, Buffalo. His laboratory is taking a molecular and biochemical approach to study mRNA processing events (mRNA capping and RNA editing) in parasitic protozoa.

Mark Odell studied DNA ligase enzymology for his doctorate at the University of Oxford, then subsequently in the USA at the Sloan-Kettering Institute with Professor Stewart Shuman. He now runs a research group at the University of Westminster, London, using structure and biochemistry to understand how proteins function.

Dimitar B. Nikolov is an Associate Member of the Memorial Sloan-Kettering Cancer Center and an Associate Professor at the Weill Medical College of Cornell University in New York City. He holds a Ph.D. degree from The Rockefeller University. His laboratory uses X-ray crystallography combined with other biophysical methods to study the structure, function, and mechanism of action of proteins.

DNA Methyltransferases, Bacterial

Albert Jeltsch
International University Bremen, Bremen, Germany

Richard I. Gumport
University of Illinois, Urbana, Illinois, USA

DNA methylation has a number of important roles in bacteria including the control of gene expression, DNA replication, and the cell cycle. In addition, it is involved in mismatch repair and protection of bacteria from foreign DNA in restriction modification systems. DNA methyltransferases (MTases) are the enzymes that methylate DNA. They deposit methyl groups on DNA at the N6-position of adenine, or the N4- or C5-positions of cytosine in a sequence-specific reaction using S-adenosyl-L-methionine (AdoMet) as the methyl group donor. Their reaction mechanism includes rotating the target base completely out of the DNA helix in a biphasic process, where fast flipping of the base out of the double helix is followed by a slower binding of the flipped base into a hydrophobic pocket of the enzyme. DNA MTases comprise two structural domains: the larger domain contains the cofactor-binding site and the binding pocket for the flipped base and the smaller domain is responsible for most of the sequence-specific contacts of the enzyme to the target site. The structures of large domains from all known DNA MTases are similar, whereas the small domains are more heterogeneous in sequence and structure. DNA MTases are an attractive model system to study how proteins recognize specific sequences of DNA and how the specificity of DNA recognition changes during molecular evolution. In addition, they illustrate how the biochemical properties of the enzymes are related to their biological functions. In this article, we shall describe the biological roles of DNA methylation in prokaryotes, discuss the chemistry of the enzymatic methylation reaction performed by the DNA methyltransferases (the focus of the review), and finally discuss aspects of the enzymology of this fascinating family of enzymes that reveal how these molecular machines perform their complicated biochemical tasks.

Introduction

After their discovery during the 1940s, methylated nucleobases have been found in the DNA of most species. DNA methyltransferases (MTases) produce three types of methylated bases, C5-methylcytosine, N4-methylcytosine, and N6-methyladenine (Figure 1). Based on the identity of the acceptor atom for the methyl group, C-MTases forming C5-methylcytosine can be distinguished from N-MTases forming N6-methyladenine and N4-methylcytosine. Whereas C5-methylcytosine occurs in higher eukaryotes and prokaryotes, the N-modified bases (N4-methylcytosine and N6-methyladenine) are present only in prokaryotes and some lower eukaryotes. Usually, DNA MTases are DNA sequence specific. In higher eukaryotes, cytosine methylation occurs mainly at CG sequences, and in plants also at CNG sequences. Such DNA methylation leads to chromatin condensation and silencing of gene expression. In prokaryotes, DNA methylation is involved in the control of gene expression, but it has a multitude of additional roles including control of initiation of DNA replication, correction of errors in DNA replication, and modulation of the destruction of DNA by restriction endonucleases.

Biological Function of DNA Methylation in Prokaryotes

Molecular Recognition of the Presence of the Methyl Groups on the DNA

DNA methylation adds an extra layer of information, viz., epigenetic information, to the genome that extends the intrinsic genetic information encoded in the unmodified sequence composed of the four usual Watson–Crick base pairs. In this sense, it can be compared to the different written diacritic marks in the French language, which are not required to read a word but rather define how the words are pronounced. Thus, diacritic signs do not carry essential information for the meaning of text, but impart important information beyond that level. Likewise, DNA methylation adds information that influences the stability, regulation, and expression of the encoded genetic information.

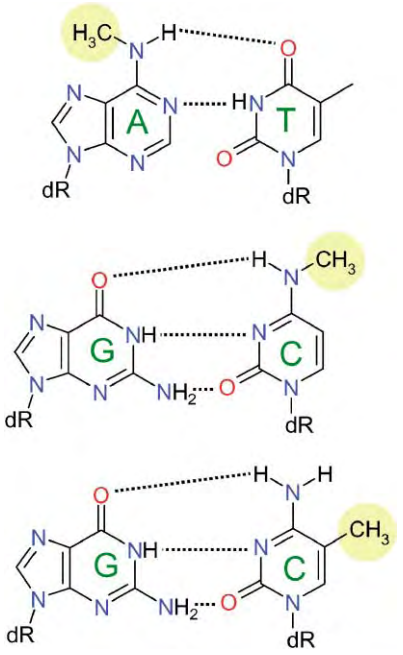

FIGURE 1 Structures of 6-methyladenine and of 5- and 4-methylcytosine in the context of an AT and GC base pairs. In all cases, the methyl group is located in the major group of the DNA and it does not interfere with the Watson–Crick base pairing.

Methylation of the DNA at the cytosine-C5, N4, and adenine-N6 positions does not interfere with Watson–Crick base pairing (Figure 1). It represents a minimal change of the molecular structure of the DNA. However, the methyl groups are positioned in the major groove of the DNA, a region where many proteins recognize the sequence of the DNA by formation of specific contacts to the edges of the base pairs. Such recognition can be severely disturbed by the presence of a single methyl group in the major groove as illustrated by the complexes of restriction endonucleases with specific DNA. These enzymes form a very tight interface with their target DNA, stabilized, in part, by several base-specific interactions. Methylation of the target DNA base sequence prevents close approximation of the enzyme and the DNA through steric hindrance, thereby effectively preventing DNA cleavage by the restriction enzyme. Thus, the introduction of a single methyl group onto a DNA base can have a profound effect on the biological functions of the modified sequence.

The Molecular Logic of DNA Methylation

The effect of DNA MTase action is to give DNA a methylation pattern that will affect its biological function. In prokaryotes, we can discern several levels of biological responses to methylation.

Sequence Context of DNA Methylation

Most prokaryotic DNA MTases are parts of restriction/modification (RM) systems, which are widely distributed in the bacterial and archeal kingdoms. These systems comprise two enzymes, a restriction endonuclease that specifically recognizes and cleaves DNA usually within or near short, often palindromic sequences. The cellular DNA is protected from cleavage by the MTase, because it modifies the DNA within the same sequence and prevents endonuclease action. Since different RM systems have different recognition sequences, the methylation pattern basically imprints a bar code on the DNA that allows the bacterium to distinguish between its own and foreign DNA. Since DNA from bacteriophages is often not modified at the sites of the resident RM systems, these systems efficiently protect against bacteriophage infection. In addition, they serve to control the uptake and incorporation of foreign DNA from any source into the bacterial chromosome. Because RM systems distinguish between self and nonself DNA and protect bacteria from phage infection, they can be compared, in biological function, to the immune system of higher eukaryotes. Like the immune system, RM systems are also involved in a molecular arms race between the invader and the host, and bacteriophages have evolved many antirestriction systems, such as multispecific MTases that modify the phage genome at many sites, and thereby provide a broad protection against the endonucleases of different RM systems.

Regulation by Hemimethylation

Coordination of DNA Replication and Cell Division In addition to the MTases that are part of RM systems, solitary MTases also occur. These enzymes are not accompanied by a restriction enzyme and are exemplified by the *Escherichia coli* dam or *Caulobacter cresentus* CcrM MTases. Both modify adenine residues; their palindromic recognition sequences are GATC and GANTC, respectively. Therefore, both strands of the DNA usually carry a methyl group, and the duplex sites are fully methylated (5′-G^{m}ATC-3′/3′-CT^{m}AG-5′ in the case of dam). Since only unmodified nucleotides are incorporated during DNA replication, the newly synthesized strand of the DNA lacks methyl groups. Therefore, replication transforms the DNA methylation status from a fully methylated into a hemimethylated state. In *E. coli*, the dam sites in most parts of the genome are remodified rapidly after replication. In contrast, the SeqA protein tightly binds to the origin of replication and protects it from being remethylated for several minutes. During this time, the origin cannot initiate a new round of DNA replication thereby coupling DNA replication and cell division. Thus, in

this system the hemimethylated status of the dam sites determines whether DNA replication will occur again.

Postreplicative Mismatch Repair As described, DNA replication generates hemimethylated dam sites in *E. coli*. Such strand-specific methylation distinguishes the parental and daughter DNA strands; the residual methylation always marks the parental strands. Strand-specific asymmetric methylation is the basis for a directed repair of replication errors by the *E. coli* Mut HLS system. Mismatched base pairs resulting from erroneous nucleotide incorporation by the DNA polymerase are recognized by the MutS protein or homologues in a mechanism that is conserved from *E. coli* to man. In *E. coli*, MutH, a partner in a complex with MutS and MutL, specifically cleaves the DNA at hemimethylated GATC sites in the unmodified, newly synthesized daughter strand. This allows differentiating the erroneous new strand from the original stand and directs the repair process to the proper strand. Therefore, strand discrimination and postreplicative mismatch repair in *E. coli* and other dam-positive bacteria is connected to dam methylation. Loss of the dam methylation generates a hypermutational phenotype that contributes to pathogenicity of *Neisseria meningitides*. Other mechanisms of strand discrimination, which do not depend on DNA methylation, are operative in higher eukaryotes and bacteria not having dam methylation.

Cell-Cycle Control *Caulobacter cresentus* is an α-proteobacterium with a well-controlled cell cycle that is coordinated to a phase transition between mobile swarmer cells and stalk cells. Its genome changes from the fully methylated to the hemimethylated state during DNA replication. The CcrM Mtase in *Caulobacter cresentus* is among the proteins whose expression is regulated during the cell cycle such that it is present only during a short time near the end of S phase. The CcrM MTase is a master regulator gene, because the change between the hemimethylated and fully methylated state itself regulates a variety of other proteins, including the CtrA global regulator.

Regulation of Gene Expression by Methylation Pattern

Examples of gene regulation by the dam MTase in *E. coli* were detected several years ago, when it was shown that the pap operon in uropathogenic *E. coli* strains is regulated by differential methylation. Analyses of the *E. coli* genome showed that there are stably undermethylated sets of GATC sites whose position can vary with environmental conditions. Most likely, these sites are blocked by other proteins tightly bound to the DNA such that the dam enzyme cannot gain access. Recent whole-genome expression profiles have revealed a much higher number of genes whose expression is regulated by dam methylation. Regulation of gene expression by dam methylation contributes to phase variations of *E. coli* and other γ-proteobacteria. This is the most likely reason that dam-negative strains of *Salmonella thyphimurium* are not pathogenic and can serve as live vaccines.

Chemistry of DNA Methylation

DNA MTases use S-adenosyl-L-methionine (AdoMet) as the donor of an activated methyl group. The activated methylsulfonium of AdoMet can be attacked by a nucleophile to effect the methylation (Figure 2). However, methylation of either the exocyclic amino groups of adenine and cytosine or the C5-position of cytosine is a difficult chemical task, because these positions are not intrinsically nucleophilic. For instance, chemical alkylation of adenine and cytosine occurs at positions 3 of cytosine and 1 or 7 of adenine rather than the atoms modified by the MTases. To overcome this intrinsic lack of reactivity, the two families of DNA MTases, N-MTases and C-MTases, have evolved highly sophisticated reaction mechanisms. Both mechanisms have in common the necessity for close contact between the

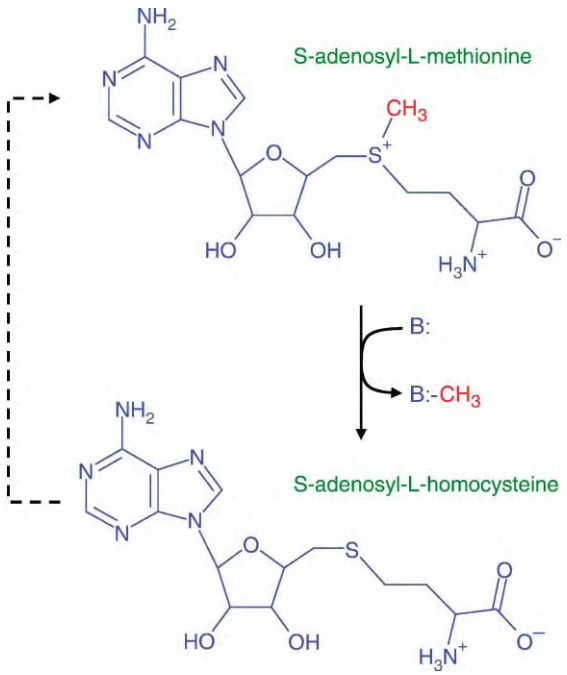

FIGURE 2 The structure of AdoMet, the cofactor of the methylation reactions catalyzed by DNA MTases. In the methylation reaction AdoMet is converted into S-adenosyl-L-homocysteine (AdoHcy). AdoMet can be regenerated from AdoHcy in a multistep pathway depending on tetrahydrofolate and Coenzyme-B12 that employs serine, which itself can be derived from 3-phosphoglycerate or glycine as the ultimate donor of a C1-group.

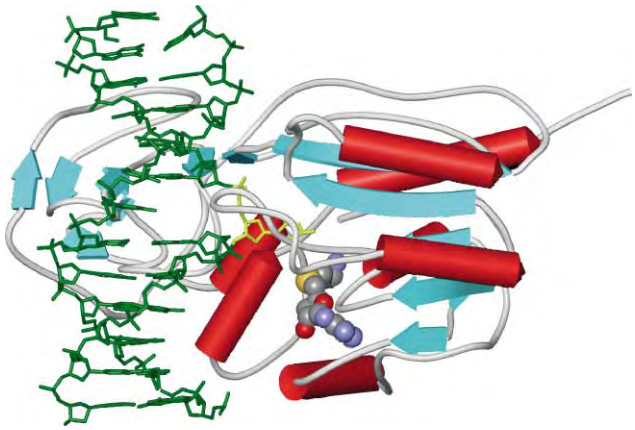

FIGURE 3 Structure of M.HhaI (gray, blue, and red) showing the target base (yellow) flipped out of the DNA helix (black). The bound cofactor AdoMet (purple) is displayed in its space-filling form.

enzyme active site and the target base. Such proximity is not possible while the base is located within the DNA double helix. In seminal studies, X. Cheng, S. Klimasauskas, R. Roberts, and co-workers demonstrated that the cytosine-C5 Mtase HhaI completely flips its target base out of the DNA double helix during catalysis – an unprecedented, dramatic conformational change in the DNA (Figure 3). Later, similar mechanisms were observed with another cytosine-C5 MTase (HaeIII) and more recently with an adenine-N6 MTase (TaqI).

Reaction Mechanism of Cytosine-C5 MTases

Methylation of the C5-position of cytosine follows a two-step reaction mechanism (Figure 4) that resembles a Michael addition and is analogous to the mechanism used by thymidylate synthase to convert dUMP to dTMP. In the first step, a cysteine residue in the active site of the DNA MTase performs a nucleophilic attack on the C6-position of the cytosine that is flipped out of the DNA and bound in a hydrophobic pocket of the enzyme. Thereby, a transient carbanion is generated, which is stabilized by a protonated glutamic acid residue that hydrogen-bonds to the flipped base and protonates the N3 atom of the base. Since the carbanion has a high negative charge density at position 5, the activated base can attack the methyl group of the cofactor yielding a stable intermediate comprising a covalently linked complex of the methylated DNA and the MTase. The catalytic cysteine and glutamic acid residues are located in two highly conserved amino acid motifs found in cytosine-C5 MTases, the PCQ motif and the ENV motif also called motif IV and motif VI. The second step of the reaction resolves the covalent intermediate. It is initiated by deprotonation of C5 catalyzed by an unknown proton acceptor; deprotonation leads to the elimination of the cysteine residues and re-establishment of aromaticity.

This mechanism is supported by several lines of evidence. The covalent complex has been detected in crystal structures and in biochemical studies, the catalytic cysteine and glutamic acid residues are highly conserved in all cytosine-C5 MTases, and mutational analyses have supported their importance. Moreover, MTases effect the methylation reaction by positioning of the substrate and the cofactor in the active site and by tight binding to the transition state of the reaction.

Reaction Mechanism of N-MTases

Chemically, methylation of either adenine and cytosine residues at their exocyclic amino group is similar, because in each case the substrate amino group is part of an electron-poor, heterocyclic, aromatic system. The reaction is difficult, because the free electron pairs formally present at the amino groups are delocalized into the aromatic system and not readily available for nucleophilic attack on the AdoMet. The catalytic center of the MTases that acts on exocyclic amino groups (N-MTase) is formed by a (D/N/S)PP(Y/F) motif. The reaction mechanism of the N-MTases (Figure 5) is illuminated by the structure of the TaqI adenine-N6 MTase. The carboxyamide group of the active site asparagine and the backbone carbonyl group of the second proline residue of the active site tetrapeptide contact the amino group of the flipped adenine target. Since the hydrogen acceptor groups are presented in a tetrahedral geometry,

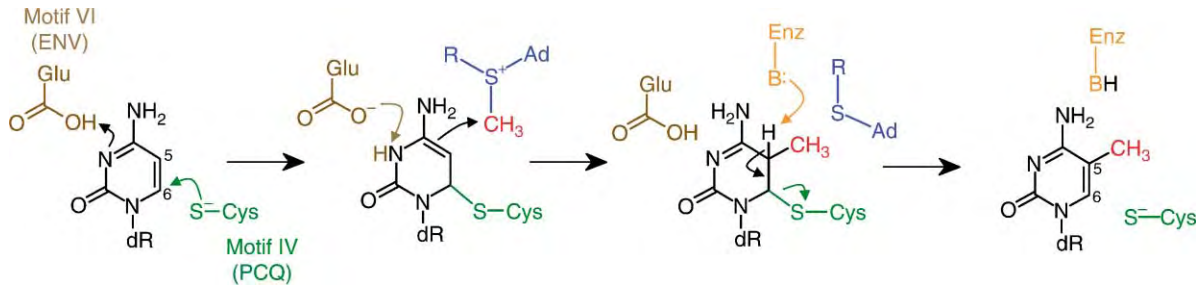

FIGURE 4 Schematic drawing of the catalytic mechanisms of C-methylation. The conserved motifs ENV and PCQ are indicated.

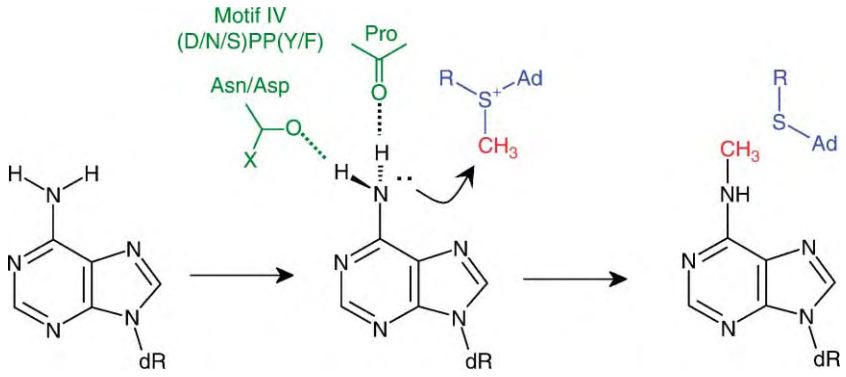

FIGURE 5 The catalytic mechanism of N-methylation. The conserved catalytic motif (D/N/S)PP(YF) is indicated.

formation of the hydrogen bonds induces a change in hybridization of the amino group from sp^2 to sp^3. This localizes the free electron pair and makes it available for the nucleophilic attack on the methyl group of the AdoMet. This mechanism is consistent with results from site-directed mutagenesis studies with many different DNA N-MTases, which demonstrate the importance of the active site (D/N/S)PP(Y/F) motifs. In addition, positioning of the base and the cofactor appear to be critical elements for catalysis by N-MTases.

It is interesting that the recognition of the flipped target base by the MTase is not necessarily precise; adenine-N6 MTases modify cytosine residues at position N4 and cytosine-N4 MTases modify adenine residues at position N6. Although these reactions occur with reduced efficiencies, they prove that the catalytic mechanisms of adenine-N6 and cytosine-N4 MTases are similar. Surprisingly, it has been shown recently that HemK enzymes, which are conserved from bacteria to human and strongly resemble adenine-N6 MTases in all their characteristic primary sequence motifs, are Glutamine-N5 methyltransferases. This unexpected finding demonstrates that the (D/N/S)PP(Y/F) tetrapeptide is a versatile active-site motif that supports methylation of various amino groups that are conjugated to an electron poor π-conjugation system, viz., the purine ring in adenine-N6 methylation, the pyrimidine ring in cytosine-N4 methylation, or a carbonyl group of glutamine-N5 methylation. It will be interesting to see whether (D/ N/S)PP(Y/ F)-containing enzymes have even more substrates, for instance if they can support methylation of arginine.

Mechanism of Base Flipping

Base flipping is a prerequisite for the catalytic mechanism of all DNA MTases; all structures of DNA MTases in complex with DNA solved so far show base flipping (Figure 3). In addition, numerous biochemical studies with different MTases demonstrate base flipping in solution. Three lines of biochemical evidence support a base flipping mechanism: (1) DNA MTases often bind substrates that contain a base mismatch at the target site more tightly than a normal substrate, because base flipping requires disruption of the base pairing between the target base and its partner base. (2) 2-Aminopurine, a base analogue that is fluorescent in solution but is highly quenched in the DNA by base stacking to its neighbor bases can be incorporated in the DNA as target base. Base flipping destroys the stacking interactions and sometimes leads to a strong and specific increase of fluorescence that is correlated with the flipping process. (3) The target base of DNA MTases shows a high propensity to react with the protein during cross-linking experiments. This result suggests that the base is flipped out of the helix and thereby available for much closer contact with the protein than it could if it remained inside the DNA helix. However, one should bear in mind that none of these assays is sufficient to prove or disprove unequivocally base flipping.

Our understanding of base flipping is limited by the high efficiency of the process, because so far no structural information is available for the specific DNA MTase complex prior to base flipping. The equilibrium favoring the flipped-base state is related to structural relaxations of the protein–DNA complex that prevent back-rotation and reinsertion of the flipped base into the DNA helix. Interestingly, these structural changes are different in all three complexes of DNA MTase with specific DNA available so far. In the case of M.HhaI, the DNA retains an almost perfect B-DNA-like conformation and the enzyme inserts a glutamine residue from the small domain into the cavity, left by the flipped base. In the case of the M.HaeIII enzyme (another cytosine-C5 MTase), the orphan G pairs with a C on the 3′ side of the target base. The partner of this C is orphaned and the large cleft in the DNA is filled with solvent. In the case of the TaqI enzyme (an adenine-N6 MTase) the orphan T moves towards the center of the DNA helix. Thereby, in part, it occupies the space left by the flipped A, and in this way optimizes its base stacking interactions.

Base flipping is at least a two-step process. The base is first extruded from the DNA and then tightly contacted by the enzyme in a binding pocket in the catalytic domain allowing base recognition and catalysis to occur. Whereas the first step of the flipping process is very fast (milliseconds), the second is much slower (seconds). It is not clear how flipping of the target base is initiated; it could simply be spontaneous DNA breathing where thermal energy occasionally leads to the flipping of the base. The function of the enzyme would be to catch the flipped base and prevent its back-rotation until after methylation had occurred. Alternatively, contacts of the enzyme with the phosphodiester groups of the backbone of the DNA might impose torsional stress on the DNA that would induce the flipping. It is clear that the interactions of the enzyme with the target base itself are not required for base flipping, at least in the case of the HhaI MTase, because with this enzyme a rotation of the deoxyribose analogous to base flipping is also observed using substrates carrying an abasic site at the target position. Finally, we do not know whether base flipping is correlated with DNA recognition. In principle, two alternative reaction schemes are possible. The enzyme could scan the DNA, recognize its target base in the unflipped state, and then induce flipping only at the specific site. Alternatively, flipping could occur anywhere and the enzyme recognized the target site only after flipping. Then it would lock the flipped base only if the correct sequence is bound.

Molecular Enzymology of DNA MTases

In this section, we shall briefly describe some features of DNA MTases, which explain how these fascinating enzymes are able to perform their complicated function.

Structures of DNA MTases

Structures of six DNA MTases are presently available: M.HhaI, M.HaeIII, M.TaqI; M.PvuII, DpnM, M.MboII, and M.RsrI. Whereas for M.HhaI, M.HaeIII, and M.TaqI ternary complexes between cofactor, DNA and enzyme are solved, all other structures are binary complexes between the Mtase and different forms of the cofactor. The single present exception is the structure of a catalytically compromised mutant of M.RsrI, L72P, that lacks bound ligand. All DNA MTases analyzed so far comprise two domains, one large and one small.

Structure and Function of the Large Domain

The large domain consists of a central mixed β-sheet, flanked by α-helices. The overall structure consists of two subdomains, which both form a hydrophobic pocket, the cofactor-binding site, and the binding site for the flipped target base. The AdoMet-binding site is composed of a subset of the conserved amino acid motifs that are found in most AdoMet-interacting enzymes, with conserved motif I ((D/E/S)XFXGXG) contributing important contacts to the AdoMet. Surprisingly, C-MTases and N-MTases show a striking similarity in the structure of their catalytic domains, with important catalytic residues (motif IV: PCQ in the case of cytosine-C5 MTases and (D/N/S)PP(Y/F) in the case of N-MTases) occupying equivalent positions in the three-dimensional structures of both MTase families. This finding was surprising, given the apparent differences in the catalytic mechanisms of both types of enzymes. It suggests an evolutionary relationship of both classes of MTases. In this context, it is interesting to note that three families of N-MTases exist that are related by circular permutations of the catalytic domain, but all known cytosine-C5 MTases belong to just one form that corresponds to the γ-family of N-MTases. Given the fact that N-MTases are structurally much more diverse and that they have a wider range of substrates (adenine, cytosine, and also amino acids), one might speculate that the C-MTases could be derived from the N-MTases, taking advantage of their established AdoMet-binding site and ability to flip the target base.

Structure and Function of the Small Domain

The second, smaller, domain of DNA MTases is much more heterogenous in size and structure. It contains most of the residues that mediate sequence-specific recognition of the DNA. Therefore, the variability of the target sequence is reflected by the loss of sequence conservation of the small DNA MTase domains. Upon specific DNA binding, base flipping is initiated or stabilized and conformational changes of the enzyme are induced. For example, in the case of M.HhaI, the loop comprising the catalytic motif IV of the enzyme undergoes a massive conformational change and approaches the DNA. Moreover, the small domain itself also moves towards the DNA. These changes are induced by the formation of base-specific contacts in a highly cooperative process that mediates the sequence specificity of DNA recognition. Thereby, the activation of the catalytic center is coupled to DNA recognition – a mechanism that is generally used by enzymes that interact with DNA in a sequence-specific manner.

Mechanism of DNA Recognition

DNA recognition by MTases arises from sequence-specific contacts of the enzymes in the major and minor grooves of the DNA as well as to its phophodiester backbone. The small domain of the MTases contacts the

DNA from the major groove side, and the body of the large domain interacts with the minor groove. For example, M.HhaI contacts the edges of the bases of the recognition sequence with 14 hydrogen bonds. In addition, in M.HhaI and M.HaeIII, residues following the active-site motif IV are involved in DNA recognition and form base-contacts with the target sequence. A contribution of loops of the catalytic domain in sequence recognition was confirmed by biochemical experiments with M.SinI and M.EcoRII, which are both C-MTases, as well as with the adenine-N-MTase M.EcoRV.

Depending on the particular enzyme, specific-complex formation sometimes, but not always, leads to strong bending of the DNA. Unfortunately, structural information is available only for enzymes that do not induce bending of the DNA. It is interesting to note that the specificities of different DNA MTase can vary dramatically. Some MTases display a very high specificity that is comparable to that of restriction enzymes whereas others interact with the DNA in a more relaxed manner, such that sites differing from the consensus target site are modified at reasonable rates. Relaxed target specificity may arise because RM systems are steadily evolving and are regularly changing or modifying their recognition sites. Most likely, MTases with relaxed specificity have been caught in the act of molecular evolution and have not yet optimized selectivity for their new target site. The EcoRV MTase provides revealing details of this process. GATATC is the target site of this enzyme, and according to multiple sequence alignments, it is most closely related to dam MTases whose target site is GATC. Interaction with the same sequence expanded by two base pairs at the 3′ end suggests that EcoRV could have been derived from a GATC methylating enzyme. In support of this model, EcoRV also modifies GATC sites. The contacts of the EcoRV and dam enzymes to the GAT-part of their recognition sites are conserved in both enzyme families. The contacts to the ATC-part of the recognition site by EcoRV supplements the contacts to the conserved core GAT sequence. Interestingly, the contacts between M.EcoRV and the conserved core occur earlier in complex formation than those to the supplemental sites suggesting a pathway by which evolution could change the specificity of protein–DNA interaction.

Mechanism of Target Site Location and Processivity of DNA Methylation

Ordinarily, DNA MTases methylate DNA only at specific sites. Localization of these specific sites in the sea of non-specific sites is a challenging process. Like most other proteins or enzymes that interact with DNA in a sequence-specific manner, DNA MTases make use of facilitated diffusion to accelerate the search for target sites. In this mechanism, the enzyme first binds to the DNA at a nonspecific site in a very fast reaction that often is close to the theoretical limit for a bimolecular association process. Then, the enzyme follows the DNA in a one-dimensional random movement.

One interesting facet in the target-acquisition mechanism of the DNA MTases is the manner in which several target sites are modified when they reside on the same DNA molecule. Enzymes can react with substrates containing several target sites in two principal ways: processively or distributively. In a processive reaction, after one turnover, the enzyme remains bound to the same substrate molecule, moves to the next target site and modifies it. Therefore, in a completely processive reaction, a DNA molecule is modified at all its target sites before the enzyme dissociates. In contrast, in a distributive reaction the enzyme releases the DNA after turnover at each site. As a consequence of these two mechanisms, the distribution of substrates, methylation intermediates, and products are completely different: methylation intermediates are not generated in a processive multiple-turnover reaction, whereas intermediates are necessarily formed in a distributive reaction. Recently, experiments with different MTases demonstrate that the solitary M.SssI, the CcrM MTase, and *E. coli* dam methylate DNA in a highly processive reaction. In contrast, the RM enzymes M.HhaI, M.HpaI, EcoRI, and EcoRV react distributively. This difference is particularly striking in the case of the EcoRV–*E. coli* dam pair, because they share high sequence similarity and show overlapping specificity.

Most likely, processive and distributive mechanisms are correlated with the biological roles played by the enzymes. One function of RM systems is to protect cells from bacteriophage infections, by cleavage of the phage DNA catalyzed by the restriction enzyme. The role of the MTase is to prevent cleavage of the host genome by methylation. However, the MTase must not modify the incoming DNA too rapidly or the phage DNA would be protected. The distributive reaction mechanism of the RM MTases would slow the complete methylation of any one molecule leaving it more vulnerable to restriction enzyme, because cleavage of one or a few sites is sufficient for inactivation of the phage. In agreement with this model, all RM MTases examined to date show a distributive reaction. However, mechanisms other than distributive ones such as compartmentation or tight control of the expression levels of both types of enzymes could also ensure proper RM MTase function. For the solitary MTases, no such evolutionary pressure against processive methylation exists, because rapid methylation of the chromosomal DNA after replication is desirable. For instance, prolonged hemimethylation of the newly replicated DNA, by delay of methylation

completion, would confuse the dam mismatch-repair system. Dam repair depends on the damage residing in the unmethylated strand, which holds true only for polymerase mistakes and not for other lesions in the DNA that might have occurred after replication.

The difference in processivity between EcoRV and *E. coli* dam is due to a pronounced difference in the order of DNA and AdoMet binding. Whereas EcoRV first binds to the cofactor and then to the DNA, *E. coli* dam prefers the opposite order of binding. Microscopic reversibility dictates that the order of DNA and cofactor release must reflect the order of binding. Thus, EcoRV first releases the DNA and then the cofactor. This mechanism precludes EcoRV from modifying DNA in a processive fashion, because it cannot exchange the product AdoHcy with AdoMet while bound to the DNA. What prevents an exchange of the cofactor in the ternary complex of M.EcoRV is presently unknown, but one could easily imagine that slight conformational changes of a few amino acid residues could open or block a channel that would permit cofactor exchange. Strikingly, subtle changes of the structure of the enzyme can be responsible for fundamental differences in the mechanism and thereby effect the adaptation of the enzymes to their biological functions.

DNA Methyltransferases, Structural Themes

Sanjay Kumar
New England Biolabs, Beverly, Massachusetts, USA

DNA methyltransferases (MTases) are enzymes that catalyze the transfer of a methyl group from a donor molecule to DNA. On the basis of their chemistry, MTases can be grouped into two general categories: C5-MTases and N-MTases (Figure 1). The C5-MTases methylate the 5-carbon of the cytosine ring forming 5-methylcytosine. The N-MTases, which can be subclassed as N4- and N6-MTases, transfer a methyl group to an exocyclic nitrogen to form N_4-methylcytosine or N_6-methyladenine, respectively. The donor molecule in all known cases is the ubiquitous, small cofactor S-adenosyl-L-methionine (AdoMet or SAM). In the process of methylation, MTases employ a unique method called *base flipping* to access the target base. These enzymes are also highly selective DNA binding proteins and will only methylate their target bases within the context of a specifically recognized DNA sequence. MTases are widely distributed and have been isolated from or identified in the genomes of a wide variety of higher eukaryotes, lower eukaryotes, bacteria, and bacteriophage.

Function

The existence of DNA methylation (and hence MTases) has been known since 1948, even before the structure of DNA was discovered. Although much has been learned, the functional role of MTases in the molecular biology of the cell is still being uncovered today. DNA methylation is not essential for survival in all organisms, as both prokaryotes and eukaryotes that lack detectable methylation are known to exist. This is especially true in simpler organisms. However, as genome size increases (with some exceptions, of course), methylation takes on an increasingly important regulatory role, and defects in methylation are often strongly deleterious in plant and vertebrate embryonic development. The role of DNA methylation in human diseases is just beginning to be understood.

MTases impart epigenetic information to an organism's genome in the form of methylated bases. The primary purpose of this information is to modulate the interaction between DNA and the proteins that bind to it, whether directly by interacting with the proteins or indirectly by altering DNA structure. In general, methylation interferes with the binding of proteins to DNA; however, proteins whose DNA-binding is enhanced by methylation also exist. The effects of methylation on DNA structure are subtler. Methylation influences a variety of properties such as the stability of the double helix, DNA curvature, and the formation of DNA triple helices and left-handed Z-form DNA.

DNA methylation is closely tied to DNA replication. When a replication fork moves through a region of methylated DNA, the replicated DNA will be hemi-methylated with methyl groups *only* on the parental template strands. Soon afterward, the hemi-methylated DNA is recognized by MTases and becomes fully methylated once again. This transient undermethylated state can be used in a variety of ways: to monitor the replication state of DNA, to differentiate between the parental strand (methylated) and the newly synthesized strand (unmethylated), and to couple cellular functions to the cell cycle.

While MTases can aid in the correction of replication errors immediately after replication (called postreplicative mismatch repair) by using methylation to mark the strand carrying the original information, C5-MTases also contribute to the mutability of genomes. Cytosine spontaneously deaminates by hydrolysis at a very low rate, converting itself to uracil. Uracil is obviously foreign to DNA and the cell easily repairs the mutation. When 5-methylcytosine is deaminated it becomes thymine, giving rise to C → T transition mutations that are difficult for the cell to correct because T is a normal constituent of DNA. In addition, C5-MTases, in the presence of low concentrations of AdoMet, accelerate the rate of deamination. Sites of cytosine methylation are therefore mutagenic hotspots, and the genomes of higher eukaryotes such as vertebrates show significant depletion in the dinucleotide CG (the target sequence for vertebrate MTases).

Prokaryotes

Prokaryotes have both C5-MTases and N-MTases (Figure 1). A significant characteristic of prokaryotic

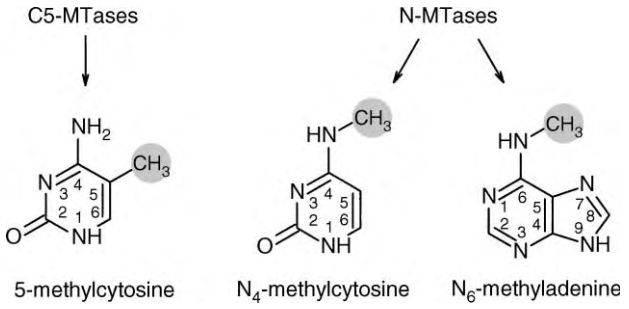

FIGURE 1 Products of DNA methylation by MTases. A shaded gray circle highlights the added methyl group.

DNA methylation is its promiscuity: prokaryotic MTases will methylate all available target sites, and do not discriminate between hemi-methylated and unmethylated targets. DNA binding proteins may, however, delay this methylation at some sites by temporarily sequestering the target sequences. MTases in prokaryotes are involved in two major groups of functions: (1) restriction–modification (RM) systems that serve as immune defenses against phage infection and (2) regulation of cellular processes.

RM Systems

In RM systems, MTases are paired with restriction endonucleases (RE). RE are enzymes that recognize target sequences in DNA with very high sequence specificity and then cleave the DNA. DNA methylation of the target sequence inhibits binding and cleavage by the RE. In an RM system, the MTase and RE have identical or overlapping target sequence specificity. The bacterium's DNA is protected from RE cleavage by prior methylation at the recognition site. Incoming foreign DNA (classically phage DNA), which does not display the same pattern of methylation as the host, is quickly fragmented by the host's REs. In this way, the bacterium uses MTases to effectively discriminate between self and foreign DNA.

Regulation of Cellular Processes

Our knowledge of the regulation of prokaryotic cellular processes by methylation is almost entirely focused on the action of one MTase: the Dam MTase, a solitary N-MTase (not part of an RM system) that recognizes the sequence GATC and methylates the adenine residue. The primary signal used for regulation is the transient undermethylation of Dam sites after replication. Dam MTase is involved in postreplicative mismatch repair, as well as controlling aspects of the initiation of chromosomal and plasmid DNA replication, transposition of transposable elements, and gene expression.

Eukaryotes

DNA methylation in eukaryotes is exclusively in the form of 5-methylcytosine and is confined to the dinucleotide CG (or CNG in plants, where N is any nucleotide), and C5-MTases are the only type of MTases found in eukaryotes. While little or no methylation is detected in unicellular, insect or invertebrate cells, both plant and vertebrate DNA are significantly methylated. Approximately 3–8% of the cytosine residues in vertebrates and 4–40% in plants are methylated. Unlike the prokaryotes, where the distribution of methylated bases mirrors the distribution of target sequences, only 60–80% of eukaryotic CG sites have methyl groups attached; however, for any given site, the cytosines in both strands of the DNA are methylated.

Pattern of Methylation

While eukaryotic DNA methylation is incomplete, it is not random. The pattern of methylation can be tissue specific and maintainable across cell generations. This implies the existence of at least two types of MTase functions: a *de novo* function to establish methylation patterns and a maintenance function to faithfully copy those patterns following DNA replication. The maintenance methylase function, exemplified by mammalian DNMT1, preferentially targets the hemi-methylated sequences that are present after DNA replication, a preference not shared by bacterial MTases. The CG dinucleotide distribution is also nonrandom. In mammals, while CG is generally depleted, it occurs at its expected frequency in blocks of sequence called CpG islands. CpG islands are often located near sites that regulate the transcription of genes. While they contain only 15% of the genome's CG sites, over half the target CG sequences in CpG islands are unmethylated. In contrast, 80% of the remaining CG sites in the genome are methylated.

Transcriptional Silencing

The effects of DNA cytosine-5 methylation in eukaryotes are complex and a thorough discussion is beyond the scope of this entry. However, there is strong evidence for its involvement in partitioning the genome into transcriptionally active and inactive functional compartments, where DNA methylation is generally correlated with silencing of gene expression. Methylation appears to accomplish this silencing by recruiting transcriptional repressors to the methylation sites, as well as histone deacetylases. The latter are involved in remodeling the chromatin structure that packages eukaryotic DNA into

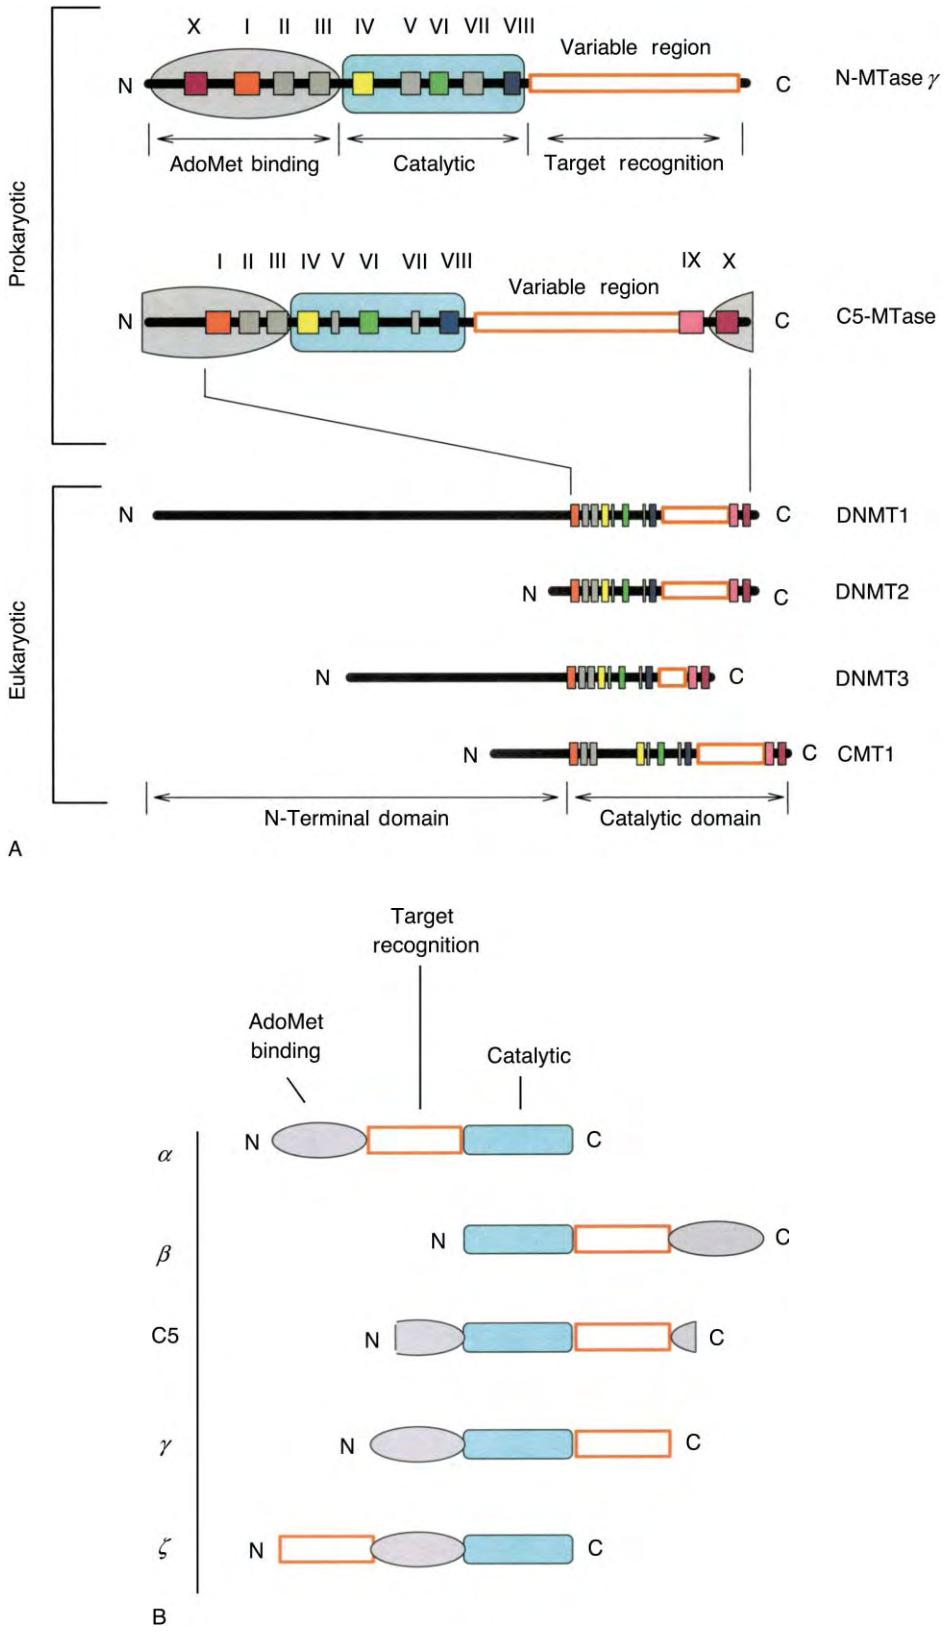

FIGURE 2 Schematic of MTase motifs and domains. (A) Sequence motifs and modules: Motifs are numbered I through X (Roman numerals). Conserved motifs are consistently represented by the same color square in all figures (not to scale). The MTase structure is divided into three modules: AdoMet Binding (gray oval), Catalytic (cyan rectangle), and Target Recognition (thin brown rectangle). The Target Recognition module and the variable region overlap completely. The N-MTase schematic is specific for the γ class of N-MTases. In C5-MTases, the components of the AdoMet Binding module are split and portions reside on the N and C termini of the sequence. The eukaryotic enzyme families (DNMT1, 2, 3,

a transcriptionally silent state. Methylation induced transcriptional silencing is believed to play a role in such processes as embryonic development, genomic imprinting, X-chromosome inactivation, and silencing of transposons and other mobile repetitive elements.

Primary Sequence Organization

Modular Arrangement

MTases are built from three basic modules that perform the primary functions required of these enzymes: DNA recognition, AdoMet binding and catalysis of methylation (Figure 2A). With few exceptions, they are monomeric proteins that range in size from approximately 300–500 amino acids in prokaryotes to over 1500 amino acids in eukaryotes. The amino acid sequence of MTases is divided into two distinct regions. The first region contains many sequence motifs that are conserved between groups of MTases. The core enzymatic functionality, consisting of the AdoMet binding and catalytic domains, is located in this region. The other region, termed the "variable region" (because its size and sequence varies greatly between otherwise related MTases), is almost completely devoid of such motifs (Figure 2A). The variable region contains the target recognition domain (TRD) and forms the third basic module. Theoretically, six permutations of the linear order of these three modules are possible (Figure 2B). To date, examples of four of the six have been identified.

Conserved Sequence Motifs

The signatures of their sequence motifs can often identify different classes of MTases. C5-MTases share a set of up to 10 motifs (labeled I–X in Figure 2A), six of which are strongly conserved. Each motif spans a total of 8–20 amino acids and usually contains two or three highly conserved positions. The linear order of these motifs is also conserved in virtually every member of the C5-MTase family, and the variable region is always located between motifs VIII and IX. The 10 motifs are also found in eukaryotic MTases, but they are confined to the roughly 500 amino acid long C-terminal catalytic domain of these larger enzymes. The eukaryotic MTases often possess an additional very large N-terminal domain that modulates their biological function.

Nine motifs can be located within N-MTases at positions that spatially overlap their C5-MTase counterparts on protein structures (Figure 2A); however, the level of similarity at the primary sequence level between corresponding C5 and N-MTase motifs is very low. Even corresponding motifs in different groups of N-MTases can show substantial differences. Only two of the sequence motifs, motif I and motif IV, can be identified without the aid of protein structure information. The N-MTases can be grouped into subclasses on the basis of motif order, but these groupings do not distinguish between N_4-cytosine and N_6-adenine MTases. The variable region is inserted in different, but conserved, positions relative to the motifs in each group.

Tertiary Structure

Reflecting the modularity seen in the primary sequences, MTases fold into structures with two domains: the core methylation machinery is localized in one large domain and the sequence recognition functions are concentrated in a second usually smaller domain. DNA binds in the cleft between the two domains, which are connected by a stalk or hinge (Figures 3 and 4).

Large Domain

The large domain is dominated by a structural motif termed the AdoMet-dependent methyltransferase fold that is conserved across a wide variety of AdoMet-dependent methyltransferases. The AdoMet fold spans both the AdoMet binding module and the catalytic module (Figure 3). It is composed of a core seven-stranded β sheet with strand order 6↓, 7↑, 5↓, 4↓, 1↓, 2↓, 3↓ (the arrows indicate relative strand direction), though strand 3 is sometimes not well formed. A characteristic feature is the insertion of strand 7 between strands 6 and 5 and antiparallel to the other six strands. The topological switch point (where the strand order changes) between strands 4 and 1 is situated in the active site. The switch point roughly divides the AdoMet fold into two parts, with strands 1 to 3 forming the core of the AdoMet binding module and strands 4 to 7 forming parts of the catalytic module including the substrate binding pocket. The two sections of the AdoMet fold β-sheet are each flanked by α helices to form β-α-β-α sandwiches. The core structure of the large domain is structurally quite similar to the Rossman fold of proteins that bind NAD or NADP.

Small Domain

The small domain corresponds to the "variable region" in primary sequence alignments of MTases.

and CMT1) all share the same motif arrangement as the prokaryotic C5-MTases, but the region of similarity is entirely confined to the C-terminal catalytic domain of these larger enzymes. (B) The modular arrangement of known MTases: The α, β, γ, and ζ classes are exclusively N-MTases. The C5 class (C5-MTases) and the (N-MTases are essentially the same class. The arrangements of domains in the β, C5, γ, and ζ classes are circular permutations of each other.

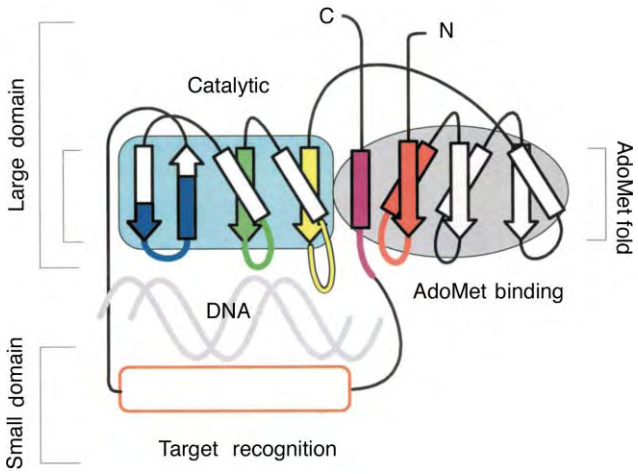

FIGURE 3 Structure of MTases: An idealized representation of the structure of a C5-MTase is shown. β strands are represented by arrows, α helices by rectangles, and loops by curved lines. Gray wavy double lines indicate DNA. Colored regions represent the locations of sequence motifs (Figure 2A). Other symbols and colors represent the same as those described in Figure 2. β strands are numbered 6, 7, 5, 4, 1, 2, and 3, from left to right as shown.

Not surprisingly, this domain is varied in size and structural arrangement. The small domain contacts the major groove face of the target DNA. In C5-MTases, the residues that specify the choice of target sequence and the base to be methylated generally reside on the small domain. In N-MTases, the contacts are more distributed between the two DNA grooves and the two domains of the enzyme.

Mechanism

Chemistry

The methylation reaction catalyzed by MTases requires only the DNA substrate and AdoMet. The products of the reaction are the various methylated bases and S-adenosyl-L-homocysteine (AdoHcy or SAH). The methylated bases are relatively stable, and the reverse reaction (demethylation) is not known to be mediated by MTases.

AdoMet

AdoMet is the most commonly used methyl donor in cellular biochemistry and the second most common

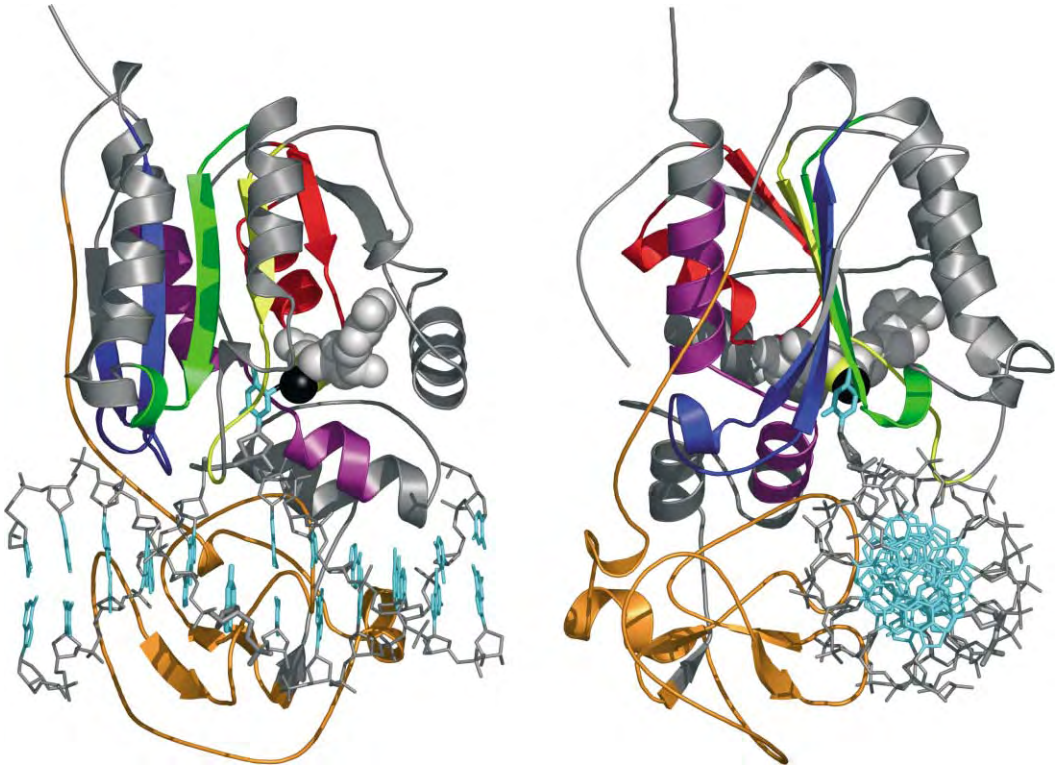

FIGURE 4 Crystallographic Structure of a C5-MTase: A three-dimensional cartoon representation of the structure of the C5-MTase M.HhaI. β strands are represented by arrows, α helices by helical flat coils, and loops by thin, curved lines. Protein is gray. The variable region is shown in brown. Other colors represent the same as those in Figures 2 and 3. DNA is seen in the lower part of the structure, with a gray sugar-phosphate backbone and cyan bases. The target base near the center of the structure is flipped out. The small gray molecule represented by space-filling spheres is AdoMet. The carbon to be transferred is colored black. The two views are related by a 90° rotation around the vertical axis of the structure.

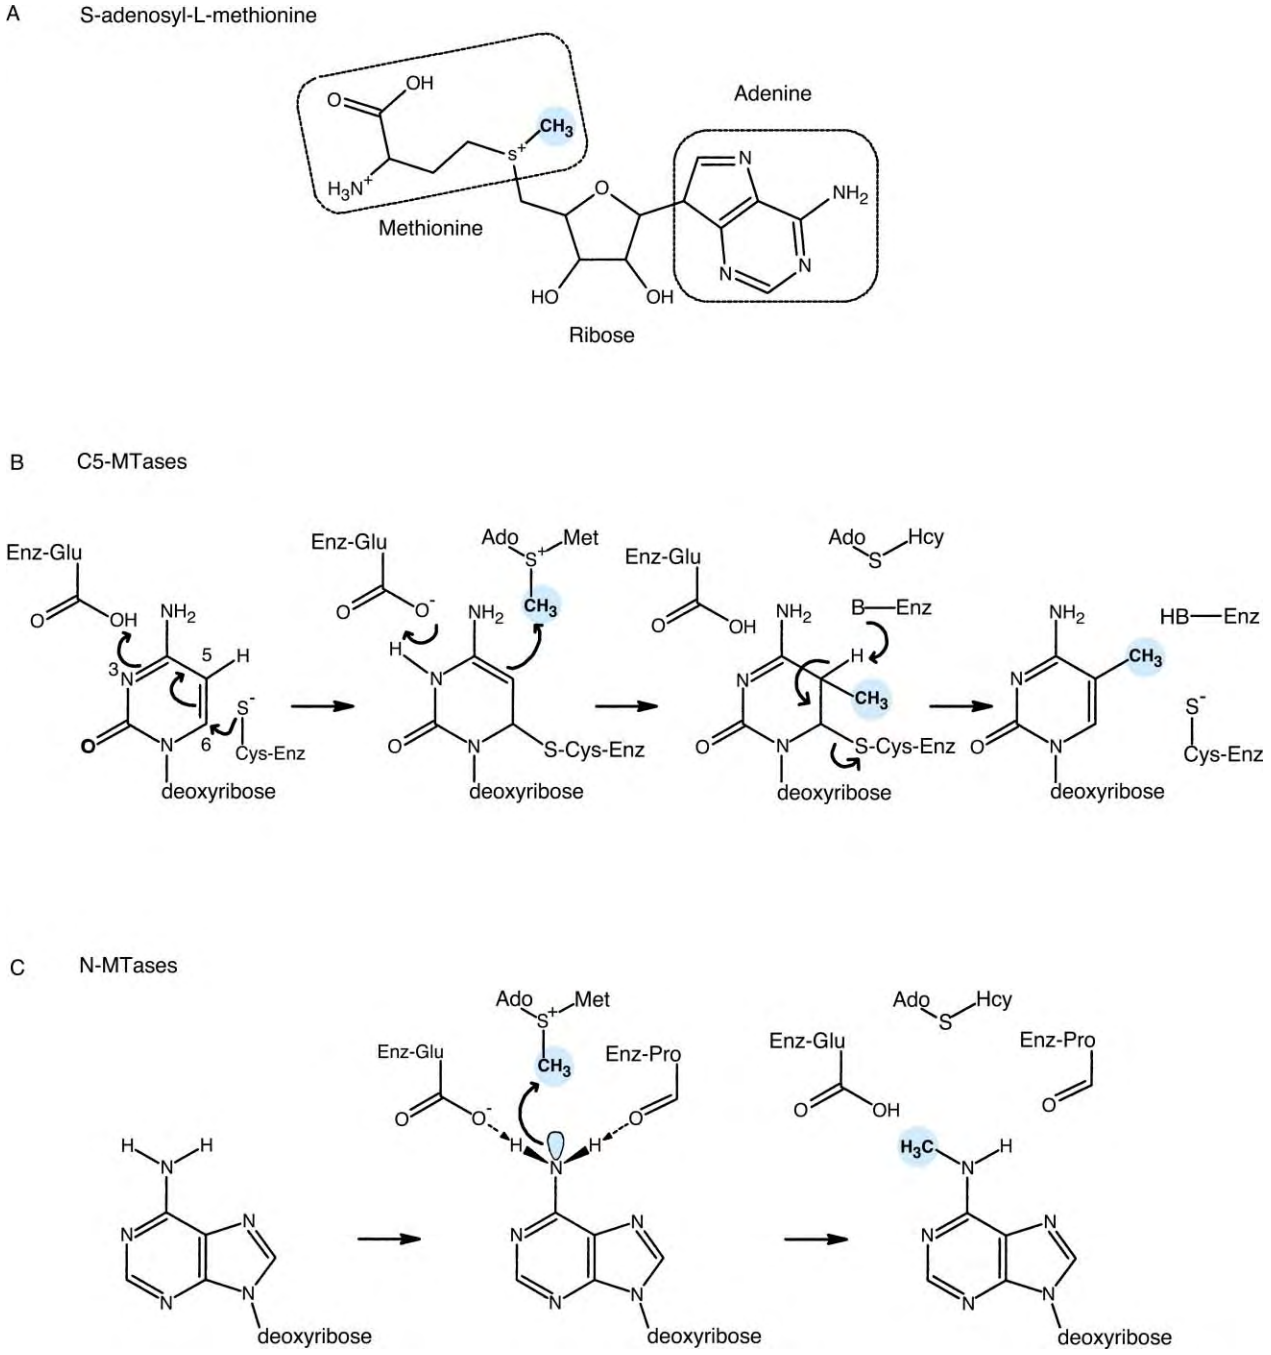

FIGURE 5 Reaction mechanisms of MTases: In each panel, a shaded gray circle indicates the transferred methyl group. The enzyme is represented by the symbol Enz. The symbol B refers to a generic basic residue. In (B) and (C), AdoMet is represented by the symbol Ado-S-Met and AdoHcy by Ado-S-Hcy. (A) The structure of S-adenosyl-L-methionine (AdoMet or SAM). (B) C5-MTase reaction mechanism. The mechanism is described in the text. Though not obvious from the diagram, the mechanism requires that the sulfhydryl group of Cys-Enz and the methyl group of AdoMet must approach perpendicular to and on opposite faces of the target cytosine. (C) N-MTase reaction mechanism based on the M.Taq I MTase. In the central structure, the coordinating hydrogen bonds (shown by dashed lines) are situated in a tetrahedral arrangement relative to the nitrogen and change the hybridization state of the nitrogen from sp^2 to sp^3. This localizes and repositions the free lone pair electrons, shown as a shaded orbital above the nitrogen, for nucleophylic attack on the methyl group.

cofactor after ATP (Figure 5A). The transferable methyl group resides on a charged sulfur atom, making it very reactive to nucleophiles such as polarized N, S, O, and activated carbons or carbanions. Interestingly, the synthesis reaction for AdoMet is the only one known to require hydrolysis of all three phosphates of ATP to drive the reaction. Transfer of the methyl group converts AdoMet to AdoHcy.

C5-MTases

C5-MTases transfer a methyl group to the 5-carbon of the cytosine base (Figure 5B). The 5-carbon of cytosine is not normally reactive enough to attack the methyl group on AdoMet to effect transfer. C5-MTases catalyze this unfavorable reaction in the following way, with a key feature of this process being the formation of a transient covalent complex between the enzyme and the DNA. First, a cysteine thiol on the enzyme serves as a nucleophile that attacks the 6-carbon of the pyrimidine ring, forming a covalent DNA-protein intermediate. This is aided by the protonation of N3 on the ring by the enzyme. The sulfhydryl is provided by the Cys in the highly conserved PC dipeptide (motif IV) found in all C5-MTases. A Glu in the highly conserved ENV tripeptide (motif VI) carries out the protonation. An Arg residue from motif VIII assists the process. This addition activates the 5-carbon and allows it to attack the AdoMet methyl group. Following transfer, AdoHcy is released. The proton left at the 5-position is abstracted by a nearby basic residue leading to resolution of the DNA-protein complex by β-elimination.

N-MTases

N_4-cytosine and N_6-adenine N-MTases methylate an exocyclic nitrogen atom (Figure 5C). Their mechanisms are believed to be similar, but they are not as clearly understood as for the C5-MTases. Methylation occurs by direct transfer from AdoMet and does not involve a covalent DNA-protein intermediate. Each of the first two residues of conserved motif IV (N/S/DPPY/F) donates a hydrogen bond to the target exocyclic nitrogen. This activates the exocyclic N for subsequent nucleophylic attack on the AdoMet methyl group. Following transfer, AdoHcy is released.

AdoMet and DNA Binding

Association of the Reactants

Methylation reactions proceed via a complex between the MTase, DNA, and AdoMet. The order of association of these components varies among MTases (sometimes being random) and no general rule applies to all MTases. The binding to DNA occurs in two discrete steps. The initial nonspecific DNA binding is accompanied by scanning linear diffusion, in which the MTase slides along the DNA in search of a specific recognition site. In the second step, the MTase binds tightly to a specific recognition sequence. When specific binding is observed, it is often associated with a substantial conformational change in the DNA and/or the MTase.

Sequence-Specific DNA Recognition

Sequence-specific recognition of DNA is achieved through multiple contacts between the MTase and the target DNA, both direct and water-mediated. The target base itself does not seem to be part of the recognition sequence as DNA sequences with missing, modified, or alternate target bases are still recognized by the appropriate MTase. In fact, several MTases show preferential affinity for DNA substrates containing base mismatches at the target base position. The vast majority of MTases recognizes palindromic sequences and thus methylates both strands of a target sequence.

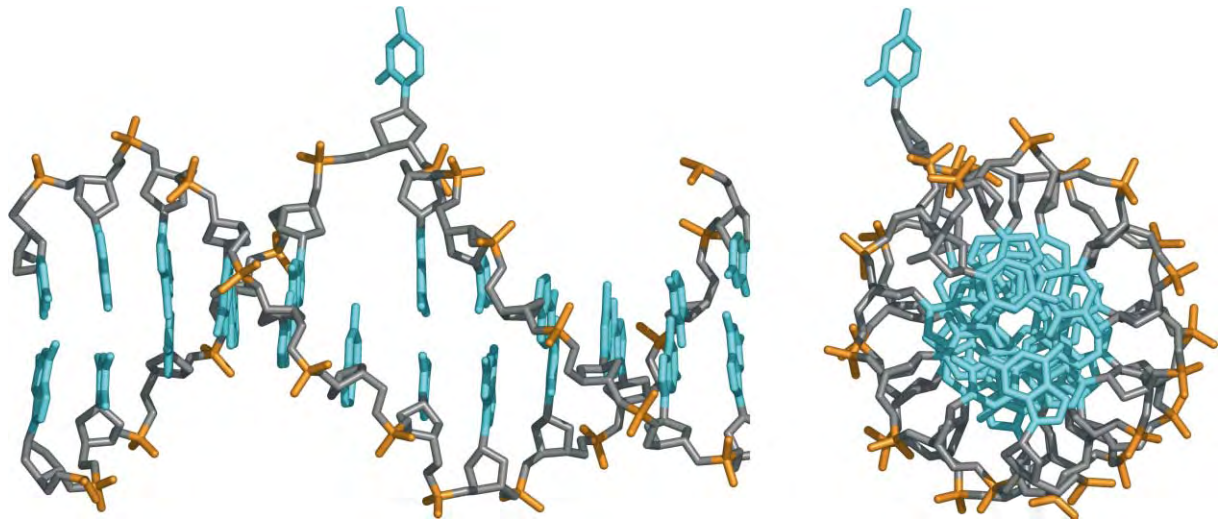

FIGURE 6 DNA base flipping: The DNA (shown from the side and end-on) is in the same orientation as in the structure shown in Figure 4. The backbone is gray with orange phosphates and the bases are cyan. With the exception of the flipped cytosine, the structure is classical B-Form DNA.

Base Flipping

The target base for MTases is normally buried in the DNA helix stack, a location that is incompatible with the stereochemical requirements of the reacting groups on the cofactor and the enzyme. The MTases overcome this spatial hurdle in a surprising and elegant manner: without seriously distorting the remainder of the DNA helix or breaking any bonds, they rotate the target base and its sugar phosphate backbone 180° out of the helix stack and into a pocket in the active site (Figures 4 and 6). This process has been termed "base flipping." The precise mechanism of base flipping is unknown. However, the identity of the target base or even its presence appears irrelevant to the mechanism, as mismatched, modified, methylated, or even missing bases at the target site still display base-flipping, or flipping of the remaining sugar-phosphate backbone at the target position. Subsequent to its discovery in MTases, base flipping was shown to be utilized by other proteins that need access to bases buried within DNA, including DNA glycosylases and AP endonucleases.

Glossary

beta sheet A flat, side-by-side arrangement of polypeptide chains linked together by hydrogen bonds. Each chain is in a zigzag conformation called a beta strand. Beta strands that run in the same direction (from amino terminal to carboxyl terminal) are termed parallel, while those that run in opposite directions are termed antiparallel.

chromatin DNA packaged around small protein cores. Roughly 200 base pairs of DNA are wound twice around an octamer of proteins called histones to form a nucleosome. Nucleosomes are the basic repeating structure of chromatin in eukaryotes.

CpG island A short region of DNA (one kilobase or less in length) that contains clusters of CG dinucleotides (the p in CpG refers to the intervening phosphodiester) at a frequency that is expected from the base composition of the DNA. CpG islands are often located in proximity to the transcriptional control regions of genes. They are normally undermethylated.

hemi-methylated Referring to a double-stranded DNA segment containing a recognition sequence for a MTase in which only one strand of the target sequence is methylated.

palindromic sequence A DNA sequence in which the sequence and its complement are identical when each is read in the standard 5′ to 3′ direction. CG, GATC, and GAATTC are examples of palindromic sequences.

Biography

Sanjay Kumar is a Staff Scientist at New England Biolabs in Beverly, Massachusetts. His research interests include DNA methyltransferases, DNA and chromatin structure, and the development of bioinformatic tools. He holds a Ph.D. in biomedical sciences from Wright State University in Dayton, Ohio. He received his postdoctoral training with Dr. Richard Roberts at Cold Spring Harbor Lab in Cold Spring Harbor, New York. Dr. Kumar and his associates authored the first paper to detail the crystallographic structure of a DNA methyltransferase, and later they made the first discovery of base flipping in DNA.

DNA Methyltransferases: Eubacterial GATC

Martin G. Marinus
University of Massachusetts Medical School, Worcester, Massachusetts, USA

Eubacterial GATC methyltransferases transfer methyl groups from S-adenosyl-L-methionine to the N-6 position of the adenine ring. Only adenines in the tetranucleotide sequence GATC in double-stranded DNA are methylated. Unlike other methyltransferases that function to protect DNA from restriction endonucleases, the eubacterial GATC methyltransferases have other biological functions that are described in this article. In general, the cell uses DNA methylation primarily to control the rate at which these functions exert their effects. Most of our knowledge about eubacterial GATC methyltransferases has come from studies using the Dam methyltransferase of *Escherichia coli* as a model system and this article will focus primarily on it.

Properties of Dam Methyltransferase

The Dam methyltransferase is encoded by the *dam* (*D*NA *a*denine *m*ethyltransferase) gene of *Escherichia coli*, which has a complex mechanism of gene regulation involving multiple promoters and terminators. The major promoter for transcription of the gene is regulated by growth rate of the cells; that is, the faster the growth rate the greater the level of initiation of transcription.

During chromosome replication, the replication fork is followed by a region of hemimethylated DNA which comprises new unmethylated DNA and the complementary methylated template strand. After ~1 min, on average, the newly synthesized DNA is methylated so that both strands are fully methylated. This delay in methylation is due to the concentration of the Dam methyltransferase; it is present at ~130 molecules per cell. Increasing the cellular concentration of the enzyme decreases proportionately the amount of hemimethylated DNA.

The enzyme is a single polypeptide chain of 278 amino acids with a molecular weight of 32 kDa and exists in solution as a monomer. The enzyme has a turnover number of 19 methyl transfers per min and an apparent K_m of 3.6 nM for DNA and double-stranded DNA is a better methyl acceptor than denatured DNA and there is one methyl transfer per site per binding event even if the substrate DNA is fully unmethylated. The protein may have two SAM binding sites: a catalytic site and one which increases specific binding to DNA perhaps as a result of an allosteric change. The methyltransferase is thought to bind the template and slide processively along the DNA, methylating about 50 sites before dissociating.

Properties and Uses of *∂am* Mutant Strains

The commonly used *dam* mutant strains do not have detectable residual methyltransferase activity nor detectable methylation at GATC sequences. *Dam* mutants are most often used to "launder" DNA molecules that have sites that are resistant to digestion with specific restriction endonucleases. These include: AlwI, BcgI, BclI, BsaBI, BspDI, BspEI, BspHI, ClaI, HphI, NruI, TaqI, and XbaI. Resistance occurs because these enzymes have recognition sequences that overlap with the GATC tetranucleotide and almost all of these are methylated in wildtype *E. coli*. After transfer through the *dam* mutant strain, there is no methylation at GATCs and DNA molecules are now sensitive to digestion with the restriction endonucleases listed above.

Dam mutants have also been useful to define the biological roles of methyl groups on adenine in DNA. The mutant strain shows a large number of phenotypic differences compared to wild type suggesting multiple functions. All the known mutant phenotypes in *E. coli* can be explained by the involvement of GATC methylation in mismatch repair, regulation of gene expression, and initiation of chromosome replication.

Dam-Directed Mismatch Repair

During chromosome replication, errors are made at low frequency by the replicative polymerase to form base

mismatches in newly synthesized DNA. Such errors need to be removed because they are potentially mutagenic. *E. coli* and most other organisms, including humans, have a highly conserved repair system that removes such mismatches in newly synthesized DNA. The Dam- (or methyl-) directed mismatch repair system in *E. coli* uses only hemimethylated DNA as a substrate thereby restricting its activity to the region of the chromosome immediately trailing the replication fork. The repair system is outlined in Figure 1. Briefly, base mismatches in hemimethylated DNA are recognized by the MutS protein followed by formation of a ternary complex with two additional proteins, MutL and MutH. MutH is an endonuclease active on hemimethylated GATC sites but only when complexed with the other Mut proteins on DNA. Following DNA incision, the UvrD helicase unwinds DNA in either the 5′ to 3′ direction or the reverse. The directionality is dependent on the location of the mismatch relative to the nearest GATC sequence. The unwound nicked DNA strand is digested by one or more exonucleases followed by resynthesis using the replicative polymerase. DNA ligation of the nick at the end of replication completes the process of repair and the hemimethylated DNA is eventually methylated.

Three lines of genetic evidence indicate the importance of DNA methylation in the process. First, overproduction of Dam methyltransferase inhibits the repair process by reducing the amount of hemimethylated DNA. Under these conditions mismatches are not repaired and lead to an increase in mutation frequency. Second, in a *dam* mutant the repair system is active but cannot discriminate the template strand from the daughter strand.

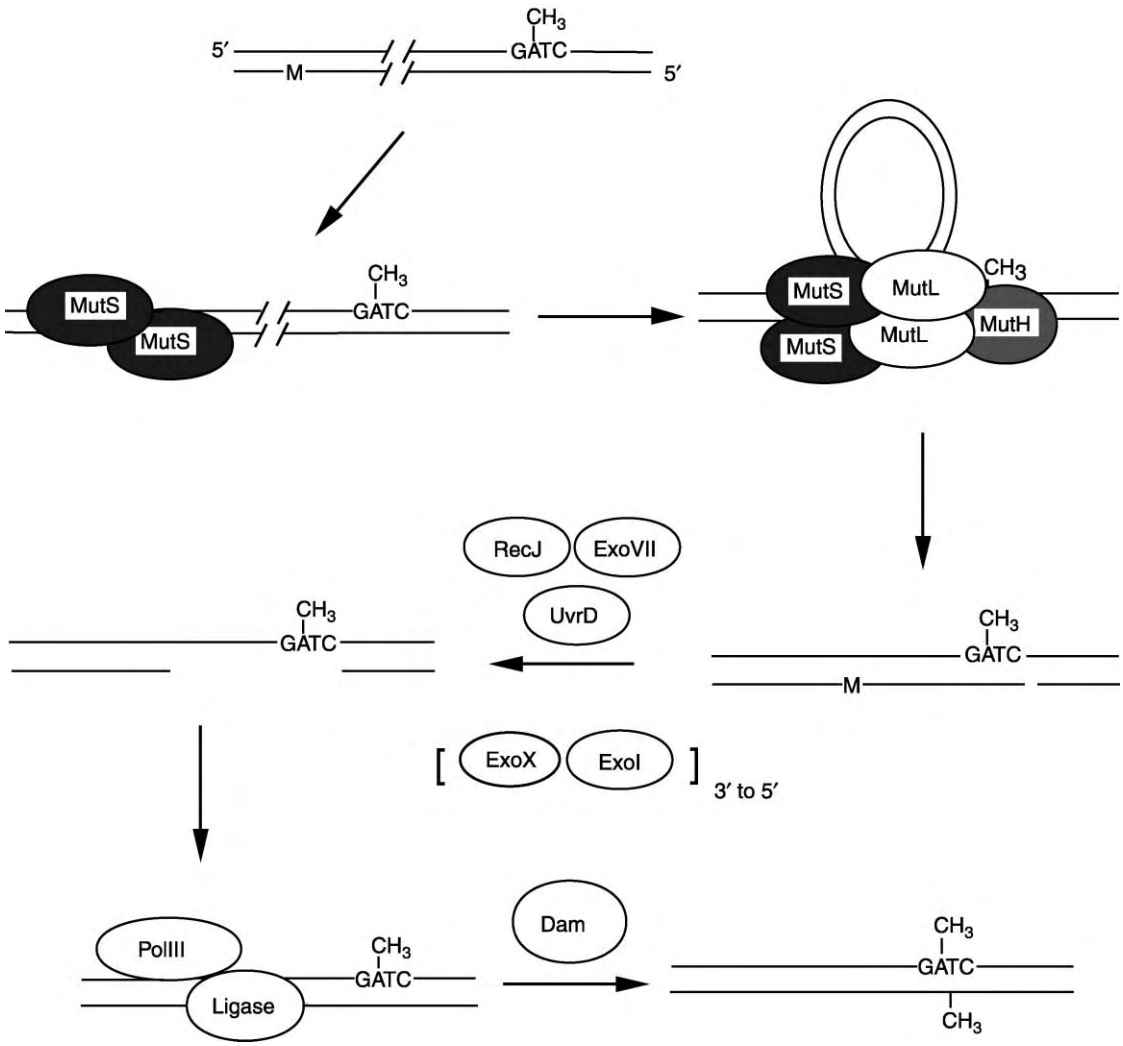

FIGURE 1 DNA mismatch repair. A base mismatch (M) in the newly synthesized unmethylated DNA strand is some distance from the nearest GATC sequence. MutS protein binds the mismatch and a complex with MutL and MutH is formed leading to cleavage of the unmethylated strand. The UvrD helicase unwinds the unmethylated strand which is digested by an exonuclease. Excision can occur in either the 3′ to 5′ direction (ExoI, ExoX) or the reverse (RecJ, ExoVII) depending on the orientation of the mismatch relative to the GATC sequence. DNA polymerase III holoenzyme synthesizes a new strand and the resultant nick is ligated by DNA ligase. The GATC sequence is eventually methylated by Dam methyltransferase.

Consequently, the repair system removes mutations from the newly synthesized strand but also introduces mutations into the parental strand yielding an increased mutation frequency. Third, DNA duplexes containing a mismatch can be constructed with no methylation, methylation on both strands, or on only one of the two strands. When introduced into cells the fully methylated DNA is not repaired, hemimethylated DNA is repaired using the methylated strand as template and the unmethylated duplex is repaired using either strand as template.

In a *dam* mutant, mismatch repair produces detectable nicks or gaps in DNA but it is not known if the nicks or gaps occur exclusively behind the replication fork as a result of replication errors or in any part of the chromosome as a result of mismatches formed spontaneously. The nicks or gaps are converted to double-strand breaks either by a replication fork encountering an unrepaired gap or by activated MutH cleavage on complementary strands at the same GATC sequence or by a combination of these (Figure 2). It is not yet known which of these mechanisms (or both) generates double-strand breaks *in vivo* but *in vitro* evidence supports the MutH cleavage model.

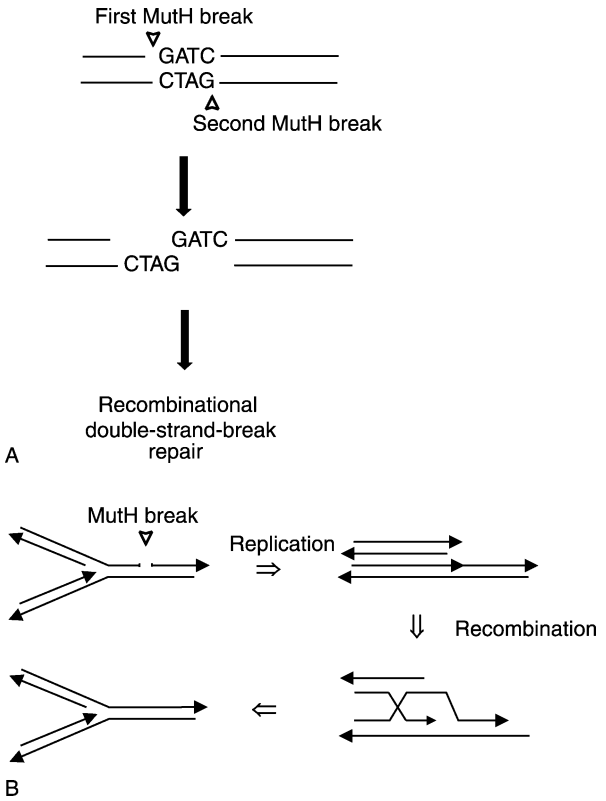

FIGURE 2 Generation of double-strand DNA breaks. (A) Mismatch repair endonuclease MutH introduces nicks on either side of a GATC sequence to produce a double-strand break. (B) Mismatch repair introduces a nick ahead of a replication fork producing a double-strand break when the fork encounters it. Recombination is required to restore the fork.

Mismatch repair in *dam* mutants is also the basis for the phenomenon of drug tolerance. The mutants are more sensitive than wild type to certain anticancer agents such as cisplatin, and methylating agents like streptozotocin. Inactivation of mismatch repair, however, renders the cell tolerant to these agents. In other words, mismatch repair sensitizes *dam* cells to the effects of these deleterious agents. This is of interest because mammalian cells in culture respond in exactly the same way; that is, they are sensitive to these agents but become tolerant upon loss of mismatch repair capacity. The molecular basis for this phenomenon has yet to be defined.

Initiation of Chromosome Replication

In *E. coli*, chromosome replication is initiated only once per cell cycle and Dam methylation is involved in this process. Chromosome replication is initiated at *oriC*, a region which has a 10 times higher than expected density of GATC sequences, by the initiation protein DnaA. The promoter region of the *dnaA* gene must be methylated for maximal expression and methylated origins are more efficiently initiated than unmethylated ones. The neighboring hemimethylated *oriC* and *dnaA* gene region is bound specifically and with high affinity by the SeqA protein which prevents methylation by Dam methyltransferase and renders the origin inert to further initiation (the eclipse period). By a process that is not understood, SeqA is released from *oriC* later in the cell cycle and methylation ensues followed by another initiation event.

Fast-growing wild type cells contain multiple origins and these initiate synchronously. The eclipse period is dependent on the level of Dam methyltransferase and can be lengthened or shortened by decreasing or increasing the enzyme level respectively. *In vivo*, *dam* and *seqA* mutants have an asynchronous initiation pattern and the eclipse period is shortened or absent. The *seqA* mutant, as expected, performs extra initiations each cell cycle but the *dam* mutant does not. This indicates that in *dam* mutants there must be an alternative mechanism preventing excessive initiation.

Altered Gene Expression

The state of GATC methylation can affect protein–DNA interaction and if this tetranucleotide sequence occurs in promoter or regulatory DNA regions, gene expression can be altered. As discussed, the *dnaA* gene is maximally transcribed only if the promoter region is fully methylated. This is consistent with its role in the initiation of chromosome replication. Another example is the

promoter for the *tsp* (transposase) gene of the mobile genetic element, *Tn*10, which controls the rate of transposition. This promoter is active only when it is hemimethylated thereby ensuring that transposition is coupled with chromosome duplication and occurs only once per cell cycle. A further example is the *pap* (pyelonephritis-associated pilus) operon in pathogenic *E. coli*, where Dam and the transcriptional activator Lrp compete for binding to specific symmetrically unmethylated GATC sequences. Depending on which protein is bound, *pap* expression is either off or on.

There are few other genes where the rationale of coupling methylation to gene expression is so clear-cut. High-density oligonucleotide array analysis of mRNA from *dam* mutants indicates that expression of many genes is altered. In several instances this is due to competition between Dam methyltransferase and transcriptional activators such as Fnr and Cap competing for the GATC sites that overlap their recognition sequences. For other genes such as *sulA* (involved in control of cell division) and *glnS* (glutamyl-tRNA synthetase), which have GATCs in their promoter regions, expression is increased when they are unmethylated. The biological rationale for this is unclear especially since in a wild type background these promoter regions would never be unmethylated. There are also many examples where GATCs in the promoter region have no effect on initiation of transcription. At present, there are no rules to predict if a GATC sequence in the promoter will increase, decrease, or have no effect on the frequency of transcription initiation.

As discussed, *dam* mutant DNA is subjected to DNA breakage *in vivo*. This results in the induction of a stress response termed SOS in which transcription of about 50 genes is increased. The gene products include those that repair DNA damage, recombination, and control cell division. In *dam* mutants, this response is constitutively expressed because three recombination proteins (RecA, RuvA, and RuvB), which are part of the response, are required for cell viability.

Role of Dam Methylation in Bacterial Pathogenesis

Altered levels of Dam methyltransferase can modulate the virulence of certain bacterial pathogens including *Salmonella*, *Yersinia*, and *Vibrio* in animal models and in *Erwinia*, a plant pathogen. The best-studied system is the *Salmonella*-mouse model. *Dam* mutant *Salmonella* are 10 000 times less capable of killing mice than wild type but a low level of tissue infectivity occurs. Mice that have been infected with the avirulent *dam* mutant become much more resistant to killing by wild-type *Salmonella* suggestive of a vaccine effect. The molecular basis for the role of Dam methylation in bacterial pathogenesis has yet to be elucidated but mismatch repair-deficient *Salmonella* are fully virulent. As there is a large group of virulence genes in *E. coli* and *Salmonella* whose expression is altered in *dam* mutants, it is likely that the basis for the avirulent phenotype of *dam* mutants is due to gene expression at inappropriate times allowing the animal hosts to mount an effective challenge to bacterial invasion.

A contrast to the *Salmonella* example is provided by *Neisseria* that can cause meningitis. These bacteria have a *dam* gene but it is not involved in pathogenesis. Rather, it is defects in the mismatch repair system (*mutS* and *mutL* gene inactivation) that allows for frameshift mutations to occur in DNA sequences controlling expression of certain virulence genes. There is no general rule about the effect of Dam methylation on virulence; it has to be investigated for each organism.

Role of Dam Methylation in Other Bacteria and Their Viruses

At present, little is known about the role of Dam methylation in other bacteria. Inactivation of the *dam* gene in *Yersinia* and *Vibrio*, however, is a lethal event, although the reason is not known. In contrast, inactivation of the *dam* gene in *Neisseria meningitidis* is not lethal, does not lead to a mutator phenotype and inactivation of recombination does not lead to lethality. This suggests a fundamentally different role for Dam methyltransferase in this species compared to the *E. coli* paradigm.

The bacterial virus P1 has its own *dam* gene that is related to that of its *E. coli* host and is essential for its life cycle. Dam methylation is required at the stage where the viral DNA is packaged into the heads. This is accomplished by filling the head with genomic DNA and then cleaving it at specific sequences, termed *pac* sites. These *pac* sites are flanked by multiple GATC sequences which must be methylated in order for cleavage to occur. In other *E. coli* bacterial viruses, however, such as T2 and T4, deletion of the *dam* gene has no discernable effect on their life cycle. Again, no generalizations can be made regarding the essentiality of the *dam* gene for viability.

Biography

Dr. Martin G. Marinus is a Professor in the Department of Biochemistry and Molecular Pharmacology at the University of Massachusetts Medical School in Worcester. His principal research interest is the molecular biological processes that involve DNA adenine methylation in *Escherichia coli*. He holds a Ph.D. from the University of Otago, New Zealand, and received his postdoctoral training at Yale University.

DNA Mismatch Repair and Homologous Recombination

Ivan Matic and Miroslav Radman
INSERM U571, Faculté de Médecine Necker-Enfants Malades, Université Paris V, Paris, France

Mismatches are mispaired or unpaired bases in the double-strand DNA molecule. Mismatches are generated as a consequence of errors during DNA replication or during homologous recombination involving nonidentical sequences. Specific mismatches can be formed by DNA damage. Enzymes that recognize and process mismatches have been identified in prokaryotes and eukaryotes. Different mismatch repair systems (MRS) are distinguished on the basis of their mismatch specificity and the size of excision tract that varies from single nucleotide to over a kilobase. The long-patch, also called the general, MRS (because it recognizes a variety of mismatches) is highly conserved during evolution. This repair system controls the fidelity of chromosomal replication by eliminating DNA biosynthetic errors and participates in the processing of some DNA lesions in transcription-coupled repair and in meiotic and mitotic recombination processes. The control of homologous recombination is particularly important because this fundamental biological process is essential for the maintenance of chromosomal integrity, generation of genetic diversity, proper segregation of meiotic chromosomes, and the speciation. Specific mismatches created by chemical modification of DNA bases (e.g., G:T mismatch due to deamination of 5-methyl-C to T or 8-oxo-G:A mismatch due to oxidation of G) are repaired by specialized short-patch MRS. When such mismatches occur in the course of recombination, their localized repair in heteroduplex DNA creates mosaic sequences, i.e., an apparent hyper-recombination effect.

Generalized Mismatch Repair Systems

Escherichia coli Methyl-Directed Mismatch Repair Pathway

The best characterized generalized MRS is *Escherichia coli* methyl-directed MRS. It has been completely reconstituted *in vitro* and involves three dedicated proteins: MutS, MutL, and MutH. Other proteins that participate in the processing of mismatches are shared with other repair pathways. MutS protein recognizes and binds to mismatches, MutL associates with MutS-mismatch complex and activates MutH, which incises the newly synthesized strand at a nearby unmethylated 5′-GATC-3′ site. GATC sites are hemimethylated because methylation of adenine by Dam methylase lags behind replication by several minutes. Thus, MutH directs the mismatch repair process to the newly synthesized strand. Neither MutH nor nonmethylated GATC are required if a single strand break is present in the substrate DNA. The helicase II (MutU) unwinds the DNA allowing degradation of the displaced single-strand DNA, assuring the irreversibility of this repair process. The involvement of different exonucleases in this repair pathway depends on orientation of the nick relative to the mismatch. The repair process is finalized by DNA polymerase III and DNA ligase activity.

MutS protein recognizes seven of eight possible base pair mismatches, C-C mismatches (the least frequent replication error) being refractory. In addition, MutS protein binds up to four unpaired bases allowing for repair of frameshift errors. MutS does not recognize mismatches in a sequence-specific manner, although sequence context does influence the efficiency of repair. MutS protein binds to mismatches as a homodimer and has affinities for various mismatches that reflect the efficiency of *in vivo* repair. MutS proteins possess an intrinsic ATPase activity, which is essential for mismatch repair. The inactivation of *mutS*, or any other of *mut* genes coding for general MRS, show identical strong mutator phenotypes with 10^2- to 10^3-fold increased rates of transition (G:C → A:T and A:T → G:C) and frameshift mutations, as compared to mismatch repair proficient bacteria.

Generalized Mismatch Repair in Eukaryotes

The knowledge about *E. coli* general MRS greatly facilitated identification and comprehension of homologous MR systems in other organisms. However, there are significant differences between these repair systems.

In most organisms, DNA strand recognition is not governed by DNA methylation. Dam methylase, coupled with the presence of *mutH* gene, has been identified in only a limited number of bacterial species. The mechanism of strand discrimination in other prokaryotes and eukaryotes is not yet elucidated.

Core functions of MRS, MutS, and MutL proteins are conserved in prokaryotes and eukaryotes. However, unlike its prokaryotic homologs, these proteins function as heteromers. The most extensively characterized eukaryotic generalized MRS is that of *Saccharomyces cerevisae*. In this organism, six MutS homologues (Msh1-6) have been identified. Msh1 functions in mitochondria, while others act in the nucleus. Heterodimers of the MutS homologs cooperate with heterodimers of MutL homologs to process different mismatches. Msh2–Msh6 (MutSα) complex preferentially targets base pair mismatches and insertions/deletions of one or two nucleotides. Msh2–Msh3 (MutSβ) binds 1–10 nucleotides large insertion/deletions loops.

Four MutL homologs (Mlh1-3 and Pms1) were identified in *S. cerevisae*. These proteins also form heterodimers. The majority of mismatch-repair activity is carried out by Mlh2-Pms1 heterodimer interacting with either MutSα or MutSβ complex. Mlh1 forms complexes with either Pms1, Mlh2, or Mlh3, each having distinct roles in the repair of mutational intermediates. As in prokaryotes, additional factors participate in *S. cerevisae* mismatch repair: proliferating cell nuclear antigen (PCNA; processivity factor for replication machinery) Exo1 ($5' \rightarrow 3'$ exonuclease), and the DNA polymerases δ and β.

In other eukaryotic organisms, invertebrates, vertebrates, and plants, multiple MutS and MutL homologs have also been identified. Different species contain different sets of homologs, without an obvious correlation to their position in the evolutionary tree. The eukaryotic mismatch-repair deficient mutants show mutator phenotypes similar to prokaryotic ones, i.e., increased rate of transition and frameshift mutations.

Mismatch Repair System and Homologous Recombination

Anti-Recombination Activity in *Escherichia coli*

Homologous recombination can be defined as interaction between two DNA sequences sharing extensive nucleotide sequence identity, present on a single or two different DNA molecules, that results in generation of mixed sequences derived from two parental ones. The homologous recombination process occurs in four basic steps: initiation, homologous pairing and DNA exchange, DNA heteroduplex extension, and resolution. The recombination process is initiated by combined action of a variety of nucleases and helicases that generate single-strand DNA. Single-strand DNA is substrate for proteins that catalyze homologous pairing and DNA exchange. The best studied homologous pairing and DNA exchange protein is *Escherichia coli* RecA.

RecA protein binds to single-strand DNA, or double-strand DNA containing single-strand DNA gaps, and forms a nucleoprotein complex containing one RecA protein monomer for every three nucleotides. RecA-single-strand DNA filaments engage search for homologous target DNA sequences. Scanning DNA for homologous sites is very fast and highly accurate even when they are very rare in the genome. *In vitro* data show that one helical turn of a RecA nucleoprotein filament containing approximately six RecA monomers and 15 bases of single-strand DNA is the functional unit sufficient to carry out the homology search. *In vivo* data show that RecA-catalyzed pairing is effective providing that the length of shared uninterrupted identity is at least 26 nucleotides.

After homologous pairing is achieved, the resultant joint molecules exchange homologous strands and establish heteroduplex DNA, where each parental DNA contributes one complementary strand. Heteroduplex DNA is extended by a unidirectional branch migration step. At this step of recombination, RecA protein tolerates DNA lesions, large heterologies, and up to 30% nucleotide sequence divergence between recombining molecules. However, pairing of nonidentical DNA sequences produces mismatched heteroduplex molecules, a substrate for MRS (Figure 1). *In vitro* experiments demonstrated that MutS and MutL proteins block RecA catalyzed strand-exchange and elongation of heteroduplex. *In vivo* MRS is capable of impeding recombination even between sequences with very low divergence. For example, transductional recombination between two serovars (Typhimurium and Typhi) of *S. enterica*, whose genomes differ only 1–2% at DNA sequence level, increases 10^2- to 10^3-fold in MRS deficient genetic background.

The antirecombination activity of the MRS is a consequence of blocking the RecA-catalyzed heteroduplex elongation but also of reducing the length of sequence identity needed for RecA-mediated homologous pairing and DNA exchange. The increased concentration of RecA protein does not prevent mismatch-repair antirecombination activity, whereas the overproduction of MutS and MutL proteins severely reduces recombination frequency between diverged DNAs (Figure 2).

Unlike the identical effect of MRS mutants on spontaneous mutagenesis, the inactivation of different MRS genes has distinct and characteristic effect on the recombination between diverged sequences. Very strong

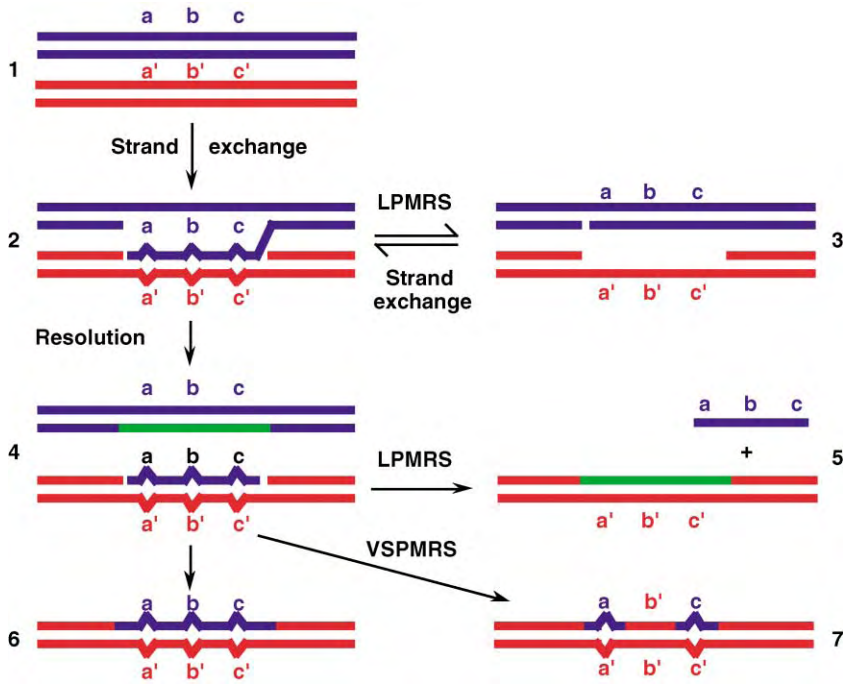

FIGURE 1 Anti-recombination by long patch mismatch repair system (LPMRS) and hyper-recombination by very short patch mismatch repair system (VSPMRS). a/a′, b/b′, and c/c′ represent single nucleotide polymorphisms between two recombining DNA molecules (blue and red) (1). For simplicity, only one kind of strand exchange (asymmetric strand exchange) is shown; a:a′, b:b′ and c:c′ are mismatched bases in the heteroduplex intermediate (2). LPMRS can destroy mismatched heteroduplex before (3) of after (4 and 5) resolution of recombination intermediates. Heteroduplexes that escape LPMRS, and which are sealed by ligase (6), will be separated by subsequent replication producing one recombinant and one parental DNA molecule. If some of the mismatches (e.g., b:b′) in this heteroduplex molecule are substrate for VSPMRS, its activity will generate a complex recombinant on the repaired strand (7). Green lines represent tracts of DNA repair synthesis.

hyper-recombination effect is observed upon inactivation of *mutS* and *mutL* genes (Figure 2), while the effect of inactivation of *mutU* and *mutH* genes is relatively weak. The presence of single strand ends in recombination intermediates (Figure 1) can explain the weak effect of *mutH* gene inactivation. The helicase II can probably be replaced by other enzymes that are involved in recombination, e.g., RecG.

Anti-Recombination Activity in *Saccharomyces cerevisae*

The anti-recombination activity of the eukaryotic MRS has been best characterized in *S. cerevisiae*, where it can inhibit recombination between diverged sequences both in mitosis and in meiosis. Even a single mismatch is sufficient for MRS to inhibit recombination, while additional mismatches have a cumulative negative effect on recombination efficiency. When DNA sequence divergence reaches several percent, the probability of a heteroduplex recombination intermediate to escape detection by the MRS is so low that the additional mismatches fail to increase anti-recombination activity. The MutSα or MutSβ complexes recognize the same types of mismatches in recombination intermediates as in replication intermediates. Although *msh2* and *mlh1* or *pms1* mutants have identical mutator phenotypes, *msh2* mutants exhibit higher recombination rates between diverged DNAs than do *pms1* or *mlh1* mutants. This indicates that Msh binding to mismatch may by itself inhibit the recombination process.

In *S. cerevisiae*, MRS processing of recombination intermediates results in gene conversion or complete destruction of recombination intermediates. Gene conversion is a genetic phenomenon in which information on one chromosome is replaced with information from the homologous chromosome, which remains unchanged (nonreciprocal recombination). In *S. cerevisae*, where it is possible to analyze all four products derived from a single meiosis, a non-Mendelian 3:1 segregation pattern of allelic sequences is diagnostic of a gene conversion event. In the absence of a functional MRS, mismatches in heteroduplex recombination intermediates are not repaired and the mismatch-containing DNA strands segregate at the first mitotic division following meiosis (postmeiotic segregation or PMS). The frequency of PMS reflects the repair efficiency for the particular mismatch. In *msh2*, *pms1*, *mlh1*, and to a lesser extent *msh3* and *msh6* mutants, meiotic gene

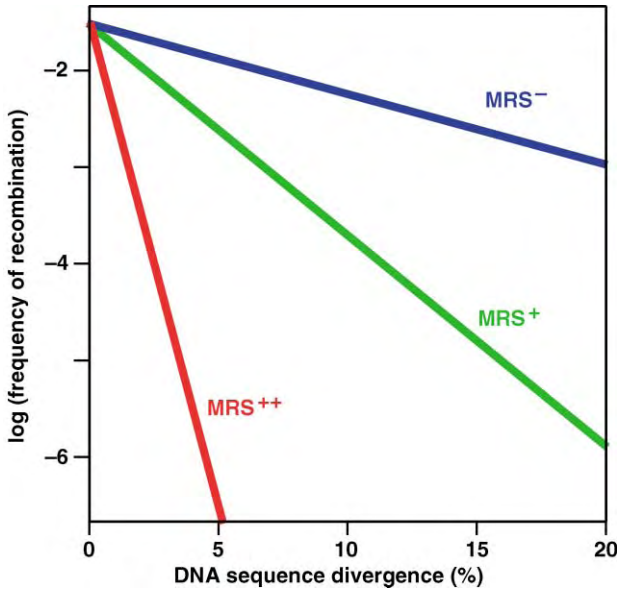

FIGURE 2 The relationship between DNA sequence divergence, homologous recombination, and mismatch repair system (MRS). Conjugational crosses between enterobacterial strains and species show that linear increase of sequence divergence between recombining genomes results in the exponential decrease in recombination frequency. This relationship shows that an increase in DNA divergence increases the difficulty for RecA protein to find the sites for initiation of homologous pairing and strand exchange. The MRS activity reduces the apparent length of these sites and blocking the maturation of RecA-catalyzed recombination intermediates. Consequently, the inactivation of MRS decreases the slope of correlation between recombination and DNA divergence, i.e., increasing the frequency of recombination between diverged sequences. In contrast, the overproduction of the key MRS proteins (MutS and MutL) increases the slope (MRS^{++}), i.e., creates new genetic barriers.

conversion events are reduced while PMS events are elevated. Since the repair patch is shorter than the meiotic heteroduplex DNA, the repair process does not necessarily interfere with the formation of crossing overs. Although the same mismatch-repair machinery detects mismatches in both recombination and replication intermediates, some accessory proteins are probably unique to each type of repair. For example, PCNA appears to play a role in correcting DNA replication errors but has not been implicated in the correction of heteroduplex recombination intermediates.

MRS inhibits crossing-over between diverged chromosomes in interspecific hybrids during meiosis, and therefore it is also important for establishing and maintaining interspecific genetic barriers. In addition, the mismatch-triggered anti-recombination activity of eukaryotic MRS proteins inhibits ectopic interactions between diverged, repetitive DNA sequences during both mitosis and meiosis, and therefore it maintains genome stability by preventing genome rearrangements. Interestingly, mitotic recombination in yeast is more sensitive (in a mismatch repair-dependent manner) to low levels of sequence divergence than is meiotic recombination, which may help reinforce the strong bias for sister chromatid versus interhomolog interactions during mitosis.

Two *S. cerevisiae* MutS homologs Msh4 and Msh5 have completely lost the ability to participate in a standard mismatch repair reaction but have acquired novel, meiosis-specific roles. The loss of either MSH4 or MSH5 is associated with an approximately 50% reduction in meiotic crossing-over, in increased levels of homolog nondisjunction, and decreased viability of meiotic products. The Msh4 and Msh5 genes are in the same epistasis group and, like the other MutS homologs, physically interact to form heterodimers. As gene conversion levels are normal in *msh4* or *msh5* mutants, the Msh4-Msh5 complex is assumed to act late in recombination. Genetic data indicate that the Msh4–Msh5 heterodimer interacts specifically with the Mlh1-Mlh3 complex to promote meiotic crossing-over. Both *mlh1* and *mlh3* mutants exhibit a reduction in meiotic crossover events, and epistasis analysis indicates that Mlh1 and Msh4 act in the same crossover pathway.

DNA Sequence Divergence, Mismatch Repair, Loss of Heterozygosity, and Cancer

Carcinomas evolve by accumulation of several somatic mutations, of which some are recessive (e.g., in tumor suppressor genes). Such mutations are expressed only when homozygous, i.e., when both alleles in diploid cells are inactivated by mutation. The transition from the heterozygous (m/+) to homozygous (m/m) or hemizygous (m/o) state usually occurs due to a chromosomal rearrangement leading to the loss of the functional gene copy (Figure 3). Such rearrangement can be due to (i) the loss of the (+) allele (e.g., a small or large deletion, or the loss of the entire chromosome), or (ii) a homologous recombination event, such as gene conversion of the allele to (m/m) or a mitotic crossover anywhere between the centromere and the allele (Figure 3). All these events, with the exception of gene conversion, lead to the loss of heterozygosity (LOH) initially present because of the maternal/paternal sequence divergence (about 0.1% of nucleotides in human population).

Two lines of experiments suggest that the functionally largely neutral sequence polymorphism between the two parental lines effectively suppresses the mitotic recombination mechanism for LOH:

(a) Gene targeting in mouse embryonic stem cells is highly sensitive to the natural sequence polymorphism of the parental strains. That suppression of mitotic

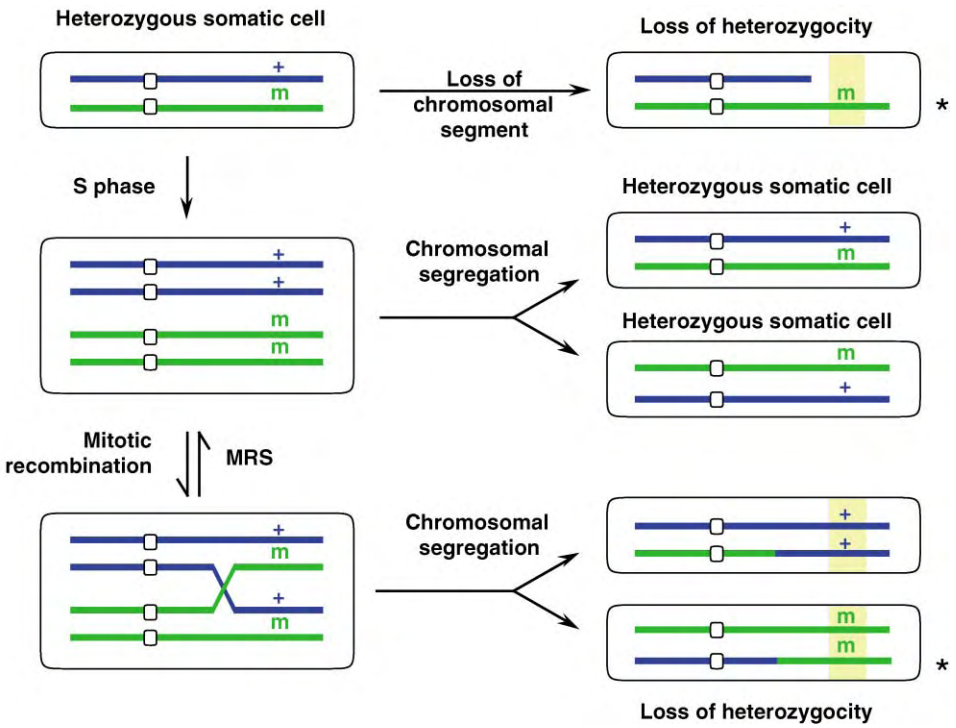

FIGURE 3 DNA sequence divergence, mismatch repair, and loss of heterozygosity. Only one pair of homologous chromosomes is shown. The chromosome colors (blue and green) indicate the sequence polymorphism between the maternal and paternal line (0.1% in human population). The symbol (m) stands for a specific recessive mutation. Only cells (*) having lost the wild type (+) allele express the (m) mutation. Such cells show loss of heterozygocity (LOH; yellow). In human tumors, most LOH occurs by chromosomal rearrangements (top right). However, in inbred mice, with little or no sequence divergence between homologs, most LOH occurs by mitotic recombination. The recombination-suppressing effect of sequence polymorphism is relieved in MRS deficient mouse cells (see Figure 1). Because LOH is an obligate step in the expression of recessive mutations in tumor suppressor genes, sequence polymorphism protects against cancer due to MRS activity.

recombination can be relieved by the defect in mismatch repair, i.e., it appears that the mammalian mismatch repair acts to prevent mitotic recombination between nonidentical sequences.

(b) The expression of a recessive heterozygous (m/+) mutation in inbred, globally highly homozygous mice, occurs at elevated frequency *via* mitotic recombination, i.e., LOH from the crossover point to the end of the chromosome including the recessive mutation (Figure 3). In hybrids between different strains, the LOH frequency is much lower than in inbred strains. The decrease in LOH is accounted by the loss of mitotic recombination due to the activity of the MRS.

Thus, it appears that – like in bacteria and yeast – the editing (suppression) of homologous recombination by the MRS, based on the sequence divergence between the recombining sequences, functions also in mammalian cells. Such genetic barriers based on the genomic sequence polymorphism are expected to: (i) delay the process of carcinogenesis by delaying the expression of relevant recessive somatic and inherited mutations, and (ii) enhance sympatric speciation by creating genetic isolation on the germ line level.

Evolutionary Role of the Control of Homologous Recombination by Mismatch Repair

Evolutionary conservation of key MRS functions illustrates the importance of this genetic system in the preservation of genomic integrity in prokaryotes and eukaryotes. In bacteria, the loss of MRS activity can provide transient selective advantage when adaptation is limited by the supply of mutations. However, the restoration of MRS proficiency is prerequisite for evolutionary success because upon adaptation, the load of deleterious mutations is no longer counterbalanced by the generation of beneficial mutations resulting in fitness reduction. In eukaryotes, the increased genomic instability resulting from MRS deficiency is apparently never advantageous. For example, in mammals, the loss of MRS activity is associated with male or female sterility and tumorigenesis.

Increased frequency of chromosomal rearrangements is a particularly deleterious phenotype of MRS deficiency in prokaryotes and eukaryotes. For example,

the inactivation of MRS increases 10-fold the frequency of chromosomal duplications resulting from recombination between *E. coli rhsA* and *rhsB* loci (0.9% divergent) and about 10^3-fold gene conversion between *Salmonella enterica tufA* and *tufB* genes (about 1% divergent). The MRS-mediated recombination surveillance is particularly important for eukaryotes because their genomes contain a multitude of repetitive DNA sequences. MRS in *S. cerevisiae* prevents intra- and inter-chromosomal crossovers and gene conversions resulting from recombination between nonidentical DNA sequences.

By controlling homologous recombination, MRS controls also the process of speciation. In bacteria, MRS controls conjugational, transductional, and transformational recombination between strains and species, thus reducing gene flow between diverged populations. Similarly, by controlling crossing-over and chromosome segregation in meiosis, MRS prevents hybridization between diverged organisms resulting in reproductive isolation of closely related species.

Glossary

homologous recombination Interaction between two DNA sequences sharing extensive nucleotide sequence identity, present on a single or two different DNA molecules, that results in generation of mixed sequences derived from two parental ones. Such recombination events can be nonreciprocal (gene conversion or "patch" recombinants) or reciprocal (crossover or "splice" recombinants).

meiosis (from Greek, *meion*, smaller) Two successive nuclear and cellular divisions resulting in the reduction of the chromosome number from diploid to haploid. The products of meiosis are haploid gametes. Because chromosome segregation in meiosis requires physical attachment of homologous chromosomes (chiasmata), each chromosome in the gamete is recombinant.

mismatch Mispaired or unpaired bases in the double-strand DNA molecule.

mitosis (from Greek, *mitos*, thread) Nuclear and cellular division of a eukaryotic somatic cell resulting in the generation of two daughter cells having the same number of chromosomes as the parent cell.

mutation (from Latin *mutare*, to change) Any heritable modification of genetic material.

Biography

Miroslav Radman is Professor of cell biology at the Medical School Necker of the University Paris 5. He is also the Director of the research Unit No. 571 of INSERM entitled "Evolutionary and Medical Molecular Genetics." He is a member of the EMBO, Academia Europea, French Academy of Science and Croatian Academy of Sciences and Arts. He is a pioneer in the study of DNA repair and mutagenesis, in particular of mutagenic SOS repair and the antimutagenic mismatch repair.

Ivan Matic is an Associate Research Professor of the French National Center for Scientific Research (CNRS). He directs the research group "Evolution of Enterobacteria" in the INSERM Unit No. 571 at the Medical School Necker, University Paris 5. He studies the mechanisms of mutation and recombination in bacteria, as well as their role in adaptive evolution of bacteria.

DNA Mismatch Repair and the DNA Damage Response

Guo-Min Li and Steven R. Presnell
University of Kentucky Medical Center, Lexington, Kentucky, USA

DNA mismatches are base-pairing errors that deviate from the Watson-Crick rules that stipulate that A pairs with T and G with C. In addition, small insertion/deletion structures, in which one DNA strand contains a small number of unpaired nucleotides, are also considered mismatches. Mismatched base pairs occur as errors during the normal course of DNA replication and recombination, and they are mutagenic if left uncorrected. DNA mismatch repair (MMR) is a cellular process that rectifies mismatches to yield correct Watson-Crick base pairs. MMR is an important genome maintenance system because defects in the system cause genomewide instability and have been implicated in the development of certain types of human cancer. In the past, the ability of the MMR system to correct DNA heteroduplexes has been considered the primary mechanism by which it contributes to genomic stability. However, more recent studies indicate that the MMR system also contributes to genomic stability by mediating protective cellular responses to DNA damage.

Mismatch Repair Proteins and Their Role in Mismatch Correction

The eukaryotic MMR pathway is similar to the *Escherichia coli* MutHLS pathway with respect to features of mechanism and involvement of several homologous activities. In fact, many of the eukaryotic MMR components were initially identified by their sequence homology to the *E. coli* MMR proteins (see Table I). The eukaryotic MMR proteins are known to include the MutS homologues (MutSα, MutSβ), the MutL homologues (MutLα, MutLβ, MutLγ), exonuclease I (ExoI), replication protein A (RPA, a eukaryotic, SSB (single strand DNA-binding protein)), and DNA polymerase δ. Although eukaryotic homologues of the bacterial MutH and helicase II have not yet been identified, studies in human nuclear extracts have demonstrated that the human MMR reaction possesses a mechanism similar to that of *E. coli*; that is, the repair is targeted to the newly synthesized strand and can occur bidirectionally. The eukaryotic system appears, however, to be more complex than the *E. coli* pathway. For example, whereas only a single form of MutS or MutL in *E. coli* has been documented, at least two MutS homologues and three MutL homologues have been identified in eukaryotic cells, each of which is a heterodimer. For example, MutSα consists of the polypeptides MSH2 and MSH6, and MutLα comprises MLH1 and PMS2 (see Table I). These MutS and MutL heterodimers, although redundant, play special roles in MMR subpathways. In human cells, MutSα and MutLα are the most abundant species among the MutS and MutL heterodimers, respectively.

Mismatch Repair Function is Required for Drug Cytotoxicity

Although MMR is well known for its role in correcting biosynthetic errors, other important roles for MMR proteins are being recognized; one of these is the mediation of programmed cell death (or apoptosis) in cells with heavily damaged DNA. This apoptotic function of the MMR system was realized from both basic and clinical studies on how chemical or physical DNA damaging agents induce tumor cells to undergo cell death.

Treatment of cells with chemical DNA-damaging agents, such as the alkylating agents, *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG), temozolomide, or procarbazine, leads to increased amounts of cell death. For this reason, these cytotoxic agents are often used in chemotherapy to destroy rapidly growing tumor cells. There is great interest in the cancer research community in understanding the mechanism by which these agents cause cell death. Interestingly, it has been found almost universally that, whereas cells that are proficient in MMR are sensitive to these agents, cells that are deficient in MMR are more resistant to killing by these agents. This was first observed with *E. coli* in the 1980s when *E. coli* MMR mutants (*mutS*$^-$ or *mutL*$^-$) were found to be more resistant to killing by

TABLE I

MMR Components and Their Function[a]

E. coli	Human	Function
MutS	MutSα (MSH2-MSH6)[b] MutSβ (MSH2-MSH3)	DNA mismatch/damage sensor
MutL	MutLα (MLH1-PMS2)[b] MutLβ (MLH1-PMS1) MutLγ (MLH1-MLH3)	Molecular chaperon and/or DNA damage signal transducer?
MutH	?	Strand discriminator
Helicase II	?	Unwinding DNA helix
ExoI, ExoVII, ExoX, RecJ	ExoI, ?	Removing mispaired base
Pol III holoenzyme	Pol δ, PCNA	Repair DNA synthesis
SSB	RPA	Protecting template DNA from degradation
DNA ligase	?	Nick ligation

MNNG than were wild-type bacterium. In addition, resistance to cytoxic agents such as cisplatin (a cross-linking agent) and MNNG has also been observed in human cells that are defective in MutSα or MutLα. An interesting example is afforded by the development of the lymphoblastoid cell line MT1. This cell line was derived from the TK6 cell line by selection with a high dose of MNNG. MT1 cells are 500-fold more resistant to killing by this agent than the parental cells and exhibit an elevated spontaneous mutation rate. The MT1 cell line was subsequently found to be defective in *MSH6*, the gene that encodes a subunit of MutSα that is necessary for MMR. Conversely, many human tumor cells that are defective in MMR have been found to be relatively resistant to alkylating agents. For example, the *MLH1*-defective colorectal tumor cell line HCT116 is resistant to killing by MNNG, and the MNNG resistance is lost by these cells when they have received a wild-type copy of the *MLH1* gene by chromosome transfer. Therefore, the cytotoxicity of DNA damaging agents is dependent on a functional MMR system.

Mismatch Repair Proteins Promote DNA Damage-Induced Cell Cycle Arrest and Apoptosis

Normal cells are known to undergo growth arrest at cell-cycle checkpoints when exposed to DNA-damaging agents. This response allows cells to respond to DNA damage either by repairing the damage or by committing programmed cell death (apoptosis). Interestingly, cells defective in MMR fail to arrest at crucial checkpoints after exposure to DNA-damaging agents. For example, MMR-proficient cells undergo growth arrest at the G2 phase of the cell cycle after treatment with alkylating agents, but MMR-deficient cells do not. The G2 phase arrest in MMR-proficient cells has been found to be associated with apoptosis. As illustrated in Figure 1, when wild-type TK6 cells and MutSα-deficient MT1 cells were treated with MNNG, apoptotic cell death was observed in TK6 cells (see the pattern of DNA

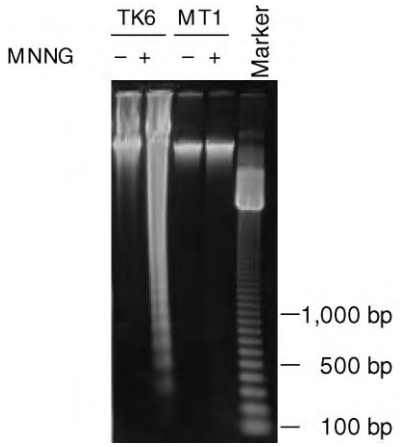

FIGURE 1 MNNG induces apoptosis in MMR-proficient cells. MMR-proficient TK6 and MMR-deficient MT1 cells were treated with MNNG for 1 h and then cultured in fresh medium for 24 h before harvesting. Genomic DNAs isolated from MNNG-treated (+) and untreated cells (−) were electrophoresed in a 2% agarose gel and detected by UV-illumination in the presence of ethidium bromide. Notice that DNA fragmentation is observed in MNNG-treated TK6 cells, but not in MNNG-treated MT1 cells. This DNA fragmentation pattern is diagnostic of apoptosis, or programmed cell death.

fragmentation, a classical characteristic of apoptosis), but not in MT1 cells. Similarly, MutLα is also required for alkylating agent-induced apoptosis. This MMR-dependent apoptotic response can be also induced by other DNA-damaging agents, including cisplatin, certain environmental carcinogens, and ionizing radiation. In addition to cell lines, DNA-damage-induced MMR-dependent apoptosis also occurs in classic laboratory animals such as the mouse and the soil nematode *Caenorhabditis elegans*.

How is the MMR pathway involved in the apoptotic response? Although the details are far from clear, MMR initiation factors may play a crucial role in this response by recognizing DNA damage. For example, it has been established that the *E. coli* mismatch recognition protein MutS and its eukaryotic homologues recognize DNA bases damaged or modified by a variety of agents. These agents include MNNG, cisplatin, chemical carcinogens, oxidative free radicals, and ultraviolet (UV) light. These damaged DNA bases, or DNA adducts, possess structures different from regular bases, thereby causing conformational changes in the DNA duplex. For example, whereas the 8-hydroxyguanine adduct generated by ionizing radiation is approximately the same size as guanine, the guanine adduct of benzo[a]pyrene dihydrodiol epoxide, an environmental chemical carcinogen, is twice as large as guanine. However, a common feature shared by these DNA adducts, as well as DNA base–base mismatches, is that they more or less distort the structure of the DNA helix. This distortion may constitute the basis of their recognition by MutS and its eukaryotic homologues.

Mismatch Repair Proteins Interact with Apoptotic Transducer in Response to DNA Damage

Apoptosis is normally mediated by the transcription factor p53 and its cousin, p73. Recent studies have indicated that both proteins are also implicated in MMR-dependent apoptosis. Upon treating cells with DNA damaging agents (e.g., MNNG), increased expression of p53 has been noted in MMR proficient cells, but not in cells defective in either MutSα or MutLα. The increased level of p53 is due to its phosphorylation by a protein kinase, whose activation is dependent on a functional MMR system. In addition to p53, cells also use p73 for MMR-dependent apoptotic response. Recent studies have shown that phosphorylation and stabilization of p73 occur in an MMR-dependent manner during cellular response to cisplatin-induced DNA damage. The phosphorylation of p73 is carried out by the c-Abl protein kinase and the stabilization of p73 requires the interaction of the protein with the MutL homologue protein, PMS2. These observations indicate that MMR-dependent apoptosis in response to DNA damage involves a signaling cascade.

Mismatch Repair-Mediated Apoptosis Eliminates Damaged Cells from Tumorigenesis

The molecular events involved in the MMR-dependent apoptotic response have not yet been established. However, based on what is already known, the apoptotic signaling is probably initiated by binding of MMR proteins to DNA adducts. This event stimulates the interactions between MMR proteins and an apoptotic transducer, p53 or p73. Two possible mechanisms for this signaling process are depicted in Figure 2. One model proposes that repetitive attempts by MMR to remove a DNA adduct in the template DNA strand cause cell death. DNA adducts in the template strand can pair with appropriate bases or lead to mispairs during DNA replication. MutSα, along with MutLα, recognizes these unusual base pairs as mismatches and provokes a strand-specific MMR reaction. However, because MMR is always targeted to the newly synthesized strand, adducts in the template strand cannot be removed and thus unusual base pairs reform upon DNA resynthesis during repair. As a result, the repair cycle can be perpetually reinitiated. Such a futile repair cycle may signal cells to switch on apoptotic machinery. Alternatively, the death signal could come from the binding of MutSα/MutLα to DNA adducts in the replication fork, the unwound DNA helix, or both and may be unrelated to the repair process. These protein–DNA adduct complexes may block DNA transactions such as replication, transcription, and repair and could be recognized as a signal for cell-cycle arrest and death. In both models, the action on DNA adducts by MMR proteins activates protein kinases to phosphorylate apoptotic transducers such as p73 and p53 that have just established their physical interactions with MMR proteins upon the MMR processing of DNA adducts. The phosphorylation of p73/p53 activates apoptotic machinery and takes the cell down the road to eventual death.

The MMR pathway is well known for its function of promoting genomic stability. The newly identified apoptotic function of MMR, however, may be as important as its replication-fidelity function for maintaining genomic stability. Normally, base excision repair and nucleotide excision repair pathways are responsible for the repair of DNA damage induced by

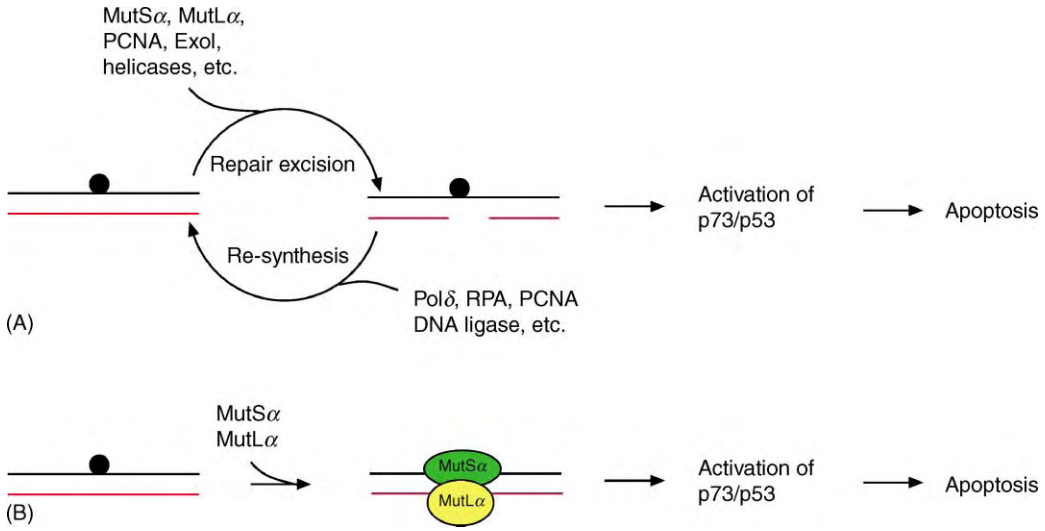

FIGURE 2 Proposed models of how MMR mediates apoptosis in response to DNA damage. (A) The futile repair cycle model. The adducted base (solid circle) could pair with an appropriate base or lead to a mispair during DNA replication. This abnormal structure can be recognized by MutSα (MSH2–MSH6) and provoke a strand-specific MMR reaction. However, because MMR can be only targeted to the newly synthesized strand (red line), the offending adduct in the template strand (black line) cannot be removed and will initiate a new cycle of MMR upon repair resynthesis. Such a futile repair cycle stimulates an interaction between MMR proteins and apoptotic transducers, including ATM/ATR, c-Abl, and p73/p53. These interactions may activate the apoptotic machinery. (B) The blockage model. The binding of MutSα/MutLα to a DNA adduct in the replication fork, the unwound DNA helix, or both could block DNA transactions such as replication, transcription, and repair. The blockage promotes MMR proteins to interact with apoptotic transducers to switch on apoptotic machinery. ExoI, exonuclease I; PCNA, proliferating cell nuclear antigen; Pol δ, polymerase δ; RPA, replication protein A.

physical and chemical agents. However, when excision repair pathways are not available or there is too much damage to be repaired, genomic DNA is in danger of accumulating a large number of mutations, a process that is tumorigenic. Eliminating these damaged cells from the body would be beneficial. It is the MMR system that initiates the elimination of these pre-tumorigenic cells by promoting apoptosis. The inability of the MMR system to commit genetically damaged cells to apoptosis may contribute to a molecular basis for cancer development.

Glossary

apoptosis An active cell death process that requires RNA and protein synthesis to specifically digest cellular DNA into nucleosomal fragments; also known as programmed cell death.

cytotoxicity The degree to which an agent possesses a specific destructive action on certain cells or the possession of such action; often used when referring to the action of antineoplastic drugs that selectively kill dividing cells.

DNA mismatch Non-G:C or -A:T DNA base pairs or small insertion/deletion (unpaired) nucleotides in duplex DNA; also called a heteroduplex.

DNA mismatch repair A DNA repair pathway that specifically coverts mismatched DNA bases (heteroduplexes) into normal G:C or A:T base pairs (homoduplexes).

tumorigenesis The process that generates tumors.

DNA Mismatch Repair Defects and Cancer

Richard D. Kolodner
Ludwig Institute for Cancer Research, University of California, San Diego School of Medicine, La Jolla, California, USA

A major source of mutagenic mispaired bases is misincorporation errors that occur during DNA replication. If such errors are not repaired prior to the next round of DNA replication, they result in mutations. These misincorporation errors are normally corrected by DNA mismatch repair (MMR). MMR recognizes the resulting mispaired base in DNA and excises the misincorporated base from the newly synthesized DNA strand, which is then resynthesized. This process significantly increases the fidelity of DNA replication. Because of the critical role of MMR in suppressing DNA replication errors, MMR defects cause an increased rate of accumulating mutations. Such mutations can activate oncogenes or inactivate tumor suppressor genes and contribute to the process of carcinogenesis.

Introduction

It has been demonstrated that increased mutation rates resulting from DNA replication errors (Figure 1) can play a role in the development of cancer by the discovery that (1) hereditary nonpolyposis colorectal carcinoma (HNPCC) can be caused by inherited mutations in some genes encoding mismatch repair (MMR) proteins, (2) somatically acquired MMR defects underlie some sporadic cancers, and (3) mice containing mutations in MMR genes or mutations that decrease the fidelity of the replicative DNA polymerases result in increased cancer susceptibility. This entry briefly reviews our understanding of MMR.

Proteins Involved in Mismatch Repair

MutS Homologue Proteins Involved in Mismatch Repair

A model has been proposed for eukaryotic MMR in which mispaired bases in DNA are recognized by heterodimeric complexes of proteins that are homologues of the bacterial MutS protein (Figure 2). MutS is the bacterial MMR protein that recognizes mispaired bases in DNA (Mut is an abbreviation for Mutator, because mutations in the *mutS* gene cause high mutation rates or a mutator phenotype). Three different MutS homologues, called MSH proteins, function in MMR. These three different MSH proteins (MSH2, MSH3, and MSH6) form two different heterodimeric complexes, the MSH2–MSH6 (MutSalpha) and MSH2–MSH3 (MutSbeta) complexes (see Figure 2). Extensive genetic studies indicate that the MSH2–MSH6 (MutSalpha) complex is the major mismatch recognition complex that functions in repair of base:base mispairs and a broad spectrum of insertion/deletion mispairs. The MSH2–MSH3 (MutSbeta) complex appears to be able to substitute for the MSH2–MSH6 (MutSalpha) complex in the repair of many insertion/deletion mispairs and may be primarily responsible for the repair of larger insertion/deletion mispairs.

The MSH2–MSH6 (MutSalpha) and MSH2–MSH3 (MutSbeta) complexes have been purified and extensively studied. Consistent with genetic studies, MSH2–MSH6 (MutSalpha) is able to support the repair of both base:base mispairs and insertion/deletion mispairs in *in vitro* MMR reactions, whereas MSH2–MSH3 (MutSbeta) is only able to support the repair of insertion/deletion mispairs. The MSH2–MSH6 (MutSalpha) and MSH2–MSH3 (MutSbeta) complexes have also been shown to preferentially bind to mispaired bases in DNA. Upon mispair recognition they appear to form a ring around the DNA that can then move along the DNA and function in MMR. The MSH2–MSH6 (MutSalpha) complex binds to both base:base mispairs and insertion/deletion mispairs, whereas the MSH2–MSH3 (MutSbeta) complex appears to bind only insertion/deletion mispairs. There is some indication that the *Saccharomyces cerevisiae* and mouse MSH2–MSH3 (MutSbeta) complex may have a relatively greater ability to function in the repair of single base insertion/deletion mispairs than the human MSH2–MSH3 (MutSbeta) complex.

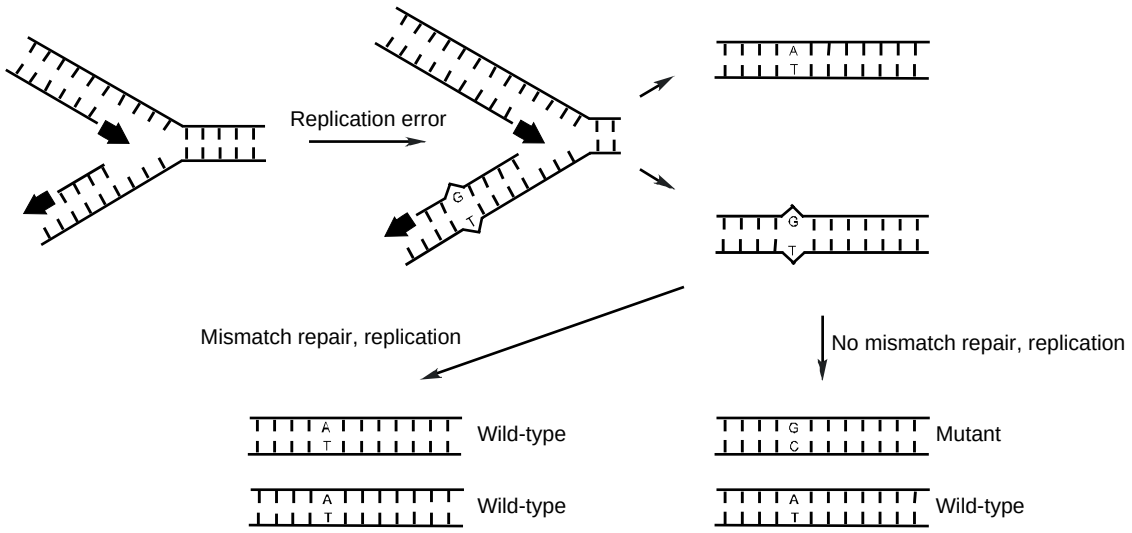

FIGURE 1 The origin of mutations as a result of errors during DNA replication. A DNA molecule in the process of being copied by DNA polymerases (large arrows) is illustrated at the upper left. Such structures are often called replication forks. After an error occurs in which a G is misincorporated opposite a T, as illustrated at the upper center, replication completes and yields one correctly paired DNA and one mispaired DNA as illustrated at the upper right. If the mispaired DNA is then replicated before it is repaired, a mutant and a wild-type DNA result as illustrated at the lower right. If mismatch repair occurs prior to DNA replication, then two wild-type DNAs result as illustrated at the lower left.

One of the key properties of the MSH protein complexes [MSH2–MSH6 (MutSalpha) and MSH2–MSH3 (MutSbeta)] is that they are partially redundant. This is relevant to the observation that defects in MMR can cause cancer (discussed later). Because MSH2 is the only protein present in both complexes, defects in the MSH2 gene completely inactivate MMR (see Figure 2). As a consequence, MSH2 defects result in increased rates of accumulation of both base substitution and frameshift mutations. Interestingly, short mononucleotide repeat sequences are often found within genes, and frameshift errors that occur by the copying of such sequences during replication are the most frequent misincorporation errors made by DNA polymerases. Thus, in MSH2-defective cells, frameshift mutations in mononucleotide repeats often occur more frequently than base substitution mutations. MSH6 and MSH3 gene defects inactivate only the MSH2–MSH6

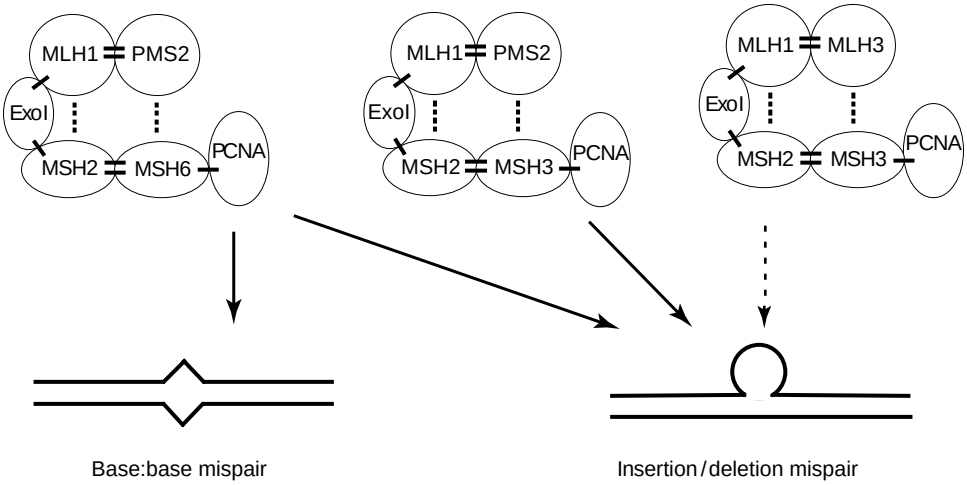

FIGURE 2 Illustration of the protein complexes that function in mismatch repair. The circles and ovals represent the MSH2, MSH3, MSH6, MLH1, MLH3, PMS2, exonuclease I, and PCNA proteins, as indicated. The double solid connecting lines indicate known stable protein–protein interactions, the single solid connecting lines indicate known, less stable protein–protein interactions, and the dashed connecting lines indicate interactions between protein assemblies in which the exact protein contacts are not yet known. Below these illustrated protein complexes are the mispaired based containing DNAs they interact with during mismatch repair. The solid connecting arrows indicate the major repair reactions, and the dashed connecting arrow indicates a minor repair pathway.

(MutSalpha) and MSH2–MSH3 (MutSbeta) complexes, respectively. Because of the partially overlapping mispair recognition specificity of each complex, defects in MSH6 cause only large increases in the rate of base substitution mutations, like that seen in MSH2 mutants, and cause small increases in the rate of frameshift mutations relative to that seen in MSH2 mutants. Defects in MSH3 have very little effect on mutation rates except for frameshift mutations in repeating sequences where the repeat unit length is 2 bases and larger. Dinucleotide and larger repeats are found less frequently in sequences encoding genes than short mononucleotide repeats, indicating that MSH3 defects should have little effect on the accumulation of mutations within the majority of genes.

MutL Homologue Proteins Involved in Mismatch Repair

MutL is a bacterial protein that is required for MMR; it is known to interact with MutS and then activate other proteins that function in MMR. There are three MutL homologues, called MLH proteins: MLH1, PMS2 (called PMS1 in *S. cerevisiae*), and MLH3, for which there is good evidence for a function in MMR in eukaryotes. These proteins form two different heterodimeric complexes, MLH1–PMS2 (MutLalpha) and MLH1–MLH3 (see Figure 2). Biochemical experiments have shown that the MLH1–PMS2 (MutLalpha) complex forms a higher order complex with both MSH2–MSH6 (MutSalpha) and MSH2–MSH3 (MutSbeta) when these MSH complexes interact with DNA. Presumably the MLH complex then acts to activate other components of MMR; however, little is yet known about this process. Neither is much yet known about the biochemical properties of the MLH1–MLH3 complex. A fourth MutL-related protein, human PMS1 (called MLH2 in *S. cerevisiae*), which appears to be able to form a complex with MLH1, was initially suggested to function in MMR. Genetic and biochemical studies performed to date, however, have failed to provide evidence that this protein plays an important role in MMR.

Genetic studies have shown that the MLH1–PMS2 (MutLalpha) complex is the major MutL-related complex that functions in MMR. The MLH1–MLH3 complex appears to play only a minor role in MMR. Like the situation with the two different MSH complexes discussed previously, the observation that two different MutL-related protein complexes function in MMR indicates that defects in each of the three MutL-related genes may cause different MMR defects. Because MLH1 is the only protein present in both MutL-related complexes, only defects in the MLH1 gene completely inactivate MMR (see Figure 2). However, since the MLH1–PMS2 (MutLalpha) complex is the major complex that functions in MMR, defects in the PMS2 gene cause almost as strong a defect in MMR as do defects in the MLH1 gene. In contrast, because the MLH1–MLH3 complex plays a minor role in MMR, defects in the MLH3 gene cause only a partial defect in MMR, resulting in a small but significant increase in the rate of accumulating frameshift mutations in mutant cells. Defects in human PMS1 or its *S. cerevisiae* homologue MLH2 cause little if any significant increase in mutation rate.

Other Proteins Implicated in Mismatch Repair

One of the important problems in the study of eukaryotic MMR is the identification of the other proteins required for MMR. Some progress has been made in this area, but unfortunately, little is known about how MMR initiates and how the newly synthesized DNA strand is recognized, nor has eukaryotic MMR been reconstituted from purified proteins.

DNA polymerase delta is required for the DNA synthesis step of MMR; similarly, there is also a requirement for its accessory factors proliferating cell nuclear antigen (PCNA), replication protein A (RPA/RFA), and replication factor C (RFC). PCNA has also been suggested to be involved in MMR at an early step prior to the resynthesis step. PCNA interacts with the MSH2–MSH6 (MutSalpha) and MSH2–MSH3 (MutSbeta) complexes through a specific motif located in the MSH6 and MSH3 subunits. This has led to the suggestions that PCNA may be required for the activity of the MSH2–MSH6 (MutSalpha) and MSH2–MSH3 (MutSbeta) complexes or that PCNA may target these MMR proteins to regions of newly replicated DNA. In considering the possibility that defects in genes encoding DNA polymerase delta, PCNA, RPA, and RFC might play a role in cancer susceptibility (see following discussion), it is important to note that each of these genes is an essential gene that would preclude mutations that cause complete loss-of-function defects.

In bacteria, at least four exonucleases have been shown to be able to function in the degradation step of MMR; each can substitute for all of the others. This redundancy of exonucleases appears to occur in eukaryotic MMR. Exonuclease 1 is a 5′ to 3′ double-strand DNA-specific exonuclease encoded by the EXO1 gene that is thought to be one of a number of redundant exonucleases that function in eukaryotic MMR. Exonuclease 1 physically interacts with both MSH2 and MLH1, and genetic studies have suggested that exonuclease 1 may in some way help to assemble higher order protein complexes that function in MMR. Biochemical studies have shown that exonuclease 1

can function in the excision step of MMR *in vitro* and plays a role in excision in both 5′ to 3′and 3′ to 5′ directions. Consistent with the view that exonuclease 1 is only one of many exonucleases that function in MMR, mutations in the EXO1 gene cause only partial MMR defects. Other exonucleases that have been suggested to function in MMR are the endo/exonuclease FEN1/RAD27 and the 3′ to 5′ editing exonuclease functions of DNA polymerases delta and epsilon. However, whether these latter three exonucleases play a direct role in MMR has been difficult to determine because these exonucleases all function in other critical aspects of DNA synthesis.

Defects in Mismatch Repair Cause Increased Cancer Susceptibility

HNPCC is a common inherited cancer susceptibility syndrome that in its most striking examples is characterized by a dominant mode of transmission, high penetrance, significantly earlier age of onset than sporadic cancers, multiple primary tumors, and a high proportion of colorectal as well as many other types of cancer, including endometrial, genitourinary, extracolonic GI cancers, ovarian, brain, and sebaceous skin tumors. A number of clinical criteria for the identification of HNPCC have been used, ranging from the highly stringent Amsterdam criteria (see Table I) that identify kindreds based on clustering of colorectal cancer and an early age of onset, to less restrictive criteria that allow inclusion of individuals with a less well documented family history of cancer and families with colorectal cancer and HNPCC-associated cancers as well as early onset colorectal cancer cases without a documented family history of cancer. DNA from HNPCC tumors often shows a high frequency of frameshift mutations in microsatellite sequences, a phenotype called microsatellite instability (MSI). MSI is an important diagnostic tool for identifying cases of HNPCC that are due to MMR defects. Tumors showing a high proportion of unstable microsatellite sequences are often designated MSI-High (MSI-H).

A high proportion of HNPCC cases defined by the Amsterdam criteria show tumor MSI, whereas a lower proportion of HNPCC cases defined by other clinical criteria show tumor MSI. Recent genetic studies suggest that almost all HNPCC cases showing tumor MSI can be accounted for by inherited defects in the MSH2 gene or the MLH1 gene. These two genes encode the common subunits of the MutS-related and MutL-related family of heterodimeric complexes, respectively, that function in MMR. The types of inherited mutations observed in these two genes include frameshift and nonsense mutations (protein-truncating mutations), missense mutations (protein sequence changes), and deletion mutations; deletion mutations appear to be more prevalent in MSH2 than MLH1, and missense mutations appear to be more prevalent in MLH1 than MSH2. There are no simple, routine molecular diagnostic methods for diagnosing mutations that cause HNPCC. However, in combination with an appropriate family history of cancer, complete MSH2 and MLH1 gene sequencing and deletion analysis along with testing of HNPCC tumors for MSI using a standard set of microsatellite markers and analysis of tumors for loss of MSH2 or MLH1 protein expression using immunohistochemistry (sometimes called IHC analysis) have proven to be useful in detecting MMR defects in suspected HNPCC families. Through the application of these methods, most HNPCC cases that have MSI-H tumors have been linked to a mutation in MSH2 or MLH1. In addition, in some cases in which inherited mutations have not been found, altered expression of MSH2 or MLH1 has been identified, indicating the presence of some type of MSH2 or MLH1 defect. It should be noted that the less restrictive clinical criteria for HNPCC (see Table I) identify many more patients suspected of having HNPCC compared to the Amsterdam criteria, but a smaller proportion of these patients ultimately prove to have inherited MMR defects.

Many other genes encoding proteins implicated in MMR have been considered as potential HNPCC genes. Of these, the most studied is MSH6. Defects in the MSH6 gene cause a partial loss of MMR due to the partial redundancy between MSH6 and MSH3. MSH6 mutations result in a large increase in the rate of accumulation of base substitution mutations but only modest increases in the rate of accumulation of single base frameshift mutations. Different studies have reported that perhaps up to 3% of HNPCC families can be accounted for by germline MSH6 defects, with these kindreds having a higher proportion of endometrial cancer than MSH2- or MLH1-detective HNPCC families. In contrast, approximately 8% of familial, non-HNPCC colorectal cancer cases were found to have germline MSH6 defects; similarly, germline MSH6 defects have been found in endometrial cancer cases associated with a weak family history of cancer. Such familial cancer cases constitute a much larger number of total cancer cases than HNPCC, indicating that germline defects in MSH6 could be almost as prevalent in the population as germline MSH2 and MLH1 defects. Compared to MSH2- or MLH1-defective HNPCC kindreds, MSH6-defective kindreds had a less striking family history and later age of onset of cancer, a result that parallels the results obtained in studies of MSH2-, MSH6-, and MLH1-defective mice. While more work on MSH6 is needed, it

TABLE I

Clinical Criteria for HNPCC[a]

Name	Criteria
Amsterdam[b]	Three relatives with CRC, one of which must be a first-degree relative of the other two; CRC involving at least two generations of the family; one or more CRC cases diagnosed before age 50.
Modified Amsterdam[c]	1. Small pedigrees, which cannot be further extended, can be considered as HNPCC if they contain CRCs in first-degree relatives; CRC must involve at least two generations and one or more CRC cases must be diagnosed before age 55. 2. In pedigrees where CRC is found in two first-degree relatives, a third relative with an unusually early-onset cancer or endometrial cancer is sufficient.
Young age of onset	A CRC case diagnosed at less than 40 years of age, without a family history fulfilling Amsterdam or modified Amsterdam criteria.
HNPCC variant	A family history of cancer suggestive of HNPCC, but not fulfilling Amsterdam, modified Amsterdam, or young age of onset criteria.
Bethesda[c]	1. Individuals in families that fulfill Amsterdam criteria. 2. Individuals with two HNPCC-related cancers, including synchronous and metachronous CRCs or associated extracolonic cancers. 3. Individuals with CRC who have a first-degree relative with CRC and/or a HNPCC-related extracolonic cancer and/or colorectal adenoma; one of the cancers diagnosed before age 45 and the adenoma diagnosed before age 40. 4. Individuals with CRC or endometrial cancer diagnosed before age 45. 5. Individual with right-sided CRC with an undifferentiated pattern (solid/cribform) on histopathology diagnosed before age 45. 6. Individuals with signet-ring-cell-type CRC diagnosed before age 45. 7. Individuals with adenomas diagnosed before age 40.

Adapted from Syngal S., Fox, E. A., Li, C., Dovidio, M., Eng, C., Kolodner, R. D., and Garber J. E., (1999). Interpretation of genetic test results for hereditary nonpolyposis colorectal cancer: implications for clinical predisposition testing. *J. Am. Med. Assoc.* **282**, 247–253.

[a] HNPCC, hereditary nonpolyposis colorectal carcinoma; CRC, colorectal cancer.

[b] All criteria must be met.

[c] Meeting all features under a single numbered criteria is sufficient.

appears that germline MSH6 defects cause an attenuated form of HNPCC.

A number of other MMR genes have been considered as possible HNPCC genes, including the MSH3 gene encoding a MutS homologue, the MutL homologue genes PMS1 (MLH2 in *S. cerevisiae*), PMS2 (PMS1 in *S. cerevisiae*) and MLH3, and the exonuclease encoding gene EXO1. However, defects in these genes have not been found to make a major contribution to HNPCC. This observation is consistent with many studies, indicating that defects in these genes do not cause complete loss of MMR because they encode partially redundant functions. It is also possible that these genes do not play roles in other MMR-related functions such as DNA damage-induced cell cycle arrest and apoptosis. Germline mutations in PMS2 appear to be only a rare cause of HNPCC, and most germline PMS2 mutations have been found to be associated with Turcot syndrome. In some sense this is surprising, because mutations in PMS2 cause strong MMR defects; however, PMS2-defective mice, while cancer prone, have a much different tumor spectrum compared to MSH2-, MSH6-, or MLH1-defective mice. Following the initial report of a germline PMS1 mutation, no other mutations have been reported, and recently the original PMS1 mutant family was shown to contain a MSH2 mutation. Mutations in MLH3 are also likely to be rare in HNPCC. Most studies have not identified germline MLH3 mutations in HNPCC cases, whereas the one study that did report potential mutations only identified missense variants that could be rare polymorphisms. Similarly, after an initial report of EXO1 mutations in HNPCC cases, a follow-up study showed that most of the initially reported variants, including a splice site mutation, were actually polymorphisms. This is consistent with the observation that EXO1 mutant mice show increased but much later onset

cancer susceptibility than MSH2 or MLH1 mutant mice. No germline defects in the MSH3 have been reported to date, although somatic mutations in MSH3 have been found as modifiers of germline MSH6 mutations consistent with studies of mutant yeast and mice. It is conceivable that defects in these genes could cause cancer susceptibility, although extrapolating from studies in model systems suggests such cancer susceptibility might be of later onset and weaker family history than HNPCC.

A variable proportion of sporadic cancers of many types has been observed to show tumor MSI indicative of a MMR defect. For example, in the case of sporadic colorectal cancer, the reported proportion of MSH-H tumors (note that MSI-H indicates a MMR defect) is around 18%. Most tumors showing MSI have been shown to lose expression of either MSH2 or MLH1, although the majority of cases show the loss of MLH1 expression. Most cases showing loss of MLH1 expression are due to somatic silencing of both copies of the MLH1 gene associated with hypermethylation of the MLH1 promoter. A small number of sporadic cases have been attributed to somatic mutations in MMR genes. These results indicate that there are both inherited and sporadic forms of MMR defective cancers, although the etiology of the two different types of cases is quite different.

How do MMR defects actually cause the development of cancer? Loss of MMR results in increased rates of accumulating mutations. This would be expected to increase the rate of accumulation of mutations that inactivate tumor suppressor genes and activate proto-oncogenes and consequently increase the rate of tumorigenesis. Considerable data exist that support this view. In addition, MMR-defective cells have checkpoint defects and are resistant to killing by DNA-damaging agents, suggesting that MMR defects also cause a defect in apoptosis that may also contribute to tumorigenesis. Because of this resistance to killing by DNA-damaging agents, MMR-defective tumors may also not be as responsive to some chemotherapeutic agents as non-MMR defective tumors.

Summary

MMR requires two different heterodimeric complexes of MutS-related proteins, MSH2–MSH3 and MSH2–MSH6, that recognize mispaired bases in DNA. Two different heterodimeric complexes of MutL-related proteins, MLH1–PMS2 (*S. cerevisiae* PMS1) and MLH1–MLH3, also function in MMR and appear to interact with other MMR proteins, including the MSH complexes and replication factors. Additional proteins, including DNA polymerase delta, RPA, PCNA, RFC, and exonuclease 1, have been implicated in MMR. Loss of function of three of these genes, MSH2, MSH6, and MLH1, has been shown to be the cause of both hereditary cancer susceptibility syndromes and sporadic cancers, whereas mutations in other MMR genes have not yet been shown to be associated with a significant number of hereditary or sporadic cancer cases.

Glossary

base substitution mutation The class of mutations that result when an incorrect base is paired with the correct base that is present in the DNA.

DNA polymerase The class of enzymes that synthesize DNA using one DNA strand as a template to direct DNA synthesis.

DNA replication The process by which cells make an exact copy of their DNA.

exonuclease The class of enzymes that degrade DNA molecules starting from the ends of DNA or breaks in DNA strands.

first-degree relative A parent, sibling, or child of the individual in question.

frameshift mutation Type of mutation that results from either insertion or deletion of one or a small number of extra bases in DNA.

germline mutation Mutation that is transmitted through the germline (e.g., inherited mutation).

heterodimer Complex composed of two different proteins.

immunohistochemistry (IHC) Use of antibodies to stain tissue slices to detect the presence of the antigen (protein or other molecule to which the antibody binds).

microsatellite instability (MSI) The accumulation of frameshift mutations within the simple repeat sequences found ubiquitously in most eukaryotic chromosomal DNA.

mispaired base An incorrectly paired base in DNA, e.g., an A paired with a C instead of a T, or an extra base inserted into DNA so that it is not paired with any base.

mutation Change in the normal sequence of a DNA molecule.

MutL Bacterial MutL protein or gene. MutL is a protein that interacts with the MutS protein during bacterial MMR.

MutS Bacterial MutS protein or gene. Mut is an abbreviation for mutator, because inactivation of a mutator gene results in increased rates of accumulating mutations. MutS is the protein that recognizes mispaired bases in DNA during bacterial MMR.

oncogene Gene whose increased or altered activity promotes the development of tumors. Oncogenes often accumulate activating mutations or are amplified during tumor development.

penetrance The percent chance that a mutation carrier will develop the disease in the individual's lifetime.

proliferating cell nuclear antigen (PCNA) A protein that forms a ring around DNA and functions to keep proteins such as DNA polymerases attached to the DNA.

redundancy Two genes or proteins are redundant when they can substitute for each other.

replication protein A (RPA)/replication factor A (RFA) Protein complex that binds to single-strand DNA, allowing it to be a better template for DNA polymerases.

replication factor C (RFC) Protein complex required to load PCNA onto DNA.

somatic mutation Mutation that occurs in a somatic cell. Such mutations are not inherited.

tumor suppressor gene Gene whose product prevents the development of a tumor. Tumor suppressor genes accumulate inactivating mutations during tumor development.

DNA Mismatch Repair in Bacteria

A-Lien Lu
University of Maryland, Baltimore, Maryland, USA

There are two major DNA mismatch repair (MMR) systems in bacteria to correct DNA biosynthetic errors. Long-patch repair systems involve a long-patch excision and resynthesis (up to 1000 nt) and are specific to a particular DNA strand. Short-patch repair systems have a repair tract shorter than 15 nt and are dictated by the nature of the mismatches. MMR enhances the fidelity of DNA replication and genetic recombination, and it participates in the cellular response to certain types of DNA damage. The inactivation of DNA repair systems can lead to genomewide instability and a predisposition to cancers in mammals. The importance of MMR in mutation avoidance is widely documented. Mutations in long-patch MMR genes result in a mutator phenotype with a spontaneous mutation frequency elevated approximately 100-fold. The mutation spectrum reveals that transitions and short nucleotide insertions/deletions predominant. MMR-defective strains are also hypersensitive to base-substitution mutagenesis and resistant to some types of alkylating agents. MMR also has an antirecombination function in limiting recombination between divergent sequences and preventing gross chromosomal rearrangement. MMR proteins have been shown to function in preventing interspecies recombination between *Escherichia coli* and *Salmonella typhimurium*.

Escherichia coli Long-Patch Mismatch Repair is Dependent of *dam* Methylation

For mismatch repair (MMR) to correct replication error, a strand-discrimination system must target the repair to the daughter DNA strand that contains the incorrect nucleotides. *E. coli* MMR is dependent on *dam* (DNA adenine methylation) methylation and is biased to unmethylated DNA strands. The *dam* methylase modifies the adenine at the 6-NH_2 group in GATC sequences. Wagner and Meselson proposed in 1976 that transient undermethylation of GATC sites in newly synthesized DNA provides the basis to direct the MMR to the daughter strands, an idea that has been confirmed both *in vivo* and *in vitro*. Because methylation is a postsynthetic process, methylation on the parental strands and transient unmethylation on the newly synthesized strands provide the signal to direct the repair to the daughter strands. MMR can be directed by hemimethylated sites located either 5′ or 3′ to the mismatch at a separation distance of up to 1 kb.

Specificity of Mismatch Repair

Methyl-dependent MMR has a broad specificity. Of the eight possible base-base mismatches, only C–C is refractory to the repair. Heteroduplexes containing short insertion/deletion loops (IDL) derived from DNA polymerase slippage can also be repaired. IDL with three unpaired nucleotides are efficiently repaired, but IDL with four to seven unpaired nucleotides are poorly repaired. The efficiency of MMR is influenced by the sequence flanking the mismatch. The MMR system has also been shown to be involved in repair of oxidative DNA damage. The major oxidative lesion, 7,8-dihydro-8-oxo-guanine (8-oxoG), can mispair with adenine during DNA replication. *E. coli* MMR can also act on A-8-oxoG mismatches that result from replication errors.

Mechanism of *E. coli* Long-Patch Mismatch Repair

An *in vitro* assay developed by Lu *et al.* has provided the basis for purifying and characterizing the *E. coli* MutH, MutL, and MutS proteins. Biochemical studies from P. Modrich's laboratory show that *E. coli* MMR involves 11 protein activities: MutS, MutL, MutH, UvrD (DNA helicase II), four single-strand specific exonucleases, a single-strand DNA binding protein (SSB), DNA polymerase III (Pol III) holoenzyme, and DNA ligase (Table I). Whereas MutH, MutL, and MutS proteins are specific for MMR, the other activities are involved in other DNA metabolic pathways, including replication and recombination. The mechanism of *E. coli* long-patch MMR is depicted in Figure 1.

TABLE I

Functions of *E. coli* Mismatch Repair Enzymes

Enzyme	Function
MutS	DNA mismatch/damage recognition
MutL	Molecular matchmarker; Enhances mismatch recognition; stimulates MutH and UvrD activities
MutH	Strand discrimination; cleaves at unmethylated DNA strands
UvrD	DNA helicase II; unwinding DNA
ExoI, ExoX	3′ to 5′ exonuclease; removes nucleotides
ExoVII, RecJ	5′ to 3′ exonuclease; removes nucleotides
DNA Pol III holoenzyme	DNA resynthesis of the long-patch mismatch repair pathway
β Sliding clamp	A subunit of DNA Pol III holoenzyme; interacts with MutS
SSB	Protecting DNA from degradation and re-anneal
DNA ligase	Nick ligation
MutY	DNA glycosylase; excises A from A/G, A/8-oxoG, A/C and G-8-oxoG mismatches and removes G from G/8-oxoG mismatches
Vsr	Endonuclease; removes T from T-G mismatch
DNA polymerase I	Repair synthesis of short-patch mismatch repair pathways

Initiation of Mismatch Repair

MMR requires specifically MutH, MutL, and MutS proteins in the initiation steps. MutS recognizes base–base mismatches and short insertion/deletion loops. MutL serves to couple mismatch recognition by MutS to activate several downstream activities, such as MutH and DNA helicase II. MutH endonuclease cleaves at the 5′ of G of an unmethylated GATC sequence. In a similar manner, MutS and MutL activate the excision process.

MutS

MutS is a homodimer of a 95-kDa polypeptide that recognizes all base-base mismatches except C–C mismatch and small insertion/deletion loops up to five unpaired nucleotides. The discrimination of a mismatch-containing heteroduplex from a homoduplex by MutS protein is not great; there is only 10- to 20-fold preference. It has been suggested that mismatch recognition by MutS may be enhanced by MutL or by the association with replication proteins. MutS has ATPase activity, which is essential for the MMR function. ATP binding reduces the MutS affinity for heteroduplex DNA. Although several models have been proposed, the role of ATPase of MutS is still under investigation. The translocation and sliding clamp models suggest that MutS moves away from the mismatch site to activate MMR. The translocation model suggests that ATP hydrolysis provides the energy and enables MutS to move like a motor protein. This model is supported by a α-loop-like DNA structure visualized under electron microscopy. The sliding clamp model or molecular switch model suggests that ATP-bound MutS slides along DNA without ATP hydrolysis. There is a conformation change from ADP-bound MutS to ATP-bound MutS. The third model suggests that the ATPase activity of MutS plays a proofreading role in MMR. The structure of MutS-DNA-ADP suggests that MutS has to bind both ATP and the mismatched DNA simultaneously to activate the repair process. Thus, the model suggests that MutS remains bound to the mismatch site and recruits MutL and MutH to initiate MMR.

The structure of *E. coli* MutS complexed with a G–T mismatch and *Thermus aquaticus* MutS with a + 1T IDL have been solved recently by the W. Yang and T. Sixma groups. Although different types of mismatches were used, both MutS structures are very similar. These structures show that a truncated form of MutS is a homodimer like an oval disk with two channels, one of which forms by domains I and IV and binds to the DNA. The bound DNA is kinked by 60° at the mismatch and the minor groove is widened and contacted extensively by MutS. Interestingly, MutS forms an asymmetric dimer with only one monomer making direct contact with the mismatched base. MutS contacts the mismatched bases through a highly conserved N-terminal motif Phe-X-Glu. The Phe residue in this conserved motif is inserted into the double helix and stacks with the mismatched thymine. The ATP binding site at the C terminus (domain V) of the protein is composed of residues from both subunits and is located far from the DNA-binding site. Domains II and III connect the mismatch-binding and ATPase domains. In the absence of DNA, domains I and IV are disordered in the crystal structure. DNA binding also alters the conformation of the ATPase domain.

MutL

MutL is a dimer of a 68-kDa polypeptide that operates as a molecular matchmaker in MMR to assemble a functional repair complex. In the presence of ATP, MutL binds to the MutS-heteroduplex complex and activates MutH and UvrD helicase activities. The divergent C-terminal domain of MutL is responsible for the dimer formation. The conserved N-terminal domain has weak ATPase activity that is stimulated by DNA. Structural and biochemical studies indicate that ATP binding and hydrolysis modulate the conformation, oligomeric state of MutL, and interactions of MutL with MutS, MutH, and UvrD helicase. Upon ATP

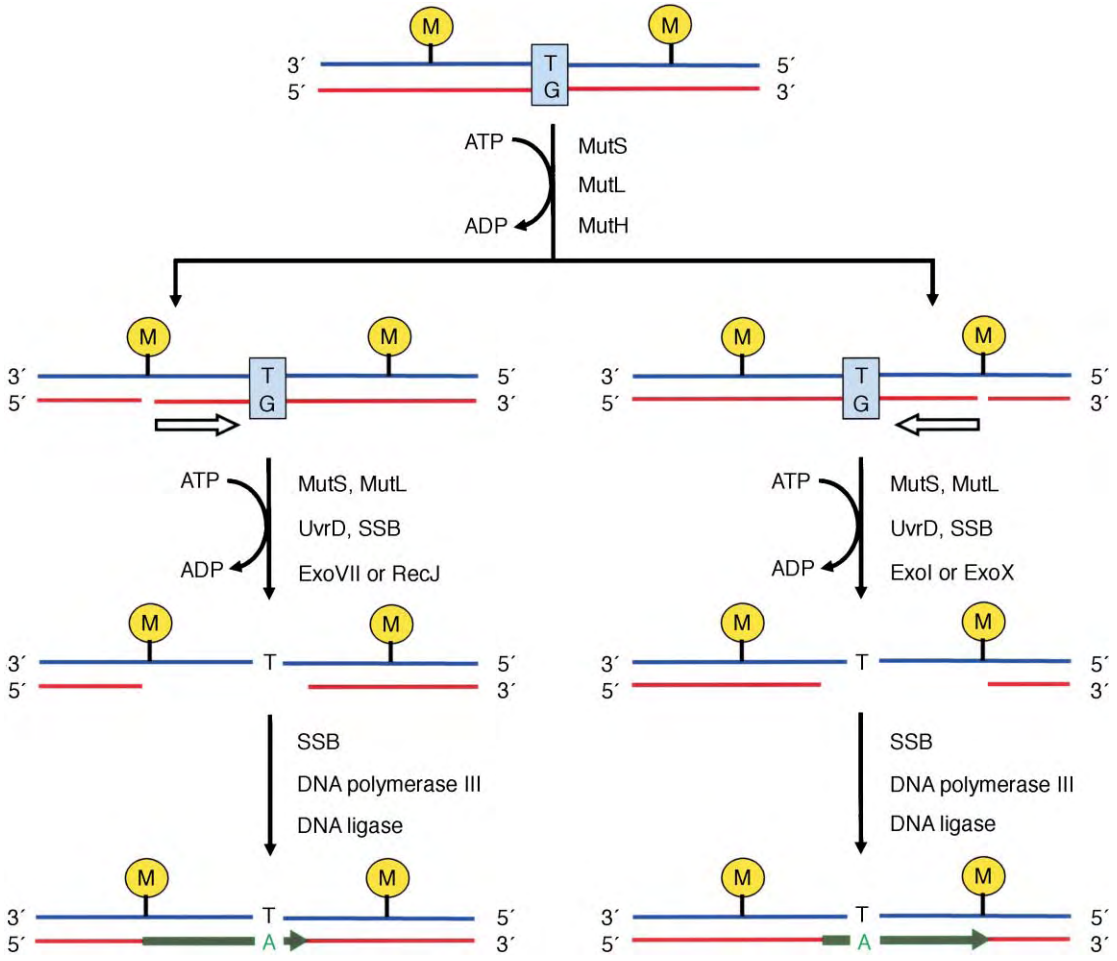

FIGURE 1 The long-patch methyl-dependent mismatch repair system of *E. coli*. Mismatches (G–T, as shown) are recognized by dimeric MutS protein. After binding of MutL and MutH, the unmethylated strand in red is nicked by MutH at the hemimethylated GATC sites (M in yellow circle represents for methyl groups). ATP hydrolysis by MutS and MutL triggers the downstream repair process. DNA unwinding by UvrD (DNA helicase II) in the presence of ATP from the nick site toward the mismatch reveals a single-stranded DNA region that is protected by SSB. Depending on the position of the nick relative to the mismatch, ExoVII or RecJ with 5′ to 3′ exonuclease activity and ExoI or ExoX with 3′ to 5′ exonuclease activity degrade the nicked strand from the nick site up to and slightly past the mismatch. The resulting single-stranded gap undergoes repair resynthesis by the DNA polymerase III holoenzyme and the nick is finally sealed by DNA ligase. Open arrows represent the direction of exonuclease degradation and thick green arrows show the direction of repair resynthesis.

binding, the N-terminal domain undergoes conformation changes and dimerizes, although the native protein exists as a dimer in solution.

MutH

The 25-kDa monomer MutH belongs to a family of type II restriction enzyme. MutH activity is activated by MutS and MutL in the presence of ATP and a mismatch-containing DNA. MutH cleaves at the 5′ side of the G of the GATC sequence on unmethylated strand located on either the 5′ or 3′ side of the mismatch. Tyr212 of MutH is important in sensing the methylation status of DNA. The structure of MutH is like a clamp with a cleft and two arms. DNA may be bound in the cleft.

Excision and Repair Synthesis of Mismatch Repair

The strand break created by MutH at a GATC site of the unmethylated strand serves as the starting point for the excision of the mispaired base. UvrD (DNA helicase II) physically interacts with MutL and its unwinding activity is dramatically stimulated by MutL. MutL facilitates the loading of helicase II on the appropriate strand to unwind DNA in the proper direction and allows repeated loading of additional helicase II molecules to continue the unwinding reaction. DNA helicase II unwinds the DNA from the nick toward the mismatch and reveals a single-stranded DNA region that is protected by SSB.

The excision of the displaced strand is then initiated from the nick by exonucleases and is dependent on MutS, MutL, and UvrD helicase. Depending on the position of the nick relative to the mismatch, ExoVII or RecJ with 5′ to 3′ exonuclease activity and ExoI or ExoX with 3′ to 5′ exonuclease activity degrade that portion of the nicked strand displaced by the helicase up to and slightly past the mismatch. The resulting single-stranded gap is repaired by the DNA polymerase III holoenzyme, and the nick is finally sealed by DNA ligase. MMR may be coupled with DNA replication via physical interaction between MutS and the β-clamp of DNA polymerase III holoenzyme.

MutY Repair Pathway

In addition to the long-patch methyl-dependent MMR, two short-patch repair pathways have been characterized in *E. coli*. Only the MutY repair pathway is described here and the very short patch (VSP) pathway initiated by Vsr endonuclease is covered elsewhere in this encyclopedia.

Oxidative damage is a major source of mutation load in living organisms. 8-OxoG is one of the most stable products of oxidative DNA damage and has the most deleterious effects because it can mispair with adenine. In *E. coli*, MutT, MutS, MutM, and MutY are involved in defending against the mutagenic effects of 8-oxoG lesions (Figure 2). The MutT protein eliminates 8-oxo-dGTP from the nucleotide pool with its pyrophosphohydrolase activity, whereas the MutM glycosylase (Fpg protein) removes both mutagenic 8-oxoG adducts and ring-opened purine lesions. MutS and MutY increase replication fidelity by removing the adenines misincorporated opposite 8-oxoG or G during DNA replication. The *E. coli* MutY protein specifically removes mispaired adenines from A–G, A-8-oxoG, and A-C mismatches and removes guanines from G-8-oxoG mismatches. A-8-oxoG mismatches are particularly important biological substrates for MutY. The mutY mutants have approximately 50-fold higher mutation frequencies of G–C to T–A transversions than wild-type cells.

MutY is a 39-kDa DNA glycosylase that removes a free base from DNA to initiate a base excision repair (BER) process. The MutY BER pathway involves DNA polymerase I and DNA ligase and may involve apurinic–apyrimidinic (AP) endonuclease (EndoIV or ExoIII). Both AP endonucleases enhance the product release with A–G but not A–8-oxoG substrates. Although MutY can form a covalent Schiff base intermediate with its DNA substrates, it is controversial whether MutY has AP lyase (β-elimination) activity in addition to the DNA glycosylase activity. It has been suggested that coupling to DNA replication ensures that MutY BER is targeted to the daughter DNA strands but not the parental strands.

MutY glycosylase contains a [4Fe–4S] iron–sulfur cluster and it belongs to a conserved helix–hairpin–helix (HhH) family that includes several DNA glycosylases.

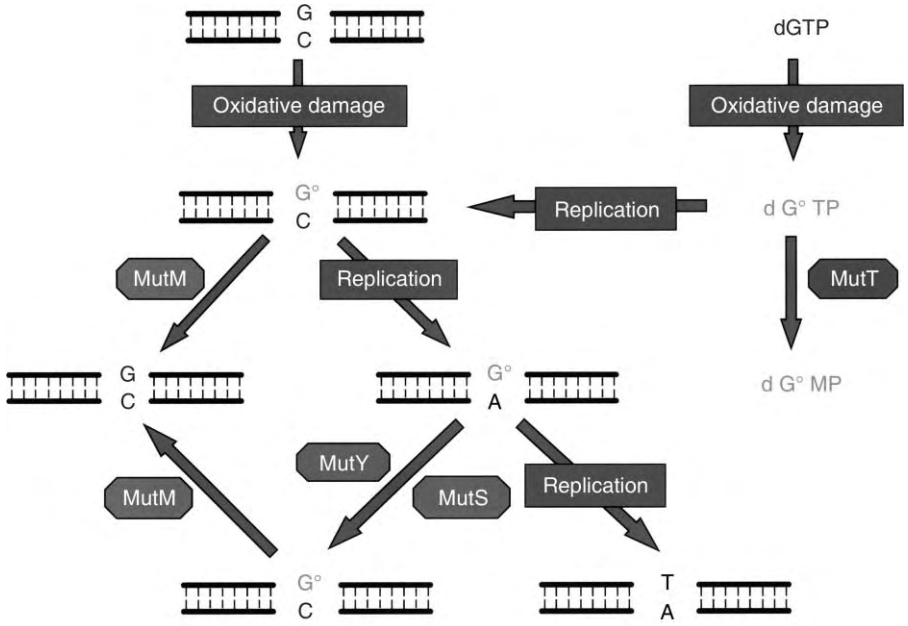

FIGURE 2 8-OxoG repair in *E. coli*. The MutT protein hydrolyzes 8-oxo-dGTP (dG°TP) to 8-oxo-dGMP (dG°MP) and pyrophosphate. The MutM glycosylase (Fpg protein) removes mutagenic 8-oxoG (G°) adducts while they are paired with cytosines. When C–8-oxoG is not repaired by MutM, adenines are frequently incorporated to the 8-oxoG bases during DNA replication. MutS and MutY increase replication fidelity by removing the adenines misincorporated opposite 8-oxoG.

The X-ray crystal structure of the catalytic domain of D138N-MutY with bound adenine shows that adenine is buried in the active site of the catalytic domain, suggesting that the mismatched adenine must flip out of the DNA helix for glycosylase action. The iron–sulfur cluster loop is important in substrate recognition and MutY stability, and the HhH motif is involved in binding to the phosphate backbone. The structure of MutY from *Bacillus stearothermophilus* in complex with A-8-oxoG-containing DNA was recently determined. Similar to several DNA glycosylases, MutY distorts the bound DNA and flips out the mismatched adenine out of the helix but the mismatched GO remains intrahelical. The C-terminal domain of MutY has been shown to play an important role in the recognition of GO lesions. The C-terminal domain of MutY has no homology to other members of the HhH superfamily, but shares some sequence and structural similarities to MutT.

Glossary

base excision repair (BER) A DNA repair pathway that is initiated by a DNA glycosylase to remove relatively small lesions. Some glycosylases are highly specific to certain lesions or mismatches.

***dam* methylation** The methylation of the adenine at the 6-NH2 group in GATC sequences by *dam* methylase. Methylation on the parental strands and transient unmethylation on the newly synthesized strands provide a signal to direct the mismatch repair to the daughter strands.

mismatch repair (MMR) Process in which the long-patch MMR removes replicative errors that are missed by DNA polymerase's proofreading activity. MMR also functions during genetic recombination and corrects certain types of DNA damage.

mutator phenotype A phenotype that is associated with elevated genomewide spontaneous mutation frequencies and is usually caused by mutations at the DNA repair genes.

replication fidelity The extremely low error rate of DNA replication, which is achieved by the accuracy of DNA replication and mismatch repair.

Biography

A-Lien Lu is a Professor in the Department of Biochemistry and Molecular Biology at the University of Maryland, Baltimore. Her principal research interest is in DNA repair, including long-patch MMR and short-patch MutY repair. She holds a Ph.D. from the University of North Carolina at Chapel Hill and received her postdoctoral training at Duke University. As a postdoctoral fellow, she developed an *in vitro* MMR assay that has been used to purify and characterize MMR proteins, and her laboratory was the first to discover the *E. coli dam*-independent MutY pathway.

DNA Mismatch Repair in Mammals

James T. Drummond
Indiana University, Bloomington, Indiana, USA

When DNA polymerases copy an organism's genomic DNA, errors that escape the replication complex appear as mismatches. Virtually every mispairing may be recognized and corrected by a set of activities known collectively as the mismatch repair (MMR) pathway. When this pathway is disabled in humans, either via mutation or epigenetic silencing, the mutation rate rises approximately 100- to 1000-fold. There is a generally predictable outcome when dividing cells become mutators; deleterious changes within critical genes that regulate cell growth or suppress tumors result in a clonal expansion that fuels a cycle of further mutation and selection for phenotypes that spur growth or avoid death. Such a sequence describes tumors in hereditary cancer syndromes such as Muir–Torre and hereditary nonpolyposis colorectal cancer (HNPCC), and it frequently can explain sporadic tumor initiation in many tissue types.

Historical Perspective and Overview

Our understanding of the contributions of the DNA MMR pathway to the long-term well being of humans has exploded over the past decade. Substantial literature describing repair processes in model organisms such as bacteria and yeast has provided an indispensable road map for identifying mammalian homologs involved in tumor initiation and progression, beginning with the identification of human *MSH2* (*MutS Homolog 2*) in 1993. It quickly became apparent that the two primary genetic loci defective in HNPCC families corresponded to human *MSH2* and *MLH1* (*MutL homolog 1*), homologs of proteins essential for repairing mismatches in most complex organisms. The cast of participants rapidly evolved with revelations that MSH2 and MLH1 were isolated as heterodimeric species with distinct MutS and MutL homologs, each with different but often overlapping mechanistic contributions. In contrast to DNA repair pathways that remove site-specific lesions, repair of mismatches depends on identifying both the mismatch and a remote site that allows discrimination between parent and daughter strand. Large tracts of DNA may therefore be excised and resynthesized during a repair event. The replication machinery that restores the excised DNA sequence also participates in genomic replication, adding these proteins to the list of participants. Many of the proteins essential for DNA replication were found to have distinct roles in mismatch correction, most prominently PCNA (identified as a proliferating cell nuclear antigen). Despite the many advances, neither the full cast of players nor the specific mechanism for mismatch correction is fully characterized.

Mechanistic Contributions of the Key Participants in Mammalian MMR

MutS and Some of Its Homologs Recognize Mismatches

During a search for genetic defects that conferred a *Mut*ator phenotype in *E. coli*, inactivation of the *MutS* gene resulted in roughly a 1000-fold increase in the mutation rate. The MutS protein proved to be a mismatch-binding homodimer composed of 90 kD monomers with an inherent weak ATPase activity that plays an essential but incompletely defined role in mismatch correction. In mammals, the corresponding protein activities are more complex (Figure 1). The MSH2 protein forms tight complexes with either MSH6 or MSH3 (not shown); defects in *MSH2* apparently eliminate all nuclear MMR activity and increase the mutation rate from 100- to 1000-fold. Partnered with MSH6, MSH2 forms a heterodimer called MutSα that can recognize base–base and many small insertion-deletion mismatches. The MSH2/MSH3 heterodimer (MutSα) is present in substantially lower amounts in tumor cells, and it recognizes primarily insertion–deletion mutations in which two or more unpaired nucleotides are present in either strand. These two mismatch-binding heterodimers provide partially overlapping mismatch recognition capabilities, and defects in either *MSH6* or *MSH3* are less severe mutators than *MSH2*. Each individual defect confers a mutation

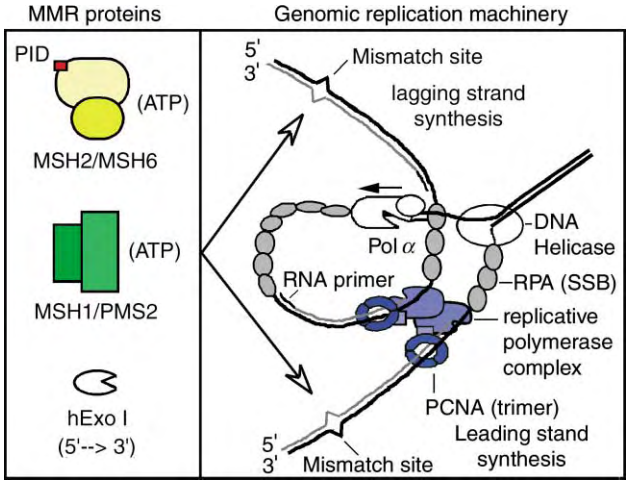

FIGURE 1 MMR activities cooperate with the DNA replication apparatus. The box on the left shows the proteins specific to mismatch correction. DNA replication is illustrated on the right as a process where leading and lagging strand synthesis is coordinated. Mismatches, identified as inverted triangles, are corrected such that the daughter strand (light gray) is targeted specifically for excision and removal. Resynthesis restores the parental strand information (darker strand). Several key proteins in replication, such as PCNA, RPA (a single-stranded binding protein complex), and polymerase delta, are also required for mismatch correction.

spectrum consistent with the selective failure to recognize different classes of mutations.

While the MSH6 and MSH3 proteins form heterodimers with MSH2 that are involved in recognizing mismatches, other MutS homologs have distinct roles in DNA metabolism. The mammalian MSH4 and MSH5 proteins also heterodimerize, yielding a complex that participates in meiotic recombination. While the precise mechanistic contribution of this complex is not known, it does not appear to recognize DNA mismatches in an error avoidance pathway. One further MutS homolog identified in yeast that might be expected in human cells, MSH1, has not surfaced. This mitochondrial protein is known to recognize DNA mismatches and stabilize the yeast mitochondrial genome by an undefined mechanism.

MutL and its Homologs are Essential to MMR

In prokaryotes such as *E. coli*, loss-of-function mutations in *Mut* L confer up to a 1000-fold increase in the mutation rate, much like defects in the *MutS* homologs. In parallel with MutS homologs, mammalian MutL homologs form heterodimers in which the MLH1 protein is central to complexes active in nuclear mismatch correction (Figure 1). MLH1 forms the primary heterodimer with PMS2 (PMS1 in yeast), which is also a *Mut* L homolog.

The mechanistic contribution of the MutL homolog heterodimers to repair, let alone other processes, is one of the least well-understood aspects of MMR. Some clues to MutL function are available from studies using yeast or *E. coli* proteins, but very little is known of their mammalian counterparts. Some MutL homologs are known to bind and utilize ATP, which is essential for mismatch correction. The nucleotide-binding motif is most similar to those of the growing category of AAA^+ proteins, which carry out diverse roles but often utilize ATP to drive dissociation of protein–protein or protein–DNA complexes. The purified human MutSα and MutLα heterodimers, as well as homologs from model organisms, have been shown to interact on longer DNA templates in the presence of ATP. This has led to models that suggest migration of a complex of both heterodimers along the DNA helix as part of the repair mechanism.

PCNA and the Replication Apparatus

When MutSα recognizes mismatches and triggers a strand-specific excision event, hundreds to thousands of nucleotides may be removed. A processive, PCNA-dependent polymerase is required to fill in the gap, which in human cells has been identified as polymerase delta. In Figure 1, the replicative polymerase complex shown synthesizing the daughter strand contains polymerase delta, and the MMR and replication functions are likely to be closely linked. A central player shared by both processes is the PCNA molecule, which forms a trimeric sliding clamp for replication and plays a complex in mismatch correction. It is essential for the MMR reaction prior to strand excision, and it interacts with MSH2 and MSH6 via a small, conserved domain through which many other repair proteins also bind PCNA (labeled PID for *P*CNA *I*nteracting *D*omain in Figure 1). Consistent with the biochemical and genetic evidence for this interaction, the key MMR proteins can be identified within replication foci *in situ*. Precisely how MMR is coupled to replication, or how the processes are coordinated, remains poorly understood.

Orchestration of Mismatch Correction in Mammals

The mechanism through which a DNA mismatch is repaired remains an intensely investigated field of research. Based on a wealth of genetic and biochemical data generated in model organisms, we have a clear idea of several participants and mechanistic intermediates along the pathway. How repair events are coordinated,

and the precise role of each of the players, remains unknown or a matter of dispute. Therefore, a series of intermediates in the process in which the proteins involved or the DNA structure is known, but for which the understanding of the mechanism remains incomplete, will be presented (Figure 2).

How Does Mismatch Binding Trigger Repair?

To be corrected, a mismatched site needs to be distinguished from correctly paired DNA. While no crystal structure is available for any eukaryotic heterodimer, prokaryotic MutS homodimers (from *E. coli* and *Thermus aquaticus*) have been crystallized complexed with either base–base or base–insertion mismatches. These structures reveal that mismatch recognition depends on the ability of MutS to kink the DNA helix sharply at the mismatch site by approximately 60°. The bend is partially enforced by the insertion of a phenylalanine side chain that stacks within the helix at the mismatch site. The MutS protein contains a domain that is poorly structured in the absence of DNA, and binding to the mismatch site orders the protein fold and sandwiches the DNA between the two halves of the homodimer. It has also been shown that eukaryotic MutS heterodimers are also capable of bending DNA upon mismatch binding.

As described above, MutSα in mammals is an ATPase, and it is clear that ATP triggers a conformational change that modifies DNA binding at the mismatch site. Precisely how that occurs, or which other protein activities might be involved *in vivo* (such as PCNA or MutLα), remains to be established. The three competing models that address this question each have clear experimental support or mechanistic plausibility, yet none provide a satisfactory overall answer.

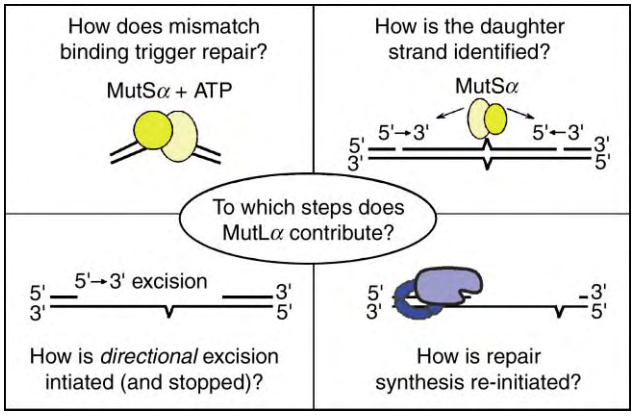

FIGURE 2 Five prominent unanswered questions about human MMR. Note that the MMR pathway is bidirectional, and that the nick shown to the right of MutSα in the upper right box could also have been accessed to trigger a 3′ to 5′ excision event toward the mismatch.

Mechanisms that suggest ATP-dependent DNA looping provide an elegant solution for how bidirectional scanning for a repair-directing signal may occur. Mechanisms that suggest diffusion-controlled migration along the DNA helix are plausible and well supported, but they require multiple copies of MutSα *in vivo* to drive bidirectional scanning. Neither of these models provides a memory for the mismatch site, since the protein that originally binds the mismatch leaves the site and travels hundreds of base pairs away. A third model suggests that MutSα might stay associated with the mismatch site and communicate through space with a marker for the daughter strand, such as with PCNA within the replication complex (see Figure 1). This allows for an anchor at the mismatch site, but it fails to provide an explanation for how directional excision is initiated.

How Is the Daughter Strand Identified?

Once a mismatch has been identified, the mandate of the MMR pathway is to target the newly synthesized DNA strand for excision and resynthesis. In a small group of prokaryotes that includes *E. coli*, the methylation status at GATC sequences reveals the daughter strand. The transient lack of methylation allows the MutH protein, stimulated by MutS and MutL at a nearby mismatch, to nick the daughter strand. However, such a methylation-based strategy apparently does not operate in mammalian cells. Instead, the most plausible mechanism to date suggests that mismatch correction is coupled with replication. By definition, the replication machinery generates the daughter strand, yielding a strand discrimination mechanism if the DNA end where synthesis occurs may be accessed.

How is Directional Excision Initiated and Controlled?

One of the hallmarks of MMR in all organisms is a bidirectional capability. In other words, the information used to distinguish DNA strands may be either "upstream" or "downstream" with respect to the mismatch (Figure 2). This capability demands that any mechanism to explain mismatch correction must account for identifying nearby signals in both directions along the DNA helix simultaneously. Once a strand signal is identified, several further constraints are introduced. The system must identify the relative orientation between the mismatch site and the point of excision, then correctly initiate an excision event that moves toward and through the mismatch site. This requires competence for degrading the intervening DNA by correctly accessing an exonuclease with either a

5′ → 3′ or a 3′ → 5′ strand polarity. It has been shown that the human Exonuclease I (Exo I) is essential for repair with either strand polarity, but only a 5′ → 3′ excision capability has been demonstrated. Note that for clarity, only a 5′ to 3′ excision reaction is illustrated in Figure 2.

How is Repair Synthesis Reinitiated?

Once DNA excision with either polarity is initiated, the replicative polymerase machinery must bring closure to it. It is clear that excision proceeds to relatively random sites approximately 150 nucleotides beyond the mismatch, with a wide variance and a few favored stopping points. Given that the single-strand excision event could span a few hundred to over a thousand base pairs, the MMR pathway must have a mechanism to ensure that excision proceeds until the mismatch site is removed. Once excision gives way to resynthesis, a new logistical problem is now apparent – if excision proceeds 5′ → 3′, the gap-filling polymerase (delta) has access to the DNA priming end from which the excision was initiated. In principle, resynthesis could track the excision process, leaving little or no gapped DNA as an intermediate. In the case of 3′ → 5′ excision, the entire excision event must be completed before the priming strand may be revealed to the polymerase. A long DNA gap is a required intermediate in this case. The repair process is formally concluded by the action of a DNA ligase that seals the nick that remains after resynthesis.

In summary, the MMR machinery is a complex assembly of proteins that can recognize DNA mismatches and restore the original DNA sequence. Failure of this pathway results in an increased mutational load and relaxed oversight of recombination events, wherein mismatches are also generated when the participating DNA strands are not identical. Such events are associated with tumorigenesis, revealing the crucial role of the MMR pathway in maintaining the genome of complex organisms under normal circumstances.

Glossary

exonuclease Enzyme that hydrolyzes nucleic acid polymers, usually to nucleotide monophosphates or short oligonucleotides, in a reaction initiated from a single- or double-stranded terminus.

mismatch Any pairing of DNA bases not described by the classical Watson–Crick G–C or A–T pairing, including addition or deletion of up to ~12 nucleotides in one DNA strand.

mutation Alternations in DNA sequence that result from processes such as unrepaired replication errors or DNA damage, which may or may not result in detectable phenotypic changes.

PCNA Proliferating cell nuclear antigen, a trimeric protein that forms a ring that can be pried open and loaded on double-stranded DNA to act as a platform for processive DNA synthesis or DNA repair activities.

Biography

James T. Drummond is an Associate Professor of Biology at Indiana University in Bloomington, Indiana. He earned his doctoral degree in Biological Chemistry from the University of Michigan Medical School; he received his postdoctoral training at Duke University. His research interest in DNA metabolism is focused on two major goals: defining the mechanism through which human DNA mismatch repair pathway distinguishes the parent from the daughter strand, and how the pathway responds to lesions.

DNA Mismatch Repair: *E. coli* Vsr and Eukaryotic G–T Systems

Margaret Lieb
Keck School of Medicine, University of Southern California, Los Angeles, California, USA

5-Methylcytosine (5meC) is found at specific sites in the DNA of *Escherichia coli* and related bacteria, and also in eukaryotes, where it functions in the regulation of gene expression. Hydrolytic deamination of 5meC produces thymine (T) (Figure 1), which is mispaired with guanine (G) in the sister DNA strand. In *E. coli*, the very-short patch (VSP) repair system replaces the mismatched T with cytosine (C), thus preventing the occurrence of a C:G to T:A mutation during the next replication of the DNA (Figure 2). In the absence of VSP repair, spontaneous mutation at the sites of 5meC increases manyfold. VSP repair requires the specific endonuclease Vsr and also a DNA polymerase, pol I, and DNA ligase. MutS and MutL, proteins that are essential for the correction of mispairs arising during DNA replication, are required for efficient VSP repair. In mammals, 5meC occurs in CpG sequences. At least two different enzymes appear to preferentially excise T in a T:G mispair that arises in this context.

VSP Repair in *E. coli*

Structure and Regulation of *vsr*

A small gene, *vsr*, coding for only 156 amino acids is present in *E. coli* and related enteric bacteria. It is located adjacent to *dcm*, whose product adds a methyl group to the second cytosine in a 5′ CC (A or T) GG sequence (Figure 2). The first seven codons of *vsr* overlap the 3′ end of *dcm* and both genes are transcribed from a single promoter. While their gene transcripts are present on the same mRNA, Dcm and Vsr proteins are expressed independently. In actively growing cultures, little Vsr is present in the bacteria, and mutation hot spots are found at the sites of 5meC. In nondividing bacteria, the concentration of Vsr increases significantly and, although deamination of 5meC continues at a rate that is time and temperature dependent, mutations do not accumulate at 5meC. Since the bacteria are expected to divide infrequently under natural conditions, VSP repair is an efficient mechanism to prevent mutation at 5meC.

Biochemistry of Vsr

Vsr endonuclease is a monomeric protein whose overall structure and active site have similarities to type II restriction endonucleases. Vsr binds to DNA containing a T:G mispair resulting from the deamination of 5meC (Figure 2). It also binds, with lower affinity, to related sequences lacking the 5′C or the 3′G of the cognate sequence. Binding requires a divalent cation; however, magnesium but not calcium promotes subsequent Vsr activity. Crystallographic studies have shown that Vsr spreads apart the DNA strands at the mispair site by inserting amino acid side chains, causing the DNA to bend. *In vitro*, absence of 5meC from the strand opposite the mispaired T reduces both the rate of DNA binding and the efficiency of enzyme action. This effect has not been observed *in vivo*, where additional factors influence VSP repair.

Biochemical studies show that Vsr nicks DNA 5′ to the mismatched T. When large amounts of Vsr are present, the endonuclease activity does not require an additional protein. However, in replicating bacteria, VSP repair activity is enhanced significantly by MutS and MutL. Since the absence of either protein, or of both, has the same effect, it is likely that these products act cooperatively, as they are known to cooperate in mismatch correction of replication errors (MMR). MutS binds to T:G mispairs in any sequence context and recruits MutL resulting in a MutL–MutS complex that interacts with an endonuclease called MutH. Dominant negative mutations in MutS that block MMR also prevent VSP repair. Although the biochemistry has not been demonstrated *in vitro*, it is likely that MutS helps to attract Vsr to T:G mispairs, perhaps because Vsr can bind to MutL *in vitro*. If Vsr is brought to a T:G that is in the DNA sequence that it recognizes, it may cause MutS and MutL to disassociate from the mispair, allowing Vsr to replace MutS.

In addition to Vsr, VSP repair requires pol I, which has an intrinsic 5′–3′ exonuclease activity that digests away a small number of nucleotides starting at the nick immediately upstream of T. It simultaneously

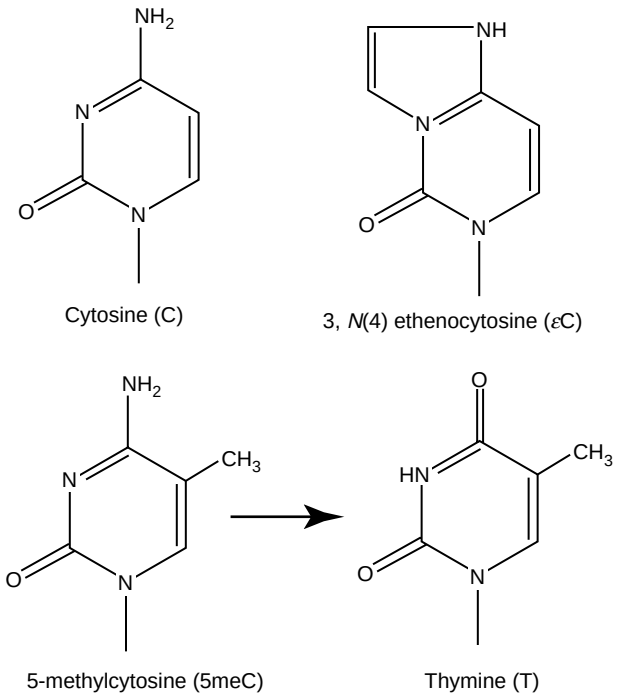

FIGURE 1 Chemical structures of cytosine and cytosine derivatives. 3,N(4) ethenocytosine is a mutagen produced in DNA by endogenous products of lipid peroxidation and by industrial pollutants such as vinyl chloride.

resynthesizes DNA in the 5′–3′ direction. Since pol I is an error-free polymerase, it inserts a C in place of the T that it has removed from the mismatch. The actual number of bases removed is known to be less than 10, and is perhaps as few as 1 or 2. This is why this repair is referred to as very-short patch. The repair is completed by DNA ligase, an enzyme that seals single-strand nicks in double-stranded DNA.

Mutagenesis by Vsr

Overproduction of Vsr increases the frequency of mutation at many sites in *E. coli*, mimicking the effect of mutations in *mutS* or *mutL*. Mutagenesis by Vsr can be attributed to its competition for a component of the MMR system. MutL has been shown to interact physically with Vsr *in vitro* and additional MutL reduces the mutagenic effect of excess Vsr. Thus, it is likely that the concentration of Vsr is maintained at a low level in dividing bacteria to prevent its titration of MutL. Vsr would also have a mutagenic effect if it corrected to C:G a T:G mispair in which the G was a replication error in a newly synthesized strand. It should be noted that MutS has a higher affinity for T:G than for any other mispair. Therefore, it is not surprising that excess MutS reduces VSP repair by competing with Vsr for binding at T:G mispairs that result from deamination of 5meC.

VSP Repair and Marker Effects

Before the advent of DNA sequencing, the relative location of different mutation sites on microbial chromosomes was determined by crossing different mutants and observing the frequency of wild-type recombinants. The frequency of recombination generally decreases with the distance between mutation sites on the parental genomes. Certain mutations (or markers) appear to recombine with other mutations in their vicinity more frequently than expected. This "marker effect," which has also been referred to as "high negative interference," is often the result of VSP repair of a C to T mutation that occurred at a 5meC.

Methyl-CpG Binding Domain 4 (MBD4) Protein in Eukaryotes

Structure and Biochemistry of MBD4

The gene for MBD4 was identified in a search of the human sequence database for a methyl-CpG-binding domain. Mbd4 genes in both the human and mouse code for a 580 amino acid protein with a methyl-CpG-binding domain near the amino-terminal end, and a carboxy-terminal glycosylase domain. The glycosylase region of the protein is related to bacterial glycosylases such as MutY. The enzyme has no lyase activity, so that the removal of the mismatched base

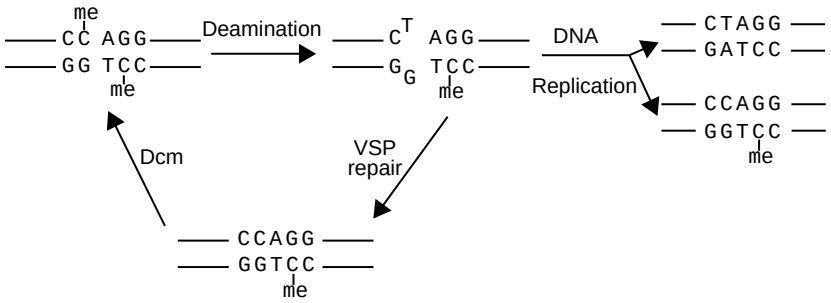

FIGURE 2 The life cycle of a dcm site in *E. coli*.

leaves an abasic site. The sugar-phosphate backbone of DNA can subsequently be cleaved by the human AP endonuclease HAP1 but other endonucleases may also perform this function. There is evidence suggesting that processing of the abasic site also involves interaction with MLH1, a homologue of bacterial MutL.

Specificity

Investigations with human MBD4 have shown that only T:G and U:G mispairs are good substrates for the enzyme. The human MBD4 enzyme binds preferentially to T:G mismatches in the meCpG/TpG context. However, removal of the mismatched base was observed when U:G and T:G mismatches were in a nonmethylated substrate. T:G mismatches in other contexts are processed at a greatly reduced rate. The fact that U is removed from a mispair with G more rapidly than T suggests that removal of T resulting from deamination of meC may not be the primary function of MBD4.

Cancer Prevention

In the cells of the intestinal mucosa of mice containing inactive *Mbd4* genes there was a two- to threefold increase in C to T mutations in CpG sequences. In combination with mutations in the adenomatosis polyposis (Apc) genes, MBD4 inactivation increased the number of tumors and tumor progression. A 3.3-fold increase of C to T mutations at 5meC was also observed in the liver and spleen of mice lacking MBD4. Therefore, it is clear that MBD4 is a significant factor in the prevention of mutations leading to cancer.

Thymine-DNA Glycosylase (TDG)

Structure and Biochemistry of TDG

TDG is an enzyme with homologues found in the cells of humans and other animals, and also in *E. coli*. It has no apparent amino acid similarity to MBD4.The enzyme is characterized by low abundance and slow action. TDG can remove from DNA the bases T or U that arise by deamination of 5meC or C, and are thus mispaired with G. Removal of the base from the DNA backbone results in an abasic site to which the TDG remains bound. Studies of human TDG *in vitro* have indicated that an apurinic exonuclease (HAP1) helps TDG turnover and cleaves the abasic sugar phosphate. Repair of the resulting nick in the DNA strand requires both a DNA polymerase and DNA ligase.

Specificity

TDG was first isolated in a search for a Vsr-like activity in extracts of human cells. The enzyme has a higher affinity for U:G mispairs than for T:G, and also significant affinity for 3,N(4) ethenocytosine (Figure 1) paired with G. TDG has a strong preference for mispairs arising in the CpG context. However, there is as yet no direct evidence that it has an important role in preventing mutation resulting from deamination of 5meC.

DNA Oxidation

Arthur P. Grollman
State University of New York, Stony Brook, New York, USA

Dmitry O. Zharkov
Novosibirsk Institute of Chemical Biology and Fundamental Medicine, Russia

Oxygen-releasing photosynthesis and aerobic respiration have provided the basic machinery of life for almost three billion years and have driven the evolution of complex life forms. Molecular oxygen is a powerful oxidizing agent whose metabolic products can cause serious damage to proteins and DNA. As the integrity of genomic DNA is critical to cell survival, a variety of intracellular systems have evolved to repair oxidative DNA damage.

Oxidants and Antioxidants

The reduction of oxygen to water consists of several sequential steps involving the reactive oxygen species (ROS) superoxide anion radical, hydrogen peroxide, and hydroxyl radical. Thus,

$$O_2 \rightarrow {}^{\cdot}O_2^- \rightarrow H_2O_2 \rightarrow HO^{\cdot} \rightarrow H_2O$$

Additionally, molecular oxygen in the $^1\Delta_g$ excitation state ("singlet oxygen") is included in the category of reactive oxygen species. In cells, ROS react with many molecules, with their average lifetime and distance of diffusion from the point of generation being inversely proportional to their reactivity. Free radicals, such as ${}^{\cdot}O_2^-$ and $HO^{\cdot}$, trigger chain reactions of oxidation, allowing unpaired electrons to propagate over longer distances. Polyunsaturated fatty-acid side chains are especially prone to reactions with free radicals; the resulting peroxyl radicals propagate by a chain reaction. Given the ubiquitous presence of lipid bilayers in cells, lipid peroxidation also plays an important role in the toxicity associated with ROS.

The primary source of ROS in eukaryotes is the mitochondrial respiratory chain. Approximately 0.1% of cellular oxygen is converted to superoxide, primarily through auto-oxidation of the semiquinone forms of ubiquinone and flavin mononucleotides, which occurs during the NADH dehydrogenase electron transfer process. In mitochondria, superoxide anions generate hydrogen peroxide and hydroxyl radicals. In plants, photosystem I is also a major producer of ROS. Other cellular redox systems also are capable of producing ROS. For example, nonmitochondrial endogenous sources of ROS include reactions catalyzed by cytochrome P450, NADPH:cytochrome P450 reductase, and xanthine oxidase. Recently, immunoglobulins were identified as a major ROS source in mammals.

The major environmental source of ROS is ionizing radiation. Radiolysis of water releases hydroxyl radicals and other reactive entities, such as solvated electrons and ${}^{\cdot}H$ and ${}^{\cdot}O^-$ radicals. Other sources of ROS include microwave radiation, ultrasound, photosensitizing dyes (methylene blue, rose bengal), transition metal ions, ozone, and a variety of salts (e.g., $KBrO_3$), as well as certain drugs and chemicals.

Hydroxyl radicals and singlet oxygen are the most reactive forms of ROS and, consequently, the most damaging to biomolecules. Hydroxyl radicals are generated from superoxide and H_2O_2 by Fenton chemistry when Fe^{2+} or other low-valency transition metal ions are present; such ions bind to DNA and these reactions play an important role in DNA damage:

$$H_2O_2 + Fe^{2+} \rightarrow HO^{\cdot} + OH^- + Fe^{3+}$$
$${}^{\cdot}O_2^- + Fe^{3+} \rightarrow O_2 + Fe^{2+}$$

In living organisms, various mechanisms have evolved to minimize the effects of oxidative damage, including deactivation of ROS by superoxide dismutases, catalases, and peroxidases. Superoxide dismutases (SODs) are ubiquitous metal-dependent enzymes that contain Cu and Zn, Mn, or Fe metal ions. All forms of SOD catalyze the dismutation of superoxide radicals into hydrogen peroxide and oxygen:

$$2\,{}^{\cdot}O_2^- + 2H^+ \rightarrow H_2O_2 + O_2$$

In the next stage of oxygen reduction, hydrogen peroxide is converted to water and oxygen by catalase:

$$2H_2O_2 \rightarrow 2H_2O + O_2$$

or peroxidase:

$$R_1SH + R_2SH + H_2O_2 \rightarrow R_1SSR_2 + 2H_2O$$

Almost any low-molecular-weight substance that contains a reducing moiety can react with ROS. Such nonenzymatic radical scavengers are present in significant quantities in cells or concentrated at ROS target sites. These scavengers include lipophilic substances (α-tocopherol, β-carotene) and hydrophilic molecules (ascorbic acid, uric acid, glucose, and glutathione) that prevent transition metals from producing hydroxyl radicals, thereby performing an antioxidant function. The low concentrations of free Fe^{2+} in living cells is a consequence of the presence of proteins in the cell that bind and sequester iron (ferritin, transferrin) or oxidize it (ceruloplasmin).

DNA Damage

DNA is an important target of oxidative damage. Both the sugar-phosphodiester backbone and the bases are subject to attack by ROS, producing single- and double-strand breaks, intra- and interstrand cross-links, abasic (AP) sites, cyclonucleotides, and a variety of modified bases. ROS also damage DNA by lipid peroxidation. All DNA bases are subject to direct oxidation; the principal lesions detected in cellular DNA are shown in Figure 1.

The most prevalent oxidized base in DNA, 8-oxoguanine (8-oxoG), is formed by oxidation of guanine at C8. Like all purine nucleotides substituted at C8, 8-oxo-2′-deoxyguanosine (8-oxodG) adopts the *syn* rather than *anti* conformation unless additional restraints, such as Watson–Crick pairing, are present. In the *anti* conformation, 8-oxodG forms a Watson–Crick pair with dC, whereas in the *syn* conformation, it forms a Hoogsteen pair with dA.

Biological Effects

Cytotoxicity and Mutagenesis

The major cytotoxic effects of ROS represent responses to DNA double-strand breaks and lesions that block DNA replication. Certain oxidized bases are mutagenic, e.g., 8-oxoG accommodates a miscoding base (A) during DNA synthesis. The proofreading activity of DNA polymerases fails to remove this base when it is incorporated opposite 8-oxodG. Thus, mutations at 8-oxoG are predominantly G → T transversions. Interestingly, DNA polymerases differ significantly with respect to nucleotide insertion opposite 8-oxoG. Thus, replicative polymerases (DNA polymerase α, DNA polymerase δ, DNA polymerase III) preferentially insert dAMP opposite the damaged base, while polymerases involved in DNA repair (DNA polymerase β, DNA polymerase I) mainly incorporate dCMP opposite the lesion. Deoxynucleotide triphosphates are also subject to damage by ROS, promoting base misincorporation, which may lead to mutational events.

Carcinogenesis

Oxidative stress is an important factor in tumor initiation and promotion. Its relative impact can be appreciated by noting that the amount of oxidized bases in DNA is significantly higher than the amount of DNA adducts formed by environmental mutagens. It is clear that somatic mutations play a central role in carcinogenesis and oxidative DNA damage has been implicated as an initiating event in this process. The role of ROS in tumor development also may be attributed, in part, to

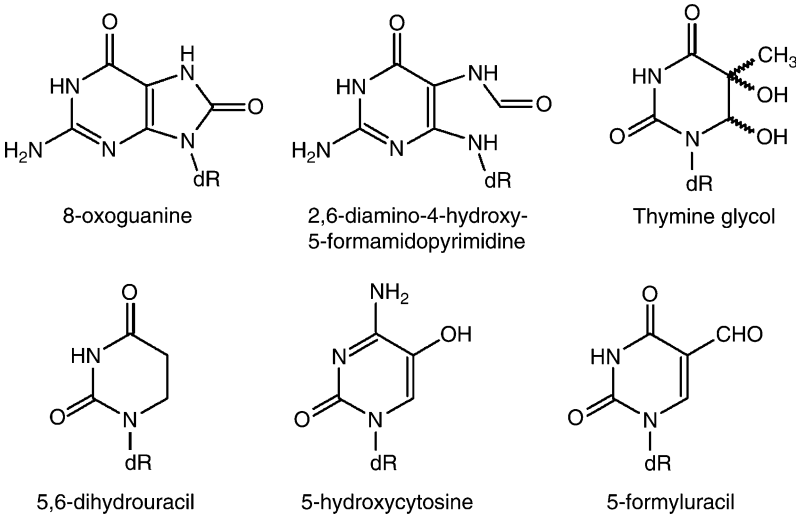

FIGURE 1 Examples of major oxidative lesions in DNA.

their mitogenic properties and their ability to damage cellular proteins and membranes.

8-oxoG and thymine glycol are frequently used as biomarkers for oxidative DNA damage. Interestingly, tumor tissue sometimes contains increased amounts of oxidized bases. As most solid tumors are anoxic and generally display *lower* levels of general oxidative damage, this increase in DNA damage appears to be a cause rather than a consequence of neoplastic transformation. For tumor development to occur, a series of mutations are generally required to inactivate tumor suppressor genes and/or alter the status of protooncogenes. The presence of G → T transversions, characteristic of 8-oxoG, suggests that oxidative damage may have been involved in these instances. This signature base-substitution mutation is found in mutated p53 and *ras* genes in many human cancers and experimental systems.

Aging

In 1956, D. Harman proposed a free-radical theory of aging. Oxidative DNA damage increases with age and the correlations between aging and DNA oxidation are reflected in increasing levels of 8-oxoG and thymine glycol. The relationship between an organism's life span and its ability to repair oxidatively damaged DNA has also been reported. Although the frequency of mutations increases with age, there are no documented cases of somatic mutations in the nuclear genome that are directly involved in causing age-related changes or age-related diseases (such as hypertension or Alzheimer's disease). There are, however, known, well-established mutations that are associated with certain spontaneous, nonhereditary cancers. Mitochondrial DNA (mtDNA), rather than nuclear DNA, has been proposed as a principal site of age-related damage accumulation. In fact, direct estimates of oxidative damage in mtDNA usually are higher than those in nuclear DNA. A specific, age-related deletion in the mtDNA of postmitotic cells, as well as multiple rearrangements, has been documented.

Repair of Oxidative DNA Damage

General

DNA damage occurs to a significant degree despite the ubiquitous presence of ROS scavengers. However, several cellular mechanisms are available to effect repair: direct reversal, base excision repair (BER), nucleotide excision (NER), methyl-directed mismatch repair, and recombination repair. Double-strand breaks are generally repaired by recombination repair; interstrand cross-links by a combination of NER and recombination repair; and intrastrand cross-links and cyclonucleotides by NER. Most oxidative damage is dealt with by BER. Here, damaged bases are excised by specific DNA glycosylases, creating an apurinic/apyrimidinic (AP) site. If the glycosylase has AP lyase activity, it can immediately cleave 3′ to the AP site; otherwise, a separate AP endonuclease cleaves 5′ to this position. Deoxyribose phosphate lyase (dRPase) removes the sugar residue, creating a substrate for a DNA polymerase. After this polymerase fills the resulting gap, a DNA ligase restores the double-stranded DNA.

Despite the wide variety of oxidatively damaged bases found in DNA, only a few glycosylases are involved in their repair. These enzymes necessarily exhibit broad substrate specificity, with some acting primarily on oxidized pyrimidines and others on oxidized purines. In *Escherichia coli*, oxidative damage to pyrimidines is repaired by endonucleases III and VIII (Nth and Nei); structurally related enzymes (NTH and NEIL) perform similar functions in eukaryotes. About 20 types of oxidized bases are excised by these DNA glycosylases. Depending on the type of chemistry performed by DNA glycosylases, modified AP sites are generated and processed by AP endonucleases to generate a suitable end for the DNA polymerase.

GO System

8-oxoG presents special problems for DNA repair. Since either dAMP or dCMP can be incorporated opposite 8-oxodG, the repair system for this lesion must convert both 8-oxodG:dC and 8-oxodG:dA mispairs into a dG:dC pair. At least two cycles of BER are required to repair 8-oxodG:dA. First, adenine, the normal base, is excised, a process followed by insertion of dCMP opposite the lesion. The resulting 8-oxodG:dC mispair is then repaired by excision of 8-oxoG and subsequent insertion of dGMP.

In *E. coli*, a system of three enzymes – Fpg (MutM), MutT, and MutY (GO system) – counters the deleterious effects of 8-oxoG (Figure 2). MutT protein, a nucleoside triphosphate hydrolase, cleanses the cellular nucleotide pool of 8-oxodGTP. Fpg is an 8-oxoguanine-DNA glycosylase/AP lyase that excises 8-oxoG from 8-oxodG:dC but not from 8-oxodG:dA. MutY protein is an adenine glycosylase specific for dA:8-oxodG and dA:dG pairs. If 8-oxoG DNA arises by spontaneous oxidation of guanine or by incorporation of 8-oxodGMP opposite dC, it is excised by Fpg. However, if dA:8-oxodG is present because of incorporation of 8-oxodGMP opposite dA, it becomes a substrate for MutY. DNA polymerase I, the principal repair polymerase in *E. coli*, preferentially inserts dCMP opposite 8-oxodG. If dAMP is again inserted, the cycle of MutY repair may repeat. If dCMP is inserted during postreplication repair, the 8-oxodG:dA mispair is converted

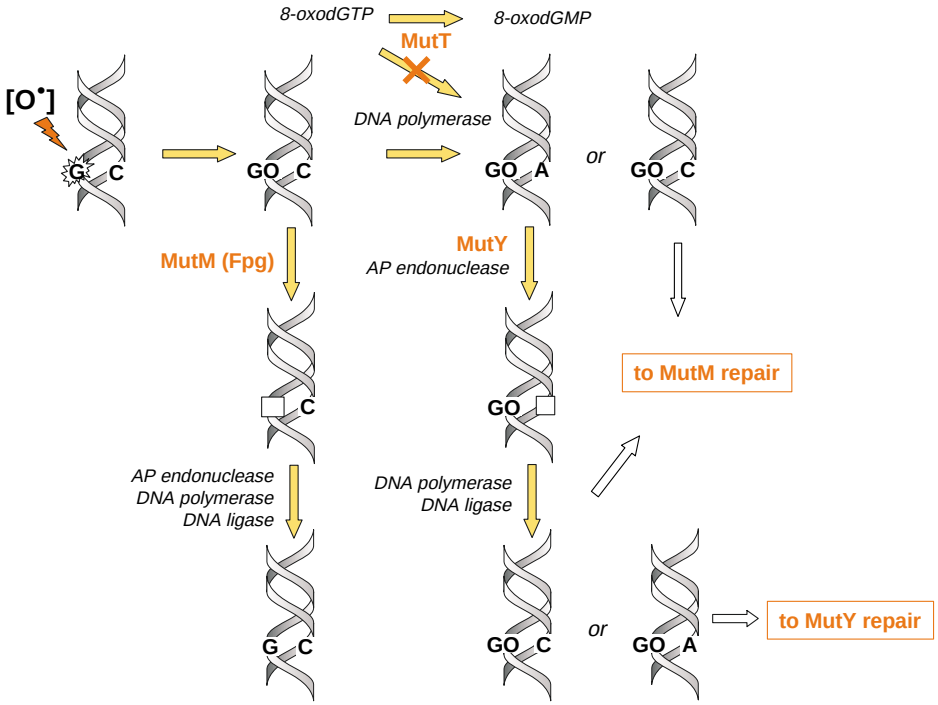

FIGURE 2 GO system in bacteria.

to 8-oxodG:dC, a substrate for Fpg. This GO system also operates in most eukaryotes.

Glossary

DNA damage Any change in the bases (A, C, G, and T) or phosphodiester backbone structure that comprise canonical DNA.

DNA repair Any process, usually enzymatic, which participates in purging DNA of damaged elements and returns it to its canonical form.

reactive oxygen species A molecule that contains an oxygen atom with a highly reactive configuration of electrons.

Biography

Arthur P. Grollman is Distinguished Professor of Pharmacological Sciences and Glick Professor of Experimental Medicine at the State University of New York at Stony Brook, where he heads the Laboratory of Chemical Biology. The Laboratory's research focuses on mechanisms of DNA damage, mutagenesis and DNA repair.

Dmitry O. Zharkov is a senior research scientist at the Novosibirsk Institute of Chemical Biology and Fundamental Medicine, Russia. His principal research interests are in the field of DNA repair and protein–nucleic acid interactions. He obtained a Ph.D. from the State University of New York at Stony Brook, where he later investigated the structure and mechanism of action of DNA glycosylases.

DNA Photolyase

Carrie L. Partch and Aziz Sancar
University of North Carolina School of Medicine, Chapel Hill, North Carolina, USA

Ultraviolet irradiation from sunlight damages DNA, and the growth of cells containing DNA lesions can lead to mutations, cell death, and cancer. Photolyase repairs UV-induced pyrimidine dimers by splitting the DNA photoproducts into individual pyrimidine bases through a process of photo-induced cyclic electron transfer using near-UV/blue light as an energy source. The reversal of the effect of far-UV (200–300 nm) by near-UV/visible light (300–500 nm), known as photoreactivation, is the most direct mechanism for repair of DNA photoproducts. Phylogenetically, the closest homolog of photolyase is a UV/blue light photo-receptor named cryptochrome, which regulates growth and development in plants and the circadian clock in animals and plants.

Classification

All members of the photolyase/cryptochrome family share a common evolutionary origin, high sequence homology, and identical chromophore/cofactors. Despite these similarities, their activities are directed toward unique substrates; photolyases repair either cyclobutane pyrimidine dimers or (6-4) photoproducts, induced in DNA by ultraviolet light. Cryptochromes do not have any repair activity; instead, they function as photoreceptors to regulate development in plants and synchronize circadian rhythms with the solar cycle in animals. Circadian rhythms are the daily oscillation of physiological processes designed to coordinate organismal activity with the solar cycle. Photoreactivation and circadian phototransduction may conceivably have had a common evolutionary origin. In the distant past, when more UV light reached the surface of the Earth, a primitive organism may have used the same protein to repair UV-induced DNA lesions and regulate daily behavior in order to minimize exposure to the harmful effects of sunlight.

Species Distribution

The two members of the photolyase/cryptochrome family are found in many members of the three kingdoms of life. Cyclobutane photolyases are by far the most predominant across species. The two most abundant photoproducts formed by absorption of far-UV light (200–300 nm) by DNA are *cis,syn*-cyclobutane pyrimidine dimers (CPD) and pyrimidine–pyrimidone (6-4) photoproducts (Figure 1). UV induces cyclobutane pyrimidine dimers in DNA 10 times more frequently than (6-4) photoproducts. Many species that contain a cyclobutane photolyase lack a (6-4) photolyase, but those with a (6-4) photolyase always contain a cyclobutane photolyase, highlighting the importance of the cyclobutane photolyase for survival. Despite the relatively widespread distribution of photolyases in the three kingdoms, many microorganisms such as *Bacillus subtilis* and *Schizosaccharomyces pombe* do not have any photolyase. In contrast, *Escherichia coli* and *Saccharomyces cerevisiae* have cyclobutane photolyase and *Drosophila* has cyclobutane photolyase, (6-4) photolyase and cryptochrome. Of special interest, placental mammals such as mice and humans have two cryptochromes but do not possess either photolyase. UV photoproducts in these organisms are removed exclusively by the nucleotide excision repair pathway. Cryptochromes are expressed in plants, most animals, and some bacteria, frequently with more than one isoform in a species.

Photolyase

Primary Structure and Chromophores

Photolyases are 50- to 55-kDa monomeric proteins with two chromophore/cofactors. Sequence identity among the 50 or so known photolyases ranges from 15 to 70% with maximal sequence conservation in the catalytic FAD-binding domain. All photolyase/cryptochrome family proteins contain two noncovalently bound chromophores: a primary chromophore, FAD (flavin adenonucleotide), required for specificity in binding damaged DNA and catalysis, and a second, or "antenna" chromophore. The second chromophore is a folate (or rarely, a deazaflavin) and increases the rate of catalysis in

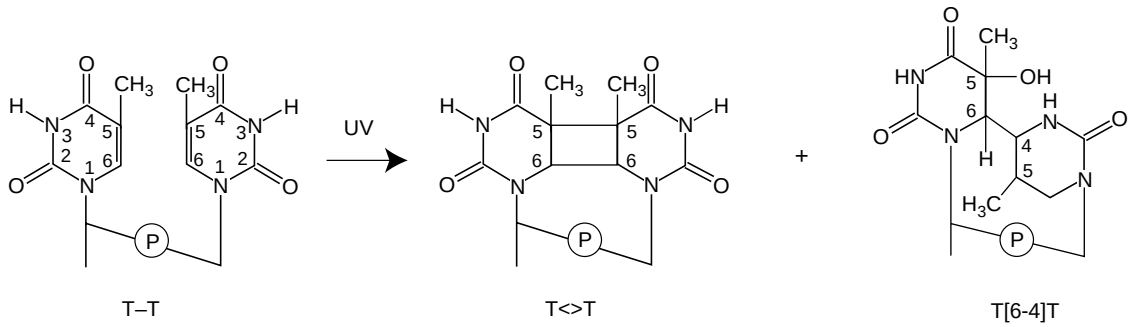

FIGURE 1 Structure of UV-induced DNA photoproducts. The two major DNA photoproducts induced by far-UV irradiation are pyrimidine cyclobutane dimers (80–90% of lesions) and pyrimidine–pyrimidone (6-4) photoproducts (10–20% of lesions). The same type of photoproduct may form between any adjacent pyrimidines, including T–T, T–C, C–T, and C–C sites, except that (6-4) photoproducts do not form at C–T sites.

limiting light by absorbing light and transferring the energy to the FAD catalytic cofactor. Native photolyase contains FAD in the two-electron reduced and deprotonated form ($FADH^-$). This is the only active form of the cofactor. During purification the flavin is often converted to the catalytically inactive neutral radical ($FADH^\circ$) form, but it can be converted back to the $FADH^-$ either chemically or photochemically.

Tertiary Structure

Crystal structures have been solved for several members of the photolyase family and despite their low sequence homology (~25% identity), the structures are remarkably similar. Photolyases exhibit a rather compact structure composed of two distinct domains: an N-terminal α/β domain (residues 1–131, *E. coli* photolyase numbering) and a C-terminal α-helical domain (residues 204–471), connected to one another by a long loop (residues 132–203) (Figure 2). The FAD cofactor is buried deep within the α-helical domain, held tightly in place by contact with 14 highly conserved amino acids. The antenna chromophore is bound loosely in a cleft between the two domains. An electrostatic representation of the surface of photolyase illustrates the presence of a large, shallow, positively charged groove that comprises the DNA-binding interface. A cavity in the middle of the groove allows the damaged nucleotide bases to fit in close proximity to the FAD during catalysis (Figure 2).

Reaction Mechanism

The cyclobutane photolyase has been extensively studied and a detailed model for its reaction mechanism had been made. The enzyme binds pyrimidine dimers

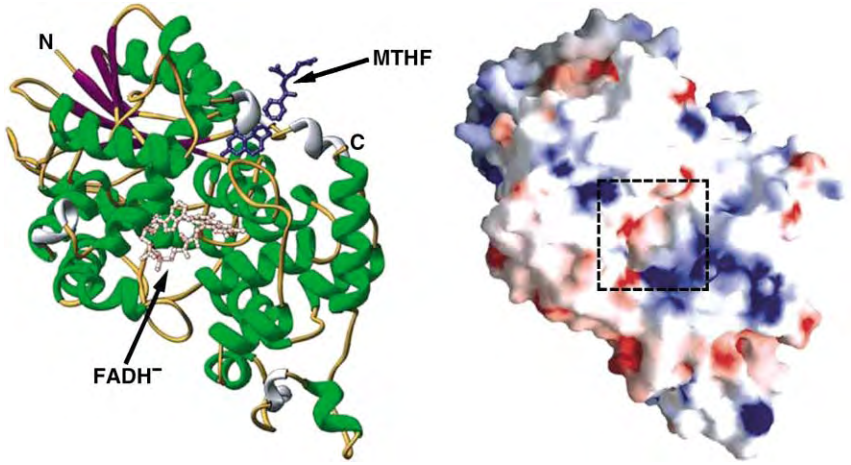

FIGURE 2 The structure of *E. coli* photolyase. The ribbon diagram representation (left) of the crystal structure of *E. coli* photolyase obtained at 2.3Å shows the placement of the two chromophores and the distinct N-terminal α/β domain and C-terminal α-helical domain. An electrostatic representation (right) of the surface illustrates the positive DNA-binding groove (shown in blue) that runs diagonally down the length of the protein and the dimer binding cavity (indicated by the dashed square).

independently of light, specifically attracted to the distorted DNA helix (bent approximately 30°) created by the DNA lesion. The dimer is flipped out of the double helix of the DNA into the active site cavity of photolyase, positioned in close proximity to the flavin (Figure 3A). Catalysis is initiated by light. A photon of near-UV/blue light (300–500 nm) is absorbed by the antenna chromophore and the excitation energy is transferred to the flavin ($FADH^-$) by fluorescence resonance energy transfer. The excited singlet state flavin $^1(FADH^-)^*$ then transfers an electron to the dimer, splitting the cyclobutane ring to form two pyrimidines. Concomitantly, an electron from the pyrimidine radical is transferred back to the neutral radical flavin ($FADH^\circ$) formed during catalysis to regenerate the active form of flavin ($FADH^-$) without a net redox change in the chromophore or substrate (Figure 3B). The repair of photoproducts by CPD photolyases occurs with a high quantum yield (photolesion repaired per absorbed photon) of 0.7–0.98.

The (6-4) photolyase has not been studied to the same extent as the cyclobutane photolyase, but it is believed to function in a similar manner with one significant difference. Upon binding the damaged DNA, the enzyme first thermally converts the (6-4) photoproduct to a four-membered ring intermediate closely resembling a cyclobutane dimer. The photo-induced electron transfer mechanism is presumed to be the same as for the classical cyclobutane photolyase, although there is no direct evidence for this mechanism and the quantum yield of repair is significantly lower for (6-4) photolyases, in the range of 0.05–0.10.

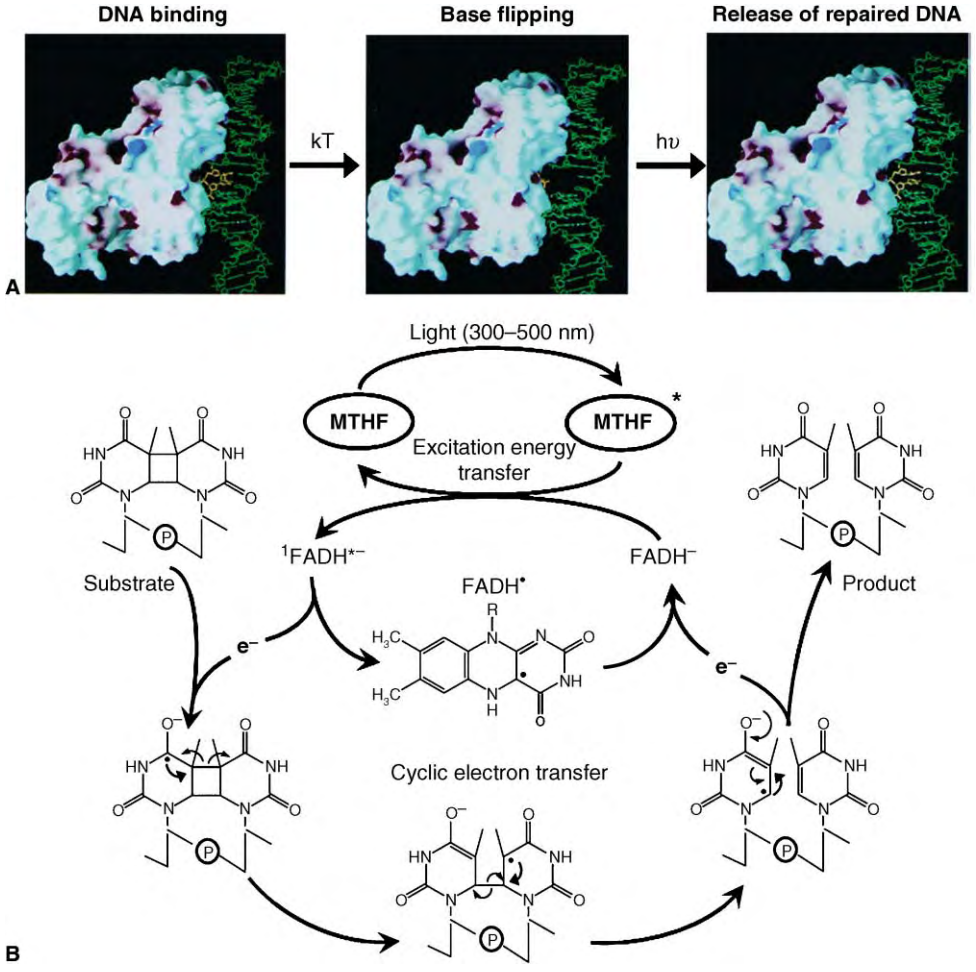

FIGURE 3 Reaction mechanism of photoreactivation by *E. coli* photolyase. (A) General outline of the repair reaction. Photolyase binds to the damaged DNA (shown in yellow), flips the dimer into its active site cavity thermally (kT) for repair, and, following photorepair ($h\nu$), ejects the repaired DNA bases into the DNA helix. (B) Photochemical steps of dimer splitting. After absorption of a photon by the folate, energy is transferred to the flavin, which donates an electron to break the cyclobutane ring. An electron is transferred back from the product to the flavin, restoring the flavin to its ground state with no net change in redox status in either the substrate or cofactor.

DAPI staining of nuclei (left, shown in blue) and Cry2 immunofluorescence (right, shown in red) are shown. Note the exclusive expression of Cry2 in the inner retina (INL and GCL). ONL, outer nuclear layer; INL, inner nuclear layer; GCL, ganglion cell layer.

Dark Repair Function

Even in the absence of photoreactivating light, photolyase plays an advantageous role in the cell by stimulating the repair of damaged DNA. This "dark function" is due to the stimulation of the nucleotide excision repair pathway by photolyase. As a general rule, the more a lesion distorts the DNA structure, the more efficiently it is recognized and removed by the excision nuclease system. Cyclobutane pyrimidine dimers cause only modest distortions of the DNA helix compared to (6-4) photoproducts and are repaired at a much lower rate in the absence of photolyase. Photolyase, presumably by binding the damage and flipping the dimer out of the helix, increases distortion of the DNA and accelerates the rate-limiting damage recognition step of the excision repair complex. In addition, photolyase recognizes DNA lesions caused by other chemical agents such as cisplatin, stimulating excision of the DNA adduct and increasing cellular survival without photoreactivation.

Cryptochromes

Structure

The basic architecture of cryptochrome is remarkably similar to photolyase. However, cryptochromes are structurally distinguished from photolyases by the presence of extended C-terminal domains ranging from 40 to 250 amino acids in length. These domains are thought to be important to the unique function of cryptochromes in circadian rhythms and growth control.

Function

In nearly all organisms, the daily oscillation of physiological and behavioral processes such as sleep, body temperature, and metabolic rate are regulated by a transcription-based endogenous clock called the circadian (circa = about, dies = day) clock. These oscillations are kept in harmony with the solar cycle by photoreceptors that adjust the phase of the endogenous clock to coordinate rest or activity with the appropriate light cycle. Cryptochromes have two roles in maintaining circadian rhythms: photoreception and light-independent control of the endogenous clock. In mammals, circadian phototransduction is mediated solely through the eye and is not dependent on the outer retina containing the visual photoreceptors. Human cryptochromes are highly expressed in the inner retina (Figure 4). Elimination of cryptochromes by genetic means seriously compromises circadian phototransduction in mice and *Drosophila*, indicating that cryptochromes are the primary circadian photoreceptors. However, in the absence of cryptochromes there is some residual circadian photoreception, indicating that functional redundancy exists between cryptochromes and opsins in circadian phototransduction.

Reaction Mechanism

The mechanism of photoreception/phototransduction by cryptochromes is not known at this time. However, catalytic residues from photolyase are conserved in cryptochromes and the unique C-terminal domains interact with effector proteins in a light-dependent manner in several organisms. It has been hypothesized that an intra- or intermolecular electron transfer mechanism may regulate accessibility of the C-terminal domain to effector proteins in response to light, thereby providing a regulated mechanism of signal transduction. The light-independent function of cryptochromes is to downregulate the expression of several clock genes by acting as a negative transcription factor.

Biography

Carrie Partch is a graduate student in the laboratory of Dr. Aziz Sancar at the University of North Carolina School of Medicine, Chapel Hill. She received her B.S. in 1997 from the University of Washington. She is investigating vertebrate cryptochrome function for her graduate work.

Aziz Sancar is a Distinguished Professor of Biochemistry and Biophysics at the University of North Carolina School of Medicine, Chapel Hill. He holds an M.D. from Istanbul University School of Medicine and a Ph.D. in molecular biology from the University of Texas at Dallas. He carried out his postdoctoral work at Yale University. He works on mechanisms of DNA repair and DNA damage checkpoints, as well as DNA photolyase/cryptochrome and circadian photoreception.

DNA Polymerase α, Eukaryotic

Teresa S.-F. Wang
Stanford University School of Medicine, Stanford, California, USA

DNA polymerase α (polα) is a replicative DNA polymerase in eukaryotic cells essential for initiation of chromosome replication. Polα exists in cells as a four-subunit enzyme complex often referred as polα-primase complex. The enzyme complex uniquely contains a RNA polymerase activity called primase activity that synthesizes a short RNA primer to sever as primer for the DNA polymerase activity of polα to extend for DNA synthesis. This unique nature of polα-primase complex to perform *de novo* synthesis bequeaths it a critical role not only in initiation of chromosome replication but also in repair, recombination, checkpoint activation, telomere maintenance, and mutation avoidance. Thus, polα-primase plays a critical role in maintenance of genomic stability of cells.

Protein Structure and Subunit Components

DNA polα consists of four subunits: a catalytic subunit of 165–180 kDa that contains the polymerase activity, a subunit of 70 kDa that has no detectable enzymatic activity but is essential for the initiation of replication both *in vivo* and *in vitro*, and two subunits with approximate molecular masses of 48 and 59 kDa that together contain the DNA primase activity. The ability of the primase subunits to synthesize a short RNA primer *de novo* renders polα unique among other eukaryotic replicative DNA polymerases. The subunit composition of polα from different organisms is conserved; their nomenclatures are listed (Table 1).

Although the predicted molecular mass of the polα catalytic subunit calculated from the mammalian cDNA or yeast gene sequence is 165 kDa, the polypeptide often appears as a 180 kDa protein due to posttranslational modifications, including glycosylation and cell-cycle-dependent phosphorylation. A degraded form with a molecular mass of 160 kDa is also frequently seen. The B-subunit (p70) of human polα as well as the budding yeast Pol12p protein are also phosphorylated in a cell cycle-dependent manner, whereas primase subunits from either human or yeast are not phosphorylated.

The human polα catalytic subunit is localized on the short (p) arm of X chromosome at Xp21.3–22.1 (not on the q-arm as erroneously indicated in other review articles). The budding yeast *POL1* is localized on chromosome XIV and the fission yeast *polα^+* is localized on chromosome 1.

Enzymatic Properties and Catalytic Mechanisms

Optimal Conditions for DNA Polymerase Activity and Mechanisms of DNA Polymerase Action

Optimal assay conditions for DNA polymerase α activity include a pH of 8.0, a DNA primer-template with a gap size of 60–150 nucleotides, four deoxynucleotide triphosphates (dNTPs), and Mg^{2+} as the metal ion activator. Polα is sensitive to inhibitors such as aphidicolin and N-ethylmaleimide, and is highly sensitive to butylphenyl-dGTP and butylphenyl-dATP. In contrast to polβ and polγ, but similar to polδ and polε, polα is not sensitive to dideoxynucleotide triphosphates (ddNTPs).

Under the optimal assay conditions, polα polymerizes DNA with moderate processivity and medium levels of fidelity, interacting first with template and then with primer. The minimum effective length of primer is eight nucleotides; the terminal three to five nucleotides of primer must be complementary to the template. Polα can interact with a primer terminating in either 3′-H or 3′-OH, but not in 3′-PO_4. Following the interaction with template and primer, polα recruits specific dNTPs as dictated by template nucleotide sequence. Hence, polα interacts with its substrates in an ordered sequential mechanism.

DNA Primase Activity and Mechanisms of Primer Synthesis

De novo initiation of primer synthesis requires the formation of a dinucleotide with a purine ribonucleotide triphosphate at the 5′ end by both primase subunits. Once the initial dinucleotide is formed, the catalytic

TABLE 1

Nomenclatures of Polα Subunits in Different Organisms

Coupling subunit	p58	Pri2p	*PRI2*	Spp2	*spp2*$^+$

subunit of primase, p49, is sufficient to extend the ribo-primer. The formation of the initial dinucleotide suggests that the primase complex contains two proximate separate ribonucleotide triphosphate (rNTP)-binding sites. One site specifically binds the purine ribonucleotide triphosphate, while the other site offers the 3′-OH group of the ribonucleotide triphosphate to the second incoming ribonucleotide, located in the RNA polymerase domain of the heterodimeric primase protein complex. Although p49 is the catalytic subunit of primase, the p58 subunit is absolutely required for the p49 subunit to bind the purine ribonucleotide triphosphate to form the initial dinucleotide, and both the rate of extension of the ribo-primer and the binding affinity (K_m) of p49 for ribonucleotides (rNTPs) are influenced by the presence of p58 subunit. Immunoprecipitation analyses of the two primase subunits in cell extracts from both human cells and fission yeast cells indicate that the human p58 and fission yeast Spp2 physically couple the polymerase catalytic subunit p180 with the primase catalytic subunit, p49.

Structure and Function of the Polymerase Catalytic Subunit

DNA polymerases are classified into A, B, C, X, and Y families, based on the similarities of their primary sequences to the three *E. coli* DNA polymerases I, II, and III, and to DNA polymerases from various organisms and DNA viruses. The primary sequences of polα from mammalian cells, budding yeast, and fission yeast cells contain six motifs that are highly conserved among many other prokaryotic, eukaryotic, and viral DNA polymerases. These conserved motifs are designated regions I–VI according to their extent of conservation; region I is the most conserved and region VI is the least conserved. Polymerases containing these six motifs are members of the B-family, or polα-family, of polymerases. Structural analysis of a polα-family member from bacteriophage RB69 (gp43) has revealed that the protein is shaped like a disk with a hole in the center that contains the active site. Similar to the Klenow fragment of *E. coli* Pol1, it also has a "right hand"-like structure composed of palm, finger and thumb domains. A 2.6 Å structural analysis of the ternary complex of RB69 polymerase in the presence of dTTP and duplex DNA primer-template revealed potential functions for many residues that have been confirmed by mutagenesis studies.

Residues Responsible for Interactions with the Metal Ion-dNTP Complex

Analyses of the ternary complex of RB69 polymerase revealed two highly conserved motifs responsible for metal ion-dNTP binding in the polα-family (B-family) polymerases: -YGDTDS- and -DFNSLYPSII-, corresponding to regions I and II, also termed motifs C and A, respectively. These two motifs form a three-stranded anti-parallel β-sheet. The aspartate residue in region II (motif A) and the second aspartate residue in region I (motif C), together with the dTTP tail, coordinate two divalent metal ions for catalysis. Mutagenesis of these residues followed by steady-state kinetic analyses has confirmed that the second aspartate residue in region I (motif C) chelates the metal ion activator-nucleotide complex and is critical for catalysis. Structure analysis also indicates that the phenyl ring of Tyr (-Y-) in region II (motif A) stacks with the ribose ring of the incoming dNTP. This interaction is confirmed by mutagenesis studies in other polα-family polymerases. Furthermore, three positively charged residues in the finger domain: Arg (-R-) and a Lys (-K-) in region VI, interact with the γ-phosphate of dNTP and a Lys (-K-) in region III forms a hydrogen bond with the bridging oxygen between α- and β-phosphates of the dNTP. Comparison of the structures of apo RB69 polymerase and its ternary

complex indicates that binding of the incoming dNTP induces a 60° rotation of the finger domain allowing the three highly positive residues, Arg and Lys in region VI and Lys in region III, to move closer to the active site.

Residues Responsible for Interactions with the Primer-Template DNA

Structural analyses of RB69 polymerase in complex with B-form duplex DNA have revealed that DNA primer-template binds in a groove between the palm domain and the thumb. Because residues involved in these interactions are not conserved among the polα-family (B-family) polymerases, the interactions most likely occur via hydrogen bonding between phosphates of the primer-template strand with the side chains of non-specific aggregates of residues. The polymerase protein or side chains directly form hydrogen bonds linking the primer-strand's phosphates, while a number of charged residues appear to interact with the template. The conserved motif of Lys-Lys-Arg-Tyr- (-KKRY-), unique to the polα-family polymerases, is involved in stabilizing the B-form DNA. The Tyr (-Y-) residue in this motif forms a hydrogen bond with the phosphodiester at the 3′-terminus of the primer, while the Lys (-K-) and Arg (-R-) interact with template phosphate to bring the primer and template strand backbones near one another.

Biological Role in the Cell

Initiation of Chromosome Replication

DNA polα primase has been regarded as the principal DNA polymerase involved in the initiation of chromosomal DNA synthesis. Reconstituted replication of an SV40 origin-containing plasmid by purified replication factors confirms that the polα-primase complex is essential to initiate both the leading and lagging strand DNA synthesis in a coordinated manner. Initiation of cell-free SV40 DNA replication requires the physical interaction of the SV40 viral large T-antigen in the pre-initiation complex with the amino terminal region residues 195–313 of the catalytic subunit of human pol α. After the synthesis of the initiation DNA primer (iDNA) by polα-primase complex, polα-primase complex is replaced by the more processive polδ, which extends the iDNA primer and completes elongation synthesis with the help of replication factor C (RFC) and proliferating cell antigen (PCNA). The human papillomavirus type 11 (HPV-11) origin recognition and initiator protein E1 also interacts with both the polα catalytic subunit (p180) and the B-subunit (p70) and the interactions are critical for the initiation of HPV-11 DNA replication. In addition, species-specific replication of polyomavirus (Py) DNA *in vitro* is dependent on the mouse primase catalytic subunit p48.

Finally, yeast cells harboring a conditional mutation in polα or primase exhibit an initiation defective phenotype when grown under restrictive conditions. Thus, biochemical studies of viral replication and yeast genetic analyses all indicate that the polα-primase complex is the principal cellular DNA polymerase for the initiation of chromosome replication.

DNA Repair and Recombination

Mutations in budding yeast (*S. cerevisiae*) polα (*POL1*) or primase (*PRI2*) compromise completion of double strand break (DSB)-induced gene conversion at the *MAT* locus. Mutation of a glycine residue (Gly^{493}) to glutamate (Glu) in an evolutionarily conserved amino terminal region of budding yeast *POL1* induces a hyper-recombination (*hpr*) phenotype; mutation of this same Gly^{493} residue to arginine (Arg) induces a high mutation rate, plasmid loss, and chromosome loss in budding yeast cells. Finally, mutation in budding yeast *POL12* (B-subunit of yeast) enhances the levels of ribosomal-DNA Holliday junction formation during S phase.

In fission yeast, developmentally programmed cell-type switching requires a strand-specific imprinting event at the mating type locus (*mat1*). This process requires the gene product of $swi7^{+}$, which encodes polα. A mutation in fission yeast *polα* can induce a defect in mating, indicating that polα is essential for mating type switching. Together, these findings indicate that polα is required for DNA repair and recombination processes in both mitotic and meiotic cells.

Mutation Avoidance

Mutations in replication genes can often induce a mutator phenotype characterized by point mutations, single base frameshifts, and deletion or duplication of sequences flanked by short homologous repeats. Mutations in budding yeast polα (*pol1*) have been shown to induce dinucleotide repeat instability, deletion mutations, gross chromosomal alterations, and high frequencies of plasmid and chromosome loss. Among all of the replication mutators analyzed, mutations in the polα catalytic subunit (*pol1* or *polα*) in either budding or fission yeast induce a higher mutation rate in cells than do mutations in primase, polδ, polδ-subunits, and DNA ligase, indicating that polα plays an important role in mutation avoidance and genomic stability of cells.

Checkpoint Activation

Checkpoints are surveillance mechanisms that monitor genomic integrity to signal the cell cycle machinery

monitor genomic integrity, the cell cycle machinery to delay mitosis to allow time for recovery and repair of replication perturbation or DNA damage. Genetic analyses and physiological studies of budding and fission yeasts have shown that checkpoint pathways are directly linked to DNA metabolism. Importantly, the establishment of a DNA replication fork is required for activation of checkpoint response. Since polα and primase are essential for replication fork establishment, their functions are required for checkpoint activation to delay the mitotic entry until completion of DNA replication.

Genetic analyses of the budding yeast *pri1* mutant have suggested that the catalytic subunit of DNA primase (Pri1p) is linked to checkpoint response. In addition, genetic and biochemical studies of fission yeast primase (Spp1 and Spp2) have shown that Spp2 plays an essential role in maintaining the physical stability of polα-primase complex in cells, which has critical impact on the intra-S phase checkpoint kinase Cds1 (the homologue of budding yeast Rad53p and mammalian tumor suppressor Chk2). Fission yeast genetic data also indicate that the initiator DNA (iDNA) synthesized by polα-catalytic activity activates the checkpoint responsible for delaying premature mitotic entry during replication. Biochemical studies of *Xenopus* extracts, however, have shown that synthesis of RNA primer by primase is sufficient to activate the checkpoint.

Initiation defects caused by mutations in polα-primase can induce replication stalling and checkpoint activation. Checkpoint activation caused by mutation in a fission yeast polα has been shown to promote tolerance through induction of mutagenic synthesis by error-prone translesional DNA polymerases κ and ζ. Furthermore, replication perturbation caused by mutations in the fission yeast polα catalytic subunit activates the checkpoint kinase Cds1, which prevents mutagenesis and stabilizes the replication fork. Thus, polα-primase complex plays a direct as well as indirect role in checkpoint processes.

Telomerase Stability and Telomere Length Maintenance

Eukaryotic chromosome ends are capped by telomeres consisting of simple tandem arrays of short G-rich repeats. Because DNA polymerases synthesize DNA in 5′–3′ polarity, the telomeric G-rich strand is synthesized by the leading strand replication machinery and the C-rich strand is synthesized by the lagging strand replication machinery. Removal of the terminal RNA primer leaves a gap of 8–12 nucleotides at the 5′-end of the newly synthesized lagging strand that cannot be synthesized by conventional DNA replication, resulting in a so-called "end replication problem". A special telomere synthesis polymerase, telomerase, containing an integral RNA molecule with a small template domain can add telomeric repeats onto the 3′-end of the telomeric G-strand to resolve the end replication dilemma.

Studies of budding yeast have shown the polα-catalytic subunit physically interacts with the telomere binding protein Cdc13. Mutations in the budding yeast or fission yeast polα catalytic subunit, as well as the fission yeast primase subunits Spp1 and Spp2, result in abnormal telomeric length extension. Moreover, the fission yeast polα catalytic subunit physically associates with the telomerase catalytic subunit (Trt1). A mutation in fission yeast polα that causes abnormal telomere lengthening also compromises both the polα-telomerase association and telomerase protein stability. Ectopic expression of wild type fission yeast polα in this *polα* mutant can restore cellular telomerase protein to normal level and returns the telomere length to near wild type. Hence, the polα-primase complex co-exists with telomerase in the telomeric complex and is important for maintaining both telomere length equilibrium and telomerase protein stability.

Biography

Dr. Teresa S.-F. Wang is a professor in the Department of Pathology at the Stanford University School of Medicine in Stanford, California. Her principal research interests are in enzymatic mechanisms of DNA polymerases and biological responses to mutations of DNA polymerases. She holds a Ph.D. from the University of Texas at Austin, Texas, and received her postdoctoral training at Stanford University.

DNA Polymerase β, Eukaryotic

William A. Beard and Samuel H. Wilson
National Institute of Environmental Health Sciences, Research Triangle Park, North Carolina, USA

DNA polymerase β (pol β) plays a crucial role in the base excision repair pathway that cleanses the genome of apurinic/apyrimidinic (AP) sites. AP sites arise in DNA from spontaneous base loss (depurination) and DNA damage-specific glycosylases that hydrolyze the *N*-glycosidic bond between the deoxyribose and damaged base. Pol β contributes two enzymatic activities, DNA synthesis and lyase, during the repair of AP sites. AP sites represent a potentially dangerous lesion to a cell since they can be mutagenic or cytotoxic.

Introduction

Endogenous and environmental agents continually threaten cellular DNA. These threats can result in physical damage (e.g., DNA strand breaks or base loss) or modification (e.g., alkylation and cross-links). Since these genetic insults lead to an altered DNA structure that can result in deleterious outcomes, cells have evolved DNA repair mechanisms to correct these abnormalities. The base excision repair (BER) pathway is responsible for removing simple base lesions and AP sites in DNA. The repair of an AP site minimally requires four coordinated enzymatic activities: strand incision by AP endonuclease, removal of the resulting deoxyribose phosphate (dRP) backbone of the AP site by a pol β-associated lyase, single-nucleotide DNA synthesis by pol β, and ligation of the DNA nick by DNA ligase. These steps are illustrated in Figure 1.

Pol β is the smallest eukaryotic cellular DNA polymerase (335 residues; 39 kDa) and it lacks a $3' \rightarrow 5'$ proofreading exonuclease activity that enhances the accuracies of replicative DNA polymerases (e.g., DNA polymerase ε and δ). Based on primary sequence alignments, pol β belongs to the X-family of DNA polymerases that also includes pol λ and pol μ.

Biological Role

Based upon the high level of sequence conservation of pol β among mammalian species, it seemed highly likely that pol β is conducting a role that is essential for animal survival. This is consistent with the embryonic lethality of pol β null mice. Pol β preferentially fills short DNA gaps (<6 nucleotides). Because of this attribute, it had generally been assumed that pol β is involved in short-gap DNA repair synthesis. In addition, early studies implicated pol β in gap-filling DNA synthesis during mammalian BER of alkylation damage and the repair of UV DNA damage, and inhibitor studies also implicated pol β in other types of DNA repair, such as the repair of oxidative DNA damage. Although these attributes and studies implicated pol β in BER and in other types of short gap-filling DNA repair, pol β's role in BER was confirmed when mouse cells lacking pol β were found to be hypersensitive to DNA-damaging agents believed to be repaired by the BER pathway.

In addition to the "simple" single-nucleotide BER pathway illustrated in Figure 1, alternate BER pathways are needed to remove modified dRP-moieties that cannot be excised by the pol β lyase activity. In this situation, pol β strand displacement DNA synthesis creates a DNA flap of about four nucleotides with a 5′-modifed dRP group that can be subsequently removed by flap endonuclease-1 (FEN-1), thereby creating a nick that will be sealed by DNA ligase. This alternate pathway is referred to as "long-patch" BER.

Pol β Domain Organization

Controlled proteolytic or chemical cleavage of pol β first demonstrated that it is folded into discrete domains. Subsequently, the X-ray crystal structure of the ternary substrate complex with DNA and an incoming nucleoside triphosphate (dNTP) defined the location of these domains in relation to the tertiary structure of the polymerase. Pol β is organized into two domains: an 8 kDa amino-terminal lyase domain and a 31 kDa carboxyl-terminal polymerase domain (Figure 2).

The structures of DNA polymerases derived from other polymerase families indicate that they also have a modular domain organization. The polymerase domain is typically composed of three functionally distinct subdomains. The catalytic subdomain coordinates two divalent metal cations that promote DNA synthesis. The other two subdomains are spatially situated on opposite

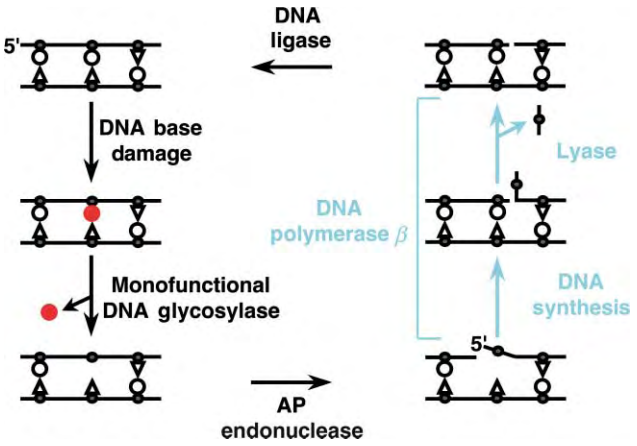

FIGURE 1 Single-nucleotide BER. AP sites are lesions in DNA that originate from spontaneous or enzymatic (glycosylase) removal of a damaged base (red). These sites are removed from DNA by four coordinated enzymatic activities, two of which are contributed by pol β (blue).

sides of the catalytic subdomain. DNA polymerases outside the X-family of polymerases share structural homology within their catalytic subdomains. This has perpetuated a nomenclature based on an architectural analogy to a right hand where the subdomains are referred to as palm, thumb, and fingers. However, the catalytic subdomain of X-family members is not structurally homologous to other DNA polymerases. Application of the "hand analogy" to the polymerase subdomains of pol β is ambiguous. To highlight the intrinsic function of the polymerase subdomains of pol β, a functionally based nomenclature has been proposed. Accordingly, the pol β polymerase domain is composed of the C- (*C*atalytic), D- (*D*uplex DNA binding), and N-subdomains (*N*ascent base pair binding) (Figures 2 and 3). These correspond to the palm, thumb, and fingers subdomains of the right-handed DNA polymerases.

Lyase Domain

The amino-terminal lyase domain (residues 1–90) has an associated lyase, metal-independent, activity that removes the 5′-dRP moiety generated during single-nucleotide BER (Figure 1). This activity plays a pivotal role in BER in that it represents the slowest step in the overall process, and if the lyase reaction is inhibited (e.g., modified dRP-moiety), alternate BER pathways will be initiated. The lyase reaction proceeds by β-elimination through a Schiff base intermediate. A stable covalently bound intermediate can be formed between the dRP-containing DNA substrate and the enzyme by $NaBH_4$ trapping. Lys72 is preferentially modified by primary amine reactive agents in both full-length pol β and the isolated lyase domain. Site-directed mutagenesis of Lys72 diminishes dRP lyase activity nearly 2 orders of magnitude indicating that this residue is the likely nucleophile that forms the Schiff base intermediate. The lyase domain is highly basic (net charge = +10), and the positively charged surface potential predicts that it would interact with the DNA backbone.

In addition to providing a crucial enzymatic activity for single-nucleotide BER, the lyase domain possesses a 5′-phosphate binding site that facilitates targeting of pol β into the 5′-position in a DNA gap. Importantly, pol β binds tightly to the 5′-phosphate only when there is DNA adjacent to the 5′-phosphate. This can be double-stranded or single-stranded DNA since a 3′-primer terminus is not required for optimum binding. Accordingly, pol β is expected to bind to the 5′-phosphate in a DNA gap of any size. The observation that pol β can processively (i.e., insert several nucleotides before dissociating from the DNA substrate) fill short gaps

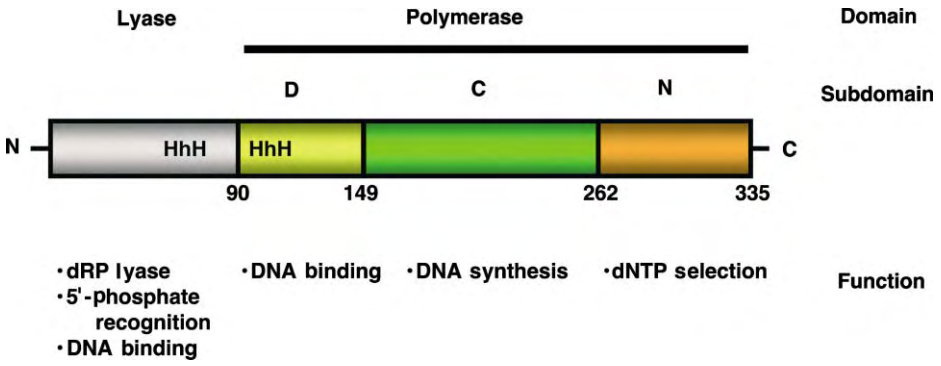

FIGURE 2 Domain and subdomain organization of pol β. Pol β is composed of a polymerase (colored) and an amino-terminal lyase domain (gray). The polymerase domain is composed of three subdomains: D- (yellow), C- (green), and N- (orange) subdomains. These correspond to the thumb, palm, and fingers subdomains of DNA polymerases that utilize an architectural analogy to a right hand, respectively. The lyase domain and the D-subdomain each have a HhH motif that interacts with the DNA backbone of the incised DNA strand downstream and upstream of the gap, respectively.

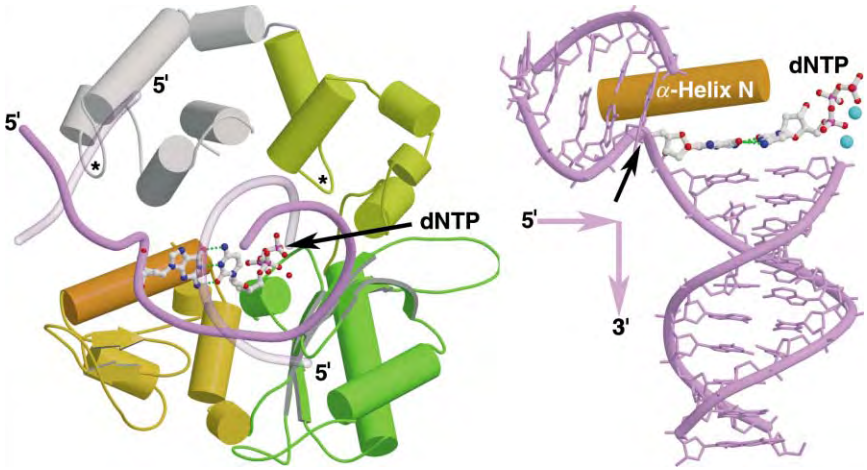

FIGURE 3 Structure of the pol β-substrate complex. Left panel: The domains and subdomains are colored as in Figure 2 and the 5′-ends of the DNA strands forming a one-nucleotide gap are indicated. The trajectory of the template strand (purple) is altered dramatically as it enters the polymerase active site. The complementary DNA strands (primer and downstream oligonucleotides) are semitransparent. Except for the nascent base pair (templating and incoming nucleotides), the sugars/bases of the duplex DNA are not illustrated for clarity. An α-helix of the N-subdomain (dark orange) contributes one face of the binding pocket for the nascent base pair. The hairpins, of the HhH motifs, are highlighted with an asterisk. Right panel: The perspective is from the major groove edge of the nascent base pair and only α-helix N of pol β is shown for clarity. The 5′ → 3′ trajectory of the template strand is indicated and the radical bend in the 5′-phosphodiester bond of the templating base is highlighted (black arrow). The active site metals that coordinate the incoming dNTP and assist catalysis are illustrated as light blue spheres.

(<6 nucleotides) suggests that the lyase domain tethers the polymerase domain to the downstream position in gapped DNA. When the primer terminus (i.e., 3′-OH) is within six nucleotides of the 5′-phosphate on the downstream DNA strand, the polymerase domain will be "within reach" of the primer terminus thereby facilitating processive DNA synthesis.

The lyase domain is composed of five α-helices (Figure 3). Structural characterization of this domain has identified a structural motif that binds monovalent metals and interacts with the DNA backbone. The helix–hairpin–helix (HhH) motif (residues 55–79) has also been identified in other DNA repair proteins as well as many proteins that bind either single- or double-stranded DNA in a nonsequence-specific manner. The crystal structure of pol β bound to a one-nucleotide gap DNA substrate indicates that the lyase domain and the N-subdomain of the polymerase domain interact (Figure 3). The interaction of the lyase domain and the N-subdomain results in a donut-like structure. The interactions between these subdomains are altered upon binding substrates resulting in a tighter complex.

Polymerase Domain

D-Subdomain

As noted above, the polymerase domain is composed of three functionally distinct subdomains. The lyase domain is connected to the D-subdomain (residues 91–149) with a protease-hypersensitive hinge region. The D-subdomain interacts with the DNA sugar-phosphate backbone of the duplex DNA upstream of the polymerase active site. In addition to the HhH motif found in the lyase domain, a second HhH motif (residues 92–118) is also found in the D-subdomain. This HhH motif interacts with the primer strand phosphate backbone through a monovalent metal ion. Thus, the two HhH motifs in pol β are observed to make DNA backbone interactions with each end of the incised DNA strand. In the crystal structure of pol β bound with an incoming nucleotide and a one-nucleotide DNA gap, the DNA is bent ~90° (Figure 3). The DNA template does not travel through the hole in the donut-like structure. The sharp bend occurs at the 5′-phosphodiester bond of the templating base and is also observed in a product complex where pol β is bound to nicked DNA. The 3′-hydroxyl and 5′-phosphate groups on the nicked DNA strand, which need to be ligated in the final step of BER, are observed to be over 27Å apart. For pol β, the function of the HhH motifs is that a sequence nonspecific phosphate-backbone binding motif that stabilizes the pronounced bend observed in the pol β-gapped DNA structure. The 90° bend also exposes the terminal base pairs of each DNA duplex that is situated in the gap. His34 of the lyase domain interacts with the first base pair of the downstream duplex, whereas the N-subdomain contributes interactions with the nascent base pair (see below). The dramatic bend of the template strand as it enters the polymerase active site is a general feature observed in crystal structures of substrate complexes of all DNA polymerases.

C-Subdomain

The C-subdomain (residues 150–262) of pol β includes three acidic residues that coordinate two essential magnesium ions. One magnesium coordinates nonbridging oxygens on the three phosphates of the incoming nucleotide (nucleotide-binding metal), whereas the other coordinates oxygens on the α-phosphate of the incoming dNTP and the DNA primer terminus (catalytic metal). These metals are believed to play critical and conserved roles in catalysis (nucleotidyl transfer) in all DNA polymerases. Although the C-subdomains of X-family members are not homologous to those of other polymerase families, crystal structures of substrate complexes of DNA polymerases from other families indicate that the reactive groups (i.e., metals, incoming nucleotide, and DNA) have a similar three-dimensional arrangement. Likewise, all DNA polymerases also follow an ordered binding of substrates where DNA binds first. The polymerase then selects a nucleoside triphosphate from a pool of structurally similar molecules to preserve Watson–Crick base pairing rules. The ability to choose between "right and wrong" is highly dependent on the identity of the polymerase. Pol β has a moderate ability to select the correct (i.e., right) nucleotide and capacity for DNA synthesis. Since it does not have an intrinsic proofreading activity, it has the potential to be highly mutagenic. The fidelity of pol β is too low (1 error per ~2000 nucleotides synthesized) for pol β DNA synthesis errors to be tolerated during DNA repair. It is generally believed that the proofreading activity of AP endonuclease, or some other extrinsic $3' \rightarrow 5'$-exonuclease, may proofread base substitution errors generated by pol β.

N-Subdomain

The N-subdomain (residues 263–335) contributes important interactions to the binding pocket of the nascent base pair (templating and incoming nucleotides). Comparison of DNA polymerase structures bound to DNA with those that include an incoming complementary dNTP reveals that the N-subdomain repositions itself to "sandwich" the nascent base pair between the growing DNA terminus and the polymerase. In the absence of an incoming nucleotide, the N-subdomain is "open," but forms a "closed" complex upon binding a correct nucleotide. Thus, the dNTP-binding pocket is formed by the template base, DNA duplex terminus, and enzyme. For pol β, subdomain interactions with the nascent base pair are contributed primarily through α-helix N (Figure 3). These include stacking interactions with Lys280 and Asp276 with the templating and incoming nucleotide bases, respectively. Additionally, Asn279 and Arg283 contribute DNA minor groove interactions. Alanine substitution for Arg283 results in a dramatic decrease in fidelity. Since Arg283 plays a critical role in the formation of the closed complex, the low-fidelity mutant (i.e., R283A) is believed to be in an open conformation thereby losing the ability to promote efficient DNA synthesis when a correct nucleotide binds. Thus, the ability to choose the correct nucleotide has been lost. As noted above, the trajectory of the duplex DNA into the polymerase active site requires that the templating strand bend by 90° (Figure 3). This bend in the template strand serves at least two functions: (1) it provides access for the N-subdomain to check whether geometrical constraints imposed by correct Watson–Crick hydrogen bonding occurs; (2) it discourages the next templating base from entering the polymerase active site prematurely which could result in the incorrect template base coding for nucleotide insertion (deletion mutagenesis).

Pol β–BER–Protein Interactions

In addition to its catalytic function, pol β also interacts with several proteins known to be involved in BER. These interactions may facilitate the coordination of the necessary enzymatic steps required in alternate BER pathways. In this context, the observations that pol β interacts with other DNA repair proteins such as AP endonuclease, DNA ligase I, X-ray cross-complementing factor-1 (XRCC1), poly(ADP-ribose) polymerase-1 (PARP-1), and proliferating cell nuclear antigen (PCNA), among others, suggest complex regulatory mechanisms that are not fully understood. Thus, pol β interacts with the enzymes involved in the steps immediately upstream and downstream of its own steps in single-nucleotide BER. Importantly, formation of binary or ternary protein complexes, rather than a "super" BER complex, has the advantage of flexibility that can accommodate alternate pathways. The influence of these protein–protein interactions on catalytic function and processing of BER intermediates remains to be determined.

Glossary

AP site DNA lesion resulting from the loss of a base (i.e., abasic site). These sites can be mutagenic since they have lost their coding potential, or cytotoxic since they are quickly incised resulting in DNA strand breaks.

DNA polymerase β A small eukaryotic DNA polymerase involved in short gapped DNA repair synthesis. In addition to its polymerase activity, this polymerase contributes an accessory lyase activity required to remove the backbone of an AP site (i.e., deoxyribose) during BER.

HhH The helix–hairpin–helix structural motif binds single- or double-stranded DNA in a nonsequence-specific manner and has been identified in a number of DNA repair proteins. Two such motifs in pol β are observed to make DNA backbone interactions with the incised DNA strand downstream and upstream of the gap suggesting that they stabilize the pronounced DNA bend observed when gapped DNA binds to pol β.

lyase In the context of single-nucleotide BER, this reaction results in the removal of the 5′-deoxyribose phosphate backbone after incision of an AP site by an endonuclease. The reaction proceeds by β-elimination through a Schiff base intermediate. The ε-NH_2 group of a lysine side chain (Lys72 of pol β) serves as a nucleophile, resulting in transient covalent attachment of the enzyme to its substrate. This Schiff base intermediate can be trapped by sodium borohydride, resulting in conversion to an irreversibly linked lyase–DNA complex.

N-subdomain One of three subdomains found in all DNA polymerases. This subdomain forms one face of the nascent base pair (templating and incoming nucleotide bases) binding pocket and it is involved in selecting the correct dNTP. It is also referred to as the fingers or thumb subdomain in the polymerase nomenclature that utilizes the analogy to a right or left hand, respectively.

Biography

Samuel H. Wilson is Head of the DNA Repair and Nucleic Acid Enzymology Section in the Laboratory of Structural Biology at NIEHS/NIH in Research Triangle Park, NC. Prior to this, Dr. Wilson was the founding Director of the Sealy Center for Molecular Science at the University of Texas Medical Branch-Galveston.

William A. Beard holds a Ph.D. from Purdue University and did postdoctoral training at St. Jude Children's Research Hospital, Memphis. He joined Dr. Wilson's group in 1990 and is currently a Staff Scientist in the Laboratory of Structural Biology at NIEHS/NIH.

Their common research interests are to understand basic mechanisms of biological catalysis and substrate recognition through a combination of site-directed mutagenesis, kinetic analysis, molecular modeling and structure determination. They have effectively applied these approaches to derive a molecular and biological description of DNA polymerase β function.

DNA Polymerase δ, Eukaryotic

Antero G. So and Kathleen M. Downey
University of Miami, Miami, Florida, USA

DNA polymerase δ (pol δ) is an essential DNA polymerase that is required for DNA replication and participates in several DNA repair pathways. It is a proofreading DNA polymerase; that is, it is capable not only of catalyzing template-directed nucleotide incorporation, but also of editing errors of incorporation by virtue of a 3′ to 5′ exonuclease activity. Pol δ is highly conserved and has been identified in multiple eukaryotic species from yeast to humans.

Structure

Pol δ comprises a core enzyme and one or more loosely associated subunits.

The Core Enzyme

The pol δ core enzyme is a heterodimer comprising a catalytic subunit of approximately 125 kDa and a small subunit of approximately 50 kDa. The catalytic subunit contains the active sites for both the DNA polymerase and 3′ to 5′ exonuclease activities, as well as a putative nuclear localization signal. The small subunit is not associated with any catalytic activity, but it is required for the interaction of the core enzyme with more loosely associated subunits and accessory proteins.

Cloning and sequencing of the cDNAs for the catalytic and small subunits of pol δ from various species demonstrated that pol δ is the most highly conserved among the eukaryotic DNA polymerases, with sequence identity of 94% between both subunits of the human and bovine enzymes and 44% identity between the subunits of the human and budding yeast enzymes. The human gene for the catalytic subunit of pol δ has been mapped to chromosome 19q13.3 and that for the small subunit has been located on chromosome 7.

Pol δ belongs to the class B, or α-like, DNA polymerases, which are found in both prokaryotes and eukaryotes. The class B polymerases include pol α, pol δ, pol ε, the herpes virus family of DNA polymerases, and the T4 and RB69 bacteriophage DNA polymerases. These enzymes contain six highly conserved domains and, in addition, pol δ also contains three highly conserved regions (ExoI, ExoII, and ExoIII), which are responsible for the 3′ to 5′ proofreading exonuclease activity and are found in all exonuclease-containing DNA polymerases.

Pol δ is very sensitive to inhibition by aphidicolin, N-ethylmaleimide, and carbonylphosphonate; moderately sensitive to butylphenyl-dGTP and butylphenyl-dATP; and resistant to dideoxynucleotides.

Other Subunits

The third subunit of pol δ is a polypeptide of 42–66 kDa that has been found in both mammalian and yeast enzyme preparations. It interacts with both the small subunit of the enzyme and the processivity factor for pol δ, the proliferating cell nuclear antigen (PCNA). The fourth subunit of pol δ, which has been identified only in fission yeast and mammalian cells thus far, is a polypeptide of approximately 12 kDa, whose function has not yet been elucidated.

Several other proteins have been identified as interacting specifically with the small subunit of pol δ. In addition to the third subunit, these proteins include the Werner's syndrome protein (WRN) and pol δ interacting protein 1 (PDIP1). All of these proteins have been shown to physically and functionally interact with the small subunit of pol δ as well as with its processivity factor PCNA.

Processivity Factor

Core pol δ is essentially a distributive DNA polymerase that is capable of synthesizing only short stretches of DNA (10–20 nt) before dissociating from the template. However, when bound to its processivity factor PCNA, pol δ becomes a highly processive enzyme, capable of synthesizing stretches of DNA containing up to 5×10^4 nucleotides before being released from the template. PCNA is a homotrimer that has a subunit size of approximately 29 kDa and forms a ring with an internal diameter capable of accommodating double-stranded DNA. PCNA, which has been called a sliding clamp, is

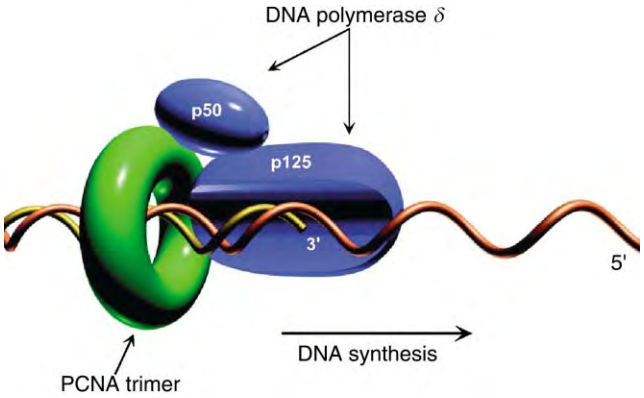

FIGURE 1 Schematic model of the pol δ-PCNA–DNA complex during DNA replication. Reprinted from Mozzherin, D. J., Tan, C.-K., Downey, K. M., and Fisher, P. A. (1999) Architecture of the active DNA polymerase d–proliferating cell nuclear antigen–template primer complex. *J. Biol. Chem.* **274**, 19862–19867 with permission from the American Society for Biochemistry and Molecular Biology.

loaded onto DNA by a clamp loader, replication factor C (RFC), in a reaction that requires ATP hydrolysis. PCNA binds to pol δ and, by virtue of being topologically linked to the DNA template primer, causes pol δ to become highly processive (see Figure 1).

Functional studies with recombinant p125 from human, mouse, and fission yeast have shown that DNA synthesis catalyzed by p125 alone is not stimulated by PCNA, whereas the activity and processivity of the recombinant human p125/p50 heterodimer is fully stimulated by PCNA to the same extent as the native two-subunit enzyme isolated from calf thymus tissue, suggesting that p50 is required for the functional interaction of PCNA with pol δ.

Functions of Pol δ

DNA Replication

There is strong evidence from studies in both higher and lower eukaryotes that pol δ plays an essential role in DNA replication. The development of an *in vitro* simian virus 40 (SV40) DNA replication system led to the identification of both pol δ and PCNA as mammalian replication proteins. Furthermore, studies in both fission and budding yeast have shown that the catalytic and small subunits of pol δ are the products of essential genes, and the phenotypes of mutants that are temperature-sensitive in these genes are consistent with a role for pol δ in replication. However, the precise role of pol δ at the replication fork is still unclear. Although it is clear that pol δ is capable of catalyzing the synthesis of the leading strand as well as elongation of the lagging-strand Okazaki fragments, after priming of these strands by the action of pol α-primase, whether either of these functions is exclusively attributable to pol δ *in vivo* and whether pol ε can carry out these functions have not yet been resolved.

DNA Repair

Although there are highly specialized DNA polymerases that are involved in the repair of specific lesions in DNA, the replicative polymerases pol δ and pol ε appear to carry out the bulk of DNA synthesis involved in filling in the gaps generated during the repair of DNA damaged by ultraviolet (UV) irradiation or the chemical alteration of bases (i.e., nucleotide excision repair and base excision repair). Genetic studies in yeast and biochemical studies in mammalian cells have also demonstrated a role for pol δ in postreplication mismatch repair.

Biography

Antero G. So is a Professor in the Departments of Medicine and of Biochemistry and Molecular Biology at the University of Miami. His principal interest is in the field of mammalian DNA replication, with major emphasis on mammalian DNA polymerases. He holds an M.D. from the University of Santo Tomas and a Ph.D. from the University of Washington; he did his postdoctoral training at Case Western University and the University of Geneva.

Kathleen M. Downey is a Professor in the Departments of Medicine and of Biochemistry at the University of Miami. Her principal interest is in mammalian DNA replication and repair. She holds a Ph.D. from the University of Washington in Seattle, Washington and received her postdoctoral training at the Swiss Federal Institute of Technology in Zurich, Switzerland.

DNA Polymerase ε, Eukaryotic

Yasuo Kawasaki and Akio Sugino
Osaka University, Suita, Osaka, Japan

DNA polymerase ε is one of the least understood cellular DNA polymerases. Recent studies have revealed that it plays a central role in chromosomal DNA replication. DNA polymerase ε activity was reported in the extract from rabbit bone marrow cells in 1985. Although DNA polymerase ε was purified from calf thymus and human cells in the late 1980s, it was described initially as a "large form" of DNA polymerase δ or PCNA-independent DNA polymerase δ whose activity is not affected by proliferating cell nuclear antigen (PCNA). This DNA polymerase is a high-molecular-weight, aphidicolin-sensitive enzyme that copurifies with a tightly associated 3′–5′ exonuclease. In addition, it is highly processive in the absence of polymerase-loading factor, PCNA. In budding yeast *Saccharomyces cerevisiae*, DNA polymerase activity called DNA polymerase II was already known in the 1970s. The complete enzyme complex was purified in 1990 and it turned out to be the yeast homologue of DNA polymerase ε. It was in 1990 that the nomenclature of "DNA polymerase ε" was established. Since then, molecular structure and biological function have been extensively studied especially in budding yeast.

Molecular Structure

DNA polymerase ε (Pol ε) is purified from yeast as a four-subunit holoenzyme. It consists of four subunits, Pol2p, Dpb2p, Dpb3p, and Dpb4p in budding yeast and p261, p59, p12, and p17 in human. The genes encoding all four subunits of yeast and human enzyme have been cloned and sequenced. The genes for the largest and the second largest subunit, *POL2* and *DPB2* respectively, were shown to be essential for budding yeast cell growth, while *DPB3* and *DPB4* are not essential.

Catalytic Subunit

The largest subunit of budding yeast Pol ε is encoded by *POL2* gene and the molecular mass is 256 kDa. Its human counterpart, encoded by *POLE*, is 261 kDa. Homologues in other eukaryotes were also found including that in fission yeast *Schizosaccharomyces pombe*, encoded by *cdc20*$^+$ gene. The catalytic domain has the consensus amino acid sequences common to B family DNA polymerases (Figure 1). Eukaryotic DNA polymerases α, δ, ε, and ζ, *Escherichia coli* DNA polymerase II, and several viral DNA polymerases (T4 phage, HSV, and EBV) belong to B family. Unlike the other catalytic subunits of eukaryotic B family DNA polymerases, Pol2p has a long stretch at carboxyl-terminal half that is not related to the catalytic activity (Figure 1). There are two putative zinc-finger motifs at the carboxyl terminus, which is required for complex formation with the other three subunits. Overlapping partly with the catalytic domain, it has 3′–5′ exonuclease activity, which is responsible for editing during DNA biosynthesis. These molecular structures are conserved in all eukaryotes.

Other Subunits

The second largest subunit of Pol ε is encoded by the budding yeast *DPB2* gene, which is essential for viability, and by *POLE2* in humans. The molecular mass is 80 kDa in yeast and 59 kDa in humans, and they share 26% amino acid sequence identity. The function of this subunit is not known yet.

Budding yeast 34 kDa subunit of Pol ε is encoded by *DPB3* gene and the 29 kDa subunit is encoded by *DPB4* gene. These genes are not essential for growth since deletion mutants are viable. However, the DNA polymerase activity from either *DPB3* or *DPB4* deletion strain is less than that from wild-type cells, presumably because the complex formation is unstable. p17 and p12 correspond to the human homologues of Dpb4p and Dpb3p. They interact physically with p261 and p59, although a four-subunit human holoenzyme has not yet been isolated. These two subunits have a so-called histone-fold motif that is found in many transcription factors and is utilized for interaction with DNA. However, the significance of these motifs with respect to biological function of Pol ε is not yet known.

Biochemical Character

The biochemical properties of Pol ε are very similar to those of DNA polymerase δ; its activity is sensitive to aphidicolin, resistant to deoxyribonucleotide analogue

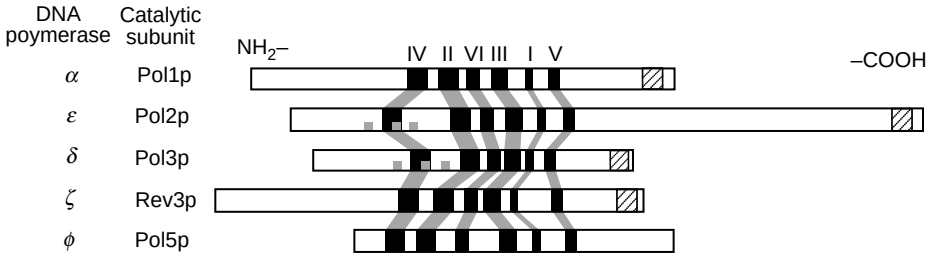

FIGURE 1 Eukaryotic B family DNA polymerases. DNA polymerases that possess B family catalytic domain are aligned. Closed boxes (I–V) represent the subdomains conserved among B family DNA polymerases. Gray boxes represent the exonuclease domains. Shaded boxes represent cysteine-rich domain which can form Zinc-fingers.

ddTTP, and characterized by high fidelity. Pol ε is distinguished from DNA polymerase δ by its high processivity in the absence of the cofactors PCNA, RFC, and RPA. However, under some conditions, it complexes with and is stimulated by PCNA, although the physiological significance of this interaction is unknown. During purification of Pol ε from yeast or mammalian cells, a small form of Pol2p ("145-kDa form" in yeast) has been identified in addition to the holoenzyme (Figure 2). Purified 145-kDa form, which lacks the carboxyl-terminal half, does not associate with the other three subunits. Both 145-kDa form and holoenzyme are highly processive and have an intrinsic proofreading $3'-5'$ exonuclease activity.

Role in DNA Replication

Role at Replication Fork

The SV40 DNA replication system, which serves as a model for eukaryotic DNA replication, has been successfully reconstituted *in vitro* with SV40 large T-antigen and mammalian proteins. Analysis of this system, which includes DNA polymerases α and δ, led to the conclusion that DNA polymerase α and δ are sufficient for synthesis of both leading and lagging strands in eukaryotes. These studies showed that DNA polymerase α, which is associated with primase activity, is required for initiation of new DNA chains. Only DNA polymerase δ was required to replicate both leading and lagging strands, leaving a replication role for Pol ε in doubt. However, several lines of evidence indicate the presence of Pol ε at the eukaryotic replication fork. Evidence for a physical interaction came from cross-linking experiments, which showed that Pol2p is located at or near the replication fork. Furthermore, the mutation rate is increased about tenfold in a yeast strain carrying a *pol2* mutation that inactivates the Pol ε proofreading capability (mutation in $3'-5'$ exonuclease domain) suggesting that this enzyme contributes to the synthesis of newly replicated DNA. A yeast double mutant lacking proofreading

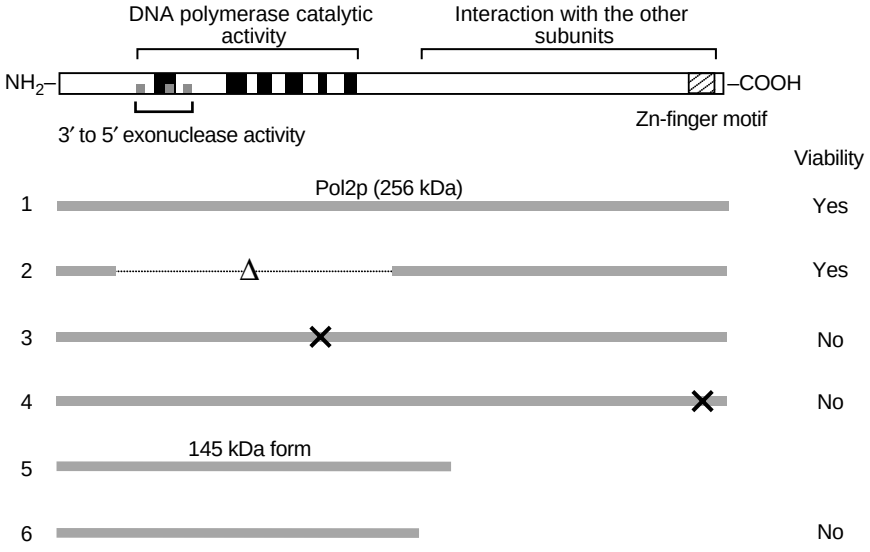

FIGURE 2 Domain structure of the yeast Pol2p subunit. Closed, gray, and shaded boxed are as described in Figure 1. Mutated or truncated versions of Pol2p are schematically shown and the viability of yeast cells which express each mutant Pol2p are indicated. 1, full-length Pol2p; 2, complete deletion of catalytic domain; 3, missence mutation in domain I; 4, missence mutation in zinc-finger motif; 5, endogenous 145 kDa form; 6, deletion of carboxyl terminus.

capability of both Pol2p and Pol3p cannot survive, presumably because the mutations accumulate to a lethal level. In addition, it has also been shown that loss of the exonuclease activity in either Pol2p or Pol3p alters the mutation spectra in a strand-specific manner. It has also been shown that DNA replication activity was drastically lost in *Xenopus* egg extracts when Pol ε was removed immunologically from the egg extract. Several conditionally lethal mutants of *POL2* have been isolated and characterized in budding yeast. Chromosomal DNA synthesis in these mutant cells ceases under the restrictive condition, indicating that Pol ε is required for normal chromosomal DNA replication. Consistent with this conclusion, the terminal morphology of mutant cells is the same as those of other DNA replication mutants in budding yeast, namely a dumbbell shape with a single nucleus localized between mother and daughter cells. Furthermore, a temperature-sensitive mutant of the *DPB2* gene also results in temperature-sensitive chromosomal DNA replication. Pol ε also exhibits the highest processivity among replicative DNA polymerases, suggesting that Pol ε synthesizes the leading strand, while the lagging strand is synthesized by DNA polymerase α and δ in a discontinuous manner.

Distinct Roles and Domain Structure

Yeast cells carrying a point mutation in the conserved catalytic domain of Pol2p are not viable. By contrast yeast mutant cells that have an internal deletion of *POL2*, resulting in loss of the DNA polymerase catalytic domain and the 3′–5′ exonuclease domain, can survive (Figure 2). However, this strain is temperature sensitive for cell growth, exhibits slow growth phenotype even at permissive temperature, and the elongation of DNA strands in the mutant cells is slow. This apparent discrepancy can be explained by considering the discrete functional domains of Pol ε. Although Pol ε may normally be present at the replication fork, in the complete absence of the catalytic domain, another DNA polymerase, presumably DNA polymerase δ, can substitute. On the other hand, the carboxyl terminus that is dispensable for the processive DNA synthesis *in vitro* is essential for growth (Figure 2). The *in vivo* requirement of carboxyl terminus may involve function in the initiation of DNA replication via interaction with the other subunits.

Role in DNA Repair

Apart from DNA replication, Pol ε participates in DNA repair and recombination. It was first suggested in human cells that Pol ε, is involved in DNA repair processes initiated by UV-damage. Human DNA polymerase ε and/or δ are required in the repair DNA synthesis step of nucleotide excision repair *in vitro*. It was also shown that the recombinational repair pathway, which repairs double strand breaks, requires both DNA polymerase δ and ε. *In vitro* studies have shown that crude extracts of temperature-sensitive *pol2* mutant cells have reduced activity in nucleotide excision repair and base excision repair. However, the suggestion that Pol ε functions in DNA repair has been questioned based on the observation that several mutant *pol2* alleles that have temperature-sensitive Pol ε activity *in vitro* do not show any significant sensitivity to DNA-damaging reagents. Since most of the evidence that Pol ε participates in DNA repair and recombination derives from *in vitro* experiments, further studies are required to confirm that this is also the case *in vivo*.

Role in Checkpoint Control

In order to prevent premature mitosis before the whole genome is completely duplicated, the S phase checkpoint is activated when S phase progression is inhibited, for example, by DNA damage. This process involves a protein phosphorylation signal cascade, slowing down of DNA synthesis, and induced transcription of certain genes. Several mutations that cannot induce checkpoint-dependent transcription after DNA damage have been isolated and characterized in budding yeast. One of these mutations is located in the carboxyl-terminal region of the *POL2* gene, suggesting that Pol ε may act as a DNA-damage "sensor" that triggers expression of checkpoint and repair genes. Additional evidence for this view is provided by the observation that Pol ε binds to a factor which participates in S phase checkpoint control under certain conditions.

Glossary

B family DNA polymerase DNA polymerases in bacteria, archaea, and eukarya are classified into six groups (A, B, C, D, X, and Y) based on their amino acid sequences.

exonuclease activity An activity which digests single-stranded DNA from an end. The direction of exonuclease activity is specific: 5′–3′ or 3′–5′.

replication fork During DNA replication, the template strands of the duplex DNA separate to form a replication fork. Leading strand is continuously synthesized and lagging strand is synthesized discontinuously.

zinc-finger motif Amino acid sequences that bind zinc, composed with two repeats of two closely spaced cysteine or histidine. It mediates protein–protein interaction or protein–DNA interaction.

DNA Polymerase I, Bacterial

Catherine M. Joyce
Yale University, New Haven, Connecticut, USA

DNA polymerase I is the most abundant DNA polymerase in eubacteria. Although it lacks the speed and processivity of the more complex polymerases which replicate the bacterial chromosome, it is ideally suited for the synthesis of short stretches of DNA in excision repair and in the removal of RNA primers during lagging strand replication. DNA polymerase I (pol I) of *Escherichia coli*, the first DNA polymerase to be discovered and studied, has long served as the prototype for this class of enzymes. Other homologues that have been extensively studied are the thermostable DNA polymerase I from *Thermus aquaticus* (*Taq* DNA pol) and the DNA polymerase of bacteriophage T7.

Overview of Structure

Pol I enzymes are multifunctional and follow the pattern seen throughout the polymerase superfamily: a modular structure with a common polymerase domain (described below) and auxiliary enzyme activities located on separate protein domains. All bacterial pol Is have an N-terminal domain with 5′ nuclease activity; this activity is responsible for the removal of DNA ahead of the growing primer strand. Attachment of the 5′ nuclease domain to the rest of the polymerase is protease sensitive; in *E. coli* pol I mild protease digestion was originally used to remove the 5′ nuclease (35 kDa) from the remainder of the molecule (called Klenow fragment, 68 kDa); nowadays this is accomplished by recombinant DNA manipulations. The linkage between the 5′ nuclease and Klenow fragment is almost certainly flexible, as shown by the observation that the 5′ nuclease does not occupy the same position relative to the rest of the molecule in different crystal forms of *Taq* DNA pol. The pol I homologues found in bacteriophage genomes resemble the Klenow fragment portion of the bacterial pol Is, in that they lack the 5′ nuclease portion of the sequence. In some cases, such as bacteriophage T7, the 5′ nuclease is encoded as a separate gene product.

The Klenow fragment portion of pol I also contains two domains. In about half of the bacterial pol Is, the N terminal of the two domains contains a 3′–5′ exonuclease (3′ exo) activity which serves as a proofreader to eliminate polymerase errors. If the polymerase were to insert an incorrect nucleotide, resulting in a terminal mispair, the 3′–5′ nuclease would remove the incorrect primer-terminal nucleotide and provide a second opportunity for correct insertion. The bacterial pol I enzymes that lack 3′–5′ exonuclease activity (from species including *Thermus*, *Bacillus*, and *Rickettsiae*) nevertheless contain the domain, though key active site side chains are absent. Aside from the thermophiles, where fraying of double-stranded DNA termini at high temperatures might encourage excessive nuclease degradation, it is unclear why certain bacterial pol I enzymes have proofreading activity and others do not.

Polymerase

Domain Structure and Relation to Other Polymerases

When the structure of Klenow fragment (the first polymerase to be studied crystallographically) was reported in 1985, the polymerase domain structure was described as resembling a half-open right hand, with subdomains called “fingers,” “palm,” and “thumb” forming a cleft. Currently, structures are available for more than 30 polymerases, encompassing all four biochemical categories of polymerase (DNA or RNA dependent, with DNA or RNA as product), and it is clear that the domain structure originally observed in Klenow fragment is a common theme (Figure 1). The palm subdomain is the most highly conserved across polymerase families; it contains a conserved structural motif (the “polymerase fold”) consisting of a three-stranded antiparallel β-sheet supported by two α-helices. This serves as the scaffold for important active site residues, in particular a pair of carboxylate ligands to the two divalent metal ions that catalyze the phosphoryl transfer reaction. The fingers and thumb subdomains are structurally much more divergent, but carry out analogous functions in all polymerases – the fingers providing important active site residues, particularly those involved in nucleotide binding, and the thumb binding the primer-template duplex.

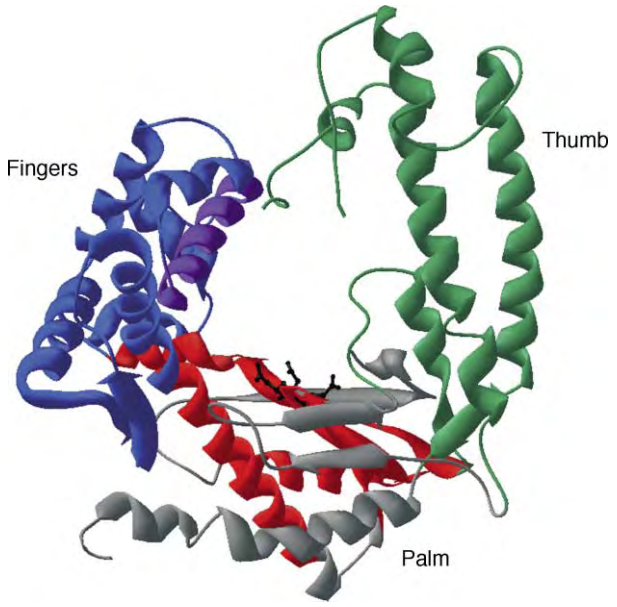

FIGURE 1 Three-dimensional structure of the polymerase domain of *E. coli* DNA polymerase I (from the work of T. A. Steitz and colleagues). The thumb and fingers subdomains are colored green and blue, respectively, with the O-helix on the fingers subdomain in purple. The palm subdomain is gray, except for the "polymerase fold," a conserved structural motif found in the majority of nucleic acid polymerases, which is shown in red. Three conserved carboxylate side chains, two of which are ligands to the catalytic metal ions, mark the location of the polymerase active site.

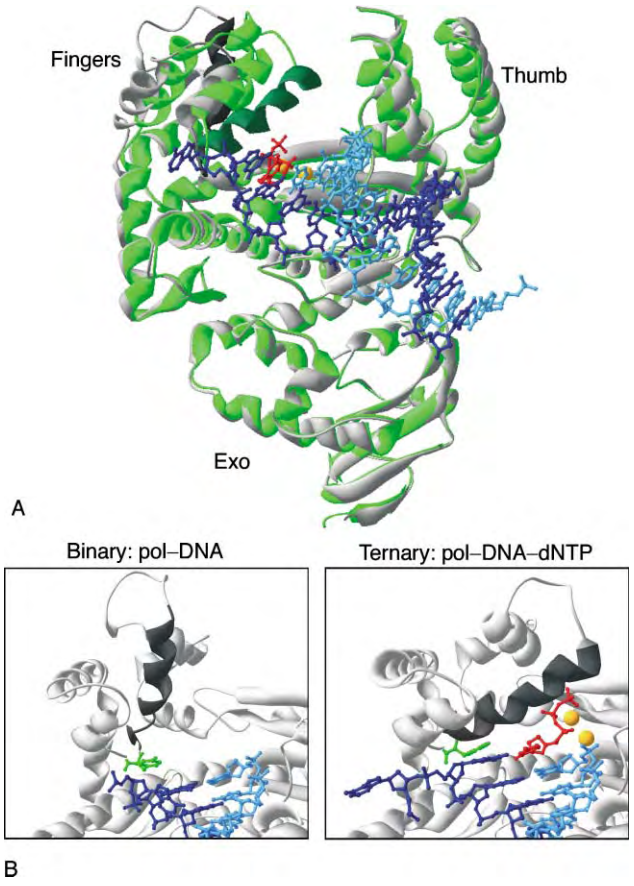

FIGURE 2 (A) Superposition of binary (pol–DNA) and ternary (pol–DNA–dNTP) complexes of Klentaq, the Klenow fragment portion of *Taq* DNA pol (from the work of G. Waksman and colleagues). The DNA template (dark blue) and primer (cyan), incoming nucleotide (red) and active-site metal ions (gold) are shown in their positions in the ternary complex. The protein backbone in the binary complex is gray, and in the ternary complex green. The two protein structures are essentially superimposable except within the fingers subdomain, where the largest movement involves the O-helix (shown in darker shades of gray and green, respectively). The domain marked "Exo" corresponds to the 3′–5′ exonuclease domain in Klenow fragment, though it has no enzymatic activity in Klentaq. (B) Detailed comparison of the active site regions in the two complexes. In each case the protein is shown in gray, with the O-helix in a darker shade. Coloring of the DNA, nucleotide, and metal ions is the same as in the top panel. The structures are oriented so that the palm subdomain and the DNA are in similar positions in both panels, emphasizing the movement of the O-helix. The side chain of the conserved Tyr at the C-terminus of the O-helix (Tyr671 in Klentaq, Tyr 766 in Klenow fragment) is shown in green. This side chain is stacked with the template side of the terminal base pair in the binary complex; in the ternary complex it has moved out of the way to allow the next template base to enter the active site (note that this template base is folded back over the template strand in the binary complex). For clarity, the top of the thumb subdomain is omitted in all the structures illustrated in this figure.

Substrate Binding

The binding of substrates at the polymerase active site has been revealed in cocrystals of several pol I homologues. The template-primer duplex (corresponding to the product of DNA synthesis) is bound in a shallow cleft between the thumb and 3′ exo domains, with the largely α-helical thumb providing important binding contacts to the phosphate backbone. In a polymerase–DNA binary complex, the primer terminal base pair abuts the side of the polymerase cleft formed by the fingers subdomain. This wall, which defines one side of the active site, is formed primarily by a long α-helix (the O-helix, shown in purple in Figure 1) which runs the length of the fingers subdomain and has a group of important and highly conserved side chains on the surface pointing into the cleft. At the C terminus of the O-helix is an invariant Tyr side chain which is stacked against the template side of the terminal base pair.

When the dNTP complementary to the templating position is added so as to form a polymerase–DNA–dNTP ternary complex, cocrystal structures indicate that the polymerase must have undergone a conformational change (Figure 2). The novel conformation seen in ternary complex structures differs from the apoenzyme and binary complex structures by a substantial movement of the fingers subdomain so as to close the polymerase cleft. In conjunction with the transition from the open (binary complex) to closed (ternary complex) conformation, the Tyr side chain at the C-terminus of the O-helix moves further down into

the active site, away from its stacked position with the terminal base pair. This allows the templating base to stack with its 3′ neighbor at the duplex terminus, and to base pair with the incoming dNTP in a snug binding pocket formed by side chains of the O-helix and nearby residues on one side and the primer-terminal base pair on the other side. Analogous conformational transitions have been inferred from crystal structures of a diverse variety of polymerases, suggesting that the formation of a closed ternary complex may be a common feature of the polymerase reaction pathway.

DNA Polymerase Reaction Mechanism

Extensive work by Benkovic and co-workers has defined the polymerase reaction pathway of Klenow fragment. There is an obligatory order of substrate binding – DNA before dNTP – as would be expected, given that templating information is required for nucleotide selection. As mentioned above, the chemical step of dNTP addition is catalyzed by two divalent metal ions coordinated at the active site (Figure 3). One metal ion facilitates deprotonation of the primer 3′-OH, making it a better nucleophile, while the other stabilizes the pyrophosphate leaving group. Both metals also stabilize the developing negative charge on the α-phosphate in the transition state. This two-metal-catalyzed reaction mechanism is beautifully illustrated in the ternary complex cocrystal structures, and is widespread in phosphoryl transfer reactions, including the 3′–5′ exonuclease reaction (discussed below). The work of Benkovic and co-workers indicates that the phosphoryl transfer step of Klenow fragment is rapid, but is preceded and followed by slow noncovalent steps. These steps must correspond to some kind of conformational transition and it is tempting to equate the step preceding phosphoryl transfer with formation of the closed complex inferred from the crystal structures. However, it is important to realize that there is currently no experimental evidence in support of this idea.

DNA Polymerase Reaction Specificity

Base Pairing

DNA polymerases function with extraordinary specificity, selecting the complementary dNTP and rejecting incorrect choices in the majority of cases. Klenow fragment makes approximately one error for every 10^5 nucleotides synthesized, about 1000-fold more accurate than would be predicted solely from the energetics of base pairing. Three major mechanisms have been proposed to account for the way in which the polymerase enhances the accuracy of DNA synthesis.

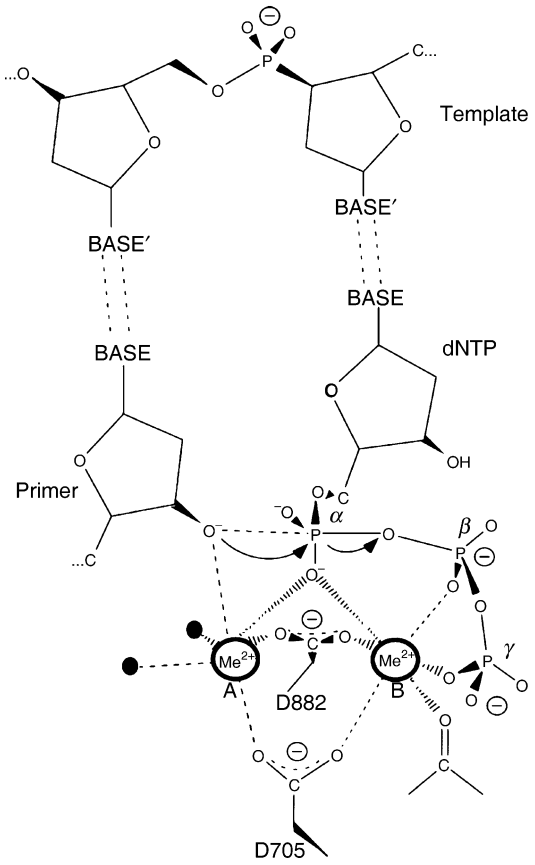

FIGURE 3 Mechanism of phosphoryl transfer, resulting in nucleotide addition, at the polymerase active site. Catalysis is mediated by two divalent metal ions, coordinated, in Klenow fragment, by Asp705 and Asp882. Metal ion A activates the primer 3′-OH for nucleophilic attack on the α-phosphate of the dNTP. Metal ion B stabilizes the negative charge that develops on the pyrophosphate leaving group. Both metal ions also assist the reaction by stabilizing the negative charge on the α-phosphate in the pentacovalent transition state. Adapted from Brautigam and Steitz (1998).

The first is exclusion of water from the active site which should amplify the energetic differences between correct and incorrect base pairings. The second is geometric selection in the binding pocket for the nascent base pair such that there is good steric complementarity to the rather symmetrical shape of a Watson–Crick base pair, but exclusion of mispairs. This model is consistent with the very snug fit seen in the binding pocket of polymerase ternary complex structures. Moreover, several polymerases, including Klenow fragment, have been shown to incorporate template-primer pairings that mimic the shape of a Watson–Crick base pair but lack any hydrogen bonds. These first two specificity mechanisms are proposed to operate at the level of nucleotide addition, and should weaken the binding or slow the incorporation of an incorrectly paired incoming nucleotide. The third selection method would operate after nucleotide addition and relies on hydrogen-bonding interactions between the polymerase and

the minor groove at or close to the primer terminus. The hydrogen-bond acceptors on N3 of purines and O2 of pyrimidines occupy similar positions in all Watson–Crick base pairs but are mispositioned in incorrect pairings, thus providing a mechanism for scanning the minor groove to ensure that template information has been correctly read. A mispair located at the primer terminus will fail to make the minor groove interactions that are seen for correct base pairs in polymerase cocrystal structures, and this, together with other geometric abnormalities, results in a much slower rate of addition of the next nucleotide. Slower polymerase addition to a mispaired primer terminus reduces the likelihood of a mispair becoming fixed as a mutation by continued synthesis, and also increases the time window during which the error may be proofread, or the mispaired DNA may dissociate.

As might be expected from the different geometries of various mispairs, a polymerase such as Klenow fragment does not make all errors at the same frequency, so that insertion of dGTP opposite a template T is relatively facile, whereas insertion of dCTP opposite C is rare. Klenow fragment mutator mutants change not only the frequency of errors but also the specificity, and may provide a valuable window into the recognition processes that take place at the polymerase active site.

Sugar Specificity

Bacterial pol Is also have stringent specificity for the sugar of the incoming nucleotide. A DNA polymerase must reject ribonucleotides, despite their higher concentration *in vivo*, and this is achieved by an invariant Glu residue positioned so as to obstruct any substituent on the C2′ position of the sugar. Mutation of this Glu to the smaller Ala in Klenow fragment results in a polymerase that can add a ribonucleotide almost as easily as a deoxyribonucleotide. However, the mutant enzyme does not function as a true RNA polymerase because it cannot efficiently add multiple ribonucleotides, most probably because the duplex binding site cannot accommodate a DNA–RNA product.

Pol I enzymes fall into two classes regarding their handling of nucleotide analogues which lack the sugar 3′ hydroxyl (dideoxy nucleotides) and therefore function as chain terminators. The majority, exemplified by Klenow fragment, discriminate very strongly against dideoxy nucleotides. The ternary complex cocrystal structures show a hydrogen bond between the 3′ hydroxyl and the β-phosphate of the incoming nucleotide; presumably, the loss of this interaction compromises the alignment of reactive groups in the transition state, resulting in a slower reaction rate. A minority of pol Is, exemplified by T7 DNA pol, discriminate only slightly against dideoxy nucleotides. In these polymerases, a conserved aromatic side chain that forms part of the nucleotide binding pocket is present as Tyr, instead of the more usual Phe, and the Tyr hydroxyl provides the missing interaction with the β-phosphate. The ability to manipulate chain terminator specificity via a single active-site point mutation has proven invaluable in DNA sequencing and related biotechnology applications.

3′–5′ Exonuclease

The 3′–5′ exonuclease, present in about half of pol Is, carries out its editing function by means of hydrolysis of the terminal nucleotide of the DNA primer strand. The hydrolysis reaction is a phosphoryl transfer, analogous to that described above for the polymerase reaction, catalyzed by a pair of metal ions liganded by a cluster of conserved carboxylate side chains. The other important component of the 3′ exo site is a binding site for single-stranded DNA. In model studies, the exonuclease can be studied using single-stranded DNA as the substrate, though the natural substrate *in vivo* is a duplex DNA whose primer terminus is frayed so as to present three or four bases of single-stranded DNA for binding at the 3′ exo site. The requirement for fraying in order to bind at the 3′ exo active site provides the specificity for editing, because a mismatched primer terminus is more easily melted and is therefore a better substrate for the 3′ exo than a correctly paired DNA. Indeed, studies have shown that, whereas a correctly paired DNA duplex is bound predominantly at the polymerase site of Klenow fragment, a single terminal mismatch results in $\approx$50:50 partitioning between polymerase and 3′ exo sites. The preference of the 3′ exo for a mispaired substrate is amplified by the slowing of the polymerase reaction caused by a mispaired primer terminus (discussed above), so that a mispair is likely to be targeted for proofreading, while a correct primer terminus will serve as a substrate for continued addition.

The contribution of proofreading to polymerase fidelity is quite variable in the pol Is. As already noted, some pol Is do not proofread at all. In others, such as *E. coli* pol I, the contribution of proofreading is relatively modest, about tenfold. Others, such as the polymerases from bacteriophages T5 and T7, have more active exonucleases. Additionally, depending on the strength of the polymerase–DNA interaction, the DNA may stay associated with the polymerase during the transfer from polymerase to editing site, as in T5 and T7, or it may reach the proofreading site via dissociation from the polymerase site and binding to the exonuclease site of another enzyme molecule. Because the selectivity of editing is determined by the structure of the DNA substrate (paired or mispaired) and does not require presentation of the primer terminus in a particular way, the intermolecular transit from polymerase to

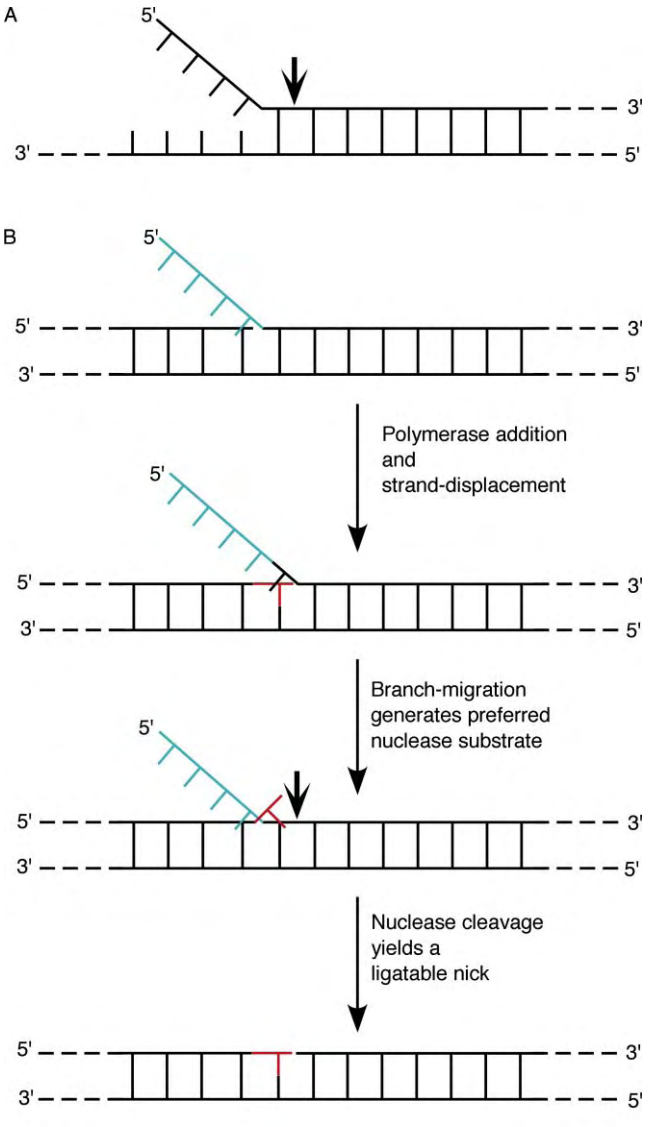

FIGURE 4 (A) Site of cleavage by the 5′ nuclease on a model substrate containing noncomplementary 5′ and 3′ extensions. The nuclease cuts between the first two paired bases. (B) The polymerase and 5′ nuclease activities collaborate in processing a DNA molecule with a 5′ single-stranded tail so as to produce a nicked product that can be sealed by DNA ligase. Cleavage of the first structure, between the first two paired bases adjacent to the 5′ tail, would yield a single-base gap. Nucleotide addition by the polymerase (in red), together with the preference of the 5′ nuclease for a melted base at the 3′ end of the adjacent primer strand, favors the formation of a ligatable product.

exonuclease site would not be expected to compromise the editing process.

5′ Nuclease

The 5′ nuclease of the bacterial pol I enzymes was described as the "5′–3′ exonuclease" in the earlier literature. However, it is now recognized that this activity is not a true exonuclease, but is a structure-specific nuclease that recognizes the junction between duplex DNA and a single-stranded 5′ end, and cuts between the first two paired bases (Figure 4A). On a nicked DNA molecule, polymerase-catalyzed synthesis causes strand displacement and generates the substrate for the 5′ nuclease, so that together the polymerase and 5′ nuclease cause "nick translation," the movement of a nick along a duplex DNA molecule. DNA binding experiments show that the polymerase and 5′ nuclease compete for binding to a DNA substrate, and this implies a mechanism in which the DNA is passed from one active site to the other, and rules out mechanisms in which both reactions take place within a single bound species. The preferred substrate for the 5′ nuclease has, in addition to the unpaired 5′ strand, an unpaired base at the 3′ end of the primer strand abutting the ss–ds junction. This substrate could be formed by rearrangement of the product of polymerase extension and, when cleaved by the 5′ nuclease, will leave a junction ready for ligation (see Figure 4B). The observed specificity of the 5′ nuclease fits well with the *in vivo* functions of the bacterial pol I enzymes in DNA repair and in the removal of primers from Okazaki fragments on the lagging strand. In both cases, the desired endpoint of pol I action is a nick that can be sealed by DNA ligase.

Several 5′ nuclease structures have been solved in the absence of substrates, but our structural understanding of the 5′ nuclease is less good than for the polymerase or 3′–5′ exonuclease because of the absence of cocrystal structures. The location of the 5′ nuclease active site has been inferred from the position of conserved sequence motifs. These contain a large number of conserved carboxylate residues, inviting speculation that, like the polymerase and 3′–5′ exonuclease activities, the 5′ nuclease may carry out phosphoryl transfer using bound divalent metal ions. The bacterial 5′ nucleases and their archaeal homologues have a protein loop or arch in their structures, and it has been hypothesized that the single-stranded 5′ end of the DNA substrate is threaded through the protein.

DNA Polymerase II, Bacterial

Judith L. Campbell
California Institute of Technology, Pasadena, California, USA

DNA must be synthesized during cellular reproduction to produce an identical copy of the chromosome, a process known as DNA replication. In addition, DNA synthesis is needed during the process of DNA repair. After DNA damage is removed from one strand, the complementary strand can serve as a template for correct resynthesis of an intact chain. DNA is synthesized from deoxynucleoside triphosphate building blocks through the action of enzymes called DNA polymerases. All cells contain several DNA polymerases, each of which is specialized either for DNA replication or for different repair pathways. *Escherichia coli* contains five DNA polymerases. DNA polymerase III is essential for DNA replication, while the remaining DNA polymerases are for DNA repair. The specific DNA polymerase being recruited to sites of DNA damage depends on a number of factors. DNA polymerase II, so-called because it was the second DNA polymerase described in *E. coli*, is specialized for DNA repair that occurs when moving replication forks encounter damaged DNA templates.

DNA Polymerase II: Structure and Biochemical Functions

DNA polymerase II (pol II) is a single polypeptide of 783 amino acids with a predicted mass of 89.9 kDa, and is encoded by the *polB* (a.k.a. *dinA*) gene. DNA pol II is the founding member of the B family of DNA polymerase structures, and contains the five motifs characteristic of this family, including both DNA polymerase and exonuclease domains. (DNA pol I belongs to family A, DNA pol III to family C, and DNA poly IV and V to family Y.) Members of the family B polymerases are found throughout the Archaea; and, interestingly, the three replicative DNA polymerases of eukaryotic cells, as well as additional repair DNA polymerases, belong to family B. This suggests the evolutionary importance of pol II.

DNA pol II is a monomeric enzyme but interacts with accessory subunits of the pol III replicase, the γ–δ clamp loading complex and the β clamp. The clamp tethers the DNA polymerase to the terminus of the growing DNA chain. These subunits confer high processivity on both enzymes, a property consistent with a role in synthesizing long stretches of DNA, either during repair or replication. In fact, all five bacterial polymerases interact with the β-clamp. This interaction is competitive, suggesting that all polymerases use the same interface on the β-clamp. This observation suggests a mechanism by which the polymerases may be transiently interchanged with the replicase to copy sites in the template that pose blocks to pol III, such as modification of the bases, bound proteins, or sequences that are inherently inhibitory to polymerase translocation because of their structure. This polymerase switching phenomenon is important for the coordination of DNA replication and DNA repair, and thus for the maintenance of DNA synthesis fidelity.

In addition to being capable of highly processive DNA synthesis, DNA pol II is highly accurate, with *in vitro* error rate as low as one in a million. Mutations in the $3'$–$5'$ proofreading exonuclease domain of the pol II protein result in a 13–240-fold increase in the error rate, depending on the type of error being edited. *In vivo*, defects resulting in a 1000-fold reduction in the proofreading exonuclease activity of pol II cause no increase in mutation frequency in cells containing normal DNA pol III. When an antimutator allele of DNA pol III was present in the cells, however, the pol II proofreading mutant experienced a significant increase in chromosomal base substitution and frameshift mutation frequencies in dividing cells. This suggests that, while pol III is the normal replicase, pol II can replace pol III at the replication fork under some circumstances. In non-dividing cells, pol II exonuclease-defective mutants and mutants completely lacking pol II due to deletion of the *polB* gene have a mutator activity for adaptive mutation. (Adaptive mutations in *E. coli* are episomal mutations arising in stationary phase, nongrowing cells, and the highly conserved pol IV is thought to introduce the mutations during synthesis initiated at the conjugal origin or by DNA repair and recombination.) Thus, an additional role of the pol II exonuclease activity may be to control the level of adaptive mutation by pol IV.

Biological Function: Replication Restart

Given that pol II is a high-fidelity polymerase and that it is highly processive in the presence of the β-clamp, pol II has properties characteristic of replicative DNA polymerases, i.e., ability to synthesize long stretches of DNA at high rates and with high fidelity. However, deletion of pol II from the cell is not deleterious to growth of *E. coli* cells, suggesting that the polymerase is present in order to carry out repair of damaged DNA. This appears to be the case, since the levels of pol II are induced sevenfold by treatment of cells with UV light, which causes lesions in the DNA. In fact, pol II is one of ~40 genes that comprises of the SOS regulon. SOS is a global response to DNA damage that induces ~40 genes, ~30 of which, like *polB*, are induced specifically by inactivating a repressor known as LexA. The level of pol II rises from ~50 molecules in normally replicating cells to ~350 after derepression. Two additional DNA polymerases (pol V and pol IV), both of which have low fidelity, are also induced after cells are treated with DNA-damaging agents.

Although the level of pol II increases in cells after DNA damage, *polB* mutants are not sensitive to DNA-damaging agents such as UV. This is because pol V can carry out repair in the absence of pol II. This conclusion derives from the observations that pol V mutants are UV sensitive and mutants lacking both pol V and pol II are even more so. The mechanism of repair catalyzed by the two polymerases is quite different, however. After treatment with UV, DNA replication is transiently inhibited. Within ~10–15 min, DNA replication resumes, eventually returning to the normal rate. Pol II is induced 30 s after treatment with UV and is required for this replication restart, also known as replisome reactivation. During replisome reactivation, efficient repair mechanisms remove most of the DNA damage. Repair carried out in the presence of pol II is error free and does not give rise to increased mutation. The steps in error-free replication restart involving pol II are shown in Figure 1. When the replisome encounters damage in the template that blocks the progress of pol III, there is a rearrangement of the replication fork. The replication of the two complementary strands, which is usually concurrent, is uncoupled. Synthesis on the damaged template strand is blocked but synthesis on the undamaged strand can continue, resulting in faithful copying of the undamaged strand beyond the site of the lesion. Next, the nascent DNA chains unwind from the parental templates in a process of rotary diffusion called branch migration, and then reassociate with each other by virtue of their complementarity. The longer nascent strand then serves as a template for the shorter, previously blocked strand, which can now be extended past the site of the lesion using the undamaged, and therefore instructional, bases from the newly synthesized complementary strand. This synthesis is thought to occur by substituting pol II for pol III, perhaps via the β-clamp, as already suggested. This part of the reaction is sometimes called template switching. In order to recreate the rapidly moving replication fork, the process is then reversed. The nascent strands unwind and switch back to the parental template, restoring the replication fork at a position downstream of the lesion. As a result of these isomerizations, the lesion is effectively bypassed by the normal replication fork and moved into the fully duplex region upstream of the fork, where it can be recognized and dealt with by the various repair systems in the cell. To complete the process of replication restart, both kinetic and genetic evidence support the notion that after restoration of the replication fork, there is a switch back to

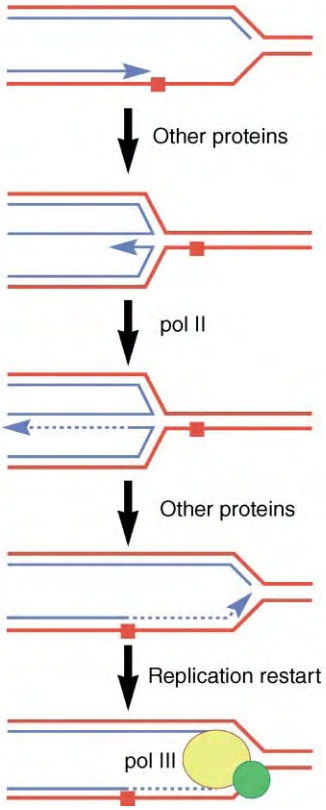

FIGURE 1 A hypothetical scheme for replication restart using bacterial DNA polymerase II. The red lines represent template DNA, and the blue lines newly synthesized DNA. The arrow represents the end of the chain where the polymerase switch occurs. The dotted line represents a lesion in the DNA that cannot be copied by pol III. Pol III replicase, depicted as the yellow and green ovals, is shown after reassociation with the fork at the bottom of the figure. The various steps are described in the text in detail. (Modified from Rangarajan, S., Woodgate, R., and Goodman, M. F., (2002). Replication restart in UV-irradiated *Escherichia coli* involving pols II, III, V, PriA, RecA, and RecFOR proteins. *Mol. Microbiol.* **43**, 617–628, with permission of Blackwell Publishing Ltd.)

the pol III replicase in order to complete normal replication. Thus, pol II carries out only transient synthesis. Several proteins in addition to pol II, as indicated in Figure 1, genetically implicated in replication restart after UV irradiation, are likely to aid in the uncoupling, branch migration, and recruitment of pol II described in the model. Since the reaction has not been reconstituted from purified proteins, however, the molecular mechanism remains to some extent conjectural. One enigma with respect to the role of pol II in replication restart is the finding that levels of pol II are substantial even in cells lacking DNA damage. This has led to speculation that pol II might be involved in error-free replication restart in the presence of endogenous blocks to replication, such as oxidative damage due to normal metabolism, deamination of cytosine, or protein blocks.

In the absence of pol II, DNA replication is still inhibited immediately following DNA damage, but replication restart is delayed for ~50 min after UV irradiation. Biochemical studies suggest that pol V directly substitutes for pol III at the growing fork, and that pol V then inserts a base directly across from the lesion. This process is called translesion synthesis (TLS). After insertion, there is a switch back to pol III for continued replication. TLS is not only fundamentally different in mechanism from pol II catalyzed replisome reactivation, it also has a very different outcome for the surviving cells. Pol V has more relaxed base recognition properties than pol II or pol III, and can efficiently incorporate bases opposite certain lesions and abasic sites, thus giving rise to mutations primarily targeted to the lesions. Thus, repair in the absence of pol II is mutagenic and is therefore known as error-prone repair. Even in the presence of pol II, mutation frequency is induced 100-fold by UV irradiation of *E. coli* cells. It is reasonable that the pol II pathway temporally precedes TLS, since pol II-dependent replication restart does not increase the mutational load. Apparently, however, TLS is a fail-safe pathway which is employed because the organism prefers high survival rates, even with increased mutation load, pending return to an environment supporting more robust growth.

While the polymerase chosen for repair of damage that blocks replication forks depends on availability of polymerase (pol II must be induced), the repair pathway chosen also depends on the type of damage. In the case of N-2 acetylaminofluorene (AAF) guanine adducts, pol II acts as an error-prone TLS polymerase and generates frameshift mutations, while pol V carries out error-free translesion synthesis.

In summary, pol II can, under some conditions, replace pol III in chromosomal replication, but its primary role is in error-free replication restart in response to DNA damage.

Glossary

adaptive mutation Mutations that arise presumably during DNA repair in cells that are not otherwise undergoing DNA replication. In bacteria, such mutations have been shown to occur on episomes. This process is probably important in evolution.

episome An extrachromosomal DNA molecule, residing in a cell, that cannot replicate on its own but needs the proteins encoded by the cellular chromosome.

processivity With respect to DNA polymerases, the ability to copy long stretches of template without dissociating from the template.

repressor A protein that shuts down production of RNA from specific genes (i.e., turns them off). Repressors can be removed or inactivated by inducers.

Biography

Dr. Judith Campbell is a Professor of Biology and Chemistry at the California Institute of Technology. In the 1970s her laboratory made contributions to the studies of the regulation of DNA replication of episomes in bacteria. Currently her laboratory studies include DNA replication and control of the cell cycle in the yeast *Saccharomyces cerevisiae*, with emphasis on DNA polymerases and DNA helicases.

DNA Polymerase III, Bacterial

Hisaji Maki
Nara Institute of Science and Technology, Ikoma, Japan

DNA polymerase III holoenzyme (pol III HE) is an enzyme that catalyzes elongation of DNA chains during bacterial chromosomal DNA replication. Bacterial cells contain several distinct DNA polymerases. In *Escherichia coli*, five DNA polymerases have been found and designated as DNA polymerase I to V in the order of their discovery. The main function of the third polymerase, pol III, is duplication of the chromosomal DNA, while other DNA polymerases are involved mostly in DNA repair and translesion DNA synthesis. Together with a DNA helicase and a primase, pol III HE participates in the replicative apparatus that acts at the replication fork. Unlike other bacterial DNA polymerases, pol III HE is a multisubunit complex, in which twin catalytic subassemblies, called the pol III core, are embedded with several other auxiliary subunits. Cooperative and coordinated action of these subunits enables pol III HE to function as the chromosomal replicase, concurrently synthesizing the leading and lagging strands of DNA. DNA synthesis by pol III HE is also characterized by a rapid chain-elongation reaction, high processivity, and high fidelity, all of which are essential for chromosomal DNA replication.

Replicative Apparatus in Bacterial Cells

In bacterial cells, the circular chromosome contains a unique origin, and DNA replication proceeds bidirectionally from the origin to the terminus. Replication of the whole bacterial genome (4700 kb for *E. coli*) is continuous from the origin to the terminus, and is accompanied by movement of the replicating point, called the replication fork. Both parental DNA strands are concurrently replicated at the fork. Since DNA polymerase can extend a DNA chain only in the $5' \rightarrow 3'$ direction, replication at a fork is semi-discontinuous: DNA synthesis is continuous on one strand (the leading strand) and discontinuous on the other (the lagging strand). Short pieces of DNA, called Okazaki fragments, are repeatedly synthesized on the lagging strand template. These Okazaki fragments are a few thousand nucleotides long in bacterial cells.

DNA replication is a complex process, involving numerous enzymes at the replication fork. In *E. coli*, more than 20 different proteins participate in DNA replication. Among these proteins, DnaB, DnaG, and pol III HE are the three basic components acting at the replication fork, forming a multiprotein complex called the "replisome" (Figure 1). The DnaB protein is a major replicative DNA helicase which moves along the lagging strand in the $5' \rightarrow 3'$ direction and opens up the duplex DNA at the tip of the replication fork to expose a pair of single-stranded DNA templates. The DnaG protein is a primase which synthesizes a short RNA to prime DNA chain elongation catalyzed by pol III HE.

The highly organized and remarkably efficient process needed for replicating chromosomal DNA is achieved by physical and functional interactions among these three components. Pol III HE associates with DnaB protein and pushes the helicase forward as it proceeds along the leading strand. Thus, the velocity of replication fork movement is determined mainly by the rate of chain elongation by pol III HE, $\sim$1000 bp s^{-1}. DnaB interacts with DnaG and activates cyclically the primase activity as the helicase moves along the lagging strand, resulting in timely initiation of Okazaki fragment synthesis. Finally, the proper recruitment of pol III HE to the replisome requires an RNA primer formed within the origin and, thus, depends upon the function of DnaG.

In bacterial cells, pol III HE and the other components of the replisome localize to discrete positions, predominantly at or near the midcell throughout the cell cycle. It is thought that the DNA is threaded through the centrally positioned replisome during duplication, and then extruded from the replisome after duplication.

Subunits and Subassembly of Pol III Holoenzyme

The machine-like action of pol III HE at the replication fork, far more complex than what is necessary for mere DNA polymerization, is based on its subunit structure. Ten different polypeptides form an isolable 17-subunit pol III HE complex in *E. coli*. The whole assembly is very stable while participating in the replisome at

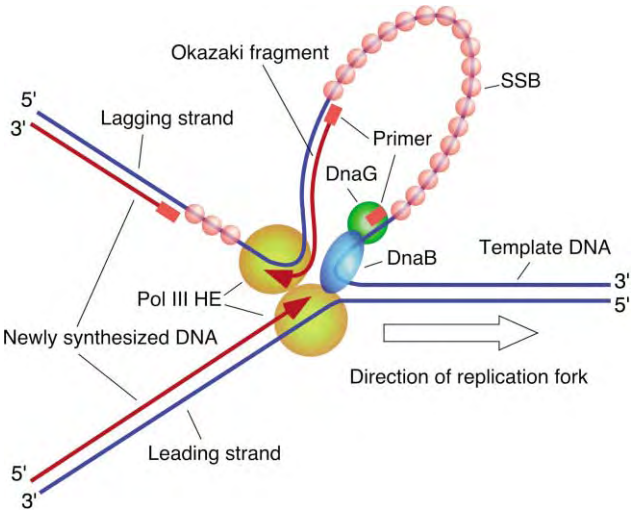

FIGURE 1 The replication fork and three basic components of the replicative apparatus in bacteria.

the replication fork. However, during the course of purification, pol III HE readily disassembles into free subunits and various subassemblies, analyses of which have greatly helped to clarify the biochemical function of each subunit and the architecture of the holoenzyme (Figure 2). Smaller numbers of subunits assemble to form the holoenzyme in *Bacillus subtilis* and other bacterial species, although the basic architecture is conserved in most bacteria.

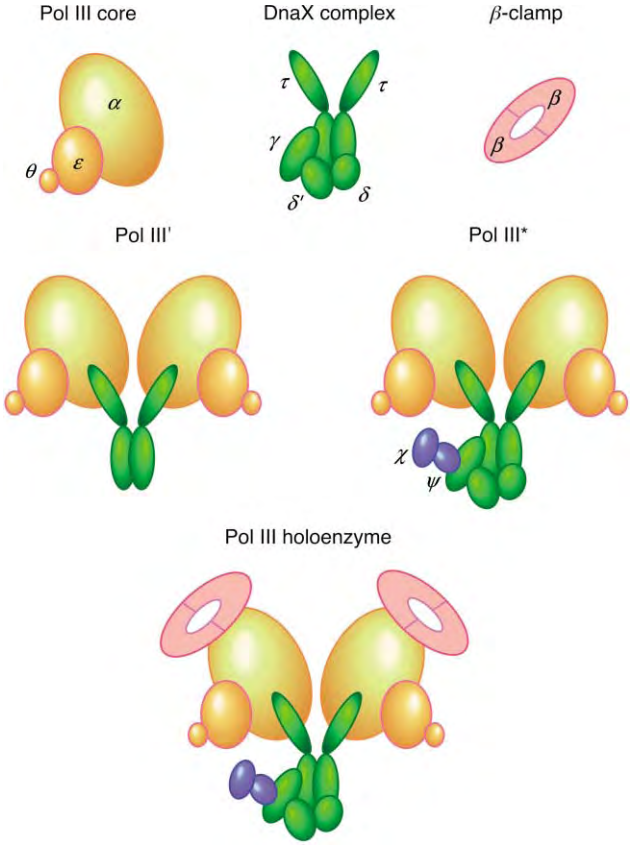

FIGURE 2 A schematic view of the architecture of DNA polymerase III holoenzyme.

Pol III Core

The α-subunit, the largest polypeptide among the holoenzyme subunits, possesses DNA polymerase activity and forms a catalytic core subassembly, called the pol III core, with one molecule each of the ε and θ subunits. The α-subunit shares an amino-acid-sequence motif with bacterial DNA polymerases I and II, and with eukaryotic DNA polymerases α, δ, ε, and ζ, which consists of six segments each containing 5–10 residues. This polymerase motif corresponds to catalytically important structural determinants for the active center of DNA polymerases. Based on small differences in the sequences of this motif, the DNA polymerases are divided into three classes: type A (pol I), type B (pol II and catalytic subunits of the eukaryotic polymerases), and type C (α-subunit of pol III). In contrast to the type A and type B polymerases, the α-subunit lacks the $3' \rightarrow 5'$ exonuclease activity required for the proofreading function, which removes nucleotides that have been incorrectly inserted by the polymerase. In the pol III core, the ε-subunit acts as the editing exonuclease and ensures highly accurate DNA synthesis by the polymerase. Cells that are defective in ε-subunit function show a strong mutator phenotype, with remarkably elevated frequencies of spontaneous mutation.

Although the pol III core has high catalytic efficiencies for DNA synthesis and proofreading, it cannot extend more than 10 nucleotide residues at once. This relatively low processivity of DNA synthesis by the pol III core is due to a low affinity of the core subassembly for template-primer DNA. Other subunits, especially the β-subunit, greatly enhance and regulate the processivity of the core.

τ-Subunit and Pol III′

The τ-subunit is the second largest subunit, and forms a stable homodimer complex when it is free in solution. An important function of the τ-subunit is to make the pol III core into a dimer. The C-terminal domain of the τ-subunit interacts with the α-subunit, and the dimeric nature of the τ-subunit itself facilitates dimerization of the pol III core. The resulting subassembly, called pol III′, consists of two pol III cores and two τ-subunits. The τ-subunit improves the low processivity displayed by the pol III core, resulting in a moderately increased processivity for pol III′.

Besides dimerization of the pol III core, the τ-subunit plays multiple roles at the replication fork. In the HE complex, the τ-dimer bridges between dimeric polymerases and other auxiliary subunits. In addition, as

a scaffold of the replisome, the τ-dimer connects pol III HE and the DnaB helicase at the replication fork.

β-Subunit and Pol III*

Among the holoenzyme subunits, the β-subunit most easily dissociates from the holoenzyme complex. Phosphocellulose or cation-exchange column chromatography effectively separates the holoenzyme into the β-subunit and pol III*, a subassembly that retains all the subunits except β. However, the association of the β-subunit with pol III* is very stable when they form a ternary complex with template-primer DNA.

The β-subunit is a crescent-shaped polypeptide, and forms a homodimer with a doughnut-like structure which encircles double-stranded DNA and slides along the DNA. The β-dimer binds to the α-subunit, even in the absence of other HE-subunits, and it tethers the α-subunit to template DNA during DNA synthesis. The sliding-clamp nature of the β-subunit and the α–β interaction are the basis of the ability of pol III HE to perform highly processive DNA synthesis. The β-subunit also interacts with the δ-subunit in an ATP-dependent manner when β is functioning in the HE complex. Albeit much more weakly than its interaction with the α-subunit, the β-dimer can associate with other proteins including all the other *E. coli* DNA polymerases, a mismatch repair protein (MutS), DNA ligase, and a replication initiator protein (DnaA). Involvement of the β-subunit in many aspects of DNA transactions other than DNA replication has been suggested.

Pol III*, the largest subassembly of pol III HE, consists of two pol III cores, two molecules of τ-subunit, and one molecule each of the $\gamma, \delta, \delta', \chi$, and ψ subunits. The architecture of pol III* is semi-symmetrical. As in pol III′, the τ-dimer connects two pol III cores in a symmetrical configuration. On the other hand, the other five auxiliary subunits impose an asymmetry on the dimeric polymerases. Among these auxiliary subunits, γ, δ, and δ' form a pentameric circular complex (the DnaX complex) with the τ-dimer, while the χ and ψ subunits form another complex that bridges the DnaX-complex and SSB (single-stranded DNA-binding protein).

DnaX Complex

The biochemical function of the DnaX complex is to load the β-clamp on DNA. The δ-subunit directly interacts with the β-subunit and opens the β-ring. Other subunits assist and regulate the action of the δ-subunit. The τ- and γ-subunits are encoded by the *dnaX* gene and, thus, are called DnaX proteins. τ is the full-length translation product, while γ is a truncated protein that arises by translational frameshifting. Hence, the N-terminal portion of τ is identical to that of the γ-subunit. Furthermore, all the subunits of the DnaX complex are structurally related to the AAA^+ ATPase family, although only τ and γ show ATPase activity.

ATP-binding and hydrolysis of ATP are crucial events for the clamp-loading action of the DnaX complex. In the absence of ATP, the five-subunit circular complex is in a tightly closed configuration, and inert for loading the β-subunit. In particular, the δ'-subunit blocks the δ-subunit's interaction with the β-subunit. When all three DnaX proteins in the complex bind ATP, the DnaX complex attains a more relaxed form in which the δ-subunit readily gains access to the β-subunit. Upon association with the δ-subunit, the β-ring is opened and mounted on primer-template DNA. Contact between the β–DnaX-complex and DNA activates hydrolysis of ATP bound to the DnaX-complex, which leads to dissociation of β from the δ-subunit, leaving the closed β-ring on the primer-template DNA.

Pol III HE in Other Bacteria

Genes encoding the subunits of pol III HE have been identified in the genomes of many species of eubacteria. Among these genes, those encoding the $\alpha, \beta, \tau, \delta$, and δ'-subunits are well conserved, while those for other subunits seem to be significantly divergent or lost. In many bacterial species, the *dnaX* gene does not show an obvious frameshifting signal sequence and, therefore, likely produces only the τ-subunit as a single DnaX protein. A group of bacterial species (gram-positive, G + C low) including *B. subtilis*, *Staphylococcus aureus*, and *Streptococcus pyogenes* possess two distinct type-C DNA polymerases, both of which are required for chromosomal replication. Despite the apparent diversity among different species, analyses of pol III HE in bacterial species that are evolutionarily distant from *E. coli* have demonstrated that the basic architecture and biochemical functions of pol III HE are common throughout the eubacteria.

Concurrent DNA Synthesis of Leading and Lagging Strands

In vitro reconstitution of the replisome with purified pol III*, β-subunit, DnaB helicase, DnaG primase, and SSB has indicated that a single pol III HE particle can simultaneously synthesize both leading and lagging strands at a replication fork. Pol III HE is a functionally and structurally asymmetric complex with twin polymerases, one of which participates in leading-strand synthesis and the other in lagging-strand synthesis. The leading-strand polymerase remains continuously

clamped to DNA, but the lagging-strand polymerase is repeatedly clamped and unclamped from DNA, to cycle from one Okazaki fragment to the next. Since the lagging-strand polymerase is held at the replication fork via the τ-subunit bridge and the leading-strand polymerase, retargeting of the lagging-strand polymerase to the next primer is so efficient and rapid that the overall rate of lagging strand synthesis matches the rate of leading strand synthesis (Figure 3).

Pol III HE is initially loaded on the chromosome DNA after the first RNA primer is synthesized within or near the replication origin. One polymerase clamped on the initial RNA primer becomes the leading polymerase, and the other polymerase in the same HE complex serves

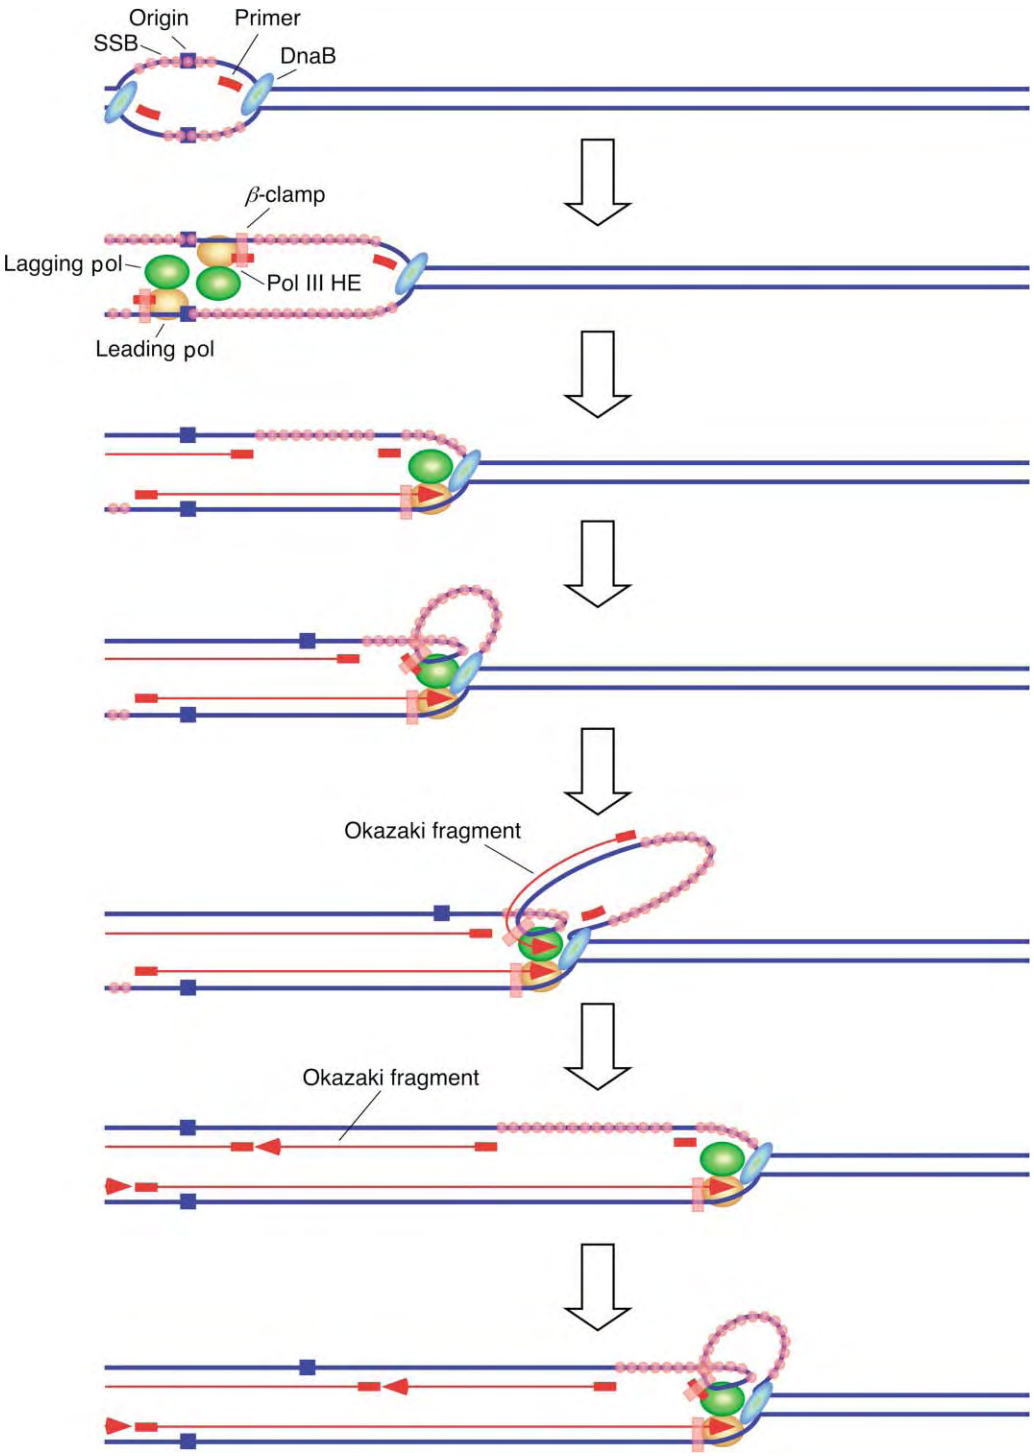

FIGURE 3 Concurrent DNA synthesis of leading and lagging strands by the bacterial replisome.

as the lagging polymerase. An asymmetric arrangement of the DnaX complex in pol III HE is the basis for the functional asymmetry of the replicative polymerase. It has been hypothesized that the position of the DnaX complex is biased to the lagging polymerase, which limits its clamp-loading activity exclusively to the lagging strand.

Other Biological Functions

Almost all plasmids, and the majority of bacteriophages, use pol III HE for their DNA replication. Pol III HE is involved in several kinds of DNA transactions that require synthesis of relatively long segments of DNA. These include long-patch nucleotide excision repair, *mutS*-dependent mismatch repair, homologous recombination, and replicative translocation of transposons.

Glossary

AAA$^+$ ATPase family An extension of the AAA (for ATPases associated with a variety of cellular activity) family, originally defined to include proteins with a common ~200 residue ATPase core.

mismatch repair A class of DNA repair that corrects mispairs and small bulge structures in DNA, which are caused mainly by replication errors.

mutator A phenotype showing an increased rate of spontaneous mutation, which is caused by a mutation within one of the genes for maintenance of replicational fidelity or repair of spontaneous damage to DNA and substrate nucleotides.

nucleotide excision repair A class of DNA repair by which a segment of DNA containing lesions is excised and replaced with resynthesized DNA.

translesion DNA synthesis A cellular process involving specialized DNA polymerases that counteract the replication-blocking damage to DNA.

Biography

Dr. Hisaji Maki is a Professor in the Department of Molecular Biology at the Nara Institute of Science and Technology in Ikoma, Japan. His principal research interests are in maintenance of genetic information, spontaneous mutagenesis, and chromosome aberration. He holds a Ph.D. from Kyushu University and received his postdoctoral training in Professor Arthur Kornberg's laboratory at Stanford University. He has isolated and analyzed several mutator genes in *E. coli*, including *dnaE* and *dnaQ* which encode the α- and ε-subunits of pol III holoenzyme, respectively.

DNA Polymerases: Kinetics and Mechanism

Kenneth A. Johnson
University of Texas, Austin, Texas, USA

Polymerases can replicate DNA with extraordinary speed and fidelity, copying a template strand at a rate of 300 base pairs per second and making a mistake only one time out of a million. When the polymerase does make a mistake, it stalls by slowing the incorporation of the next correct base pair on top of the mismatch, giving time for a proofreading exonuclease to remove the mismatched base. Selective removal of mismatched bases by the proofreading exonuclease contributes an additional factor of ~1000, resulting in a net fidelity of approximately one error in a billion bases copied. Not all polymerases achieve such high fidelity, however. Rather, each polymerase has evolved a fidelity that balances the biological needs for stability and adaptability. Although the fidelity varies greatly among the polymerases that have been examined in detail, the pathway by which a correct base pair is selected remains invariant. This article briefly summarizes our understanding of the kinetic, structural, and thermodynamic bases governing the fidelity of DNA replication.

Elementary Steps in Polymerization

The free energy difference between a correct and incorrect base pair is quite small (1–2 kcal/mole), which leads to a selectivity factor of only 5–30 in favoring the correct base pair over a mismatch. Therefore, the polymerase does not simply stitch together base pairs that form in solution; rather, the fidelity of DNA replication is largely a function of the kinetics of the reactions, involving nucleotide binding, recognition, and incorporation. The polymerase uses not only the base pair free energy but also the base pair geometry in selecting the correct base pair. The new base pair is buried at the active site of the polymerase, shielding it from water molecules, which enhances the free energy difference between correct and incorrect base pairs and facilitates rapid catalysis.

DNA polymerases achieve their extraordinary fidelity by using a two-step nucleotide-binding sequence to select the proper nucleotide for incorporation, as shown in Figure 1.

The deoxynucleoside triphosphate (dNTP) initially binds in a rapid equilibrium reaction to an "open" state of the enzyme to form the "ground state" complex (E·DNA·dNTP). A correct base pair enables a change in enzyme structure (at rate k_2) to a "closed" form in which the active catalytic residues are brought in to the proper orientation necessary for catalysis of the chemical reaction (at rate k_3). This two-step nucleotide-binding sequence is important for two reasons. First, the binding of the nucleotide to the open enzyme form allows a rapid selection of the correct base pair from the four competing nucleotides in solution, using base pair free energy to favor the correct base. Second, the conformational change in the enzyme to the closed form provides additional selectivity dependent upon the proper base pair geometry, and it leads to a close alignment of protein residues around the reactants, shielding them from solvent and bringing about rapid catalysis. A mismatched base pair is discriminated against at each step in the sequence. An incorrect base binds weaker in the ground state, inhibits the rate of the conformational change, and may lead to a misalignment of the reactive groups necessary for catalysis, leading to a much slower rate of incorporation.

Selectivity Contributions of Each Step

Fidelity varies greatly for different DNA polymerases. The DNA polymerase responsible for replicating the viral genome of HIV (human immunodeficiency virus), known as reverse transcriptase (RT) because it copies RNA templates as well as DNA, has a much lower fidelity, making one mistake in only 10,000 base pairs. This higher error rate is essential for the survival of HIV by affording a fast mutation frequency that gives the virus the ability to evade the immune system and all modern drugs, by constantly changing and evolving resistance via the process of natural selection.

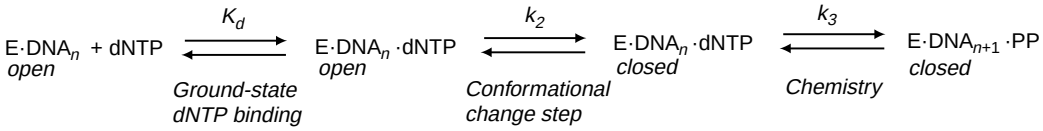

FIGURE 1 Pathway of nucleotide binding and incorporation.

In contrast, the human DNA polymerase responsible for replicating the mitochondrial genome has an intermediate fidelity, making one error in 300,000; with proofreading, the error frequency is increased to one error in 1.5 million.

Table I shows the net selectivity observed in each step of the reaction for several polymerases. It is interesting to note that each of the polymerases shows a nearly constant selectivity of approximately 200–300 for the ground state nucleotide binding, whereas the selectivity afforded by the conformational change step (and ensuing chemistry step) contributes a widely varying selectivity. For a high-fidelity enzyme such as T7 DNA polymerase, the selectivity in the second step is 5000, leading to a net fidelity of 1.5 million. In contrast, the HIV RT shows a selectivity factor of only 50 in the conformational change step, leading to an average overall fidelity of only 13,000. Effectively, HIV RT makes at least one error each time it replicates the 9 kb viral genome, allowing the virus to rapidly evolve to evade the host immune system and any single antiviral drug. Its low fidelity is due to the small contribution of the conformational change and/or chemistry toward the net fidelity. Moreover, because HIV RT lacks a proofreading exonuclease, once a mismatch is incorporated it is not readily removed.

Measurement of the Kinetics of Incorporation

Measurement of the kinetics of DNA polymerization is complicated by the processivity of the enzyme, defined by the tendency of the polymerase to remain bound to the DNA template/primer and to continue multiple rounds of polymerization (Table II). The processivity is calculated by the rate of polymerization divided by the rate of dissociation of the E·DNA complex and is equal to the average number of bases incorporated before the complex dissociates. Although polymerization can be quite fast (50–300 s^{-1}), the rate of dissociation is slow (typically 0.02–0.2 s^{-1}). Therefore, in the measurement of the kinetics of incorporation of a single nucleotide in the steady state with an excess of DNA and limiting enzyme, the rate that is measured is due solely to the dissociation reaction and provides no information pertaining to the nucleotide incorporation reaction, unless incorporation is slower than DNA dissociation. Therefore, steady-state rate measurements are virtually meaningless. To circumvent these difficulties, the kinetics of incorporation are measured by examining the rate of extension using single-turnover kinetic methods. A stoichiometric E·DNA complex is rapidly mixed with the correct dNTP and Mg^{2+} and then quenched by mixing with EDTA to chelate metal ions needed for catalysis. The time course of extension of the DNA by one base pair is then quantified after resolution on a DNA sequencing gel.

To resolve the time dependence of extension, the reaction must be examined on the time scale of a single turnover, which usually is in the range of milliseconds. Definitive experiments require a rapid mixing device to achieve rapid mixing of small volumes. Compared to experiments using steady-state kinetic methods, single-turnover kinetic experiments may be slightly more difficult to perform, but they can be interpreted directly and often unambiguously. The nucleotide concentration dependence of the rate of the incorporation in the single-turnover reaction defines the maximum rate of incorporation, k_{pol}, which may be limited by k_2, k_3, or a combination of the two steps (Figure 1) and the ground state nucleotide dissociation constant, K_d. Because the nucleotide binding is a rapid equilibrium reaction and k_{pol} is the single, rate-limiting step in polymerization, the ratio of k_{pol}/K_d is equal to k_{cat}/K_m, the specificity constant for the reaction. Thus, this one experiment defines the key kinetic parameter governing nucleotide selectivity and resolves it into the two steps contributing to fidelity, the ground state nucleotide dissociation constant and the rate of incorporation, k_{pol}. Most importantly, these methods provide a measurement of

TABLE I

Fidelity Contributions of Ground State Binding and Polymerization[a]

Polymerase	$K_{d,inc}/K_{d,cor}$	$k_{pol,cor}/k_{pol,inc}$	Overall fidelity
T7 DNA polymerase	300	5,000	1,500,000
Pol γ DNA polymerase	200	1,500	300,000
Klenow	170	2,300	210,100
Pol β	290	610	19,700
HIV RT	260	50	13,000

[a] The average contribution of ground state binding ($K_{d,inc}/K_{d,cor}$) and the maximum rate of polymerization ($k_{pol,cor}/k_{pol,inc}$) to the net fidelity are shown for various polymerases, where *inc* represents an incorrect while *cor* represents a correct nucleotide, respectively.

TABLE II

Kinetics of Polymerization

Polymerase	K_d (nM)	k_{pol} (s^{-1})	k_{pol}/K_d ($\mu M^{-1}s^{-1}$)	k_{off} (s^{-1})	Processivity	$K_{d,DNA}$ (nM)
T7 DNA polymerase	18	300	15	0.2	1500	18
Pol γ DNA polymerase	0.8	40	50	0.02	2250	10
Klenow	5	50	5	0.2	250	5
Pol β	10	10	1	0.3	30	50
HIV RT	4	30	8	0.2	150	5

the equilibrium constant for the binding of the substrate to the enzyme in a complex that is poised for catalysis.

Structural Determinants of Fidelity

The structure of T7 DNA polymerase in the closed complex is shown in Figure 2. The E·DNA·dNTP closed complex was formed with the correct dNTP and a dideoxy-terminated DNA primer/template to prevent the chemical reaction from occurring. It shows the tight arrangement of the protein around the DNA and the dNTP poised for the chemical reaction to proceed. The DNA lies largely on the surface of the protein, making contacts through the phosphodiester backbone. As the DNA approaches the active site, the structure changes from standard B-DNA to an A-form DNA with a more open minor groove that allows contacts with several residues that are thought to be important for sensing mismatches in the incoming base pair as well in the primer/template. Also important to note is that the next residue in the template strand is rotated out from the active site at 90°, and protein residues stack with both the templating base and the incoming dNTP. These contacts are all thought to be important in enforcing the proper base pair geometry.

Comparison of the T7 DNA polymerase closed complex with the structures of other polymerases in

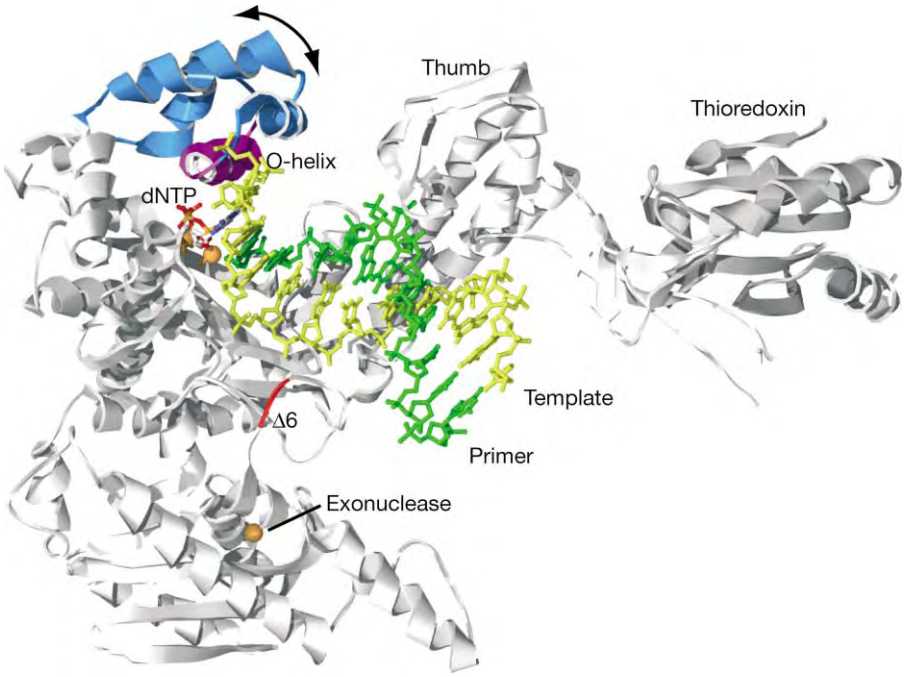

FIGURE 2 Structure of T7 DNA polymerase. The structure shows the "closed" complex resulting from the rotation (arrow) of the recognition domain (blue) to bring the O-helix (magenta) into contact with the incoming dNTP (CPK colors). The template strand is shown in yellow, the primer strand in green, and the thioredoxin accessory protein in gray. The two metal ions at the polymerase active site and the single metal ion at the exonuclease site are shown in gold. The location of the six-residue deletion (Δ6) to create the exo-mutant is shown in red. Drawn from Protein Data Bank structure file 1T7P.

the E·DNA state reveals that there is a large conformational change in a nucleotide recognition domain involving a 45° rotation to bring key residues into contact with the dNTP at the active site. Included among these residues are positively charged lysine and arginine, amino acids that bind to the β- and γ-phosphates to facilitate catalysis, and a tyrosine that stacks with the dNTP to help align the reaction center. This conformational change step provides the most significant contribution to nucleotide selectivity by sensing the proper base pair geometry and leading to fast catalysis of the chemical reaction.

Chemistry of Catalysis

A close-up view of the reaction center is shown in Figure 3. Two tetrahedrally coordinated Mg^{2+} ions are ligated by conserved acidic residues at the active site (D475 and D654), orient the reactants, and facilitate catalysis. Metal A activates the 3′ OH and is ligated to the non-bridging oxygen of the α-phosphate of the incoming dNTP, while metal B is ligated to non-bridging oxygens of α-, β-, and γ-phosphates and stabilizes the pyrophosphate leaving group as the reaction proceeds.

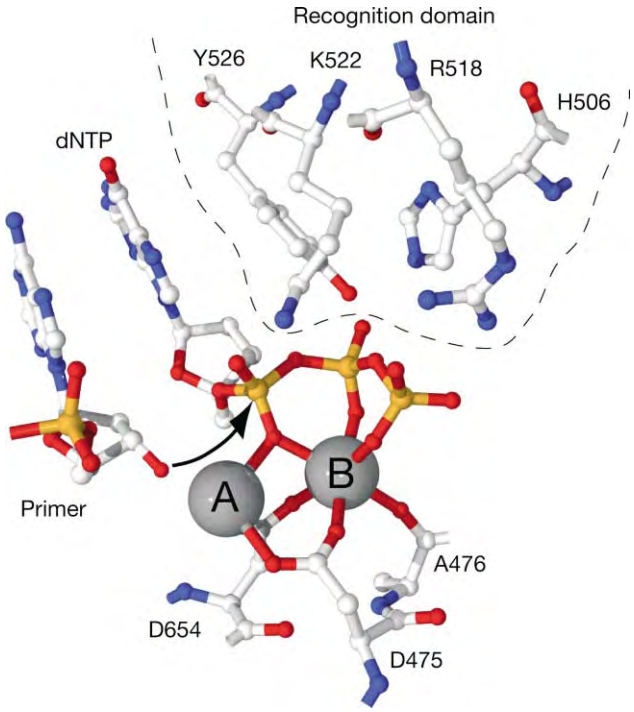

FIGURE 3 Two-metal ion mechanism. A close-up view of the active site shows the 3′ OH of the terminal base in position to react with the incoming dNTP, bound to the two metal ions. Residues from the recognition domain contact the incoming dNTP to facilitate catalysis. Drawn from Protein Data Bank structure file 1T7P.

This two-metal ion mechanism appears to be common for all polymerases.

Catalysis is also critically dependent upon contacts made involving residues from the recognition domain. Positively charged residues K522, H506, and R518 contact the α-, β-, and γ-phosphates, respectively; and Y526 stacks against the incoming dNTP. These contacts are formed following the conformational change and facilitate catalysis by binding and orienting the dNTP for reaction and stabilizing the development of negative charge on the pyrophosphate. Thus, the structure provides a rationale for the importance of the conformational change in nucleotide selectivity and incorporation efficiency.

Selectivity of the Proofreading Exonuclease

The polymerase contains a proofreading function to efficiently remove mismatches after they are formed. This is accomplished by the polymerase recognizing it has made an error by stalling in its attempt to insert the next correct base on top of the mismatch to give time for the primer strand to flip over into the exonuclease site to have the 3′-terminal base excised. Although the exonuclease active site is 25 Å away from the polymerase site (see Figure 2), the DNA primer strand is able to flip back and forth between the two sites.

The selectivity of the exonuclease is governed by kinetic partitioning between the polymerase and exonuclease active sites, with the decision to excise being made at the polymerase site. As summarized in Figure 4, during successive correct nucleotide incorporation reactions, the polymerase continues down the DNA template, inserting bases at a rate of $300\ s^{-1}$. Occasionally, the DNA will dissociate from the polymerase or flip into the exonuclease site at a rate of $0.2\ s^{-1}$. Therefore, the cost of having a proofreading exonuclease site next to the polymerase active site is $0.2/(300 + 0.2) = 0.07\%$ of the correct nucleotides removed after correct incorporation. However, after the polymerase inserts a mismatched dNTP (occurring at an infrequent rate of $0.002\ s^{-1}$), the rate of incorporation of the next correct base on top of the mismatch is reduced to $0.012\ s^{-1}$, while the rate at which the primer flips over into the exonuclease site is increased to $2.3\ s^{-1}$. The probability of removing the mismatch increases to $2.3/(2.3 + 0.012) = 99.5\%$. Thus, the kinetic partitioning defining the relative probability of reaction at the polymerase and exonuclease sites is inverted when the polymerase encounters a mismatch in the primer/template.

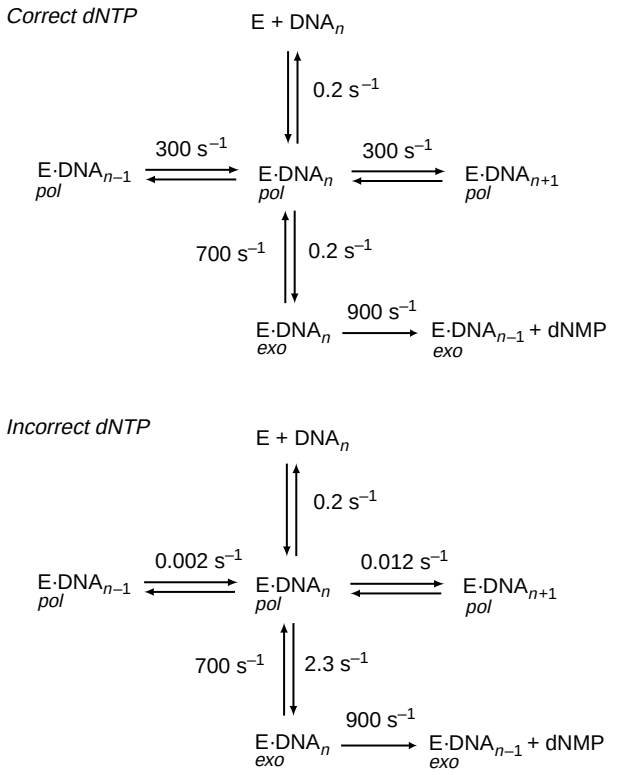

FIGURE 4 Kinetic partitioning for exonuclease proofreading. The changes in the rates of polymerization and exonuclease removal for correct and incorrect base pairs are summarized. Correct base pairs are incorporated sequentially at a rate of 300 s^{-1}, while occasionally the DNA will dissociate (0.2 s^{-1}) or slide into the exonuclease site (0.2 s^{-1}). Mismatches are incorporated at a slow rate (0.002 s^{-1}) and extension to incorporate the next correct base is also slow (0.012 s^{-1}), but the rate of sliding into the exonuclease site is increased to 2.3 s^{-1}. This change in kinetic partitioning leads to selective removal of mismatches based upon testing for proper base pairing at the polymerase site.

The dynamics of the reaction provides a perfect solution to the problem of designing a proofreading function. A single-stranded primer in the exonuclease site is needed to excise the 3′-terminal base, but the DNA must be in duplex form in order to know whether the base pair is correct. According to the kinetics, the DNA spends most of the time at the polymerase site and makes only brief excursions to the exonuclease site, by melting out a single-stranded segment of the primer strand sufficient to reach the exonuclease site 25Å away. The decision as to whether to remove a base pair is made solely at the polymerase site, based upon the ability of the enzyme to sense a mismatch in the primer template and inhibit the rate of forward reaction, thereby changing the probability of excision versus extension.

It is interesting to note that the binding of the next correct base pair is not significantly impaired with a mismatch in the primer/template; rather, the rate of the conformational change and/or the chemical reaction is reduced by the presence of a mismatch. This again is in keeping with the postulate that one purpose of the conformational change step is to test for mismatches. The proofreading selectivity demonstrates that the polymerase is capable of sensing a mismatch not only in the incoming base pair but also at the adjacent position in the primer/template, and this ability is used to increase the selectivity at each step.

Summary

DNA polymerases are remarkable machines central to the replication of all life forms on earth. The fidelity of different DNA polymerases varies widely in order to meet the requirements of the biology in balancing the conflicting needs for stability and adaptability. All polymerases studied in sufficient detail show a similar two-step binding mechanism to select the correct base pair using both the base pair free energy and base pair geometry.

Glossary

discrimination The ratio of the specificity constant for a correct base pair divided by that for a particular mismatch.

fidelity The reciprocal of the error frequency; for example, an error frequency of 0.000002 is expressed as a fidelity of one error in 500,000.

proofreading exonuclease An exonuclease that removes a single base from the 3′ end of the primer strand.

selectivity The fidelity contribution of individual constants; for example, the selectivity in the ground state binding is equal to the ratio of the K_d for the incorrect dNTP divided by the K_d for the correct dNTP binding.

specificity constant The apparent second-order rate constant for nucleotide binding and incorporation, defined by the steady-state kinetic parameters, k_{cat}/K_m, but more accurately measured using pre-steady-state kinetic methods to define k_{pol}/K_d, where k_{pol} is the maximum rate of incorporation and K_d is the apparent ground state nucleotide dissociation constant.

Biography

Kenneth A. Johnson is the Roger J. Williams Centennial Professor of Biochemistry at the University of Texas at Austin. His research focus is on the mechanistic and kinetic basis for DNA polymerase selectivity, especially as it pertains to the effectiveness and toxicity of drugs used to combat viral infections, especially HIV and HCV. He holds a Ph.D. from the University of Wisconsin and received postdoctoral training at the University of Chicago. He is President and CEO of KinTek Corporation, a company he founded to manufacture instruments that he designed to examine enzyme reaction kinetics on the millisecond time scale.

DNA Replication Fork, Bacterial

Nancy G. Nossal
National Institutes of Health, Bethesda, Maryland, USA

The complete duplex DNA chromosome of bacteria is replicated before each cell division. In *E. coli* the length of the single circular chromosome is 4.6×10^6 base pairs, and it can be copied in 40 min in rich media. Replication of bacterial DNA is thus rapid and is also extremely accurate. The error frequency during *E. coli* replication is estimated to be about 10^{-7}, before additional correction by the mismatch-repair system. The timing of replication must be coordinated with the cell division cycle, and the synthesis of the two strands of the DNA duplex must be coordinated with each other. Replication in *E. coli* is initiated when the dnaA protein binds to a specific DNA sequence, the *oriC* origin, beginning a series of reactions in which the DNA duplex is opened to allow the binding of the other replication proteins. Replication from the origin is bidirectional, so that two replication forks moving in opposite directions are established. DNA synthesis at each fork is accomplished by a complex of many proteins, called the replisome. It includes the leading- and lagging-strand DNA polymerases, and their associated polymerase clamps and clamp loader, collectively known as the polymerase holoenzyme, which synthesize the new DNA on each strand. The replisome also contains a primosome with a primase to make short RNA chains to initiate new DNA fragments, a helicase to unwind the parental duplex, and a helicase loading protein.

The Two Strands of the DNA Duplex are Copied by Different Mechanisms

The two strands of a DNA duplex have opposite polarity, one goes 5′–3′ and the other 3′–5′ (Figure 1). All known DNA polymerases add new nucleotides only to the 3′ end of the chain. The parent strand that runs 3′–5′ is called the leading-strand template and serves as a template for the continuous synthesis of the new leading strand, which grows in the 5′–3′ direction. The lagging-strand template runs 5′–3′, so that the polymerase copying this strand moves away from the fork. However, microscopic studies have shown that the most recently replicated DNA on each strand is located close to the fork. On the lagging strand this is accomplished by a discontinuous mechanism of replication in which the polymerase makes short fragments that begin near the fork and extend for 1000–3000 bases (Figure 1). These fragments, which are often called Okazaki fragments in honor of their discoverer, are subsequently joined to each other by DNA ligase. Since DNA polymerases cannot begin new chains, each fragment is started by a short RNA chain (primer) that is made by a specialized RNA polymerase called a primase. To allow synthesis on the leading and lagging strands to be coordinated, Bruce Alberts proposed that the lagging strand folds into a loop, bringing the two polymerases together (Figure 2). This has been called a trombone replication model, because the expansion of the loop as each fragment is synthesized resembles a trombone slide.

Proteins Required for DNA Replication

Much of our current understanding of bacterial replication comes from the characterization of the replication system of *E. coli*, and the simpler but mechanistically similar systems of the *E. coli* bacteriophage T7 and T4. The classes of proteins needed at the fork are shown in Figure 2, and the specific proteins in these three replication systems are shown in Table I.

DNA Polymerase Holoenzymes

The distinguishing feature of a replicative DNA polymerase is that it is highly processive, which means that it can incorporate thousands of nucleotides each time it binds to the template. *E. coli* polymerase III and T4 polymerase remain bound because they are connected to circular-clamp proteins that surround the duplex and move with the polymerase. These clamp proteins are in turn loaded on the DNA by multisubunit complexes of proteins called clamp loaders. *E. coli* Pol III holoenzyme can be isolated as a complex containing a leading and a lagging DNA polymerase core, two clamps, and a single multi-subunit clamp loader. The clamp loader (γ-complex) is physically attached to each polymerase by the C-terminal domain of the one of two τ-subunits in

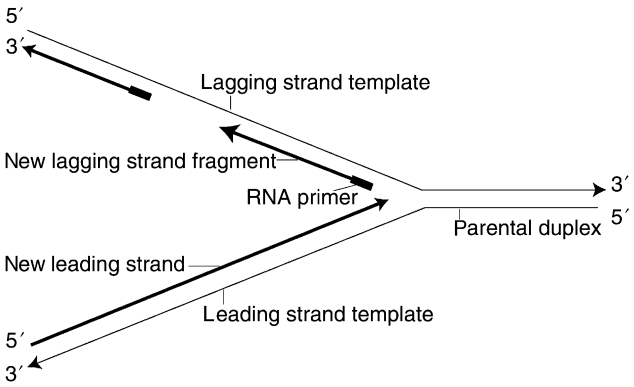

FIGURE 1 Synthesis of the leading- and lagging-strands at a DNA replication fork. Because the two strands in a DNA duplex are antiparallel (run in opposite directions), and strands grow by addition of nucleotides to the 3′ end, the lagging strand is made by the synthesis of short fragments that are then joined together. Light lines: parental DNA template; heavy lines: new DNA.

the complex, and travels with the polymerases. The T4 proteins are less tightly connected, and are isolated as separate proteins. There is evidence that the two T4 polymerases at the fork do interact with each other at least transitorily. T7 DNA polymerase is isolated as a complex with *E. coli* thioredoxin, which increases the processivity of the polymerase.

Primosomes

In the bacterial replication systems there is a close physical and functional relationship between the primase that makes the very short RNA chains (4–12 b) initiating each lagging-strand fragment and the helicase that unwinds the duplex ahead of the leading-strand polymerase. The length and sequences of the primers are different in each of these systems. The bacterial replicative helicases are hexamers that surround the lagging-strand template strand, and move 5′–3′ on that strand to unwind the duplex by a reaction that requires hydrolysis of nucleotide triphosphates. The loading of the *E. coli* dnaB helicase is promoted by dnaC protein, which is thought to open the preformed helicase hexamer to allow ssDNA to bind inside. The T4 59 helicase loading protein binds to the replication fork, and facilitates the assembly of the 41 helicase subunits into a hexamer surrounding the lagging-strand template. The T7 helicase and primase activities are both catalyzed by the gene 4 protein, a hexamer with adjoining rings of the primase and helicase domains of the protein.

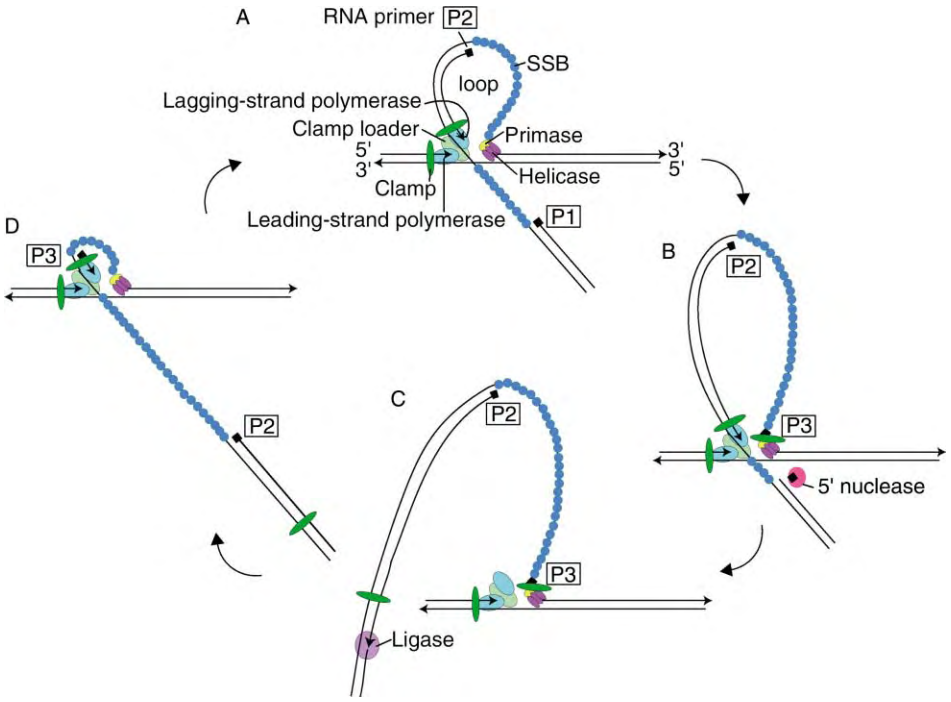

FIGURE 2 Cycle of the reactions on the lagging strand of a bacterial DNA replication fork. The functions of the proteins are described in the text. In this model, the lagging strand has been folded to bring the leading- and lagging-strand polymerases together. (A) Extension of a lagging-strand fragment that began with primer P2 in the early elongation stage. (B) Late elongation-synthesis of a new primer (P3) for the next fragment, and hydrolysis of the primer (P1) from the previous fragment, occur as the nascent fragment is extended. (C) Fragment termination-polymerase is released after it completes the fragment. The clamp is frequently left behind. The nick between fragments is sealed by DNA ligase. (D) Polymerase is transferred to the new primer (P3) to begin elongation of the next fragment. This figure shows the reactions that must be completed in each cycle, but the order of some of the reactions, such as ligation of the adjacent fragments relative to polymerase transfer, has not been established.

TABLE I

Proteins in the *E. coli* and Bacteriophage T4 and T7 DNA Replication Systems

Replication system	*E. coli*	Phage T4	Phage T7
Polymerase holoenzyme	Pol III holoenzyme		
Polymerase	Polymerase core (α, ε, θ)	T4 DNA polymerase (gp43)[a]	T7 DNA polymerase (T7 gp5 + *E. coli* thioredoxin)
Clamp	β (dimer)	gp45 (trimer)	
Clamp loader	γ-complex (γ, τ, τ, δ, δ')	gp44/62 complex	
Primosome			
Primase	dna G	gp61 primase	gp 4[b] (hexamer)
Helicase	dna B (hexamer)	gp41 helicase (hexamer)	gp 4[b] (hexamer)
Helicase loader	dna C (hexamer)	gp59 helicase loader	
ssDNA-binding protein	SSB	gp 32	gp 2.5
5′ nuclease	DNA pol I 5′ nuclease	T4 RNaseH	T7 exo6
DNA ligase	*E. coli* DNA ligase	T4 DNA ligase	T7 DNA ligase

[a] gp stands for gene product. The gene name is 43.
[b] T7 gp4 hexamer catalyzes both primase and helicase reactions.

Kinetic studies of the T7 primase–helicase show that DNA binds first to the primase site on the outside of the ring, before the ring opens to allow the DNA to reach the helicase active site in the center.

Single-Stranded DNA-Binding Proteins

The single-stranded DNA (ssDNA) regions of the lagging strand are covered by tight single-stranded DNA-binding proteins called SSB = s. In addition to protecting the ssDNA from nucleases, SSB proteins bind specifically to several other replication proteins, including polymerases, primases, and in the T4 system, the helicase loading protein, and modulate their activities.

5′–3′ Nucleases and DNA Ligases

The RNA primers on lagging-strand fragments must be removed before the fragments can be joined by DNA ligase. The enzymes responsible for removing the primers are 5′–3′ nucleases that are capable of degrading both RNA:DNA and DNA:DNA duplexes. Thus, they can remove the RNA primers and a short stretch of adjoining DNA from the discontinuous fragments.

DNA Replication Cycle

Leading-Strand Synthesis

The leading strand at the replication fork is synthesized continuously (Figure 2), beginning with an RNA primer that is made, in different systems, by either an RNA polymerase or a primase. Once the leading-strand polymerase and helicase are loaded, this polymerase can in principle remain bound to complete synthesis of the chromosome. The rate of synthesis by the polymerase, and duplex unwinding by the helicase, are much greater when these proteins work together at a replication fork, than when these reactions occur separately. The τ-subunit of the *E. coli* clamp loader connects the polymerase holoenzyme with the helicase. Although synthesis on the leading strand is extremely processive, recent evidence shows that bacterial replication forks frequently stall before completing the chromosome and need to be reassembled.

Lagging-Strand Synthesis

Because the lagging strand is made by joining short fragments, there is a cycle of reactions needed to initiate, elongate, and seal these fragments (Figure 2A–D). These reactions must be coordinated with each other, as well as with the reactions on the leading strand. The lagging-strand cycles are completed in only a few seconds because the fragments are 1000–3000 bases, and replication is proceeding at 400–1000 bases/second.

Early Elongation Stage

In the beginning of the elongation stage of this cycle, the clamped lagging strand polymerase is synthesizing a fragment that began with the primer labeled P2 (Figure 2A). At the same time, the helicase surrounding the lagging-strand template at the fork is unwinding the duplex ahead of the leading-strand polymerase.

SSB proteins coat the ssDNA between the helicase and the nascent elongating fragment, and the ssDNA between the lagging-strand polymerase and the previous fragment. Although the protein-covered ssDNA in Figure 2 is shown as a linear array for simplicity, there is evidence discussed below that it is actually in a more compact structure.

Late Elongation and Primer Synthesis

Each lagging-strand cycle can be completed rapidly because reactions required to prime the next fragment, elongate the present fragment, and remove primers from the previous fragment can occur simultaneously. In the latter part of the elongation stage (Figure 2B) as synthesis of the nascent fragment continues, primase, associated with the helicase at the fork, makes the RNA primer (P3) that will be used to start the next fragment. In the *E. coli* and T4 systems a clamp is loaded on the new primer by the clamp loader. The *E. coli* clamp loader is bound to the two polymerases at the fork, as well as to the helicase, while the clamp is recruited from solution. Dilution experiments suggest that both the T4 clamp and clamp loader must be provided from solution at the beginning of each cycle. At the same time, the $5'-3'$ nuclease is removing the RNA primer (P1) and a small amount of adjacent DNA from the previous fragment. This is the DNA that was first added to the primer, and its removal may increase the accuracy of replication. In the T4 system the SSB (T4 32 protein) between the polymerase and the nuclease increases the rate of these two reactions, and controls the extent of DNA removed along with the RNA primer.

Fragment Termination

When the lagging-strand polymerase completes the nascent fragment (Figure 2C), creating a nick, polymerase is released, but the clamp is frequently left behind on the DNA. In *E. coli*, the C-terminal domain of the τ-subunit of the clamp loader acts as an unloader, releasing the lagging-strand polymerase core from the β-clamp. The T4 proteins are less tightly bound, and there is no evidence that the clamp loader is needed to disengage the clamp and polymerase. If the polymerase fails to be released at the nick, it can continue strand-displacement synthesis, forming a flap from the $5'$ end of the downstream fragment. However, all of the prokaryotic $5'$ nucleases with a role in primer removal have flap endonuclease activities, which can remove these displaced strands. The nicks that are formed between adjacent fragments are sealed by DNA ligase.

Transfer of Polymerase to the New Primer

The *E. coli* lagging-strand polymerase released from the completed fragment remains attached to the clamp loader at the fork, and can be transferred directly to the clamped new primer (P3) to begin synthesis of the next fragment (Figure 2D). Under some conditions, the addition of primase acts as a signal that causes the lagging-strand polymerase to be released prematurely, before the previous fragment is finished. This leaves a gap between fragments that must ultimately be repaired by loading another polymerase. Structural and functional studies of the T7 primase-helicase show that the DNA-binding domain of the primase binds the new primer and transfers it to the lagging-strand polymerase.

Coordination of Leading and Lagging-Strand Synthesis

The *E. coli* leading and lagging-strand polymerases are connected because they are each joined to the same clamp-loading complex. The two polymerases at the T4 and T7 replication fork are not joined through a clamp loader. However, on synthetic templates in which dGTP can only be incorporated into the leading

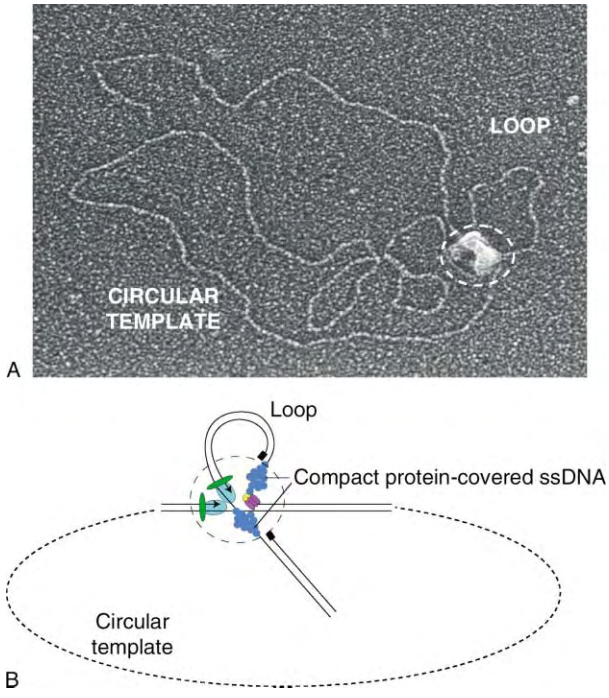

FIGURE 3 The single-stranded DNA on the lagging template is in a compact structure. (A) Electron micrograph of a replication fork with bacteriophage T4 proteins. The loop at the fork is all duplex DNA. The dense complex at the fork contains the replication proteins, as well as protein-covered ssDNA that has been folded into a compact structure. (Adapted from Chastain *et al.* (2003) *J. Biol. Chem.* **278**, 21276). (B) Model of a fork with compact ssDNA. Compare this model with that in Figure 2A.

strand and dCTP into the lagging strand, leading-strand synthesis stopped when a chain terminator was added to block lagging-strand synthesis, indicating a close interaction between the polymerases on the two strands. In addition, dilution experiments suggest that these phage polymerases can recycle from one lagging-strand fragment to the next.

The ssDNA on the Lagging Strand is in a Compact Structure

Electron microscopic analysis of DNA being replicated by the phage T7 or T4 proteins has confirmed that there is a loop at the replication fork, as predicted by the trombone replication model. While the model envisioned that the loops would be composed of the new duplex lagging-strand fragment and the ssDNA behind it (Figure 2A), the observed loops were entirely double stranded (Figure 3). The dense complex at the fork contains the replication proteins, as well as the protein-covered ssDNA folded into a compact structure. The path of the DNA and the proteins in this structure remain to be determined. The compact nature of the lagging-strand template may limit access of the primase and clamp loader, and thus be a factor in controlling when new lagging-strand fragments are initiated.

Replication Factories

Studies of the location of *B. subtilis* DNA polymerase first showed that replisome proteins are concentrated into discrete regions of living cells that have been called replication factories. It is likely that the reactions at a replication fork take place as DNA template is pulled through a stationary replisome, rather than having the replisome proteins move along the DNA.

Glossary

DNA helicase An enzyme that unwinds the two strands of a DNA duplex.

DNA ligase An enzyme that covalently joins two DNA strands together.

DNA polymerase An enzyme that synthesizes DNA by incorporating nucleotides at the 3′ end of the new strand that are complementary to the nucleotides on the strand serving as the template.

lagging strand The strand at the replication fork that is synthesized discontinuously by making shorter fragments that are sealed together by DNA ligase.

leading strand The strand at the replication fork that is synthesized continuously as one long strand.

primase An enzyme that synthesizes the short RNA primers that are used to begin the discontinuous fragments on the lagging strand of a replication fork.

University of Maryland Biotechnology Institute, Rockville, Maryland, USA

During the S phase of the cell cycle, DNA replication duplicates chromosomes into two identical copies, which segregate to daughter cells during mitosis. In DNA replication, a double-stranded molecule of DNA is copied into two daughter molecules. DNA replication occurs at replication forks – structures consisting of DNA and replication proteins that allow the two strands of DNA to be copied accurately and completely.

Introduction

All organisms must replicate their chromosomal DNA in order to propagate their genetic information. During the S phase of the cell cycle, DNA replication duplicates chromosomes into two identical copies that segregate to daughter cells during mitosis. Chromosomal DNA replication begins at regions of the chromosomes called origins of replication and can be divided into three phases: initiation, elongation, and termination. In the initiation stage, an origin recognition protein (ORP) binds the origin of replication and recruits additional initiation factors to the origin. Next the helicase is recruited to the DNA to form the initial replication bubble. The single-stranded DNA (ssDNA) exposed behind the helicase is coated with ssDNA-binding protein (SSB). The polymerase and the rest of the replication machinery are associated with the SSB/origin complex to form the two replication forks and to initiate bidirectional DNA synthesis (the elongation phase). During termination, replication forks collide and are resolved, and the resulting daughter DNA molecules are completed and separated. A number of proteins and complexes that participate in replication fork progression are described below.

Due to the antiparallel nature of DNA and the unidirectionality of the polymerase, one strand of the chromosome is synthesized continuously (the leading strand) while the other is copied discontinuously (the lagging strand) as a series of Okazaki fragments (Figure 1). It is believed that at the replication fork, the two polymerases responsible for replicating the leading and lagging strand are associated (either directly or indirectly via other molecules) (Figure 1). Thus, the replication of the two strands is coupled.

Minichromosome Maintenance (MCM) Complex

MCM is a family of six proteins (Mcm2–7, molecular masses of 101, 91, 97, 82, 93, and 81 kDa, respectively) with highly conserved amino acid sequences between the six different polypeptides. All MCM proteins are essential for cell viability and have been identified in all eukarya. In addition to forming a heterohexamer, *in vivo* and *in vitro* studies have revealed the presence of several additional MCM complexes composed of different combinations of the MCM proteins. Biochemical studies with the various complexes in yeast and mammals have shown that a dimeric complex of the Mcm4,6,7 heterotrimer contained $3'–5'$ DNA helicase activity, ssDNA binding, and DNA-dependent ATPase activities, while its interactions with either Mcm2 or Mcm3,5 inhibited the helicase activity. However, all six proteins were shown to be essential for replication fork movement. Based on genetic and biochemical studies, the MCM complex is presumed to be the helicase responsible for the separation of duplex DNA during chromosomal replication.

Replication Protein A (RPA)

RPA (also called replication factor A, RFA) is the eukaryotic single-stranded DNA-binding protein. It is a heterotrimeric complex of proteins with molecular

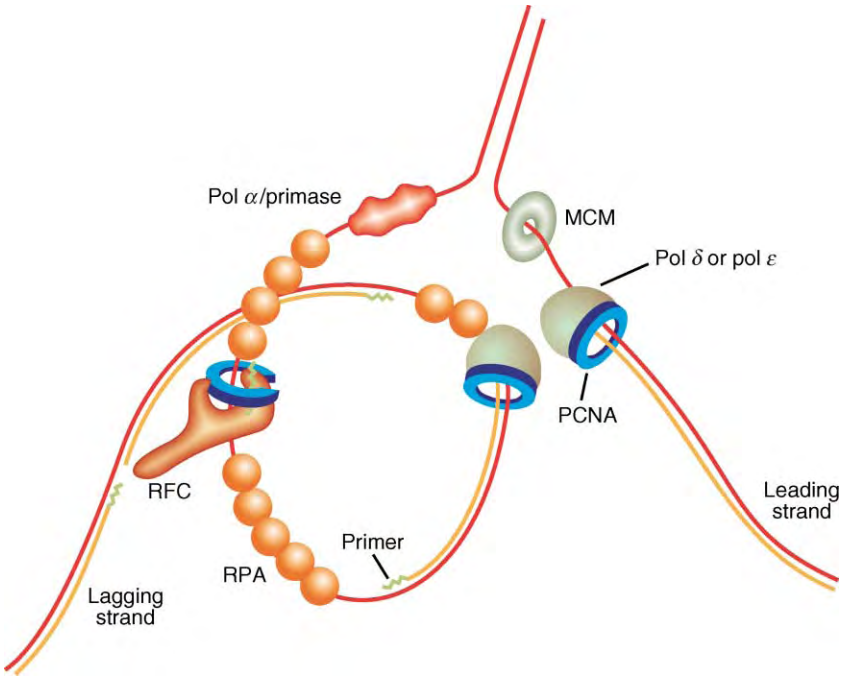

FIGURE 1 A schematic representation of the proteins at the eukaryotic replication fork. Although it is not shown in the figure, it is thought that all proteins shown interact with each other.

masses of 14, 32, and 70 kDa; these essential proteins have been found in all eukarya studied. SSBs are essential components of all replication systems. The protein coats the ssDNA exposed behind the helicase, thus protecting it from attack by nucleases and chemical modification. In addition, RPA stimulates the activity of DNA polymerases by removing secondary structures that interfere with polymerase movement, creating a uniform substrate for polymerase activity. RPA was shown to play an instrumental role in the coordination of DNA synthesis on the lagging strand and to interact with a large number of cellular factors needed for DNA metabolism.

DNA Polymerase α/Primase (Pol α/Primase) Complex

DNA polymerases are incapable of initiating DNA synthesis *de novo* and require DNA primases, which synthesize short RNA primers on template DNA that are subsequently extended by the polymerase. In eukarya, DNA primase is part of a four-subunit complex, the Pol α/primase complex, containing subunits with molecular masses of 180, 68, 58, and 48 kDa. Two of the subunits, p48 and p58, are required for primase activity, with p48 serving as the catalytic unit. Primase synthesizes short RNA primers (8–12 nucleotides (nt)) which are then elongated by Pol α to ~30 nt, forming pre-Okazaki fragments. These RNA–DNA hybrid molecules are recognized by the polymerase accessory complex, replication factor C (RFC) to initiate processive DNA synthesis by the replicative polymerase. On the lagging strand Pol α/primase activity is required at the initiation of each Okazaki fragment.

Polymerase Accessory Proteins

The processivity of DNA polymerases is quite low. This means that only a few nucleotides are incorporated into the newly synthesized DNA before the polymerase dissociates from the substrate. Processivity is conferred by a ring-shaped protein, referred to as the DNA polymerase sliding clamp (also called DNA polymerase processivity factor) that encircles DNA and acts to tether the polymerase catalytic unit to the primed template for processive DNA synthesis. The eukaryotic sliding clamp is proliferating cell nuclear antigen (PCNA). However, PCNA cannot assemble itself around the DNA, but must be loaded onto DNA by a protein complex, known as the clamp loader (also called polymerase accessory complex), which in eukarya is RFC. RFC recognizes the 3′ end of the single strand/duplex (primer–template) junction of the pre-Okazaki fragment and utilizes ATP hydrolysis to assemble PCNA around the primer. PCNA encircles the primer DNA and then binds the polymerase catalytic

unit, allowing rapid and processive DNA synthesis. Upon completion of an Okazaki fragment, the polymerase dissociates, leaving the clamp assembled around the duplex DNA.

Proliferating Cell Nuclear Antigen (PCNA)

PCNA, the eukaryotic sliding clamp, is a ring-shaped homotrimer of a 29 kDa protein. Upon its assembly around the primer of the pre-Okazaki fragment by RFC, PCNA associates with Pol δ or Pol ε to initiate processive DNA synthesis. *In vitro* studies demonstrated that upon assembly around duplex DNA, PCNA could slide freely and bidirectionally along the duplex. Although PCNA has no enzymatic activity, it plays a major role in chromosomal DNA replication. Besides its role as a processivity factor for Pol δ and Pol ε, PCNA was shown to play a regulatory role during chromosomal replication. A number of proteins that inhibit DNA synthesis were shown to operate via interaction with PCNA, preventing its association with the polymerase. Upon completion of an Okazaki fragment, PCNA disengages from the polymerase and is left on the duplex DNA. The PCNA molecules left on replicated DNA play diverse roles in postreplication DNA metabolic processes.

Replication Factor C (RFC)

RFC, the eukaryotic clamp loader, is a five-subunit complex of 140, 40, 38, 37, and 36 kDa proteins (for Rfc1–5, respectively). All five subunits are essential for cell viability. The amino acid sequences of each subunit reveal significant homology in seven regions (boxes II–VIII). The large subunit (Rfc1) contains an additional box (box I) within its N-terminal region. RFC recognizes the 3′ end of the pre-Okazaki fragment and utilizes ATP hydrolysis to assemble PCNA around the duplex DNA. It was shown that the interactions between RFC and RPA play a role in the switch that removes Pol α/primase from the DNA, allowing the loading of PCNA. In addition to its role as a clamp loader, *in vitro* studies suggest that RFC also functions as a clamp unloader, i.e., removing free PCNA from DNA.

Polymerase δ (Pol δ) and Polymerase ε (Pol ε)

Both Pol δ and Pol ε are essential polymerases required for chromosomal replication. However, their precise function at the replication fork remains unclear. Although Pol δ is found in all eukarya, its polypeptide composition is different in different organisms. To date, Pol δ isolated from either mammals or *Schizosaccharomyces pombe* is a heterotetramer of 125, 66, 50, and 12 kDa protein (only the human molecular masses are given) while the *Saccharomyces cerevisiae*, Pol δ, is a heterotrimer. *In vitro* studies with these enzymes indicate that all Pol δ complexes are monomers. Following the assembly of PCNA at the primer, Pol δ associates with the clamp to initiate rapid and processive DNA synthesis.

Pol ε is a four-subunit complex of proteins with molecular masses of 261, 59, 17, and 12 kDa (for the mammalian complex). As is the case with Pol δ, Pol ε is a monomeric polymerase. Like Pol δ, the PCNA clamp is required for the Pol ε-catalyzed DNA synthesis in the presence of physiological salt concentrations. However, at low ionic strength Pol ε alone can elongate primed DNA chains, in contrast to Pol δ.

Reconstitution of the simian virus 40 (SV40) DNA replication system with mammalian enzymes demonstrated that only Pol δ was required for replication of both leading and lagging strands and did not require Pol ε. Both *in vivo* experiments in yeast and *in vitro* experiments with the *Xenopus* cell free replication system indicate that Pol ε and Pol δ are required for replication. Genetic experiments in yeast showed that Pol ε is located at the replication fork. Furthermore, mutational rate studies in *S. cerevisiae* suggest that the proofreading functions of Pol δ and Pol ε act on different DNA strands. However, the precise location of each polymerase (i.e., lagging or leading strand) could not be deduced. These results suggest that each polymerase acts on a specific strand during replication. However, conflicting results in yeasts indicate that cells deleted of the catalytic domain of the large subunit of Pol ε (at the N terminus) are viable, provided that the C terminus of this subunit is expressed. The C terminus was shown to play an important role in the regulation of DNA replication. Interestingly, point mutations in the conserved catalytic site of Pol ε result in loss of viability. Thus, although Pol ε is normally present at the replication fork, in the absence of the catalytic portion of its large subunit, it is likely that Pol δ can substitute for its function. Further studies are needed to determine the cellular functions of Pol δ and Pol ε.

Topoisomerases

During replication, DNA is supercoiled in front of and behind the polymerase. Positive supercoils are produced in front of the replication fork, while negative supercoils result behind it. Topoisomerases prevent excessive supercoiling and regulate the level of supercoiling within the DNA molecule. These enzymes are essential for replication fork progression.

Topoisomerases introduce transient breaks in the phosphodiester backbone of the DNA, which allow supercoils to be added or removed.

Conclusion

The replication of eukaryotic chromosomes is a very complex and highly coordinated process involving dozens of proteins. Although most of the proteins assembled at the replication forks have been identified and isolated, the precise biochemical properties and roles of some of these proteins remain to be elucidated.

DNA Replication, Mitochondrial

David A. Clayton
Howard Hughes Medical Institute, Chevy Chase, Maryland, USA

Nearly all eukaryotic cells contain organelles called mitochondria that contain enzymes which utilize oxygen and nutrient molecules, such as sugars, to produce most of the ATP that in turn provides energy to support cellular molecular activities. The mitochondria, in addition to being the principal sites of energy production, contain their own genomes, mitochondrial DNA (mtDNA), which are different structurally and functionally from the much larger nuclear genome. DNA replication is the process by which new DNA is synthesized by copying the strands of pre-existing DNA. Replication of mtDNA occurs by a distinctive mechanism independent of the replication of DNA in the cell nucleus. Proper synthesis and maintenance of mtDNA and the mitochondrion as a whole requires the coordinated participation of both nuclear and mtDNA gene products.

Mitochondrial Constituents and their Functions

Mitochondria comprise several hundred macromolecules, including mtDNA, mitochondrial RNA (mtRNA), and proteins.

mtDNA

Although certain cells can exist without mtDNA under special nutrient and growth conditions, where oxidative phosphorylation activity is not essential, in all other cases, mtDNA is needed. This is due to the fact that mtDNA encodes some of the proteins necessary for mitochondrial function in energy production. The sizes of mitochondrial genomes are quite broad. Vertebrate mtDNAs are typically 16–18 Kb in size, with yeast mtDNA being several times larger. Plant mtDNAs can be 30-fold larger than vertebrate mtDNA. In addition, the number and identity of mtDNA genes is not constant across all mtDNAs. Human (and vertebrate) mtDNAs contain 37 genes, of which 13 are for proteins involved in bioenergetics. Although larger mtDNAs can contain more genes, the coding information is not directly linear with genome size.

RNA

The RNA inside the mitochondrion is almost exclusively that which is encoded by mtDNA. For mammals, this generally includes two rRNAs and 22 tRNAs. These 24 RNAs are thought to be necessary and sufficient to support fully the mitochondrial translation machinery, responsible for decoding the 13 mammalian mRNAs for mtDNA-encoded proteins.

Other RNAs, encoded by nuclear genes, include additional tRNAs, in cases where mtDNA contains an insufficient number of its own tRNA genes. In addition, certain RNA-processing activities, consisting of enzymes with nucleus-encoded RNA components, have been implicated as participants in processing mtRNA sequences. These include an RNase P for processing tRNA precursors and an RNase that cleaves mtRNA sequences at the origin of leading-strand DNA replication. This latter activity is thought to provide 3′-primer RNA ends for elongation by mtDNA polymerase.

Protein

The protein components of mitochondria are of several classes. Although mitochondria play key roles in apoptosis, calcium regulation, iron metabolism, and the synthesis of amino acids, sterols, and heme, the principal function of the organelle is energy production. It is, therefore, not surprising that all of the mtDNA-encoded proteins participate in the formation of one or another of the several bioenergetic complexes that support the chain of reactions leading to ATP production. Although the vast majority of mitochondrial proteins are encoded by nuclear genes, those encoded by mtDNA are essential and there are no nuclear genes present that can substitute for a loss of mtDNA.

The several hundred nucleus-encoded proteins that comprise the bulk of mitochondrial proteins fall roughly into two classes. One class is devoted to the task of energy production and mitochondrial function, including maintenance and expression of mtDNA. The second population consists of structural elements that provide the infrastructure that maintains basic mitochondrial morphology, mobility, and organelle physiology.

Most mitochondrial proteins, being nuclear-gene products, are produced by translation on cellular ribosomes and then targeted to mitochondria by their sequence (the most common feature directing the process is a signal sequence at one end of the protein, the amino terminus). Physical importation of the protein involves specific portions of the mitochondrion's inner and outer membranes that form ports for entry of these proteins. Initially, a general internalizing import mechanism applies to most proteins regardless of their final destination within the mitochondria. This is followed by other mechanisms leading to sorting of protein according to function.

Replication of the Mitochondrial Genome

Replication of mtDNA occurs within the confines of the mitochondrial-organelle network, which is usually organized dispersively throughout the cell's cytoplasm. As such, it represents a separately managed genome, physically and functionally distinct from nuclear DNA replication. The cellular copy number of mtDNA varies according to cell type. For example, mature lymphocytes have a few hundred mitochondrial genomes, whereas mammalian oocytes contain tens of thousands. Unlike nuclear DNA replication, which is subject to cell cycle control, it appears that mtDNA is able to initiate and complete a round of replication in dividing cells at any time.

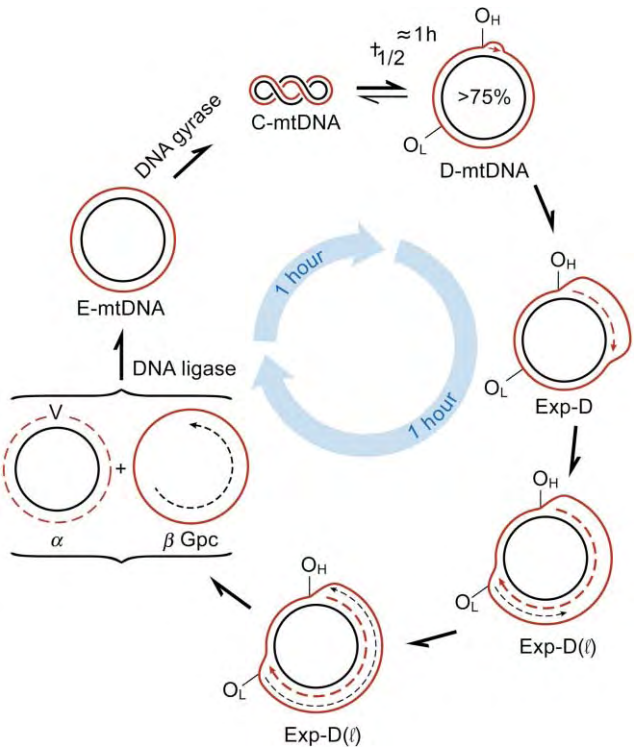

FIGURE 1 Diagram of mtDNA replicative intermediates. In the strand-displacement model closed-circular mtDNA (C-mtDNA) is in equilibrium with D-loop mtDNA (D-mtDNA). Productive replication is defined by elongation of the leading strand (red), which progresses around the genome (dashed red; Exp-D) until exposure of the major lagging-strand origin, which sponsors initiation of synthesis in the counterclockwise direction. End products are the new α- and β-circles, which are finished to closed circles (E-mtDNA). Superhelical turns are introduced (C-mtDNA) and finally a new D loop is synthesized. There is a rapid conversion back-and-forth between D-mtDNA and C-mtDNA.

Mammalian mtDNA

The historic replication model posits that leading-strand replication of mammalian mtDNA begins at closely spaced, defined sites located downstream from a major transcription promoter and proceeds unidirectionally with displacement of the parental leading strand until approximately two-thirds of the closed circular mtDNA has been copied (Figure 1). As a consequence, the replication fork passes a major origin for lagging-strand synthesis, leaving it in single-stranded form. Displacement as a single strand is thought to allow the characteristic secondary structure of this origin to occur, thereby permitting initiation of lagging-strand synthesis. A natural consequence of the separate and distinct locations of the two origins is that the two segregated progeny mtDNA circles are of two types: one a duplex circle with a newly synthesized leading strand and the other a gapped circle with a partial newly synthesized lagging strand. In each case, the final steps of synthesis and closure result in the mature closed circular mtDNA products.

Convincing biochemical isolation and characterization of mammalian mtDNA began in the 1960s. The key technical breakthrough was the use of dye-salt buoyant density centrifugation to isolate even relatively rare closed-circular DNAs in highly purified form. This technique was exploited to perform mtDNA analyses by sophisticated analytical centrifugation techniques, by electron microscopy, and eventually by gel electrophoresis. It is fortuitous that mammalian mtDNA molecules are small enough to be easily manipulated and analyzed by a variety of techniques.

Unique to mammalian mtDNA and a few viral DNA genomes is a bias in the content of guanosine plus thymine in one strand of the double helix compared to the other strand. A consequence of this situation is that the two strands of mammalian mtDNA can be physically separated to an extent that allows their individual identification. Therefore, one can isotopically label mtDNA and directly assay the extent of mtDNA synthesis that has occurred in each strand.

Perhaps the most signature feature of mammalian mtDNA is the displacement-loop (D loop). The D-loop nomenclature follows from the fact that closed-circular

mtDNA contains a region of varying size, depending on the species, in which leading-strand DNA synthesis has initiated and elongated to a size between 0.5–1 Kb. Molecules exhibiting progressive growth of this nascent leading strand, approaching full genomic size, were identified and argued as support for the proposed model for replication.

Lagging-strand synthesis is revealed by the appearance of duplex DNA within the context of the ever-increasing displaced parental-single strand. A preferred initiation site is located about two-thirds of the genomic distance away from the D-loop origin of leading-strand synthesis. Recent studies have suggested that other sites can serve as points of lagging-strand DNA replication initiation and thereby provide a broader range of duplex replicative intermediates.

Future Studies

In contrast to studies on mtDNA, the mitochondrial system has been challenging with respect to identifying, purifying, and characterizing the critical proteins and other factors that sponsor mtDNA replication. A principal reason for this is that although low-abundance mammalian mtDNA can be successfully purified to a high state because of its closed circular physical form, in general, the mitochondrial proteins involved in mitochondrial nucleic acid syntheses tend to be similar to their much more abundant nuclear counterparts. With the current availability of mammalian genomic sequences, and cloning and expression technologies, it should be possible to make more advances in this area. A partial listing of known and predicted activities include mtDNA and mtRNA polymerases, transcription factors, single-strand DNA binding protein, specialized RNase activities, helicases, and topoisomerases.

It is now clear that mitochondrial function and the integrity of normal mtDNA are important for normal physiology in mammals. There are numerous reports of human disease in particular that have mtDNA mutations, and even loss of mtDNA, as the underlying basis for what is usually manifested as neuromuscular disorder phenotypes.With this understanding, it will be important to learn the nature and rate of mtDNA turnover in different cells and tissues. Unlike nuclear DNA, which is not replicating in nondividing cells, mtDNA continues in its need to replicate due to continuous turnover and renewal of the mitochondrial organellar population. Thus, at least the opportunity to accumulate mutations in mtDNA during an individual's lifetime can be appreciated. Knowledge of the global pattern of mtDNA-turnover rates could prove valuable in predicting risk factors for human mitochondrial disease.

There are now a number of studies that are identifying the key activities that regulate the fission and fusion of individual organelles. This will likely involve further consideration of how the mitochondrial network travels along microfilaments and is positioned within the cellular cytoplasm. In turn, it will be important to learn more about the precise location of mtDNA-replication sites to determine if replication is site-specific or can occur generally.

Yeast and Others

Historically, the yeast system has been the most widely used to study almost all aspects of mitochondrial biogenesis. It has provided a wealth of information on bioenergetics, organelle assembly, protein import, and other areas of mitochondrial biology, including the details of mtDNA gene expression.

However, studies of mtDNA replication in yeast have been challenging due, in part, to the plasticity of the genome and the very aggressive rate of recombination of yeast mtDNA in cells. Thus the isolation and analysis of productive replicative intermediates have proved much more difficult than for mammalian systems with their small genomes and almost complete absence of recombination, including the nucleases usually associated with breakage and rejoining of DNA strands. Nevertheless, there are a few intriguing similarities between yeast and mammalian mtDNAs with regard to potential yeast mtDNA origins resembling origin sequences in D loops. It will be interesting to learn whether origins of replication have been conserved over this period of evolution, or whether other roles for these sequences, such as attachment to membranes to facilitate segregation of mtDNA molecules after replication, are the driving force for these similarities. In this regard, recent studies have suggested that mtDNA can be isolated in close association with specific proteins, which may be key to understanding genomic placement in the organelle.

Responsible for the institute's Science Department, he led the early phase of planning for the Janelia Farm Research Campus. He received his Ph.D. from the California Institute of Technology, and is a biochemist and geneticist whose research focuses on understanding the nature and role of mitochondrial DNA in cells. He is also a Professor at Stanford University and a member of the Institute of Medicine of the National Academy of Sciences.

DNA Replication: Eukaryotic Origins and the Origin Recognition Complex

Melvin L. DePamphilis

Cong-jun Li
Animal and Natural Resources Institute, US Department of Agriculture, Beltsville, Maryland, USA

Eukaryotic DNA replication is a highly conserved process that begins with the assembly of an origin recognition complex (ORC) composed of six different subunits (Orc1 to Orc6) at DNA replication origins distributed throughout the genome. Thus, it is the interaction between ORC and DNA that determines where DNA replication begins in the genomes of eukaryotic cells. Moreover, regulation of ORC activity is the premier step in determining when replication will occur. Pre-replication complexes (pre-RCs) are assembled at ORC/chromatin sites during the G1 phase of the cell division cycle. Pre-RCs consist of six ORC proteins, Cdc6, Cdt1, and six Mcm proteins. The role of Cdc6 is to identify ORC/chromatin sites; the role of Cdt1 is to load Mcm(2–7) hexamers onto these sites. The role of Mcm(2–7) hexamers is to unwind the DNA into two single-stranded DNA templates. DNA synthesis (S phase) is triggered by the addition of Mcm10 followed by the action of three protein kinases: Cdc7/Dbf4, Cdk2/cyclin E, and Cdk2/cyclin A. These events allow Cdc45 to escort DNA polymerase-α:DNA primase to the pre-RC and initiate RNA-primed DNA synthesis at or close to the ORC-binding site.

DNA Replication Origins

The Generic DNA Replication Origin

All DNA replication origins require two core components: (1) one or more binding sites for an origin recognition protein or protein complex, and (2) an easily unwound sequence called the DNA-unwinding element (DUE). A DUE is not sequence specific, but consists of a nucleotide composition with a low melting temperature. DNA unwinding begins within the DUE, and then DNA synthesis begins on each of the resulting single-stranded DNA templates. Additional "auxiliary" components may include one or more transcription factor binding sites that facilitate either binding of origin recognition proteins or DNA unwinding, but that are not required for origin activity. Auxiliary components are commonly found in viral replication origins. In cellular genomes, the sites where DNA replication begins, particularly in multicellular organisms, are determined by epigenetic as well as genetic parameters. This allows metazoans the flexibility to change their pattern of replication origins to accommodate changes in the length of S phase and in the pattern of gene expression that can occur during animal development. Thus, evolution has retained the same basic mechanism for DNA replication throughout the eukaryotic kingdom without sacrificing the flexibility needed in gene expression and genomic changes needed to create complex, multicellular organisms.

Eukaryotic replication origins initiate DNA replication in both directions, resulting in a transition from discontinuous to continuous DNA synthesis on each template strand (origins of bidirectional replication (OBR)) (Figure 1). This transition occurs because the two complementary DNA strands are antiparallel ($5' \rightarrow 3' : 3' \leftarrow 5'$), and all DNA polymerases travel along their template in only one direction ($5' \rightarrow 3'$). Therefore, DNA synthesis can occur continuously on one template of a replication fork in the same direction as DNA unwinding (this process is termed leading strand synthesis), but it must occur discontinuously on the complementary template, in the direction opposite to DNA unwinding, through the repeated initiation of short nascent DNA fragments called Okazaki fragments (lagging strand synthesis). Okazaki fragments are initiated by the enzyme DNA polymerase-α:DNA primase, extended by DNA polymerase-α:PCNA, and eventually ligated to the $5'$ end of the long growing daughter strand by DNA ligase I. The two leading strand initiation events that mark the OBR are separated by only one or two nucleotides.

Eukaryotic replication origins depend on DNA sequence information, although the requirements are less stringent than viral replication origins. Cellular

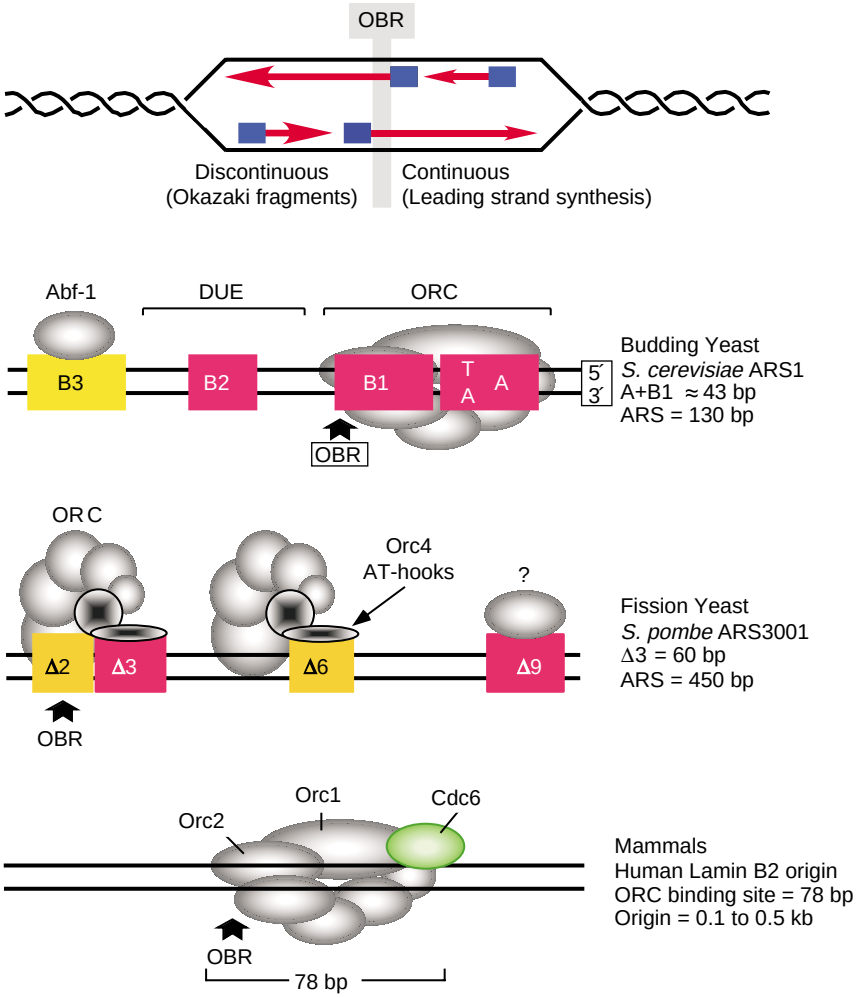

FIGURE 1 Replication origins. Some sequence elements are required for origin activity (red) while others facilitate origin activity (yellow). The *S. cerevisiae* ARS1 origin consists of a binding site (elements A + B1) for the six subunit origin recognition complex (ORC), and a large DNA-unwinding element (DUE) that contains a genetically defined B2 element. It also contains a binding site for transcription factor Abf-1. The origin of bidirectional replication (OBR) is the site where leading strand synthesis begins on each template. The *S. pombe* ARS3001 origin consists of four genetically defined elements. Δ3 and Δ6 bind SpORC. Δ2 contains the OBR. Δ9 is required for origin activity, but its function is unknown. The human lamin B2 origin has been mapped to a ~0.6 kb site at the 3′-end of the lamin B2 gene. No genetically defined elements (replicators) have been reported, but other mammalian replicators occupy <1 kb. The OBR and DNA contact points for Orc1, Orc2, and Cdc6 have been identified.

replication origins contain a "replicator" sequence that imparts origin activity when translocated to other chromosomal sites; this can be inactivated by sequence alterations. The genomes of viruses, yeast, and protozoa also contain an autonomously replicating sequence (ARS) that allows extrachromosomal DNA (e.g., plasmids) to replicate when provided with the cognate origin recognition proteins and essential replication proteins. All ARSs exhibit replicator activity, but all replicators do not exhibit ARS activity. Such differences presumably reflect the effects of sequence context and chromatin structure on origin activity.

The most well characterized replication origins are found in the genomes of animal viruses and yeast cells. Genomes such as simian virus 40 (SV40), polyomavirus, and papillomavirus contain a single species-specific sequence of approximately 60 bp that is the binding site for the single origin recognition protein encoded by the virus. For example, SV40 encodes T-antigen, which in the presence of ATP binds specifically to the SV40 replication origin where it assembles into two hexamers with the DNA passing through their centers. The two hexamers unwind DNA in opposite directions, one hexamer for each newly formed replication fork. T-antigen hexamers assembled in the absence of DNA cannot unwind the origin. Thus, viral replication origins not only determine where replication begins, but also are required for assembly of an active helicase to initiate DNA unwinding, a prerequisite to DNA synthesis.

Yeast origins are similar to animal virus origins in that they both exhibit ARS activity. However, yeast origins differ from viral origins in four ways: (1) Viral origins initiate replication many times per cell division cycle, whereas yeast origins (like all eukaryotic origins) are activated once and only once per cell cycle. (2) Viral origins exhibit a rigid modular anatomy in which the sequence elements require a specific spacing and orientation with respect to one another, whereas yeast origins exhibit a flexible modular anatomy in which the same functional modules from different origins are interchangeable, even though they are not similar in sequence. (3) Viral origins function independently of their DNA context, whereas both the activity and the timing of the activation of yeast origins are strongly influenced by neighboring sequences. (4) Finally, viral origins are sequence-specific binding sites for a unique virally encoded origin recognition protein, whereas yeast origins exhibit little sequence specificity and bind a complex of six different proteins (ORC). ORC, in turn, recruits a helicase [Mcm(2–7)] to the replication origin.

The Budding Yeast Paradigm

Replication begins at specific DNA sites in *Saccharomyces cerevisiae* consisting of 100 to 150 bp. The core component consists of an ScORC binding site (~30 bp) that includes two genetically identifiable elements, A and B1, as well as a DUE that usually contains the genetically identifiable B2 element (Figure 1). (Note that species is indicated by prefixes such as Sc, Sp, Xl, Dm, and Hs for *Saccharomyces cerevisiae*, *Schizosaccharomyces pombe*, *Xenopus laevis*, *Drosophila melanogaster*, and *Homo sapiens*, respectively.) Element A contains an asymmetric A:T-rich ARS consensus sequence that is required for origin activity. B1 facilitates A in binding ScORC. B2 appears to be a weak ScORC binding site that facilitates pre-RC assembly. Some origins also contain an auxiliary component, element B3 (~22 bp), that binds transcription factor Abf-1. The OBR is marked by two start sites for leading strand DNA synthesis at specific nucleotides separated by only 1 bp. The OBR resides between the ScORC binding site and the DUE. Despite the fact that only ~15% of the sequences in *S. cerevisiae* origins are shared (parts of elements A and B1), they exhibit a flexible modular anatomy in which homologous elements from different origins are interchangeable. Yeast origins vary considerably in the frequency at which they are activated during cell proliferation and in the temporal order they are activated during S phase. Sensitivity to their DNA (chromatin?) context most likely accounts for the facts that not all ARS elements function as replication origins in yeast chromosomes and that some origins can bind ORC but still cannot initiate replication.

The Fission Yeast Paradigm

S. pombe replication origins (0.5 to 1 kb) are five to ten times larger than those in *S. cerevisiae*. *S. pombe* replication origins contain ARSs that function *in vivo* as replication origins, but *S. pombe* ARSs are not interchangeable with those in *S. cerevisiae*. Furthermore, they lack a genetically required consensus sequence. *S. pombe* replication origins contain two or more regions that are required for full ARS activity. These regions consist of asymmetric A:T-rich sequences with A residues clustered on one strand and T residues on the other. Some exhibit either orientation or distance dependence, and some bind SpORC, assemble a pre-RC, and initiate bidirectional DNA replication, while others with a similar AT content do not. Thus, despite the absence of a required consensus sequence, *S. pombe* origins still exhibit sequence specificity in their design.

For example, ARS3001 (Figure 1) consists of four genetically required sites contained within ~570 bp; Δ2 and Δ6 are weakly required while Δ3 and Δ9 are strongly required. SpORC binds strongly to the Δ3 site, weakly to the Δ6 site, and not at all to the remaining sequences. Pre-RC assembly appears to occur primarily at the Δ3 + Δ2 region, and an OBR has been mapped to the Δ2 site. Thus, the Δ3 + Δ2 region (~100 bp) is equivalent to a simple *S. cerevisiae* origin. Δ6 appears similar to the B2 element in *S. cerevisiae* origins in that it is a weak SpORC binding site that facilitates origin activity. Remarkably, the Δ9 region, which is required for origin activity to the same extent as the Δ3 region, neither binds ORC nor functions as a centromere, although it does bind an as yet unidentified protein throughout the cell cycle. Therefore, Δ9 may be a novel origin component. This and other examples suggest that *S. pombe* replication origins contain at least two SpORC binding sites, consisting of asymmetric A:T-rich sequences, that act synergistically to facilitate assembly of a single pre-RC at an adjacent site.

Metazoan Replication Origins

Replication origins in multicellular animals such as flies, frogs, and mammals differ in two critical ways from those found in animal viruses and in yeast. First, metazoan replication origins exhibit replicator activity more readily than they do ARS activity, suggesting that metazoan replication origins function better in large chromosomes than in small extrachromosomal elements. Second, metazoan ORCs do not require binding to specific DNA sequences in order to initiate assembly of a pre-RC. For example, early embryos undergoing rapid cell cleavage (e.g., frogs, flies, sea urchin, fish) initiate DNA replication with no obvious requirement for any specific DNA sequences,

and DmORC or HsORC can replace XlORC in frog egg extracts with the same result.

Nevertheless, in the differentiated cells of flies, frogs, and mammals, OBRs have been mapped repeatedly to specific genomic loci. The nature of these loci, however, is not clear. Studies employing 2D gel fractionation of total genomic DNA to detect replication bubbles or to map the polarity of replication forks generally conclude that initiation events are distributed uniformly over intergenic regions as large as 55 kb (initiation zones), whereas methods that map either the relative distribution or the relative abundance of nascent DNA strands along the genome invariably conclude that initiation events originate within specific loci of ~1 kb or smaller, similar in size to fission yeast origins. Moreover, these specific loci contain replicators that can be inactivated by internal deletions, but they lack an identifiable, genetically required consensus sequence, such as the ARS consensus sequence found in budding yeast replicators. They also contain an OBR that is comparable to those found in yeast, and at least one ORC-binding site (e.g., lamin B2) (Figure 1). In addition, origin activity can be regulated from sequences such as locus control regions that are many kilobases distal to the OBR but affect the accessibility of initiation sites to replication proteins. Thus, replication origins in mammals appear more similar to those in fission yeast than to those in budding yeast.

How might such disparate data be reconciled? The answer is that metazoan genomes contain many potential initiation sites for DNA replication, but during animal development some of these sites are selectively activated whereas others are suppressed. This is evident from the simple fact that site-specific initiation is developmentally acquired. Initiation sites are uniformly distributed throughout the genome in embryos undergoing rapid cell cleavages prior to the onset of zygotic gene expression, with no apparent preference for specific sequences. After this stage, initiation events become restricted to specific sites. Therefore, epigenetic as well as genetic parameters determine where initiation will occur.

Epigenetic Parameters

Epigenetic parameters that can affect origin activity include nucleotide pool levels, transcription factor binding sites, concentration of replication proteins, transcription, chromosome structure, nuclear organization, and DNA methylation. For example, under normal culture conditions, one particular 128 kb locus in the hamster cell genome initiates predominately at a single primary (high-frequency) origin. However, reducing dNTP pools distributes initiation events equally among six different origins within this locus (the primary origin plus five secondary or low frequency origins). This implies that synchronization of cells at their G1/S boundary by reducing nucleotide pools would favor the appearance of initiation zones, a caveat that may account for some of the data in the literature. It also implies that the frequency of initiation sites in mammals is similar to the frequency in yeast and in frog eggs (1/20 to 1/30 kb).

Similarly, transcription factors binding close to ORC-binding sites can facilitate origin activity. Because they are expressed in specific cells and at specific times during development, transcription factors could impart both developmental and DNA site specificity to origins. High ratios of ORC to DNA should favor initiation at low- as well as high-affinity DNA binding sites, whereas low ratios would favor initiation at high-affinity sites only. Since the concentration of ORC in the eggs of the frog, *Xenopus laevis*, is about 10^5 greater than in frog somatic cells, this could account for the transition from "random" to site-specific initiation events that is observed during frog development. In addition, the onset of zygotic gene expression will repress initiation events in the transcribed regions, because RNA synthesis through replication origins represses their activity. Similarly, changes in chromosome structure will make some genomic sites more accessible to ORC while making others less accessible. Changes in nuclear organization may also contribute to origin specification, because site-specific initiation of DNA replication has been observed only with intact cells or with intact (impermeable) nuclei incubated in cell extracts. Finally, DNA methylation is associated with repressed chromatin, and changes in DNA methylation patterns have been correlated with changes in initiation site activity.

Primary and secondary origins clearly exist in yeast, where some origins are activated once each cell division cycle while others are not, and in bacteriophage such as T7, where deletion of the primary origin simply shifts replication to a secondary origin. Most mammalian origins contain AT-rich sequences of the type commonly found at matrix attachment regions and in the replication origins of fission yeast and flies. In fact, ORCs from *S. pombe*, *Xenopus* eggs, and human cells all target asymmetric A:T-rich sequences. Perhaps their affinity for a particular site depends on epigenetic factors.

The Origin Recognition Complex

Eukaryotic ORCs are functionally, if not structurally, conserved among yeast, frogs, flies, and mammals. They all bind to DNA with nanomolar affinity, and they all bind preferentially to asymmetric A:T-rich sequences. ORC subunits 1, 4, and 5 bind ATP. The ATP-binding site in Orc1 is required for ORC

activity, and ORC exhibits ATPase activity. Only two of the six ORC subunits contain multiple consensus sites for phosphorylation by cyclin-dependent protein kinases, suggesting that these subunits are targets for regulation. These are Orc1 and Orc2 in the metazoa and Orc2 and Orc6 in yeast. Nevertheless, there are notable differences.

The ability of ORC to bind specific DNA sequences appears to be species dependent. Site-specific DNA binding by *S. cerevisiae* ORC requires subunits 1 to 5 and ATP; once ScORC is bound to origin DNA, it remains there throughout the cell division cycle. ScORC covers ~80 to 90 bp, and origin binding is facilitated by Cdc6. ScORC bound to dsDNA origins exists in an extended conformation, whereas ScORC bound to ssDNA forms a bent conformation. In addition, ScORC ATPase activity is stimulated by ssDNA but inhibited by dsDNA. Thus, it appears that *S. cerevisiae* double-stranded origin DNA, ATP, and Cdc6 stabilize bound ScORC in a conformation that allows pre-RC assembly, whereas ssDNA, ATP hydrolysis, and the loss of Cdc6 converts ScORC into a form that may release the Mcm(2–7) helicase to continue unwinding DNA at replication forks.

Like *S. cerevisiae*, all six *S. pombe* ORC subunits remain tightly bound to chromatin throughout the cell cycle. In contrast to *S. cerevisiae*, however, site-specific DNA binding by *S. pombe* ORC requires only the SpOrc4 subunit; neither the presence nor the absence of ATP and the other five subunits affects SpOrc4 binding to DNA *in vitro*. The SpOrc4 subunit is unique among eukaryotes in that its N-terminal half contains nine AT-hook motifs that specifically bind the minor groove of AT-rich DNA. The C-terminal half of SpOrc4 is 35% identical and 63% similar to the human and *Xenopus* Orc4 proteins. SpOrc4 has a general affinity for all AT-rich DNA, but it has a higher affinity for specific asymmetric A:T-rich sequences found within *S. pombe* replication origins. In fact, chromatin immunoprecipitation assays reveal that SpORC is bound to *S. pombe* origins and not to other AT-rich sequences in the regions between origins. Thus, while each AT-hook motif binds tightly to [AAA(T/A)], site specificity likely results from the arrangement of all nine motifs acting in concert.

Whereas the six ORC subunits in yeast and frogs form a stable complex *in vitro*, human ORC consists of a stable ORC[2–5] subcomplex to which Orc1 and Orc6 are only weakly bound. Both frog and human ORC binds preferentially to asymmetric A:T-rich sequences *in vitro* or during DNA replication in frog egg extracts, and the sequences selected by these metazoan ORCs are the same as those targeted by SpOrc4. Nevertheless, HsORC is localized at specific DNA replication origins *in vivo*.

Regulating ORC Activity: The ORC Cycle

One universal feature of eukaryotic DNA replication is that the genome is replicated once and only once each time a cell divides. This is accomplished in two ways. First, pre-RCs that are assembled during the M to G1 phase transition are inactivated during S phase, and second, new pre-RCs cannot be assembled until G1 phase. This is accomplished by blocking pre-RC assembly and activation at multiple steps such as the Cdc6, Cdt1, Mcm(2–7), and Cdk2 functions. However, the premier step in determining both where and when DNA replication begins is the assembly of functional ORC/chromatin sites, and this step appears to be regulated by inactivating ORC during the G1 to S phase transition and then preventing re-establishment of ORC activity until mitosis is completed and, in the metazoa, a nuclear membrane is reassembled.

In contrast to mammals and frogs, all six ORC subunits in yeast remain tightly bound to chromatin throughout their cell division cycles. Nevertheless, yeast ORC subunits undergo cell cycle-dependent phosphorylation that contributes to preventing reinitiation of DNA replication before cell division is finished. Orc2 and Orc6 are phosphorylated by Cdk1(Cdc28)/cyclin B during the S to M transition, and then dephosphorylated during early G1 phase when pre-RC assembly occurs. In *S. pombe*, Cdk1(Cdc2)/cyclin B associates with replication origins during S phase and remains there during G2 and early M phases. This association is ORC dependent and prevents reinitiation of DNA replication before mitosis has been completed (Figure 2).

In frog eggs, all six ORC subunits remain stably bound to one another throughout the cell division cycle, but their affinity for chromatin is cell cycle dependent. When sperm chromatin replicates in a *Xenopus* egg extract, the affinity of XlORC for chromatin becomes salt-labile following pre-RC assembly and then appears to be released during G2/M phase as a result of hyperphosphorylation by Cdk1/cyclin A. However, when somatic cell chromatin replicates under the same conditions, XlORC binds to the chromatin, initiates pre-RC assembly, and is then released upon completion of pre-RC assembly. Thus, the affinity of XlORC for chromatin depends on at least three factors: pre-RC assembly, chromatin structure, and the action of Cdk1/cyclin A (Figure 2).

In mammalian cells, ORC subunits two to five remain bound to chromatin throughout the cell division cycle, but the affinity of the largest subunit, Orc1, for chromatin is selectively reduced during S phase and then restored during the M to G1 phase transition (Figure 3). During G1 phase, Orc1, Orc2, Cdc6, and Mcm3 proteins can be cross-linked to replication origins (e.g., lamin B2

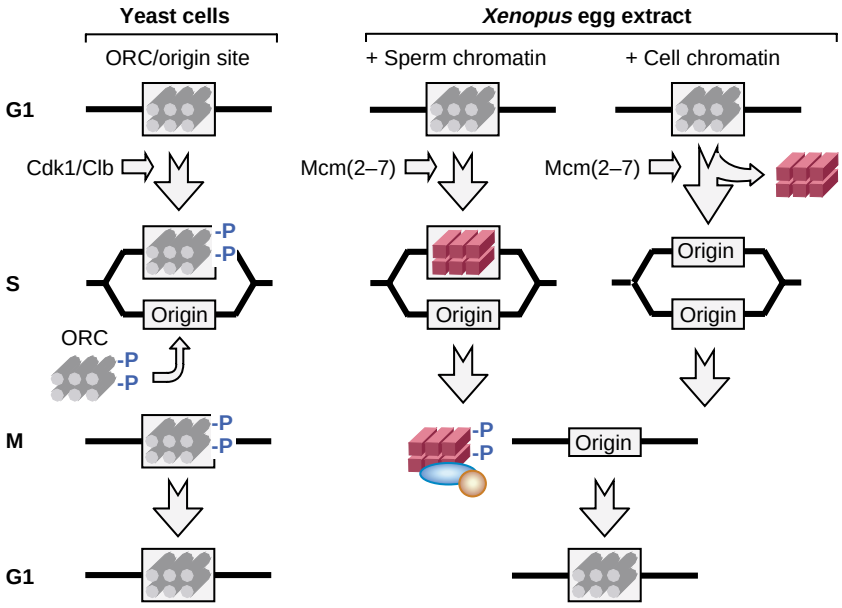

FIGURE 2 Three manifestations of the ORC cycle in eukaryotes. Yeast cells: ORC (six gray cylinders) remains bound to replication origins throughout the cell cycle, but ORC is phosphorylated (-P) during the S to M periods; this phosphorylation inhibits its ability to assemble a pre-RC. *Xenopus* egg extract: ORC binds to sperm chromatin, but the stability of ORC/chromatin sites is reduced (red boxes) following pre-RC assembly. ORC is phosphorylated by Cdk1/cyclin A (yellow ball) during G2/M and released from chromatin. If somatic cell chromatin is incubated in the extract instead of sperm chromatin, then ORC is released from chromatin following pre-RC assembly.

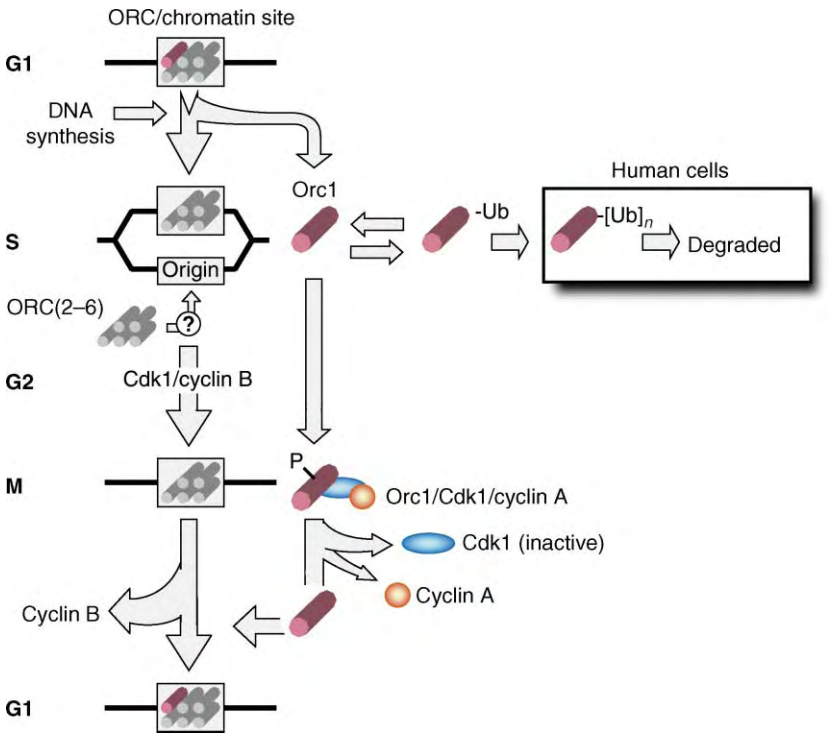

FIGURE 3 The ORC cycle in mammalian cells. ORC subunits 2 to 6 (grey cylinders) remain bound to chromatin throughout the cell cycle, but the Orc1 subunit (red cylinder) is selectively destabilized and released from chromatin when DNA synthesis begins (S phase). Orc1 is then mono-ubiquitinated (Ub) and in some cases polyubiquitinated ($[Ub]_n$) and degraded. Orc1 in mitotic cells is hyperphosphorylated by its association with Cdk1/cyclin A. When this enzyme is inhibited during the M to G1 transition, the phosphorylated state of Orc1 is reduced and it binds to chromatin.

origin; Figure 1), but during S phase, only the Orc2 protein can be cross-linked, consistent with release of Orc1 and disassembly of a pre-RC and with the fact that mammalian metaphase chromatin lacks functional ORCs. Rebinding of Orc1 to chromatin follows the same time course as degradation of cyclin B, suggesting that exiting mitosis triggers Orc1 binding to chromatin. Furthermore, Orc1 binding to chromatin precedes the appearance of functional pre-RCs at specific origins of bidirectional replication, suggesting that assembly of functional ORC/chromatin sites is the rate-limiting step in the assembly of pre-RCs at specific genomic sites.

What prevents Orc1 from rebinding to chromatin? In human cells, most of the Orc1 is selectively released, polyubiquitinated, and degraded during S phase. However, in hamster cells, the Orc1 is released but it is mono-ubiquitinated and not degraded *in vivo*. Moreover, during the S to M transition in hamster cells, mono-ubiquitinated Orc1 is replaced by Orc1, and the Orc1 in G2/M phase cells is hyperphosphorylated by its association with Cdk1/cyclin A (Figure 3). Inhibition of protein kinase activity in M phase cells allows dephosphorylation of Orc1 and rapid reassociation of Orc1 with chromatin. The association of Orc1 with chromatin appears to be the rate-limiting step in assembly of functional pre-RCs during the M to G1 phase transition. Thus, there is a universal control point in eukaryotic cell division cycles: the same cyclin-dependent protein kinase that regulates the onset of mitosis (Cdk1) also prevents premature assembly of functional ORC/chromatin sites until mitosis is complete and a nuclear membrane is present.

Glossary

autonomously replicating sequence (ARS) A DNA sequence that imparts origin activity to extrachromosomal elements in the presence of appropriate replication proteins, and whose activity is sensitive to genetic alterations.

Cdc Cell division cycle protein. A large number of Cdc genes have been identified in eukaryotes that affect various stages in cell division. Cdc6 is the name used in the budding yeast, *Saccharomyces cerevisiae*; Cdc18 is the name used in the fission yeast, *Schizosaccharomyces pombe*. The nomenclature for budding yeast proteins is generally applied to other organisms.

Cdk Cyclin-dependent protein kinase. This phosphorylates specific amino acids in proteins, but only when associated with a cyclin protein.

Cdt1 A protein encoded by Cdc10-dependent transcript 1 in *S. pombe*. Cdt1 is the same as RLF-B in *Xenopus laevis*.

DNA replication origin The DNA site where replication begins; also called an origin of bidirectional replication.

Mcm Minichromosome maintenance proteins. These were identified as genes required to maintain plasmids in *S. cerevisiae*. At least seven of these proteins are involved in DNA replication.

origin recognition complex (ORC) Six different proteins that bind to DNA replication origins and thereby initiate assembly of a pre-replication complex.

pre-replication complex (pre-RC) Fourteen different proteins consisting of ORC, Cdc6, Cdt1, and Mcm(2–7) that form a complex with chromatin during G1 phase of the cell cycle and that become the site where DNA replication begins during S phase.

replicator A DNA sequence that imparts origin activity when translocated to other chromosomal regions, and whose activity is sensitive to genetic alterations.

Biography

Melvin L. DePamphilis began his career in the field of DNA replication as a postdoctoral fellow with Paul Berg at Stanford University Medical School, and continued in this field as a Professor at Harvard Medical School, an Adjunct Professor at Columbia Medical School, a member of the Roche Institute of Molecular Biology, and most recently a Section Chief at the National Institutes of Health. He has published over 150 papers, reviews, and books on the subject of DNA

replication, chromatin structure, and gene expression in a variety of experimental systems.

Cong-jun Li began his career in the field of DNA replication as a graduate student with the late Earl F. Baril at the Worcester Foundation for Experimental Biology and continued in this field as a postdoctoral fellow with Paul T. Englund at the Johns Hopkins School of Medicine and then with Melvin L. DePamphilis at the National Institutes of Health. He has published over 20 papers and reviews on DNA replication and related subjects. Currently he is a Principal Investigator at the Animal and Natural Resources Institute, a division of the U.S. Department of Agriculture.

DNA Replication: Initiation in Bacteria

Jon M. Kaguni
Michigan State University, East Lansing, Michigan, USA

The study of *Escherichia coli* as a model organism has led to significant advancements in understanding the molecular mechanisms of DNA replication. This bacterium carries a circular duplex genome of 4.7×10^6 bp, and DNA replication initiates from a single replication origin, *oriC*. This locus is the site at which the duplex DNA opens to become single stranded. The replication fork machinery then assembles at this site, and moves bidirectionally as it copies the parental DNA to terminate chromosomal DNA replication in a region 180° opposite *oriC*. The daughter chromosomes are then segregated to progeny cells at cell division.

The *E. coli* Replication Origin, *oriC*

Escherichia coli oriC was identified genetically, then more precisely mapped by molecular DNA methods. Its isolation was based on its ability to confer autonomous replication to a plasmid formed by joining *oriC* to a DNA fragment that conferred drug resistance and lacked a replication origin. Subsequently, *oriC* was studied extensively by mutational analysis which, together with biochemical studies, showed that it carries five similar 9 bp motifs called DnaA boxes that are bound by DnaA protein, the initiator of bacterial chromosomal replication (see Figure 1). Each of the DnaA boxes (R1–R5) and their orientation relative to one another is critical for the function of *oriC* as the replication origin. For example, insertions are not tolerated in the region between the AT-rich region and R1, R5, and R1 or R5 and R2, indicating that the spacing between respective sequence elements in the left half of *oriC* must be rigorously preserved. In the right half, the spacing can be varied as long as the helical phasing of DnaA boxes is maintained. Collectively, these results suggest that the geometry of DnaA protein monomers relative to the DnaA boxes is critical for the initiation process.

oriC also contains binding sites for factor for inversion stimulation (FIS) and integration host factor (IHF). Mutation of these sites inactivates *oriC*, confirming their functional importance. IHF acts directly in initiation by stimulating DnaA-dependent opening of an AT-rich region of *oriC*, perhaps by bending the DNA to bring DnaA bound to DnaA boxes near the AT-rich region to support opening (Figure 1). Alternatively, IHF may act by binding to the unwound single-stranded DNA to stabilize it. IHF also contributes to the proper timing of initiation. Whereas wild type strains growing exponentially initiate new rounds of DNA replication synchronously, a null mutant of *himA*, encoding one of the subunits of the IHF heterodimer, is defective in this timing.

Similarly, *fis* mutants are asynchronous in initiation, and maintain *oriC* plasmids poorly at temperatures ≥ 37°C. Furthermore, deletion of DnaA box R4 at the chromosomal *oriC* locus, but not when *oriC* is carried in a plasmid, can only be tolerated when the *fis* gene is functional. Whereas these observations suggest a positive role for FIS, it is not required *in vitro* for *oriC* plasmid replication. Instead, FIS is inhibitory by sequestering the negative superhelicity that is essential for *oriC* plasmid replication.

IciA protein binds to 13-mer sequence motifs in the AT-rich region of *oriC* to prevent DnaA-dependent unwinding of this region. Because *iciA* null mutants are viable and do not show an asynchrony phenotype, the physiological importance of IciA as a regulator of initiation is uncertain.

Finally, *oriC* has eleven copies of the sequence GATC which is recognized by DNA adenine methyltransferase (Dam). This enzyme acts in mismatch repair in the discrimination of the parental DNA from the unmethylated progeny DNA strand after a cycle of DNA replication. The GATC sites in *oriC* remain hemimethylated for about one-third of the cell cycle whereas most other sites are methylated much more rapidly. Hemimethylated *oriC* associates with proteins in the inner membrane, including SeqA and SeqB to prevent premature reinitiation.

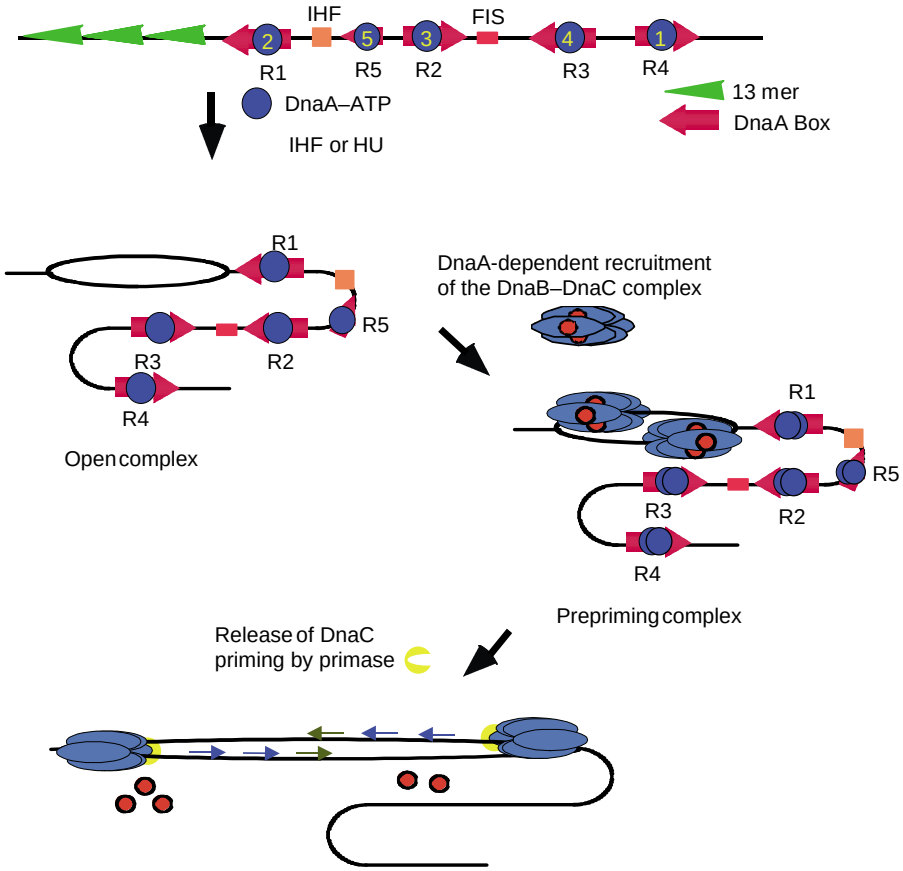

FIGURE 1 Mechanism of initiation of DNA replication from the *E. coli* replication origin, *oriC*. Sequence elements in *oriC* include the DnaA boxes (red arrows), 13-mer motifs (green triangles) in the AT-rich region near the left border, and binding sites for IHF and FIS. In the first step, DnaA protein binds to respective DnaA boxes sequentially, as indicated by the superimposed numbers. Complexed to ATP, DnaA then opens an AT-rich region that contains 13-mer sequences near the left *oriC* boundary to form the open complex. Entry of hexameric DnaB (blue ellipse) from the DnaB–DnaC complex follows to assemble the prepriming complex. In the import of DnaB to *oriC*, DnaB initially binds to *oriC*-bound DnaA protein. The hydrolysis of ATP bound by DnaC (red circle) in the DnaB–DnaC complex releases DnaC. Bound to each parental DNA template, DnaB then moves in the 5′–3′direction and interacts periodically with primase, which synthesizes RNA primers necessary for both leading and lagging strand synthesis. These primers are then extended by DNA polymerase III holoenzyme during semiconservative DNA replication.

Mechanism of Initiation at *oriC*

The molecular mechanism describing initiation of DNA replication from *oriC* is based primarily on the study of plasmids carrying this sequence. Such plasmids are useful model systems because its DNA replication resembles that which occurs at the chromosomal *oriC* locus. First, *oriC* plasmids replicate in synchrony with the bacterial chromosome. Second, they are duplicated with bidirectional fork movement. Third, *oriC* plasmids require the same gene products needed for copying the bacterial genome. Purified enzyme systems have been developed that sustain DNA replication on a plasmid carrying the *oriC* sequence. This has led to the biochemical analysis of the replication process, including the function of DnaA protein, the replication initiator.

DnaA Protein and the DnaA Box

DnaA protein performs a number of essential functions in initiation, including recognition of each DnaA box sequence in *oriC*. DNA binding assays first showed that DnaA specifically recognizes *oriC* as well as to other DNAs carrying the DnaA box sequence. DNase I foot-printing revealed that DnaA protected the DnaA box in addition to flanking sequences. In *oriC*, DnaA binds to the five boxes with different affinities, apparently as a monomer to each site. Whereas DnaA box R3 is the weakest site, DnaA must be bound to it and to the other DnaA boxes to promote initiation *in vitro*. This finding corroborates *in vivo* foot-printing studies showing that DnaA bound to R1, R2, and R4 throughout the cell cycle, but that it bound to DnaA box R3 only at the time of initiation.

Unwinding of the AT-Rich Region

DnaA is a nucleotide binding protein with a preference for ATP. In a complex with ATP and bound to *oriC*, DnaA induces unwinding of an AT-rich region near the left border of *oriC*. Whereas DnaA alone can induce this topological alteration, IHF stimulates this reaction, perhaps by binding to the IHF site in *oriC*. HU, a small basic protein that binds with higher affinity to nicked, gapped or cruciform DNA than to duplex DNA or RNA can replace IHF, and may stabilize the region of single-stranded DNA opened by DnaA. If so, IHF may similarly act to stabilize the single-stranded DNA as it is similar to HU in amino acid sequence.

DnaA is a weak ATPase, but ATP hydrolysis is not required for unwinding because a nonhydrolyzable ATP analogue is as effective as ATP in supporting strand opening of *oriC* and initiation. As DnaA bound to ADP is far less active in both unwinding and initiation, a nucleoside triphosphate or its analogue is required. A discrepancy is that the binding affinity (K_d) for ATP of 0.03 μM is much greater than the 1–5 mM ATP that is optimal for the unwinding reaction. It is likely that the complex of DnaA bound to *oriC* is reduced in its affinity for ATP.

Helicase Recruitment

Following the unwinding of *oriC*, DnaA then directs the binding of two DnaB helicase molecules to *oriC* to assemble the prepriming complex. The function of DnaB as a helicase is to unwind the parental duplex DNA so that it can be copied by the replication fork machinery. Helicase recruitment involves a physical interaction between DnaA and DnaB in the DnaB–DnaC complex. The interaction of DnaA with DnaB is interesting to consider in the context of the orientation of DnaA boxes in *oriC* and in plasmid replicons that require DnaA, DnaB, and DnaC protein for DNA replication. In these plasmids that replicate unidirectionally, the DnaA boxes can be viewed to "point" in the direction of replication fork movement. In *oriC*, four of the boxes are arranged as two sets of repeats that point in both directions, corresponding to the bidirectional mode of replication fork movement. An attractive model is that DnaA orients the binding of DnaB at *oriC* so that it is pointed in the proper direction for replication fork movement.

If DnaA orients the binding of DnaB to *oriC*, inverting the DnaA boxes should affect the directionality of replication fork movement. However, inverting DnaA boxes R1, R2, and R4 individually abolished *oriC* function, probably because this perturbs the architecture of the nucleoprotein complex. Recall that the spatial arrangement of the DnaA boxes relative to each other is critical for *oriC* function.

Hexameric DnaB of identical subunits is a ring-shaped molecule with a central cavity. One of the two strands of duplex DNA passes through the central cavity of DnaB as it unwinds DNA. For its assembly into the prepriming complex, DnaC transiently bound to the unwound region of *oriC* via its cryptic single-stranded DNA-binding activity may assist at this step in loading DnaB onto the DNA. ATP hydrolysis is then required to liberate DnaC from DnaB, a necessary step for DnaB to act as a helicase else the helicase activity of DnaB is suppressed.

Events after Prepriming Complex Formation

Upon the delivery of DnaB to *oriC*, DnaB is first bound to the unwound region of *oriC*. DnaB then unwinds the parental duplex, driven by ATP hydrolysis. Primase transiently interacts with the translocating DnaB to synthesize primers that are extended by DNA polymerase III holoenzyme. Single-strand DNA-binding protein binds to the single-stranded DNA formed by DnaB helicase activity. DNA gyrase and topoisomerase IV relieve the positive superhelicity created ahead of the replication fork. To process the Okazaki fragments formed on the lagging strand template, DNA polymerase I removes the RNA primers by nick translation, and DNA ligase seals the resulting discontinuities to make the progeny DNA fully duplex.

Functional Domains of DnaA Protein

The alignment of many *dnaA* homologues led to the proposal that DnaA is composed of four structural domains (see Figure 2). A small region of moderate sequence conservation near the N terminus is followed by a region of variable length that is species-dependent and not conserved. The C-terminal two-thirds of DnaA protein is highly conserved in this broad range of species. Most notable is the absolute conservation of the P-loop motif or Walker A box (residues 172–179 in *E. coli* DnaA) involved in nucleotide binding. The region of DnaA carrying this portion forms a Rossmann fold by the EMBL PHD method of secondary structure prediction.

In addition to these in silico observations, characterization of a large collection of *dnaA* alleles led to the identification of functionally distinct domains that correspond well with the domain structure derived from sequence homology, and from the crystal structure of the C-terminal two-thirds of *Aquifex aeolicus* DnaA. As a brief summary, domain I functions in self-oligomerization and in retention of DnaB in the

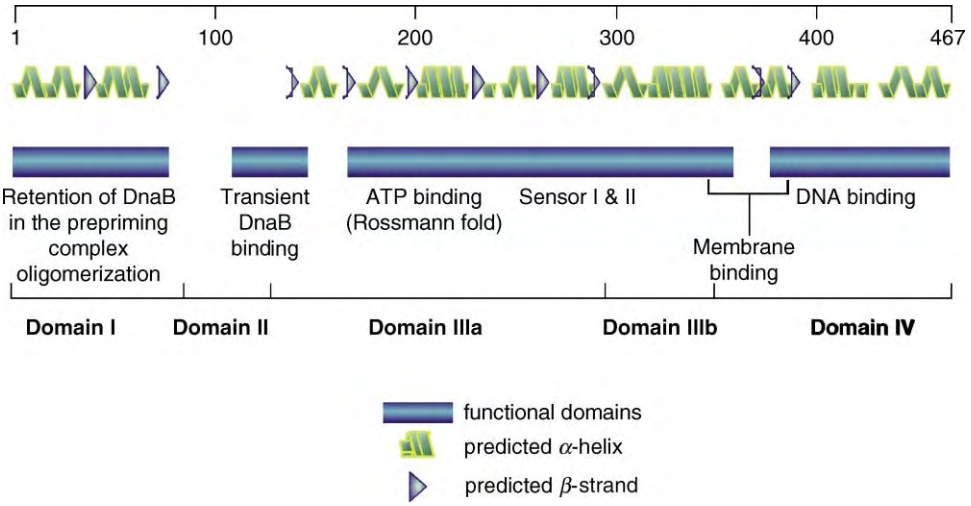

FIGURE 2 Functional domains of DnaA protein. The top line represents the primary sequence of DnaA protein of 467 amino acids. The predicted secondary structure is below, with α-helices in yellow and β-strands in purple. DnaA is a member of the AAA^+ family of proteins (ATPases associated with a variety of cellular activities) which have Walker A and B motifs involved in nucleotide binding and hydrolysis, and the sensor 1 and sensor 2 motifs that may function to sense nucleotide binding and hydrolysis. The Walker A motif is also known as the P-loop. The colored diagram near the bottom represents functional domains of DnaA in comparison to the domain structure of DnaA predicted by amino acid sequence alignment, and confirmed by analysis of the crystal structure of *A. aeolicus* DnaA protein.

prepriming complex. Domain II varies in length and sequence among bacteria and apparently functions as a flexible linker because an in-frame deletion of amino acids 87–104 of *E. coli* DnaA does not affect replication activity. A region overlapping domain II and III interacts with DnaB, and is involved in loading of the helicase at *oriC*. Domain III contains the Walker A and B boxes, and the sensor I and II motifs shared among AAA^+ proteins that typically bind ATP to regulate protein function. ATP binding induces a conformational change of DnaA, and mutant proteins bearing amino acid substitutions in or adjacent to the Walker A box are defective in ATP-binding activity. Domain IV carries a helix-turn-helix motif that recognizes nucleotides in the major groove of the DnaA box sequence via amino acids in the DnaA signature sequence. Near the N-terminal border of domain IV, a region involved in phospholipid binding has been described.

Regulation of DNA Replication in *E. coli*

DNA replication is regulated at the step of initiation at *oriC*. For example, *E. coli* cultures can have generation times that vary over a tenfold range from 20 to 200 min. In cultures growing faster than 60 min, the time needed to duplicate the genome is relatively constant at about 40 min. For a culture with a 20 min generation time, new initiations occur before the replicating chromosome is completed. In cells growing more slowly, the time needed to duplicate the chromosome is interspersed by a period when no DNA replication occurs. Under these conditions, replication forks move at constant speed due to the concerted actions of DnaB helicase and DNA polymerase III holoenzyme. Thus, DNA replication is controlled by modulating the frequency of initiation, occurring more often in rapidly growing cells compared to more slowly growing *E. coli*.

Because DNA replication in *E. coli* and all other free-living organisms is a periodic event in the cell cycle, factors act to regulate DNA replication either prior to or after initiation to prevent DNA synthesis from occurring at the wrong time. Several concepts have emerged from physiological studies in bacteria. One is initiation mass, the ratio of cell mass per replication origin. This ratio is a constant value, and DnaA protein contributes to setting this ratio. Other cellular factors that govern how this ratio is kept constant have not been identified. Thus our understanding of this process is rudimentary. A second concept is initiation synchrony. In rapidly growing cultures, individual cells initiate additional rounds of DNA replication synchronously, as measured by flow cytometry under conditions in which cell division and new initiations are blocked, but ongoing DNA replication proceeds to completion, so that cells carry 2^n chromosomes where $n \geq 0$ and is an integer. In contrast, asynchronous DNA replication results in odd numbers of chromosomes (1^n) as observed in mutants carrying *dnaA*(Ts) alleles defective in ATP binding, suggesting that ATP binding by DnaA

is necessary for proper regulation of initiation. Other mutations in *fis*, *himA*, *seqA*, *dam*, *hupA*, and *hda* also result in an asynchrony phenotype because the respective mutations perturb the initiation process by direct or indirect effects.

DnaA Protein and the Regulation of Chromosomal Replication

Among the genes required for *E. coli* DNA replication, the *dnaA* locus is unique in that conditionally defective mutations specifically affect initiation of DNA replication. By comparison, mutations in the *dnaB* and *dnaC* genes result in either an elongation- or initiation-defective phenotype, consistent with biochemical studies which show their dual roles in initiation at *oriC* and during elongation. All other replication genes display an elongation-defective phenotype because the respective proteins function in progression of the replication fork.

Several observations indicate that DnaA protein acts as a regulatory factor in the initiation process. First, DnaA protein appears to be limiting for initiation because its overproduction increases the frequency of initiation. In one study, the *dnaA*$^+$ gene (plasmid borne) was expressed from a regulated promoter in a *dnaA*(Ts) strain at nonpermissive temperature, causing initiation to be dependent on the level of induced expression. At an intermediate level of expression (13%), the synchrony of replication was comparable to the wild type control. Apparently, cyclic variation of DnaA protein is not required for initiation synchrony despite experiments showing that expression of the *dnaA* gene is autoregulated, to maintain a relatively constant cellular level of DnaA. Recent evidence implicates the *datA* locus in regulating initiation by controlling the availability of DnaA. A second line of evidence is the hyperactive initiation promoted by a mutant *dnaA* allele named *dnaAcos*. Recent experiments show that the replication activity of DnaA$^+$ protein is normally regulated to prevent unscheduled initiations whereas DnaAcos fails to respond to negative regulation. Third, some *dnaA* mutations at permissive temperature display an increased initiation mass. As the mutant proteins have reduced initiation activity *in vitro*, the lower frequency of initiation *in vivo* may lead to an increased initiation mass by promoting initiation later in the cell cycle. Together, these results suggest that DnaA protein activity controls initiation in the cell cycle.

The *datA* Locus

Interestingly, a 1 kbp chromosomal segment called *datA* is one of eight sites in the *E. coli* genome that are bound by DnaA with high affinity. The *datA* locus carries five DnaA boxes to which several hundred DnaA monomers can bind. Strains lacking this chromosomal segment exhibit both asynchronous initiations as well as an increased frequency of initiation. The *datA* site is unique among the eight strong binding sites for DnaA in that its deletion and not others leads to aberrant initiation. Apparently, when the level of DnaA is elevated that would otherwise lead to increased initiations, the extra DnaA can bind to the *datA* locus, thus modulating the initiation process.

SeqA at *oriC*

E. coli DNA replication occurs only once per cell cycle. Several proteins have been identified that bind to newly duplicated origins to block premature initiations. Specific binding to the newly replicated origins is by virtue of hemimethylated GATC sequences, as exists when the progeny DNA strand annealed to the methylated parental DNA has not yet been modified by DNA adenine methylase (the *dam* gene product). One protein is SeqA, which binds to the left half of *oriC* with tenfold greater affinity when this DNA is hemimethylated compared to when it is fully methylated. Footprinting experiments showed that SeqA specifically recognizes the hemimethylated GATC sequence in each 13-mer motif of *oriC* (Figure 1). These observations support a model in which SeqA blocks reinitiation by inhibiting the unwinding of the 13-mer region of *oriC*. In addition, SeqA seems to limit the binding of DnaA to *oriC*.

In *E. coli* with a generation time of 30 min, methylation of *oriC* after its duplication is delayed for ~13 min (~one-third of the cell cycle). In *seqA* mutants, methylation occurs after 5 min, so the 8 min difference is apparently because SeqA protein complexed to hemimethylated *oriC* impedes methylation. However, the 5 min delay indicates the participation of other factors. One of these is SeqB, a membrane-associated protein which appears to act in concert with SeqA. SeqB in a membrane fraction stimulates the binding of SeqA to hemimethylated *oriC* by at least 30-fold in DNA binding assays.

Interaction of DnaA with Hda and the β-Subunit of DNA Polymerase III Holoenzyme

DnaA complexed to ATP is more active than the DnaA–ADP complex in initiation and unwinding of *oriC*, leading to the notion that the nucleotide bound state of DnaA controls initiation. Although DnaA alone can slowly hydrolyze ATP, hydrolysis is stimulated by

incubation with a recently discovered protein named Hda (for homologous to DnaA, specifically domain III), duplex or single-stranded DNA, and the β-subunit of DNA polymerase III holoenzyme. The β-subunit confers processive DNA synthesis to DNA polymerase III holoenzyme by tethering the enzyme to DNA during DNA synthesis. Because any duplex or single-stranded DNA suffices, ATP hydrolysis is not necessarily coupled to DNA replication. However, under appropriate *in vitro* conditions, the ATP bound to DnaA can by hydrolyzed by incubation with the β-subunit and Hda in coordination with DNA replication.

Hda protein is similar at the amino acid level to domain III of DnaA, and carries AAA^+ sequence motifs. Initially, the *hda* gene was described to be essential for viability. More recent experiments showed that viability, growth rate, initiation frequency, and replication synchrony were unaffected when a drug resistance gene interrupted the *hda* coding region. However, deletion of *hda* coding sequences caused asynchronous initiation. A model has been proposed that the interaction of DnaA with Hda and the β-subunit of DNA polymerase III holoenzyme, in coordination with DNA replication, stimulate the hydrolysis of ATP bound to DnaA to modulate the frequency of initiation. If so, the capacity for initiation after one round of initiation should diminish, reflecting the inactivation of DnaA function by ATP hydrolysis. However in the absence of sequestration, the initiation activity of DnaA was not diminished but was elevated instead. This suggests that the hydrolysis of ATP bound to DnaA does not control initiation frequency.

Summary and Perspectives

Studies of the process of initiation from *oriC* has led to a molecular understanding of the events that lead to assembly of the replication fork machinery. Determination of the biochemical mechanisms that control this process will reveal how DNA replication occurs only once per cell cycle.

Glossary

DnaA box A 9 bp DNA sequence motif recognized by DnaA protein.

DnaA protein The initiator of DNA replication, recognizing the chromosomal replication origin by binding to DnaA box sequences.

DnaB protein The replicative helicase that functions to unwind the parental duplex. Composed of six identical subunits, the single-stranded DNA passes through the central cavity of this ring-shaped protein when it unwinds double-stranded DNA.

DNA polymerase III holoenzyme The replicative DNA polymerase.

DNA replication The process of duplication of DNA.

oriC The *Escherichia coli* chromosomal replication origin where DNA replication is initiated by recognition of DnaA box sequences.

primase The enzyme that forms primers needed for DNA replication by DNA polymerase III holoenzyme.

Biography

Jon M. Kaguni is a Professor in the Department of Biochemistry and Molecular Biology at Michigan State University. His principal research interests are on the mechanisms of DNA replication and its regulation. He holds a Ph.D. from the University of California, Los Angeles and received his postdoctoral training at the Stanford University School of Medicine. He developed the enzymatic system to study DNA replication from the *Escherichia coli* replication origin, and has studied the process of initiation of DNA replication throughout his professional career.

DNA Restriction and Modification: Type I Enzymes

David T. F. Dryden
University of Edinburgh, Edinburgh, UK

The original genetic studies of type I DNA restriction and modification (R/M) enzymes were published in 1953 by Bertani and Weigle, the same year that Watson and Crick presented their structural model of B-form DNA. Bertani and Weigle showed that some strains of *Escherichia coli* could reduce (restrict) the ability of bacteriophage to propagate through the bacterial population. Arber and colleagues later showed that surviving phage acquired a modification specific to the host bacterial strain, a modification which was lost upon subsequent passage through different hosts. The biological results were eventually linked to an enzyme-specific modification of DNA by type I R/M enzymes. These enzymes were designated *Type I* because they were the first restriction enzymes to be purified and characterized biochemically by Meselson and Yuan. The type II restriction enzymes prepared some years later had the very desirable property of cutting DNA into defined pieces, and they became the backbone of the genetic engineering revolution. In contrast, the type I enzymes, which cut DNA into unpredictable pieces, have provided important molecular models for complex biological mechanisms.

Biochemical Function

Type I restriction enzymes are large complexes with multiple enzymatic functions, and they possess the ability to switch between these functions depending upon the chemical nature of specific nucleotides within a target DNA sequence. A demonstrated function of type I enzymes in their natural hosts, eubacteria and archaea, is to protect the host from infection by foreign DNA from bacteriophage. This is achieved by two processes; modification of the host DNA by methylation at the N6 position of adenine nucleotides within the recognition sequence targeted by the enzyme and destruction of invading DNA, which typically lacks the appropriate modification of the target sequence. For a host specifying a type I restriction enzyme, typically far fewer than one in one thousand phage successfully infect the host. Therefore, they are a very effective defence system despite the considerable resources devoted by the host cell to their synthesis. This protective function is termed *restriction* and results in the destruction of the phage DNA once it has entered the host cell. Methylation of host DNA occurs during each round of DNA replication. The newly synthesized DNA strand lacks the appropriate methylation; the type I restriction enzyme recognizes this DNA as hemimethylated and adds the methyl group to the adenine in the target sequence in the newly synthesized strand. In this way, the type I restriction enzyme recognizes three different states of methylation of its target sequence, unmodified, hemimethylated, and fully modified, and performs a different reaction on each form of DNA, Figure 1. *In vitro*, the efficiency or accuracy of the switching between activities varies depending upon the particular type I restriction enzyme. For example, EcoKI, the type I restriction enzyme in *E. coli* K12 and EcoR124I, a plasmid encoded type I R/M system, are very precise—methylating only hemimethylated targets and cutting only unmodified ones. In contrast, EcoAI from *E. coli* 15T$^-$ methylates unmodified targets as effectively as hemimethylated targets, and, as a result, this activity competes with the restriction of unmodified DNA. These three enzymes are the best characterized examples of the type I restriction enzymes.

Genes and Protein Structure

It has been shown that three genes are required to specify a type I system, *hsdS*, *hsdM*, and *hsdR*, where *hsd* refers to host specificity for DNA and *S*, *M*, and *R* stand for specificity, modification, and restriction, respectively. Typically, the *hsdR* gene is expressed from its own promoter and the *hsdM* and *hsdS* genes are expressed from a single promoter upstream of *hsdM*. *hsdR* is typically close to *hsdM/hsdS*, although some genome sequences suggest that this is not always the case. Genome rearrangements also occur around the *hsd* locus and this is used to induce some interesting switching of the expression and target sequence specificity of alternative type I R/M systems within a cell. Most studies

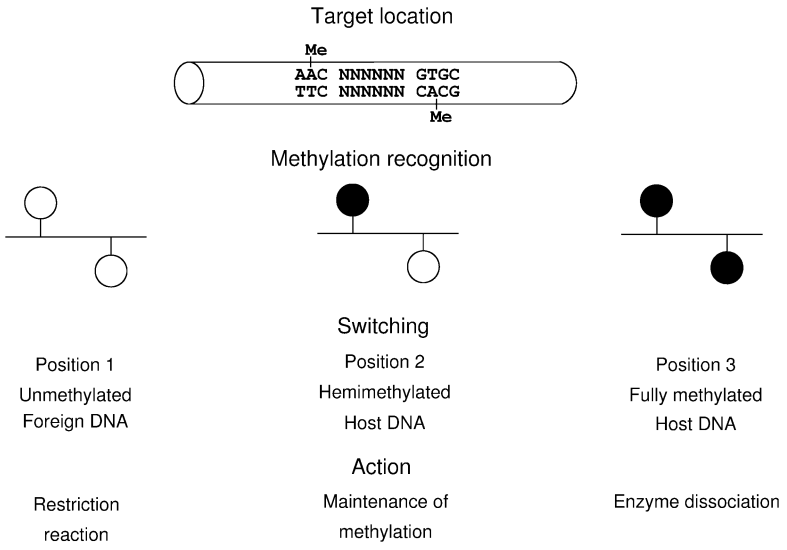

FIGURE 1 The operations performed by a typical type I restriction enzyme are illustrated using the EcoKI enzyme binding to its DNA target sequence AACNNNNNNGTGC and determining the methylation status of the target. The sequence of operations is target location, methylation recognition, switching between different activities, and performance of the selected action.

have concentrated upon the type I systems of *E. coli* and *Salmonella enterica*, and it has been found in these hosts that type I R/M systems can be divided into at least four families based upon the following criteria: DNA hybridization, antibody cross reactivity, and genetic complementation of the *hsd* genes from different systems. These families are known as types IA, IB, IC, and ID. Structural and bioinformatics studies of the Hsd subunits have been used to understand the basis of these families. Within a family, amino acid sequence identity of the three expressed polypeptides is very high except for two regions of HsdS involved in DNA target recognition. Amino acid sequence identity between polypeptides from different families is much lower and is usually confined to regions of HsdS involved in DNA target recognition if the R/M systems being compared share at least part of the same DNA target sequence specificity, and to short motifs involved in catalysis.

The Sequence Specificity Subunit

HsdS, often referred to as the S subunit, is responsible for recognizing the characteristic bipartite, asymmetric DNA target sequence of type I restriction enzymes, for example, the target for EcoKI is 5′-AACNNNNNNGTGC-3′, where N is any base. S subunits have a mass of approximately 50000 and comprise five regions of primary structure (polypeptide sequence), Figure 2. There are sequences (conserved regions) at the N terminus, the central part of the polypeptide, and at the C terminus that are highly conserved within a family of type I restriction enzymes and show some identity between families. Separating these three conserved regions are two longer sequences that display very limited sequence identity between different S subunits unless the different S subunits recognize the same DNA target sequence or one part of the same target sequence. These polypeptide sequences (variable regions) are associated with recognition of DNA target sequence and each region recognizes one part of the bipartite target sequence of the enzyme. These two variable regions each fold into a tertiary structure domain referred to as a target recognition domain (TRD). A weak sequence identity exists between the TRDs of S subunits and the TRD of methyltransferases from type II R/M systems. This identity covers a region involved in DNA sequence

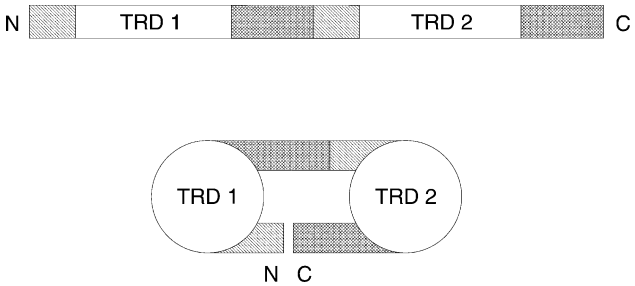

FIGURE 2 Diagrams of a typical S subunit of a type I restriction enzyme. The upper diagram shows the subunit as a linear representation from the N terminus to the C terminus. Regions of sequence conservation between different S subunits are shown hatched. Regions within the subunit with sequence conservation have the same sort of hatching. The conserved regions flank the target recognition domains responsible for DNA sequence recognition. Each TRD recognizes one part of the bipartite target sequence. The lower diagram depicts the folded arrangement of these regions making apparent the approximate twofold rotational symmetry axis of the S subunits.

recognition, and extensive mutagenesis of a TRD from HsdS of EcoKI corroborated this similarity between TRDs from type I and type II R/M systems. The conserved polypeptide regions flanking the TRDs are structural components required to position the TRDs against the DNA target and to act as a scaffold for the binding of the M and R subunits. Some *hsdS* genes have been manipulated to exchange TRDs from different type I R/M systems. The resulting chimeric HsdS recognize new target DNA sequences. In addition, sequence similarity between conserved regions within an S subunit suggested an approximate twofold degree of symmetry in the subunit. A polypeptide comprising one TRD and part of the conserved regions formed a dimeric protein recognizing a twofold symmetrical DNA target. Within a family, the length of the central conserved region influences the number of nonspecific bases found in the DNA target sequence. Naturally occurring variation in the structure of *hsdS* genes has led to the evolution of new target specificities.

The Modification Subunit

Two M subunits bind to HsdS to form a core trimeric enzyme with the properties of sequence specificity, detection of DNA methylation (whether hemimethylated or unmethylated), binding of methylation cofactor S-adenosyl-methionine (SAM), and methyltransferase activity. These M subunits are approximately 60000 molecular mass. The central one-third of the polypeptide sequence contains a series of amino acid motifs that are found in SAM-dependent methyltransferases and are involved in binding of the cofactor, binding of the adenine base specified for methylation, and catalytic transfer of the methyl group from SAM to the N6 position of the adenine base. This region of the M subunit has been successfully modeled upon the catalytic domain of the methyltransferases of type II R/M systems. Mutations in the motifs found in this catalytic domain have deleterious effects on activity. Methylation by type I restriction enzymes almost certainly occurs via the same nucleotide flipping mechanism used by methyltransferases of type II R/M systems in which the base targeted for modification is displaced from the DNA double helix into a catalytic pocket in the SAM-binding catalytic domain. The N terminal part of the M subunit of EcoKI appears to play a role in recognition of the methylation status of the DNA target sequence and mutations reduce the preference of EcoKI for methylating only hemimethylated DNA. The C terminal region of M subunits appears to play a role in interacting with the S subunit to form the core assembly. The polypeptide sequence of M subunits are almost identical within the same type I family but identity between families is mostly confined to the motifs in the catalytic domain.

The Restriction Subunit

The complete type I restriction enzyme is formed by adding two R subunits to the core trimer to form a complex with subunit stoichiometry $R_2M_2S_1$ and a mass of around 440000, an enormous multifunctional molecular machine. As for HsdM, the R subunits show high sequence identity for members in the same family but lower identity, confined to a series of amino acid motifs, for comparisons between families. The complete restriction enzyme is still capable of methylating the DNA target sequence if it is hemimethylated and, if it is a type I system of low preference such as EcoAI, of methylating unmodified targets as well. However, unmethylated DNA target sequences primarily trigger the restriction reaction. The R subunits contain three main regions. An N terminal domain contains an amino acid motif found in DNA endonucleases particularly endonucleases from type II R/M systems. Mutagenesis experiments reveal that this domain is responsible for DNA cleavage by type I restriction enzymes. The central portion of the subunit contains a further set of amino acid motifs characteristic of the so-called DEAD-box helicases, enzymes which translocate or move DNA. These motifs form a multidomain structure that binds and hydrolyzes ATP and couples this hydrolysis to the movement of DNA relative to the enzyme (DNA translocation). Mutation abolishes the ability to hydrolyze ATP and translocate DNA. In the absence of translocation, the enzyme cannot cut DNA and restriction activity is lost even though the endonuclease domain is unaltered. The C terminal region of HsdR appears to be required for interaction with the core trimer.

Assembly and Control of the Type I Restriction Enzyme

The assembly of the complete type I restriction enzyme is a complex affair and many type I R/M systems can form proteins with different subunit stoichiometries. The main partially assembled form of type I restriction enzymes is a trimer M_2S_1, which forms a fully functional modification methyltransferase recognizing the same DNA target as the complete enzyme. Other partially assembled forms and even individual subunits can be isolated and can display some limited activities such as sequence specificity, cofactor binding, and, for the $R_1M_2S_1$ form of EcoR124I, DNA methylation and ATP hydrolysis-driven DNA translocation. Intracellular concentrations of the Hsd subunits may vary with host conditions and it has been suggested that concentration-dependent assembly may play a role in the establishment of type I R/M systems in new hosts. It has also been shown that when the host cell acquires unmodified target sequences after suffering DNA

damage, the restriction activity of type IA and IB R/M systems is controlled by proteolytic digestion of hsdR. This control process prevents the type I restriction enzyme from attacking the unmodified target sequences in the damaged host chromosome.

The Restriction Reaction

DNA Binding and Recognition of Unmodified DNA

The type I restriction enzymes display a strong preference, in the presence of their cofactors, for binding to their DNA target sequence rather than to other DNA sequences. Although sequence specificity resides within HsdS, the presence of HsdM appears to be essential for strong binding to DNA. Once bound, the HsdM plus SAM detect the presence of adenine methylation on each strand of the DNA target using the base flipping mechanism. If the adenine is already methylated, then it will not be able to fit properly into the catalytic site as the methyl group will clash with the methyl group of SAM. This steric hindrance appears to change the conformation of the enzyme to allow the methylation reaction to proceed upon hemimethylated DNA or to dissociate from fully modified DNA. However, if both adenines are unmethylated, they can be accommodated within the HsdM along with SAM. The absence of steric hindrance for both target adenines appears to be the trigger for the highly complicated restriction reaction.

Upon recognition of an unmodified target site, the restriction enzyme becomes strongly attached to the DNA target site and does not appear to dissociate from the DNA after carrying out the restriction reaction. Strictly speaking, this lack of enzymatic turnover in the complete process means that type I restriction enzymes are not "enzymes." If the DNA molecule contains more than one target site, the type I restriction enzymes bound at each site can stick to each other to form a large complex. This additional DNA-dependent dimerization of the enzyme arises from diffusional motion of the DNA molecule bringing the bound enzymes into contact and does not depend upon enzyme activity. The functional role, if any, of this dimerization is not known, as it is not necessary for restriction.

ATP Hydrolysis

Unmodified DNA target sequences trigger the hydrolysis of large amounts of ATP. The ATPase activity continues throughout the DNA translocation and cleavage process and even continues after DNA cleavage. The purpose of this continuing ATP hydrolysis observed *in vitro* is not known but may represent continuing DNA translocation on the cleaved DNA substrate.

DNA Translocation

The enzyme remains bound to the target sequence and commences pulling DNA on either side of the target sequence toward itself. Because it is still attached at the target sequence, loops of DNA appear to be extruded from the enzyme, Figure 3. This process requires ATP hydrolysis and generates extensive supercoiling in the DNA. The reeling in of DNA occurs at approximately 100 to 400 base pairs per second and has been shown to occur over huge distances up to approximately 50000 base pairs. Stalling of the movement appears to occur when the translocating enzyme collides with a blockage on the DNA. This blockage can be another translocating type I restriction enzyme if there are two or more target sequences on a particular DNA molecule, stalling on a circular DNA molecule containing only one target sequence or collision with a complex DNA structure such as a fixed Holliday junction.

Cleavage of DNA

Translocation blockage appears to be the signal for cutting of the DNA strands at the stalling location. Cutting does not occur at the original target sequence. As translocation rates of individual type I restriction enzymes on a DNA molecule may vary depending upon

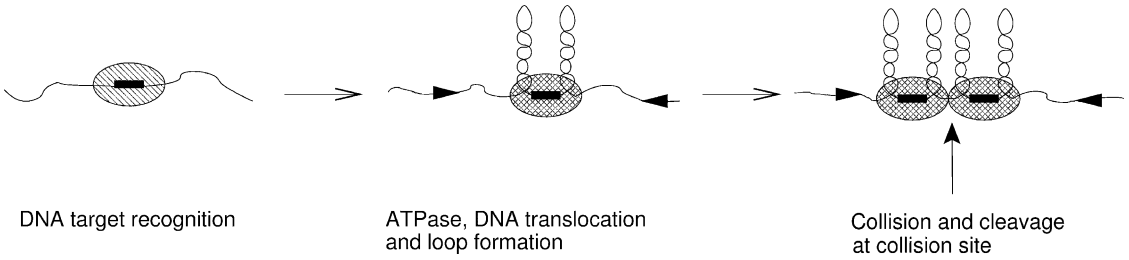

FIGURE 3 The sequence of events occurring after the type I restriction enzyme (oval) has bound and recognized an unmodified DNA target sequence (black box) on a DNA molecule (thin line). ATP hydrolysis drives the translocation of DNA, reeling the DNA in toward the enzyme with, as a consequence, the extrusion of loops of DNA. Eventually, translocation is blocked by, in this example, collision with a second translocating type I restriction enzyme, whereupon cleavage occurs at the collision point. After cleavage *in vitro*, the enzymes remain bound to their target sequence.

the particular enzyme species and upon the sequence being translocated, individual enzymes will stall or collide with each other at different locations on the DNA. Therefore, in a solution containing many DNA molecules, translocation blockage and DNA cleavage occur at a range of locations. For a DNA molecule containing two or more target sequences for the same type I restriction enzyme, cleavage occurs approximately half way between the original DNA target sequences. For a DNA molecule containing target sequences for different type I restriction enzymes, the approximate location of cleavage depends on the relative translocation speeds of the different enzymes. DNA cleavage by type I restriction enzymes does not produce DNA fragments of defined length and sequence but rather a broad range of fragment lengths. Circular DNA molecules containing one target sequence are also cleaved at an undefined distance from the target sequence. The presence of a nick in a DNA molecule appears to bias the cleavage event to be close to the nick.

Antirestriction

Despite their complexity, type I restriction enzymes are very effective barriers against bacteriophage propagation. Bacteriophage have developed a range of countermeasures to overcome this barrier. These antirestriction strategies include selection against presence of target sequences, modification of DNA bases, coinjection of bacteriophage proteins to inhibit restriction enzymes, hydrolysis of the SAM cofactor, and the use of genes encoding specialized proteins that act as competitive inhibitors of DNA binding by type I restriction enzymes. This last strategy is employed by bacteriophage T7, which produces gene 0.3 protein, also known as Ocr (overcome classical restriction), immediately upon infection of *E. coli*. This protein binds very strongly to all characterized type I restriction enzymes, irrespective of their DNA target sequences, and prevents the enzyme from binding to DNA. The structure of Ocr shows that negatively charged aspartate and glutamate side chains are arranged on the protein surface to perfectly match the three-dimensional positioning of the phosphate groups on DNA. Ocr appears to fit perfectly into the DNA-binding site of type I restriction enzymes and acts as a DNA mimic.

Glossary

hsd Host specificity of DNA. In a host expressing a type I R/M system, DNA containing the specificity target sequence becomes modified or restricted depending upon the methylation status of the target sequence.

modification The process accompanying restriction by which host DNA is maintained in a state of sequence-specific methylation. Most restriction enzymes cannot cleave DNA that has been modified by the methyltransferase partner. Type I restriction enzymes combine both restriction endonuclease and methyltransferase in one protein complex.

restriction The process of hindering the propagation of bacteriophage through a bacterial culture. This process requires cleavage of the bacteriophage DNA by DNA-sequence-specific endonucleases commonly referred to as restriction enzymes.

translocation Usually, the processive motion of an enzyme along DNA. However, for type I restriction enzymes which remain bound to their initial target sequence, refers to the pulling in of DNA toward the enzyme.

Biography

David Dryden is a lecturer in physical chemistry at Edinburgh University, Scotland. He earned a degree in chemical physics and a Ph.D. in chemistry from Glasgow University. He gained postdoctoral experience with Roger Pain at Newcastle University. In 1989, he joined Noreen Murray at Edinburgh University to study type I DNA restriction enzymes. He started research on antirestriction proteins after being awarded a University Research Fellowship by the Royal Society in 1994. In 2002, he published, with Malcolm Walkinshaw (Edinburgh University), the first atomic structure of an antirestriction protein.

DNA Restriction and Modification: Type II Enzymes

Darren M. Gowers and Stephen E. Halford
University of Bristol, Bristol, UK

Type II restriction–modification (RM) enzymes are two separate proteins that act in concert to destroy foreign DNA as it enters a bacterial cell, while protecting the host DNA. Destruction of the foreign DNA is accomplished by a sequence-dependent restriction endonuclease, while a modification methyltransferase protects identical sequences in the host DNA. Restriction–modification systems are present in virtually all bacterial genera and show a huge range of DNA specificities. A complete listing can be found at REBASE (rebase.neb.com).

History

The ability of bacteria to defend themselves from viral infection was first reported by Luria and Bertani in 1952, who noted that some strains of *Escherichia coli* could restrict the growth of bacteriophage λ. This was accounted for a decade later by W. Arber, who proposed the existence of restriction–modification (RM) enzymes; the restriction enzymes were envisaged to cleave DNA in response to a particular sequence of bases, but only if the sites had not been protected by prior modification.

A landmark was reached in 1970, when H. O. Smith identified a novel restriction enzyme that cleaved DNA at a specific sequence. In collaboration with D. Nathans, he showed that this enzyme could be used to dissect DNA into discrete fragments. By 1978, when Arber, Nathans, and Smith shared the Nobel Prize in Medicine, nearly 50 restriction enzymes had been discovered. Today, that number stands near 3700. The early availability of restriction enzymes as off-the-shelf reagents heralded the age of recombinant DNA technology.

Classification

At least three distinct categories of RM systems have been identified from their subunit compositions and their modes of action: types I, II, and III. This article focuses on the type II systems. In brief, most type II systems consist of two proteins: a restriction endonuclease that, in the presence of Mg^{2+}, cleaves DNA at a particular sequence, its recognition site; and a modification methyltransferase that blocks restriction activity by transferring a methyl group from S-adenosyl methionine (AdoMet) to a particular base in the recognition site. Only the nucleases from type II systems cleave DNA at specific positions and it is these, unlike the type I and the type III enzymes, which have the myriad applications in recombinant DNA technology.

The enzymes within the type II category display a variety of reaction mechanisms and subunit compositions. Many have been allotted to various subtypes, for example, the type IIS, IIB, IIE, and IIF enzymes.

Discovery of New Restriction–Modification Systems

The value of type II restriction enzymes for DNA manipulations has driven extensive searches for more enzymes of this sort. A common means of identifying new restriction enzymes has been to screen bacterial lysates for endonucleases that cleave DNA into discrete fragments. Phage or adenoviral DNA are often used as test substrates. The recognition sites are then determined by sequencing methods. About one-half of the bacterial strains tested in this way are found to have a RM system, in some cases two or three such systems. But if the enzyme fails to cleave the test DNA for some reason, it will not be detected by this procedure.

New RM systems have also been identified by analyzing the genome sequences of bacteria. Such analyses show that almost all bacteria possess multiple candidates for RM genes, in some cases over 10 such candidates. Subsequent studies showed that a high proportion of the candidate genes were active RM systems, although some did not encode an active endonuclease.

Organization of Genes

Modification and Restriction Genes

The type II systems generally feature two separate genes: one for the restriction enzyme and one for the modification enzyme. In all such systems examined to date, the gene for the endonuclease is adjacent to that for the methyltransferase, although the order of the genes varies between systems. In some cases, they are in head-to-tail orientation and in others head-to-head or tail-to-tail.

Modification genes from different type II systems are often homologous to one another. In many cases, the methyltransferase genes encode 10 highly conserved blocks of amino acid sequence which are involved directly in catalysis and S-adenosyl methionine and AdoMet binding. Another block of protein sequence, which is not conserved, is involved in DNA recognition.

The restriction genes in the type II systems are never homologous to the modification gene from the same system, despite coding for proteins recognizing the same DNA sequence. Moreover, the restriction enzymes from different type II systems have dissimilar amino acid sequences, apart from enzymes with the same recognition site. The only well-conserved feature is the motif Pro-Asp-X_{10-20}-(Asp/Glu)-X-Lys (where X is any amino acid), which is often found at the active site. The aspartate and glutamate residues form part of the binding site for Mg^{2+}.

There are, however, many type II systems that deviate from the standard pattern of one modification gene and one restriction gene. For instance, some systems employ two modification enzymes, one for each strand of the DNA. Others have two restriction genes to encode an enzyme comprising two different subunits. In further cases, one gene encodes a single polypeptide with both modification and restriction activities.

Regulating Restriction–Modification Expression

Whenever a bacteria gains a new RM system, expression of the RM genes has to be stringently coordinated. The methyltransferase must be produced first, to protect all the recognition sites in the chromosome, before significant amounts of the endonuclease are made. To do this, some type II RM systems, such as PvuII and BamHI, contain a gene upstream of the restriction gene that codes for a protein that regulates gene expression in this manner.

The Type II Restriction Endonucleases

Recognition Sequences

The recognition sequences for the majority of the type II restriction enzymes possess three attributes (Table I). First, the sites are usually 4–8 bp long. Second, the sites are palindromic: they read the same in 5′–3′ directions on both strands. Third, the sites are fully specified, in that every position in the sequence is occupied by a particular base. These enzymes cleave DNA at their recognition sites much more rapidly than any other sequence.

For some other enzymes, the recognition sequence is degenerate, in that certain positions can be occupied by alternative bases. For example, the recognition sequence for Cfr10I (Table I) has either G or A at its 5′-end and either C or T at its 3′-end. Similarly, the central base pair in the target site for EcoRII can be either an A:T or a T:A. For some systems, the recognition sequence is discontinuous, for example, SfiI (Table I). Such sites contain two blocks of specified sequence interrupted by a section of unspecified sequence but defined length that varies from just 1 bp (e.g., HinfI at GANTC) to 9 bp (e.g., XcmI at CCA$(N)_9$TGG). In most cases, the specified base pairs in the degenerate and in the discontinuous sites are still symmetrical palindromes.

Some recognition sites are truly asymmetric. For example, the 5′–3′ sequence in the top strand of the recognition site for BbvCI is not the same as the bottom strand (Table I). Many enzymes that recognize asymmetric sequences cleave the DNA some distance away from the site, at fixed positions on one side of the site. These are called the type IIS enzymes. One example is FokI at GGATG(9/13); it cleaves 9 bases downstream from its site on the top strand and 13 bases away on the bottom strand (Table I). However, some cut just one strand, for example, N.BstNBI (Table I). Conversely, some enzymes that recognize asymmetric sequences cleave both upstream *and* downstream of the recognition site, for example, BcgI (Table I). They cut four phosphodiester bonds in their reactions to liberate a small DNA fragment, 32 bp in the case of BcgI, which contains the intact recognition site. Such enzymes belong to the type IIB category.

The 3700 known enzymes have only 230 different recognition sequences, so enzymes from different species often have the same recognition site. Those that cut at exactly the same position are called isoschizomers; for example, HhaI and CfoI both cut GCG↓C. Those that cut at different positions within the same sequence are called neoschizomers; HinP1I, which cuts G↓CGC, is thus a neoschizomer of HhaI.

TABLE I

Recognition Sites for Type II Restriction Endonucleases

Site	Enzyme	Genus	Recognition site
Palindromic			
4 bp			
5′ overhangs	Sau3AI	*Staphylococcus aureus*	5′ ↓ G-A-T-C 3′ 3′ C-T-A-G ↑ 5′
Blunt ends	AluI	*Arthrobacter luteus*	A-G ↓ C-T T-C ↑ G-A
3′ overhangs	HhaI	*Haemophilus haemolyticus*	G-C-G ↓ C C ↑ G-C-G
6 bp			
5′ overhangs	EcoRI	*Escherichia coli*	G ↓ A-A-T-T-C C-T-T-A-A ↑ G
Blunt ends	EcoRV	*Escherichia coli*	G-A-T ↓ A-T-C C-T-A ↑ T-A-G
3′ overhangs	PvuI	*Proteus vulgaris*	C-G-A-T ↓ C-G G-C ↑ T-A-G-C
8 bp			
5′ overhangs	NotI	*Nocardia otitidis*	G-C ↓ G-G-C-C-G-C C-G-C-C-G-G ↑ C-G
Blunt ends	PmeI	*Pseudomonas mendocina*	G-T-T-T ↓ A-A-A-C C-A-A-A ↑ T-T-T-G
3′ overhangs	SgfI	*Streptomyces griseoruber*	G-C-G-A-T ↓ C-G-C C-G-C ↑ T-A-G-C-G
Degenerate			
	Cfr10I	*Citrobacter freundii*	(G/A) ↓ C-C-G-G-(C/T) (C/T)-G-G-C-C ↑ (G/A)
	EcoRII	*Escherichia coli*	↓ C-C-(A/T)-G-G G-G-(T/A)-C-C ↑
Discontinuous			
	SfiI	*Streptomyces fimbriatus*	G-G-C-C-N_4 ↓ N-G-G-C-C C-C-G-G-N ↑ N_4-C-C-G-G
Asymmetric			
Cleaves within site	BbvCI	*Bacillus brevis*	C-C ↓ T-C-A-G-C G-G-A-G-T ↑ C-G
Cleaves outside site	FokI	*Flavobacterium okeanokoites*	G-G-A-T-G-N_9 ↓ N-N-N-N C-C-T-A-C-N_9-N-N-N-N ↑
Cleaves one strand	N.BstNBI	*Bacillus stearothermophilus*	G-A-G-T-C-N-N-N-N ↓ N C-T-C-A-G-N-N-N-N-N
Cleaves both sides	BcgI	*Bacillus coagulans*	↓ N_{10}-C-G-A-N_6-T-G-C-N_{12} ↓ ↑ N_{12}-G-C-T-N_6-A-C-G-N_{10} ↑

Protein Structures

The enzymes that recognize palindromic DNA sequences are generally dimers of identical subunits. They interact with their recognition sequences symmetrically so that all the contacts between one subunit of the protein and one half of the recognition site are duplicated by the second subunit with the other half of the DNA. One active site in the dimer is positioned against the scissile phosphodiester bond in one strand of the DNA and likewise the second active site on the other strand.

The structures of several type II endonucleases, and their complexes with DNA, have been determined by X-ray crystallography. As with most other proteins that act at specific DNA sequences, restriction enzymes recognize their target sequences primarily by multiple hydrogen bonds to the bases in the major groove of the DNA. However, the restriction enzymes do not usually employ the elements of protein structure that are common amongst DNA-binding proteins, such as the helix–turn–helix or the zinc-finger. Instead, their DNA-recognition

elements encompass a wide variety of nonstandard structures, including loops, sheets, and helices. These also differ considerably from one enzyme to the next. In some cases, such as EcoRV, contacts to the specific sequence also depend on deformations to DNA structure.

Despite the differences in their structural elements for DNA recognition, and indeed in the overall dissimilarity in their amino acid sequences, some type II restriction enzymes have similar tertiary structures, for example, EcoRI and BamHI or EcoRV and PvuII. Similar structures have since been found in many other proteins that act on DNA, including enzymes involved in replication, recombination, repair, and transposition.

Cleavage of Specific DNA Sequences

Enzymes such as EcoRI or EcoRV find their recognition sites in long DNA molecules by first binding to the DNA anywhere along the chain and then translocating to the recognition site. The transfer seems to occur primarily by multiple rounds of dissociation and reassociation events with the same chain. However, one-dimensional diffusion along the chain may also play a role, particularly over short distances of DNA. Once at the recognition site, each active site in the dimeric enzyme catalyzes the hydrolysis of its target phosphodiester bond in independent reactions. Both reactions are usually complete within the lifetime of the DNA–protein complex, so the initial product released from the enzyme is the DNA cut in both strands. However, if the complex dissociates before both strands are cut, for example, in reactions at high ionic strength, DNA cleaved in one strand is liberated.

With very few exceptions, the type II endonucleases require Mg^{2+} for their reactions. Some other metal ions, such as Mn^{2+} or Co^{2+}, give low levels of activity but others, such as Ca^{2+}, give no activity at all. The Mg^{2+} ions play direct roles in the catalytic reaction, but the precise roles vary from enzyme to enzyme. Some, such as EcoRI and BglII, seem to have one metal ion at each active site, whereas EcoRV, BamHI, and many others use two ions.

The hydrolysis of phosphodiester bonds by type II endonucleases yields termini with 5′-phosphate and 3′-hydroxyl groups. Some enzymes introduce staggered breaks into the DNA, leaving fragments of double-stranded DNA with single-strand extensions at either their 5′-ends (e.g., EcoRI in Table I) or their 3′end (e.g., PvuI in Table I). Others cut both strands at equivalent positions, producing blunt-ended fragments (e.g., EcoRV in Table I).

Interactions with Nonspecific DNA

The type II restriction enzymes are extremely specific for their cognate sequences. They cleave their recognition sites over a million times more rapidly than DNA sequences that differ from the recognition site by just 1 bp. Surprisingly, this specificity in catalysis need not be accompanied by an equivalent specificity in DNA binding. In the absence of Mg^{2+} ions, many restriction enzymes bind to all DNA sequences with equal affinities. Their extraordinary specificities for DNA cleavage arise instead from the catalytic reaction, with only the cognate DNA giving rise to a catalytically competent enzyme–Mg^{2+}–DNA complex. For example, the complex of EcoRV with nonspecific DNA has a low affinity for Mg^{2+}, whereas its complex with specific DNA has a high affinity for Mg^{2+}, so only the specific DNA is cleaved.

Certain reaction conditions can, however, enhance the activities of these enzymes at alternative sites. This is termed star activity. The star sites are generally sequences that differ from the recognition site by 1 bp; sequences differing in two or more positions are normally resistant even under star conditions. The conditions that cause star activity include high pH, low ionic strength, the addition of organic solvents, and the replacement of Mg^{2+} with Mn^{2+}.

Subsets of Type II Restriction Enzymes

In recent years, many type II enzymes have been found to have distinctive properties and have been classified into subsets. Most of these enzymes have to interact with two copies of their recognition site before cleaving DNA. The restriction enzymes that need two sites are in effect double-checking the DNA to ensure that they cleave DNA only at the correct sequence.

Type IIS

Type IIS enzymes recognize asymmetric sequences and cleave the DNA short distances downstream of the recognition site, typically 1–20 bp away. FokI (Table I) is the archetype of the type IIS enzymes. It is a monomeric protein containing two domains connected by a flexible linker: a DNA recognition domain that makes all of the contacts to the recognition site and a catalytic domain that has an active site capable of cleaving one DNA strand. To cut both strands, two monomers of FokI have to aggregate to a dimer via their catalytic domains to create a unit with two active sites. The dimer is formed most readily when both monomers are bound to separate FokI sites in the same DNA molecule. FokI is thus more active on molecules with two sites than on DNA with one site. This is a common feature of the type IIS enzymes. Most of them cleave DNA with two target sites more rapidly than DNA with one site even though they are not all monomers. Instead,

some are dimers, such as BfiI at ACTGGG(5/4), and others are tetramers, such as BspMI at ACCTGC(4/8).

Type IIE

Another subset of type II enzymes is the type IIE group, typified by EcoRII and NaeI, which consists of dimers of identical subunits. In these enzymes, the interface between the subunits has two binding clefts for the recognition sequence rather than the single cleft in enzymes such as EcoRV and BamHI. One cleft has the catalytic functions for DNA cleavage, but these are inactive unless the other cleft has bound another copy of the recognition site. Interactions spanning two DNA sites occur more readily with sites in *cis* on the same molecule of DNA than with sites in *trans* on different molecules. The type IIE enzymes thus cleave DNA with two recognition sites faster than DNA with one site, but only one of the two sites is cut per turnover.

Type IIF

SfiI, Cfr10I, NgoMIV, and several other restriction enzymes show further differences from the orthodox pattern, and this group is now known as the type IIF enzymes. They are tetramers of identical subunits, two of which interact with one copy of a palindromic recognition sequence while the other two interact with a second copy. To cleave DNA, both binding sites must be filled with cognate DNA. Hence, like the type IIE enzymes, the type IIF enzymes also interact with two copies of the target sequence, but, in contrast to the IIE systems, the IIF enzymes cut both sites in both strands. They thus cleave four phosphodiester bonds per turnover to convert a DNA with two sites into the product cut at both sites. They display optimal activity with sites in *cis* – the concurrent binding of the enzyme to sites in the same molecule of DNA traps the intervening DNA in a loop. Nevertheless, they can also act, albeit less efficiently, with sites in *trans* by bridging separate molecules.

Type IIB

By cutting both strands of the DNA on both sides of their recognition sites, the type IIB enzymes such as BcgI (Table I) cut four phosphodiester bonds at *each* recognition site. Moreover, like many other restriction enzymes, the IIB enzymes are more active against DNA with two recognition sites than DNA with a single site. They thus have the potential to cleave eight phosphodiester bonds per turnover. The IIB enzymes also differ from the orthodox enzymes in subunit composition. For instance, BcgI contains two different subunits: one carries both the endonuclease and methyltransferase activities and the other recognizes the cognate DNA. Other type IIB enzymes contain a single subunit with endonuclease, methyltransferase, and DNA recognition functions. Moreover, some require AdoMet for not only the methyltransferase but also the endonuclease activity.

The Type II Modification Methyltransferases

Purpose of Methylation

The methyltransferases of type II RM systems are altogether different from the partner endonucleases; their only commonality is recognition of the same DNA sequence. The purpose of the modification enzyme is to protect recognition sites in the host DNA from the restriction enzyme. They achieve this by transferring a methyl group from AdoMet to a particular base in the recognition sequence. Some methylate the carbon at position 5 (C5) of the cytosine ring, some the exocyclic amino group at position 4 in cytosine, and some the exocyclic amino group at position 6 in adenine. Each turnover of a modification enzyme methylates the recognition sequence in one strand. This is sufficient to block the activity of the restriction endonuclease. Hence, following semiconservative replication of fully methylated DNA, the hemimethylated daughter strands are protected. The unmethylated strand must then be modified by the methyltransferase before the next round of replication.

The Methyltransferase Enzymes

The methyltransferases from type II RM systems are monomeric proteins. The same enzyme methylates both strands of palindromic sites, but two methyltransferases are needed at asymmetric sites: one for the top strand and another for the bottom strand, although both activities are sometimes present in one polypeptide. The crystal structures of these enzymes have revealed two domains, one on either side of a DNA-binding cleft. One domain contains the DNA-recognition functions, which are unique to each methyltransferase, and the other the binding site for AdoMet and the catalytic residues for the transfer reaction.

The crystal structure of the HhaI methyltransferase bound to its recognition sequence revealed a novel perturbation of the DNA. Remarkably, the target cytidine had been swiveled completely out of its stacked conformation in the DNA helix and into the active site of the enzyme, deep in the catalytic domain. Other DNA-processing enzymes also use this mechanism, for example, the uracil DNA glycosidases in DNA repair. Base flipping may be a ubiquitous device used by enzymes that require access to the nucleotide bases in DNA that are otherwise buried in the double helix.

All methyltransferases use AdoMet as the methyl donor. With the cytosine C5 methyltransferases, the

carbon must first be activated. This is achieved by forming a covalent bond between the adjacent C6 position on the cytosine and the thiol group of a cysteine in the active site of the protein. The subsequent transfer of the methyl group to C5 expels the cysteine from C6, thus breaking the covalent link between protein and DNA. With the cytosine N4 and the adenine N6 methyltransferases, the exocyclic amino group may function directly as a nucleophile to attack the transferable methyl group of AdoMet.

Restriction Enzymes in the Laboratory

Various factors have contributed to the adoption of type II restriction enzymes as essential research tools. The foremost is their specificity in cleaving DNA at fixed positions at particular sequences, that is, their abilities to recognize simple DNA sequences within any DNA molecule and to cleave the DNA at those sites without cleaving other sites to any detectable extent. Consequently, a restriction digest yields a discrete set of defined fragments determined by the positions of the recognition sites in the DNA molecule. Moreover, the resultant fragments of duplex DNA may, depending on the restriction enzyme being used (Table I), possess single-strand extensions that are mutually complementary. Such fragments can be then ligated to other DNA molecules with the same single-strand extensions.

The applications of restriction enzymes have led to the emergence of several companies for whom restriction enzymes are the primary product line. The availability of these enzymes permitted far-reaching technical advances, such as the construction of recombinant DNA molecules, restriction mapping, DNA sequencing, and the use of restriction-fragment-length polymorphisms (RFLPs) as genetic markers for genealogical analysis and gene isolation.

One feature of type II nucleases that concerns users is their star activity (noted previously). Under altered conditions, the barriers that prevent the enzymes from cleaving DNA at noncognate sites are less severe than those under optimal conditions. There is no general remedy for this, other than avoiding the conditions that cause it: low ionic strength, high pH, organic solvents, and Mn^{2+}. A further concern is the fact that many restriction enzymes cleave DNA only after interacting with two recognition sites. Such enzymes have low activities against DNA molecules with one target site, but they can be activated against single-site substrates by adding oligonucleotide duplexes that have the recognition sequence.

Biography

Darren Gowers is a postdoctoral researcher at Bristol University. His interests include the mechanisms of restriction enzymes that interact with two DNA sites, and the mechanisms by which sequence-specific DNA-binding proteins locate their target sequences. He gained his Ph.D. degree in 1998 from Southampton University.

Stephen Halford has led a research group at the University of Bristol since 1976, examining several different sorts of enzyme reactions on DNA, primarily the type II restriction endonucleases. He received his Ph.D. from Bristol University in 1970. In 2000, he was awarded the Novartis Medal of the Biochemical Society.

DNA Restriction and Modification: Type III Enzymes

Desirazu N. Rao and S. Srivani
Indian Institute of Science, Bangalore, India

Type III restriction–modification (RM) enzymes are multifunctional proteins that exhibit both restriction and modification activities. Five members in this class of enzymes have been characterized to some extent: *Eco*PI from prophage P1, *Eco*P15I from the prophage P1-related plasmid p15B in *Escherichia coli*, *Hin*fIII from *Haemophilus influenzae*, *Sty*LTI from *Salmonella typhimurium*, and *Lla*FI from *Lactococcus lactis*. These enzymes are composed of two subunits, products of the *res* and *mod* genes, and require ATP, S-adenosyl-L-methionine (AdoMet) and Mg^{2+} for restriction. The Mod subunit alone functions as a methyltransferase in the presence of AdoMet, whereas restriction activity requires the cooperation of both the Res and Mod subunits. Type III restriction enzymes characteristically recognize DNA sequences that lack symmetry and cleave DNA 25–27 base pairs downstream of the sequence. Two inversely oriented (→←) unmethylated sites are the substrates for cleavage by type III restriction enzymes. It has been shown that ATP hydrolysis is required for DNA cleavage by the type III enzymes. In contrast, methylation proceeds regardless of the number and orientation of recognition sequences.

*Eco*PI and *Eco*P15I

*Eco*PI and *Eco*P15I restriction enzymes (R.*Eco*PI and R.*Eco*P15I) recognize the sequences 5′-AGACC-3′ and 5′-CAGCAG-3′, respectively. The *res* gene product is a 106-kDa protein, while the product of the *mod* gene is a 75-kDa protein. Analytical ultracentrifugation and gel quantification of *Eco*PI and *Eco*P15I restriction enzymes revealed a common Res_2Mod_2 subunit stoichiometry. The *Eco*PI and *Eco*P15I systems are closely related, in which complementation as well as recombination between the structural genes are possible. Electron microscopic analysis of heteroduplexes between the *Eco*P1 and *Eco*P15 genes reveals that the *res* genes of the two systems are largely homologous. The *mod* genes are a mosaic of homologous and nonhomologous regions, the latter being responsible for sequence specificity of these enzymes.

Substrate Requirements

Cleavage of DNA by *Eco*P15I restriction enzyme (and the type III restriction enzymes in general) can be explained by a tracking–collision model (Figure 1). The model states that one *Eco*P15I molecule bound to a recognition site produces a DNA loop of increasing size as it tracks along the DNA until it collides with another *Eco*P15 molecule bound to another site tracking in the opposite direction. Translocation thus positions the two inversely oriented enzyme–site complexes appropriately for cleavage to occur. However, cleavage occurs at only one of the two possible cleavage positions and is a random event.

DNA translocation requires a driving force (ATP hydrolysis). It has been shown that the ATPase activity of *Eco*P15I and *Eco*PI is uniquely recognition site-specific. The collision complex is considered to be the endonucleolytically active form of the enzyme. Both cleavage products contain the original recognition sites, allowing the enzyme to remain bound and continue tracking. A DNA substrate possessing one *Eco*PI and one *Eco*P15I site in a head-to-head configuration was cleaved only in the presence of both enzymes, clearly demonstrating that these two different type III enzymes can functionally cooperate in DNA cleavage. Results from such cooperation assays using mutant enzymes suggest that double-strand breaks result from top strand cleavage by a Res subunit proximal to the site of cleavage, while bottom strand cleavage is catalyzed by a Res subunit supplied in trans by the distal endonuclease in the collision complex. DNA translocation appears not to be required for cleavage initiation, as two adjacent head-to-head or tail-to-tail oriented sites are efficiently cleaved. Post cleavage, the enzyme remains bound to the DNA. An exonuclease is required to act on these molecules releasing the enzyme for subsequent rounds of catalysis. Thus, efficiency of enzyme increases with decreased affinity for cleaved DNA.

One of the fundamental differences between type I and type III enzymes is that cleavage occurs at the point where the two DNA-translocating restriction enzyme complexes collide. While the cleavage by type III R–M

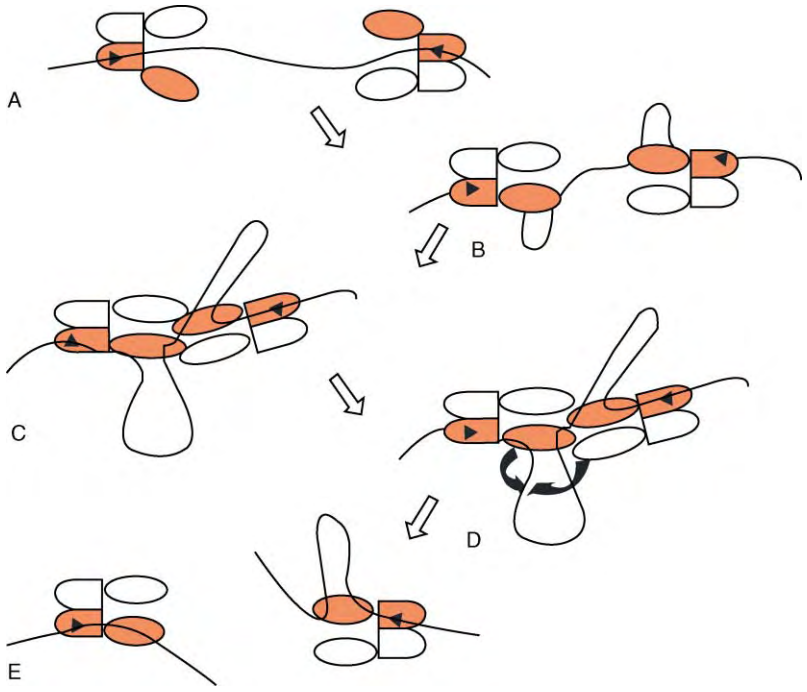

FIGURE 1 Schematic diagram showing the model proposed for DNA cleavage by type III RM enzymes (and represent Mod subunit; and represent Res subunit). (**A**) Enzyme binds two inversely oriented recognition sequences. (**B**) ATP-dependent DNA-translocation commences resulting in looping of DNA. (**C**) Collision of the two complexes results in conformational changes in Res subunit. (**D**) DNA cleavage: top strand is cut by the proximally attached Res subunit and bottom strand is cut by the distally attached Res subunit. (**E**) Cleaved DNA with the RM enzyme attached.

enzymes occurs 25–27 base pairs from the recognition sites, type I enzymes cleave 1000–7000 base pairs away from their recognition sites. Type III enzymes cleave at the recognition site proximal end of the tracking loop as illustrated in Figure 1. An unspecific molecular barrier such as a bound Lac-repressor, which would halt DNA translocation, is not adequate to evoke DNA cleavage by the type III enzyme, *Eco*P15I. Despite differences in structure and mode of action, type I and type III enzymes appear closely related mechanistically.

Cofactor Requirements

Both *Eco*P15I and *Eco*PI restriction enzymes possess sequence-specific ATPase activity. Nonhydrolyzable analogs of ATP, such as AMP-PNP or ATP-γS, cannot replace ATP in the reaction. DNA restriction by *Eco*PI restriction enzyme requires exogenous addition of AdoMet, while the closely related *Eco*P15I enzyme has bound AdoMet and therefore, does not require the addition of this cofactor for DNA cleavage. Reconstitution experiments, which involve mixing of the isolated subunits of R.*Eco*P15I result in an apoenzyme form, which is restriction proficient only in the presence of AdoMet. However, mixing the Res subunit with Mod subunit deficient in AdoMet binding does not result in a functional restriction enzyme, suggesting that AdoMet binding causes a conformational change, which is necessary for DNA cleavage.

Organization of Genes and Regulation of Restriction Activity

Several observations implied that the *mod–res* operon was transcribed as a single unit. Sequence analysis of the genes showed a two base pair gap between the end of *mod* and the beginning of *res* gene. This led to the conclusion that translation of the *res* gene was due to ribosomal shuffling from the terminator to the initiator codon, an initiation factor independent event.

A tight control of the potentially lethal activity of the restriction enzyme must be ensured for efficient establishment of type III restriction–modification (RM) system in a cell. Two independent post-transcriptional regulatory mechanisms control the expression of restriction activity: (a) The modification activity is expressed immediately after the RM genes enter the cell, whereas the expression of restriction activity is delayed until the complete protection of cellular DNA is achieved by methylation. The expression of the modification subunit regulates the amount of restriction subunit present in the cell, suggesting that the correct folding of Res into active and stable configuration is promoted by its interaction with the Mod subunit. (b) *In vivo* restriction activity is modulated by a decrease in the efficiency of translation and by varying ribosomal accuracy conditions.

Domainal Organization in Restriction Subunit

Multiple sequence alignment of all known and putative Res subunits suggests a modular structure (Figure 2). The ATPase and helicase domains are present in the N-terminal region of Res subunit. The C-terminus contains the P-D…(D/E)-X-K motif that is commonly present in the catalytic center of type II restriction endonucleases. Amino acid sequence comparison of the restriction subunit of *Eco*PI and several putative Res subunits revealed the so-called DEAD box motif that is present in the helicase superfamily II. The members of the DEAD family have seven conserved motifs (motifs I, IA, II–VI). The first of the seven motifs of the DEAD family of helicases resembles the Walker A domain. Mutational analysis of motif I resulted in a loss of DNA cleavage and ATP hydrolysis, while that of motif II significantly decreased ATP hydrolysis but had no effect on DNA cleavage. These motifs must, therefore, clearly play a role in ATP hydrolysis. Mutations in motif VI abolished both activities while mutations in the putative endonuclease active site of Res P1 and Res P15 abolished DNA cleavage, but not ATP hydrolysis.

*Eco*PI and *Eco*P15I restriction enzymes are also modification methylases, more efficient than their methylase counterparts. Studies with *Eco*P15I enzyme revealed that the cofactor requirements for methylation by the modification methylase were different from those for the restriction enzyme. Mg^{2+} is an absolute requirement for the modification methylase, while the restriction enzyme could methylate DNA in the absence of Mg^{2+}. Another contrasting feature is that while ATP stimulates methylation activity of the restriction enzyme, the activity of the modification methylase is not altered. It is thought that stimulation of methylation activity of *Eco*P15I restriction enzyme could be due to DNA tracking which transforms modification from a distributive to a processive reaction.

Hinf III

Hinf III and *Hine*I restriction enzymes recognize the sequence 5′-CGAAT-3′. *Hinf* III enzyme exists as a large complex of two subunits with a molecular size greater than 200 kDa. Two forms of the enzyme, one with AdoMet bound and the other without the cofactor bound are known to occur. Both forms of the enzyme cleave DNA, only in the presence of ATP and Mg^{2+}, which is stimulated by AdoMet.

A search of the whole genome sequence of *H. influenzae* strain Rd identified tetra nucleotide repeats in a gene, with low homology to *Eco*PI *mod* gene. The adjacent downstream gene in the *H. influenzae* genome has low homology to the *res* gene of the type III family. This homology and organization is a strong indication that these genes indeed encode a type III restriction system. It is, therefore, likely that *Hinf* III purified from *H. influenzae* Rf strain is encoded by the *mod* and *res* genes described above. The number of repeats within the *mod* gene influences the rate of phase variation and expression of the *mod* gene. Similarly, a pentanucleotide repeat in the *mod* gene of *Pasteurella haemolytica* may modulate expression of a resident type III system.

Other Type III RM Systems

With the sequencing of a number of genomes, a number of putative RM systems have been discovered. A few RM systems have been characterized but not in extensive detail such as those mentioned earlier.

The *res* and *mod* genes for *Sty*LTI system have been cloned and sequenced. The sequence 5′-CAGAG-3′ was found to be the canonical recognition sequence and methylation was limited to the second adenine in this sequence. Based on the derived amino acid sequence, the *Sty*LT system shows a high degree of homology with the other type III systems. *Lla*FI is the first type III RM system to be characterized from a Gram-positive bacterium, *Lactococcus lactis*. *Lla*FI has cofactor

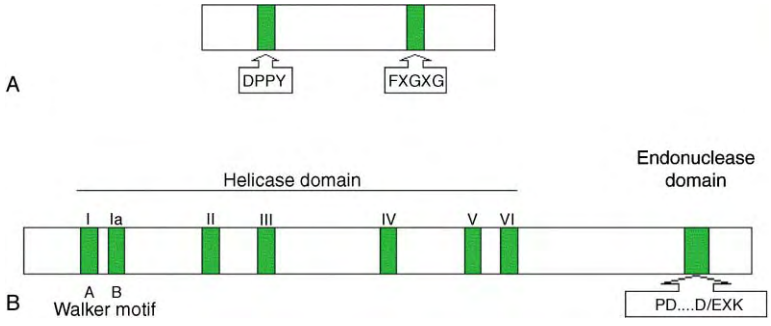

FIGURE 2 Modular structure of type III restriction enzyme. (**A**) Mod subunit showing the location of conserved amino acid sequence regions; catalytic motif, DPPY (motif IV) and AdoMet binding motif, FXGXG (motif I). (**B**) Res subunit showing the location of conserved sequences, helicase motif, and putative endonuclease motif.

requirements that are characteristic of type III enzymes. ATP and Mg^{2+} are required while AdoMet stimulates DNA cleavage. An open reading frame (ORF) from an 8 kb fragment from *Bacillus cereus* ATCC 10987 showed 29.3% identity with the *Eco*PI *res* gene product and 67.6% identity with the deduced amino acid sequence of *Sty*LTI system. Based on these observations, a type III system has been suggested to exist in *B. cereus*. The complete genome sequence of the gastric pathogen *Helicobacter pylori* has revealed four type III RM systems identified on the basis of gene order and similarity to endonucleases and methyltransferases.

DNA Methyltransferases

One unique feature of methylation by *Eco*PI and other type III RM systems is that only one strand of the asymmetric recognition sequence is methylated. Thus, unmodified DNA is the only substrate for the reaction. *Eco*P15I DNA methyltransferase (*Eco*P15I MTase) adds a methyl group to the second adenine in the recognition sequence 5′-CAGCAG-3′ in the presence of AdoMet and Mg^{2+}. *Eco*P15I MTase occurs as a dimer in solution. The kinetic mechanism for *Eco*P15I MTase has been elucidated and the order of substrates binding is random. *Eco*P15I MTase binds about threefold more tightly to DNA containing its recognition sequence 5′-CAGCAG-3′ than to nonspecific sequences in the absence or presence of cofactors. In the presence of ATP, the discrimination between specific and nonspecific sequences increases significantly, suggesting a role for ATP in DNA recognition by these enzymes. *Eco*P15I DNA MTase makes contacts in the major groove of its substrate DNA. The first guanine of the recognition sequence does not show any altered reactivity toward dimethyl sulfate, but the second guanine was modified 3.5-fold better in the presence of the enzyme. This hypermethylation of guanine next to the target adenine could be due to a conformational change in the DNA as a result of protein binding. This probably indicates that the protein flips out the target adenine residue. Both potassium permanganate footprinting and fluorescence spectroscopic measurements support a base flipping mechanism for *Eco*P15I DNA MTase. *Eco*P15I MTase and *Eco*PI MTase, like other N^6-MTases, contain two highly conserved sequences, FxGxG (motif I) and DPPY (motif IV) postulated to form the AdoMet binding site and catalytic site, respectively. Mutations in motif I completely destroy AdoMet binding but leave target DNA recognition unaltered. Mutations in motif IV result in loss of enzyme activity but enhance crosslinking of AdoMet and DNA, implying that DNA and AdoMet binding sites are close to motif IV.

*Eco*PI DNA methyltransferase methylates the second adenine in the recognition sequence 5′-AGACC-3′. Replacement of tyrosine in the conserved DPPY motif with tryptophan results in a mutant enzyme that binds AdoMet almost as well as the wild-type but is catalytically inactive. However, DNA binding is at least threefold stronger than that of the wild-type enzyme.

Clear plaque mutants of phage P1 were isolated to those defective in DNA modification and map to the nonhomologous region of the *mod* gene of P1. These mutant methylases (*c*2 mutants) have either very little or no AdoMet binding and therefore have very weak or no methylating activity. However, the mutant proteins bind specifically to DNA containing *Eco*P1 recognition sequences.

Biography

Desirazu N. Rao is a Professor in the Department of Biochemistry at the Indian Institute of Science, Bangalore, India. His principal research interests are in the area of DNA–protein interactions using restriction–modification enzymes and DNA mismatch repair proteins as model systems. He holds a Ph.D. from the Indian Institute of Science and received his postdoctoral training at the National Institutes of Health, Bethesda, Maryland; Biozentrum, University of Basel, Switzerland; and the University of Cambridge, United Kingdom.

S. Srivani is a Ph.D. student in the Biochemistry Department, Indian Institute of Science.

DNA Secondary Structure

Albino Bacolla and Robert D. Wells
Institute of Biosciences & Technology, Houston, Texas, USA

The term secondary structure refers to all DNA conformations (non-*B*-DNA) other than the antiparallel right-handed double helix (*B*-DNA). The conventional and commonly accepted structure of the majority of DNA in a cell is that of *B*-DNA, as first proposed by Watson and Crick in 1953. However, experimental data have shown for almost 50 years that nucleic acids exist in a variety of other conformations, including left-handed duplexes and three- and four-stranded helices, with parallel and antiparallel strand orientations. In addition, recent nuclear magnetic resonance (NMR) studies have revealed the assembly of nucleic acids into pentameric and hexameric architectures. These non-*B* conformations are favored by specific sequence motifs at certain chromosomal loci and by defined topological or environmental conditions, such as negative supercoil density or cations.

B-DNA

In 1980, the crystal structure of a helix turn of DNA was reported, which confirmed the Watson and Crick model. Since then, analyses of many sequences agree that the structure of DNA (*B*-DNA) is a right-handed double helix rotating about a central axis of symmetry and forming a major and a minor groove (Figure 1A). The Watson and Crick base-pairing scheme between a purine and pyrimidine base (adenine (A) with thymine (T) and cytosine (C) with guanine (G)) was confirmed. Deviations from these pairings (mismatches) perturb the helix structure and are readily corrected by the cellular DNA repair enzymes.

Z-DNA

The first crystal structure of a DNA minihelix, reported in 1979, revealed a left-handed double helix. It was called *Z*-DNA because of the zigzag shape of the phosphate and sugar backbone.

Structure

Z-DNA is formed by alternating purine–pyrimidine (RY·RY) sequences (where R indicates a purine, A or G, and Y indicates a pyrimidine, C or T; the dot designates the complementary strands), such as the repeating $(CG{\cdot}CG)_n$ and $(CA{\cdot}TG)_n$ motifs (Table I). Structurally, the *Z*-DNA helix is slimmer and more elongated than *B*-DNA, and it lacks a major groove (Figure 1B). *Z*-DNA represents a high-energy state for DNA; *in vivo*, most energy required for the *B* to *Z* transition is supplied by negative supercoiling, a topological state found in chromosomal DNA.

Biology

Alternating (RY·RY) tracts are common in eukaryota, and *Z*-DNA formation has been found mostly in transcribed regions of the genome. In the current model, high negative supercoiling generated behind RNA polymerase complexes during transcription drives the (RY·RY) tracts into a left-handed conformation. The alternative structure, in turn, regulates gene expression. For example, the rat nucleolin promoter contains a $[(CA)_{10}(CG)_8]$ motif that represses promoter activity upon adopting a left-handed conformation. Allelic variants differing in the number of dinucleotide repeats show a quantitative effect on the rate of gene transcription that correlates with the stability of *Z*-DNA. Sera from patients with the autoimmune systemic disease *Lupus erythematosus* contain antibodies against *Z*-DNA. Two eukaryotic proteins, both γ-interferon-inducible, bind and stabilize *Z*-DNA structure: ADAR1, an RNA-editing enzyme, and DLM-1, a protein that is up-regulated in tumor stromal cells.

Triplex DNA

The association of synthetic nucleic acids into three-stranded structures (three-stranded DNA or H-DNA) was reported in 1957 and was confirmed in 1968 with naturally occurring sequences.

Structure

In a three-stranded nucleic acid, consecutive purine bases in a *B*-DNA duplex engage a third base through additional hydrogen bonds, referred to as Hoogsteen hydrogen bonds. These bonds differ from the Watson

Warren, *Genetic Instabilities and Hereditary Neurological Diseases*, p. 563, Copyright 1998, with permission from Elsevier.

and Crick model and were described by Hoogsteen in 1963 when an A·T base pair was first reported. The formation of a triplex requires DNA to contain only purines in one strand and pyrimidines in the complementary strand (R·Y) in a mirror repeat orientation (Table I). In an intramolecular triplex, one-half of the purine-rich (or pyrimidine-rich) strand dissociates and folds back to engage the remaining Watson and Crick paired purine-rich strand in the major groove (Figure 1C). Alternatively, in an intermolecular triplex, a purine (or pyrimidine) strand from one DNA tract engages in Hoogsteen bonds with a duplex from a different DNA tract. Specific bonds form between A and A, G and G, A and T, and G and protonated C.

Biology

R·Y tracts are common in eukaryotic genomes. In humans, sequences with thousands of such asymmetric base pairs exist, such as in the intron 21 of the

polycystic kidney disease gene 1. Triplex structures have been shown to inhibit transcription and replication, but increase recombination rates and promote genome instability. Sticky DNA (Figure 2) is a long triplex between two tracts of $(GAA{\cdot}TTC)_n$ (where $n = 59-270$) that are distantly located in a circular DNA. Friedreich's ataxia (FRDA), the most common hereditary ataxia, is caused by the expansion of the GAA·TTC tract in intron 1 of the frataxin gene, which subsequently inhibits its transcription. Sticky DNA is likely to be involved in the etiology of this neurological disease. In mammalian nuclei, actively transcribed chromatin is organized in specific domains, and centromeres are involved in such organization. Visualization of triplexes in nuclei revealed a colocalization of such structures from centromeres and other loci, supporting a model in which triplexes are implicated in the organization of chromatin domains.

Pharmacology

The delivery of synthetic triplex-forming oligonucleotides (TFOs) that adopt Hoogsteen pairs with complementary purine-rich genomic targets has been shown to form triplexes in nuclei. This strategy has been explored as a therapeutic tool to inhibit gene expression. For example, a TFO targeting an R·Y tract in the third intron of the *ICAM-1* gene, whose up-regulation is associated with inflammatory diseases, inhibited protein synthesis in human keratinocytes in cell culture and is considered a therapeutic agent in the treatment of psoriasis.

Tetraplex DNA

The ability of G residues to assemble in tetrameric arrangements (quadruplex DNA, four-stranded DNA, or G4 DNA) was noted in 1962. In 1988, tetraplex DNA was reported in biological systems.

Structure

Tetraplex DNA (also called G4 DNA because of the G quartets) forms when DNA sequences are composed of four repeating motifs that contain G residues (Figure 1D, Table I). Gs from each motif stack on one another and the four stacks form the sides of a cube. In each stack, four Gs hydrogen-bond and constitute a tetrad. NMR and X-ray crystallography studies showed that, in fact, all four nucleotides can form heterotetrads (or homotetrads), and therefore tetraplex DNA is likely to be observed with a greater variety of sequences *in vivo*.

Biology

Tetraplex DNA is involved in the maintenance of telomere ends and in the control of gene expression.

Maintenance of Telomere Ends

The DNA sequence at the ends of eukaryotic linear chromosomes, the telomeres, is a repetitive sequence that contains tetraplex-forming Gs. It is postulated that such capping protects the chromosome ends from being degraded and mediates chromosome condensation. Several proteins assist in the formation of tetraplex DNA; others disassemble the structure.

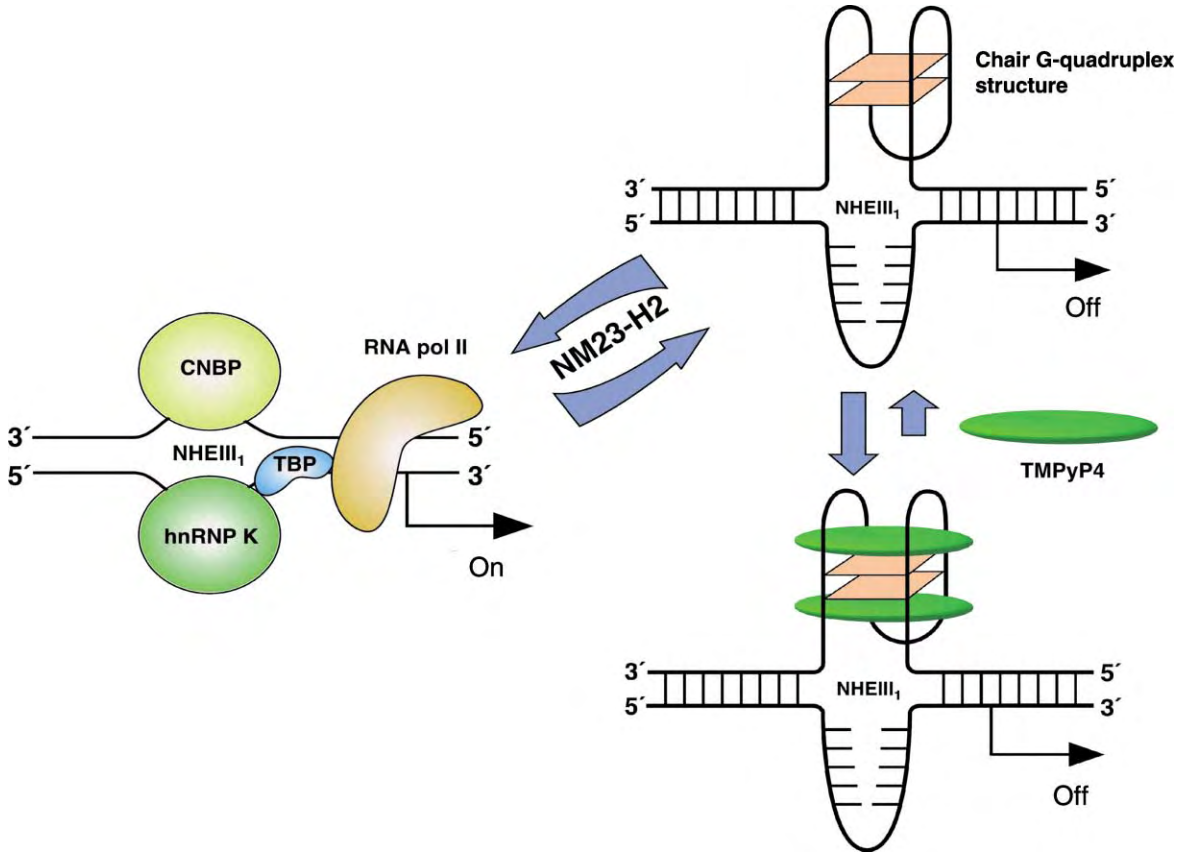

FIGURE 3 Inhibition of transcription by tetraplex DNA, a model for the inhibition of transcription at the *c-MYC* promoter. Left, the transcriptional complex assembles at the promoter and supports initiation of transcription by an RNA polymerase II complex. Top right, the cellular factor NM23-H2 promotes the transition from duplex to tetraplex, preventing assembly of transcription factors. Bottom right, TMPyP4 binds to, and stabilizes, the tetraplex structure driving the equilibrium toward stable transcriptional repression. TMPyP4, 5,10,15,20-tetra(*N*-methyl-4-pyridyl)porphine, a porphyrin derivative, and pyrelene derivatives such as *N*,*N*′(-bis[2-(1-piperidino)-ethyl]-3,4,9,10-perylenetetracarboxylic diimide (PIPER) are explored as therapeutic agents because their tetraplex binding activity inhibits telomerase, which is up-regulated in 80–90% of malignant tumors. Nuclear hypersensitive element III_1 ($NHEIII_1$) is a 27-bp promoter sequence cleaved when probed with single-stranded-specific nucleases or other chemicals. This sequence is shown in Table I. Reprinted from Siddiqui-Jain, A., Grand, C. L., Bears, D. J., and Hurley, L. H. (2002). Direct evidence for a G-quadruplex in a promoter region and its targeting with a small molecule to repress a c-*MYC* transcription. *Proc. Natl Acad. Sci. USA* **99**, 11593–11598. Copyright 2002, with permission of National Academy of Sciences, U.S.A.

Control of Gene Expression

Human sequences in the immunoglobulin switch region and in the promoters of other genes, including the oncogenes *c-MYC*, *c-MYB*, *c-FOS*, and *c-ABL*, contain repeating Gs that have been shown to form G-quartets. Experiments in cell cultures indicate that the promoter region of *c-MYC* is under the regulatory control of a secondary DNA structure, including a tetraplex. Specifically, its formation decreases transcriptional activity by interfering with the assembly of an RNA–polymerase complex (Figure 3).

Cruciforms and Slipped Structures

Cruciforms and slipped structures are formed by repetitive DNA sequences, but do not require a specific base composition.

Cruciforms

In inverted repeats, a DNA sequence is followed by its complementary sequence read in the opposite orientation (Table I). Thus, each strand may form a fully paired duplex, giving rise to a cruciform (Figure 1E). Inverted repeats are common at replication origins and at chromosomal locations associated with genomic instability.

Origins of Replication

Bacteria may carry extra-chromosomal DNA elements called plasmids. pT181 belongs to a class of plasmids whose replication requires nicking on one strand; under optimal conditions, negative supercoiling drives the formation of a cruciform that positions the nicking site on a single-stranded loop, allowing

nicking and the replisome to assemble and carry out replication. Studies have indicated a dynamic distribution of cruciforms in mammalian nuclei, their number being maximal at the G_1/S phase boundary, when DNA synthesis takes place. The concentration of a family of proteins (called 14-3-3) with cruciform-binding activities is also maximal in this period. Experiments on monkey *ors8* and *ors12* replication origins support the involvement of such proteins and DNA secondary structures in the initiation of DNA replication.

Genetic Instability

The recurrent human translocation t(11;22) involves the fusion of chromosomes 11 and 22. The site of translocation contains several hundred base pairs of AT-rich sequences on both chromosomes that may form large cruciforms. Breaking points were observed at the center of an inverted repeat sequence on both chromosomes, supporting the formation of a cruciform structure as the cause of translocation (Figure 4).

Slipped DNA

Repeating motifs of identical sequence composition (direct repeats) may base-pair in an out-of-register manner and thus form looped-out (slipped) structures (Figure 1F). Di-, tri-, tetra-, and pentanucleotide repeats are common in prokaryotes and eukaryotes and are often present in regulatory regions. Their copy number varies within a population, and this variation modulates gene expression (Table I). The simple sequence contingency loci are repeating tracts (microsatellites) in pathogens, such as *Haemophilus influenza* and *Neisseria meningitis*, that are involved in phase variation, a high-frequency gain or loss of the expression of virulence associated with changes in the number of repeats. Slippage of the complementary strands during replication is the accepted mechanism involved in such length changes. The involvement of slipped structures in the genetic instabilities of triplet repeat sequences has probably been studied most extensively. At least 14 hereditary neurological diseases, including myotonic dystrophy, fragile X syndrome, and FRDA, are caused by the massive expansion of CTG·CAG, CGG·CCG, and GAA·TTC, respectively. The capacity of one of the complementary strands in each duplex to preferentially adopt a quasi-stable slipped structure during replication–repair–recombination, thus causing primer realignment, is the mechanism. Also, the first two repeating sequences are flexible and writhed, contributing to their genetic instability.

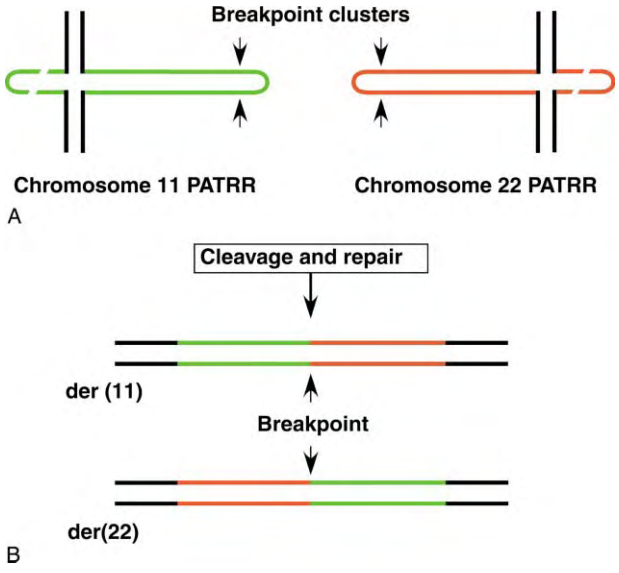

FIGURE 4 Human t(11;22) translocation. (A) Chromosomes 11 and 22 contain A/T-rich inverted repeats (PATRR) that form cruciform structures cleaved by nucleases. (B) Cleavage sites are repaired by joining chromosome 11 with 22, which yields the translocations der(11) and der(22). Adapted from Kurahashi, H., and Emanuel, B. S. (2001). Biography

Robert D. Wells is Director of the Center for Genome Research at the Institute of Biosciences and Technology in Houston, TX, and a Professor in the Department of Biochemistry and Biophysics at Texas A&M University. His principal research interest is in alternative DNA structures and their roles in medicine and biology. He holds a Ph.D. from the University of Pittsburgh and received his postdoctoral training at the University of Wisconsin. He has served as the President of the American Society for Biochemistry and Molecular Biology and the Federation of American Societies for Experimental Biology.

Albino Bacolla is a Senior Research Associate at the Institute of Biosciences and Technology in Houston, TX. His research interest is in the biological role of secondary DNA structure and topology. He holds a Ph.D. in Biology from the University of Turin, Italy.

DNA Sequence Recognition by Proteins

Arabela A. Grigorescu and John M. Rosenberg
University of Pittsburgh, Pittsburgh, Pennsylvania, USA

Recognition of specific DNA sequences by proteins refers to the ability of proteins to distinguish and preferentially bind particular DNA sequences in the genome. DNA sequence recognition is vital to cellular processes such as regulation of gene expression, site-specific recombination, DNA replication, and DNA repair; accordingly, in all living organisms, there are many different families of DNA binding proteins. The primary mechanism for this recognition is the formation of a tight complex between the target DNA sequence and a specific protein that has evolved to recognize it. The shapes of the protein and the DNA match each other precisely across the protein–DNA interface. That match is chemically complementary: opposite charges are situated across the interface from each other, as are hydrogen bond donors and acceptors. How they get there is the basis of sequence-specific recognition.

What Features of DNA Sequences are Recognized by Proteins?

The Watson-Crick model of the DNA double helix is a uniform structure with a negatively charged phosphate backbone at the exterior and a core of stacked base pairs forming a column up the center. What unique features of a DNA sequence can be recognized by a protein?

Functional Groups on DNA

The four constituent bases of DNA, adenine (A), thymine (T), guanine (G), and cytosine (C) have unique chemical groups available at their edges to interact with atoms of the protein. These chemical groups – termed functional groups of the DNA bases – are lying on the floors of the two DNA grooves (the concave surfaces of the double helix formed by the edges of the DNA deoxynucleosides (Figure 1)). Because of the asymmetric attachment of the DNA base pairs to the furanose rings, the two grooves of the double-helical DNA molecule have different dimensions. The narrower groove is referred to as the minor groove while the wider groove is referred to as the major groove.

Complementary Interactions with the Functional Groups

As initially pointed out by A. Rich and co-workers, the A-T and G-C base pairs display unique patterns of hydrogen bond donors and acceptors in the DNA grooves (Figure 1B). Also, the methyl group on the C5 position of the thymine base can interact favorably with CH_2 and CH_3 groups on amino acid side chains of the protein. The shape of a particular base pair can be recognized by proteins through series of adjacent van der Waals contacts.

Thus, recognition interactions require precise juxtaposition of complementary chemical groups on the protein and on the DNA (chemical complementarity). This complementarity is the basis of recognition, because once a particular protein has achieved the positioning of its functional groups such that they are complementary to those presented by one base sequence, they would not match the functional groups presented by a different sequence.

Water-mediated interactions are also common at protein–DNA interfaces. Polar atoms from amino acid side chains such as Asn, Gln, Thr, and Ser, as well as the amino and carboxyl groups of the protein's main chain, often trap water molecules between the protein and the DNA. The water molecules bridge the protein and the DNA, forming hydrogen bonds to both. Because of the functional groups often involved, these bridging interactions can form simple extensions of the complementarity described above.

Reading Heads

In order to "read" even a short sequence of DNA, the protein must group appropriate amino acid side chains in close proximity. Indeed, some short sequences are recognized by the single structural element of the protein (sometimes referred to as a reading head) that is brought in close proximity to the functional groups of the DNA bases. These structural elements, often called

motifs, provide a scaffold for functional groups that do the reading.

Reading heads can be α-helices, β-sheets, or loops. In some cases, they pre-exist as rigid secondary structural elements in the unbound protein, but in others they represent flexible protein regions that adopt a regular structure in response to DNA binding (many proteins couple local folding with site-specific DNA binding – an idea originally proposed by T. Record based on thermodynamic premises).

In the example shown in Figure 2A, the reading head is an α-helix inserted into the DNA major groove. In the example shown, the α-helix positions four protein side chains for recognition of a total of three base pairs of the DNA. The dimensions of the protein α-helix and of the DNA major groove are ideal for this mode of interaction.

Although not as common as α-helices, two stranded β-sheets have also been observed to serve as reading heads. In the example shown in Figure 2B, the convex side of a curved, two-stranded β-sheet runs parallel to the surface of the major groove; six amino acid residues (three in each β-strand) make direct readout interactions with a total of six consecutive DNA base pairs.

Indirect Readout

Despite the existence of several such simple and attractive examples, in general, direct readout by a rigid fit of α-helices and/or β-sheets to the DNA major groove is not the predominant mechanism employed by proteins for DNA recognition. Only a limited number of sequence-specific DNA-binding proteins exclusively use direct readout, and very often direct readout alone cannot explain the energetic preference of a protein for a particular DNA site. A second, more subtle mechanism for sequence discrimination originates in the distortability of the DNA helix, as shown by structural analysis of a large number of protein–DNA complexes. They reveal that DNA is characterized by remarkable flexibility. In a complex with a protein, the DNA often adopts a conformation that departs significantly from a regular double helix. Several examples given in Figure 3 show that DNA can be, for example, bent, kinked, elongated, and wrapped around a protein. Many lines of experimental evidence suggest that the energetic cost of distorting the DNA into a particular conformation is sequence dependent, and this dependence is exploited by proteins for sequence recognition.

As the DNA is distorted, its chemical groups change their spatial positions. Because the energy required to achieve that distortion is sequence dependent, the resulting spatial positioning of the functional groups reflects the sequence. This is true even for functional groups that do not change with base sequence, such as backbone phosphate groups. Thus, the energy liberated by contacts between a protein and a distorted DNA molecule depend subtly on the distortability of the base sequence. This mechanism of sequence recognition is referred to as indirect readout.

Most site-specific DNA-binding proteins combine the direct and indirect readout mechanisms in order to maximize the information content of DNA sequences. This combination also diversifies the available structural strategies for DNA binding. For example, certain distortions of the DNA helix can alter the dimensions of the DNA grooves such that they can accommodate α-helices, β-sheets, or loops in various orientations. In some cases, dramatic bending of the DNA molecule can completely open up the major or minor groove. In the specific complex of the TATA-binding protein (TBP) and DNA (Figure 3E), the protein is bound on the minor groove side of the DNA, but the DNA is bent by approximately 80° toward the major groove. This distortion alters the minor groove such that it becomes a wide concave surface that is complementary to the curved surface of the TBP protein. In the specific protein–DNA complex of the prokaryotic integration host factor (IHF) (Figure 3F), the DNA molecule is wrapped around the protein. This is possible because the protein induces a bend of approximately 160° in the DNA, and three distinct regions of the DNA molecule are directly contacted and held in place by the IHF protein.

Structural Motifs in Protein–DNA Recognition

As exemplified in Figure 3, the structural strategies for DNA recognition and binding are remarkably diverse among various classes of DNA-binding proteins. Similar binding strategies and common design principles, however, appear to exist between members of a given protein family; several structural motifs for DNA recognition have been identified in families such as bacterial repressors, eukaryotic transcription factors and other gene regulatory proteins, and particular classes of DNA enzymes.

The Helix-Turn-Helix Motif

Historically, the helix-turn-helix (HTH) motif was one of the first DNA-binding motifs to be identified and analyzed. DNA recognition by the HTH motif has been reviewed by S. Harrison and A. Aggarwall and more recently by C. Garvie and C. Wolberger.

Common to many prokaryotic gene regulatory proteins and also found in eukaryotic homeodomain proteins, the HTH motif consists of two α-helices connected by a turn (Figure 3A). One of the α-helices (termed the recognition helix) inserts into the major

The amino acid side chains are omitted for clarity. Only regions of the protein that are close to the DNA are visible in the figure. In the examples shown, the DNA reading heads (highlighted in red) are (A) an α-helix in λ repressor, (B) a two-stranded β-sheet in MetJ repressor.

groove, making direct or water-mediated contacts with the DNA bases. The other α-helix acts primarily to spatially stabilize the motif through hydrophobic interactions in the interior of the two-helix elbow but, in some cases, also contributes to the binding specificity by interacting with the DNA phosphate backbone. Most of the proteins that use this motif for DNA recognition are homodimers; by using two symmetrical HTH motifs, recognition of longer DNA sequences as well as modulated affinity for a series of closely related DNA sequences can be achieved.

Although highly conserved in its internal structure, the HTH motif is highly variable in its precise placement within the major groove of DNA, i.e., the geometry of the DNA–HTH interaction is not as highly conserved. This apparent paradox has been resolved by noting that the HTH motif forms a highly stable bulge on the surface of a protein, a structural requirement for an effective reading head. Thus, although primarily found in DNA-recognition roles, HTH motifs have been found in other situations where there is a structural requirement for a small bulge.

The Zinc Finger Motif

The zinc finger DNA-binding motif is common to many transcription factors in the human genome. The first zinc finger domains were identified in the structure of *Xenopus* transcription factor IIIA in 1985. This motif consists of a relatively short α-helix and a two-stranded antiparallel β-sheet (Figure 3C). The fold is stabilized by a core of residues (most commonly two cysteines and two hystidines) coordinating a Zn^{2+} ion. Typically, the N-terminal part of the α-helix is inserted in the major groove, contacting 3 to 4 DNA bases. Many gene regulatory proteins in eukaryotes contain several copies of this motif connected by linkers; variations in the number and sequence of the zinc finger motifs and the length and flexibility of the linker regions allow transcription factors and other similar proteins to recognize long and complex DNA target sites using a relatively simple structural motif. Here, too, the zinc finger forms a bulge found most often, but not exclusively, as a DNA recognition element.

The Leucine Zipper Motif

The basic leucine zipper (bZIP) binding motif is another structural motif employed by eukaryotic gene regulatory proteins for DNA recognition. It consists of two long, approximately parallel α-helices wrapped partially around each other to form a type of structure called a coiled coil. The contacts between the α-helices are stabilized by hydrophobic interactions made by a series of leucine residues. The N termini of the α-helices are the DNA reading heads that insert into the major groove (Figure 3B). They are unstructured in the absence of DNA; thus, the basic leucine zipper motif couples local

folding with DNA recognition. T. Hakoshima and co-workers have reviewed the structural basis of DNA recognition by bZIP transcription factors.

Diverse Structural Strategies are Employed by Proteins for DNA Recognition

In general, structural DNA-binding motifs such as helix-turn-helix, zinc fingers, and leucine zipper are used by proteins as DNA-binding modules. In some proteins, they facilitate multiple independent intermolecular contacts and allow modulated affinity for a series of related sites. Proteins with stringent sequence specificity, such as restriction enzymes, use a more integrated recognition mode. Several structural elements of the protein are involved in DNA recognition over a large structural area, but these interactions are not independent. Extensive networks of hydrogen bonds and other favorable interactions form cooperatively at the molecular interface upon site-specific binding; such networks contribute to the specificity and stability of these complexes. These networks often extend to enzymatic active sites, e.g., the cleavage sites of restriction enzymes, thereby integrating recognition and cleavage.

One of the few common trends among the various families of DNA-binding proteins is that most proteins bind to DNA as homodimers, heterodimers, or pseudo-dimers. This strategy has several purposes: first, it is a relatively simple way to bring two or more DNA reading heads in proximity at the interface and to create a larger interface from a globular protein and a helical DNA molecule. Second, additional specificity can be achieved by coupling DNA recognition interactions with quaternary structure interactions within the dimer. Third, the symmetry or the asymmetry of these dimers is often required for the specific function of the protein. For example, type II bacterial restriction endonucleases that recognize short palindromic DNA sites make double-strand breaks in DNA by positioning the two scissile bonds in the two symmetric catalytic sites of the homodimeric enzyme. Proteins that are required to bind DNA in a precise orientation are often

pseudodimers or heterodimers; such examples include eukaryotic TATA-binding protein and prokaryotic integration host factors, respectively.

Conclusion

As the number of structurally characterized protein–DNA complexes continues to expand, it is becoming evident that evolution has engineered a diversity of DNA-binding proteins and DNA recognition modes. By correlating the structural analysis with energetic and functional characterization of DNA-binding proteins, it is becoming increasingly clear that DNA recognition is tightly coupled with the protein function. Conservation of DNA-binding motifs and design principles within protein families reflects the fact that the structural strategies and energetic principles for DNA recognition have been shaped by evolution such that proteins can achieve simultaneously both the desired level of sequence specificity and optimal functionality in their complexes with DNA.

Glossary

direct readout Recognition of the identity of the functional groups of the DNA bases by a protein through specific interactions (hydrogen bonds, hydrophobic, van der Waals contacts, etc).

DNA distortion in a protein–DNA complex A significant departure of the DNA conformation within the complex from that of the free DNA (with the same sequence) in solution (under physiological conditions).

DNA reading head A structural element or motif of the protein that makes specific contacts with functional groups of the DNA bases when it is brought in close proximity to those bases; typically contains several amino acid residues that are involved in the recognition interaction.

indirect readout Recognition of the sequence-dependent conformational features of the DNA, including the energetic cost of distorting the DNA into a particular conformation.

sequence specificity in DNA binding The preference of a given protein for binding DNA of a particular sequence over binding DNA independently of its sequence (nonspecific binding); typically expressed via the differential free energy of binding.

DNA Supercoiling

Tao-shih Hsieh
Duke University Medical Center, Durham, North Carolina, USA

DNA supercoiling describes a higher-order DNA structure. The double-helical structure of DNA entails the interwinding of two complementary strands around one another and around a common helical axis. The writhing of this helical axis in space defines the DNA superhelical structure (DNA tertiary structure). For a circular DNA or a linear DNA with its ends anchored to create a loop, there is a tight topological coupling between the DNA superhelical structure and the double-helical structure (DNA secondary structure). Hence, DNA superhelicity can influence the DNA winding/unwinding, thereby affecting the biological functions of DNA. In nature, there exists a ubiquitous class of enzymes, DNA topoisomerases, that can mediate the topological transformation in DNA molecules.

Background

The beauty and elegance of the double-helical structure of DNA, as first proposed by Watson and Crick in 1953, also imparts critical functions of DNA. However, the unwinding of the DNA double helix during the process of replication, transcription, and recombination creates intriguing topological problems. The potential topological problem intrinsic to a circular, double-stranded DNA molecule was first noted by Cairns in 1963. In his autoradiographic analysis of chromosome replication in the bacterium *Escherichia coli*, Cairns pointed out that the bihelical DNA structure of a circular molecule poses a topological constraint on the strand separation necessary in the process of DNA replication. Vinograd and his associates about the same time demonstrated that an animal virus, polyomavirus, also has a circular genome. Furthermore, the helical axis itself winds and turns in space, thus producing a superhelix. Since then, circular genomes have been discovered in many organisms, including most bacteria, bacterial plasmids, and organelles such as mitochondria and chloroplasts. For example, Figure 1 shows an electron micrograph of a small bacterial plasmid DNA. The DNA superhelicity results in a duplex making crossovers (intersections) with itself. For most circular DNAs isolated from natural sources, the number of superhelical turns is directly proportional to the length of DNA. There are approximately six to eight superhelical turns per 1 kb DNA. We discuss the quantitative details in later sections.

The biological significance of DNA superhelicity was first realized when Vinograd and his co-workers discovered that there is a tight coupling between the DNA secondary structure and superhelical structure. Therefore, DNA superhelicity can influence the unwinding and rewinding of DNA duplex, and vice versa. Because such a coupling is direct, it allows one a rare opportunity in molecular biology to design experiments to gain insight into the structure of DNA and to probe the mechanism of the enzymes that affect DNA structure. The theoretical consideration of the coupling between DNA secondary and tertiary structures, based on mathematical topology, was later extended in the treatises by Fuller, White, and Crick. It should be pointed out that such a topological coupling also applies to linear DNA with anchored sites to create the loop structure that is found in the chromosomes of essentially all cells.

Nature has evolved unique enzymes to solve the topological problems that arise during the process of unwinding/rewinding DNA helix. The first such enzyme, topoisomerase I from the bacterium *E. coli*, discovered by Wang in 1970, can remove negative supercoils efficiently. Many new families of topoisomerases have since been discovered, and these enzymes are present in all organisms and have essential biological functions.

Quantitative Relationship between Twist and Supercoil

For a circular DNA without any nicks, in which both DNA strands are covalently continuous, the sum of DNA twists (*Tw*) and writhes of the DNA helical axis (*Wr*), a measure of DNA superhelical structure, is invariant. Because the algebraic sum of these two numbers is equal to the number of times that one of the DNA strands winds around its complementary strand in space, it defines the topological linkage between DNA strands, termed the linking number (*Lk*).

FIGURE 1 An electron micrograph of a bacterial plasmid DNA. The DNA has about 3 superhelical turns, as evidenced by the number of crossovers made by the DNA duplex.

We therefore have the following equation:

$$Tw + Wr = Lk$$

where Lk is a constant for a covalently closed circular DNA. Tw is related to the DNA secondary structure, the bihelical winding of two DNA strands, and it can be calculated if one knows the size of the DNA and the average helical pitch in this DNA. For example, in a 1-kb B-form DNA with a helical pitch of 10.5 bp/turn, $Tw = 95$. Wr is a measure of the superhelical structure of DNA. It relates to the number of times that the helical axis crosses itself in space. The higher the Wr, the more supertwisted the DNA. Lk is a topological quantity and defines the total linkage between the two complementary strands. Whereas Tw and Wr can be any real number, Lk is always an integer. This is because, for a closed circular DNA, strands have to wind around one another an integral number of turns to avoid nicks or gaps.

Handedness and the Sign of *Tw* and *Wr*

An important feature for all three parameters is that each has a sign, positive or negative, depending on the handedness of the double helix and superhelix. Because most of the DNA duplexes are right-handed, we define right-handed as positive and left-handed as negative. We can define whether the crossover of two curves in space is left-handed or right-handed if an axis is clearly marked. For example, Figure 2 shows two curves, denoted as two arrows in space, one making a left-handed cross and the other a right-handed one. The axis is shown as a thin vertical line going through the crossover. The significance of the definition of the axis can be visualized in this figure as well. If one chose instead a horizontal line as the axis, then the assignment of handedness is reversed. Figure 2B would then be left-handed and Figure 2A would be right-handed. For the duplex DNA structure, the axis definition is rather intuitive and straightforward. The helical axis is the axis around which the two strands are wrapped with respect to one another. For the DNA superhelix, it is necessary to define an axis in a manner that is consistent with what we defined for secondary structure. An example is shown in Figure 3. A figure-eight superhelix is the simplest possible DNA supercoil. If one lays down the figure-eight superhelix horizontally, then the axis is the vertical line going through the crossover. With this definition of axis, the superhelix shown in Figure 3A has a left-handed crossover, and thus it has a negative superhelical turn ($Wr = -1$). Figure 3B has a positive superhelical turn ($Wr = +1$).

Because it is not practical to measure the absolute value of Wr or Lk, they are usually determined experimentally with respect to a reference state, DNA in a relaxed state. The linking number and writhe for the relaxed state are denoted with a subscript zero.

Because $Wr_0 = 0$, the measure of DNA supercoils, Wr, is equal to the writhe difference with respect to the reference state:

$$Wr = \Delta Wr = Wr - Wr_0$$

Assuming that Tw for the supercoiled and relaxed DNA is about the same ($Tw = Tw_0$), then it follows that:

$$\Delta Wr = \Delta Lk$$

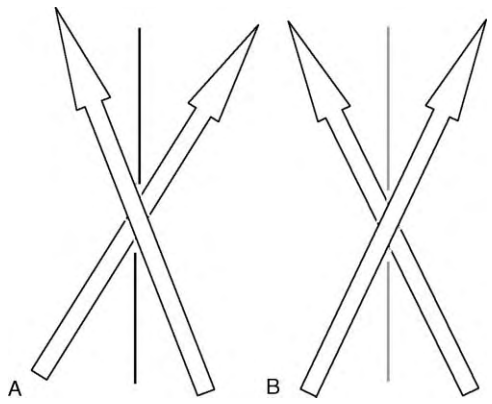

FIGURE 2 Diagrams of (A) a left-handed crossover and (b) a right-handed one. The arrows shown here simply serve to illustrate the point that the two perpendicular axes, one vertical and one horizontal, are not equivalent. The vertical line has been chosen arbitrarily as the axis for determining handedness.

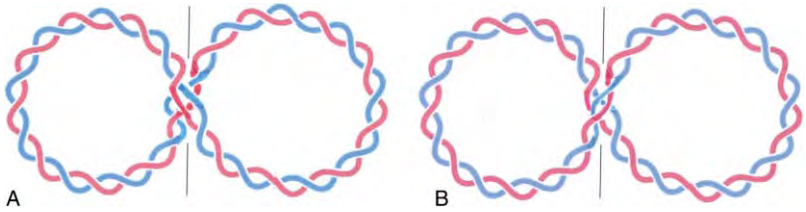

FIGURE 3 Diagram of a DNA with (A) a left-handed supercoil and (B) with a right-handed supercoil. Notice the two complementary strands (in red and blue) are wound in a right-handed helix. The axis for determining the handedness of the superhelical turn is shown as a vertical line going through the DNA crossover.

Because *Lk* is a topological invariant, it does not change for a given DNA in different environments. It is thus a more useful parameter for tracking the structure of DNA. ΔLk is thus frequently used to mark the superhelicity of DNA. If ΔLk is negative, DNA is underwound; the absolute value of ΔLk in this case gives a measure of negative supercoils or linking deficiency. If ΔLk is positive, then the DNA is overwound; its absolute value relates to the number of positive superhelical turns. DNA superhelicity can also be expressed as a fraction with respect to the linking number in a relaxed DNA. This is usually referred to as superhelical density, σ.

$$\sigma = \Delta Lk/Lk_0 = \Delta Lk/Tw_0$$

because $Lk_0 = Tw_0$, when $Wr_0 = 0$.

Most of the circular DNAs isolated from natural sources are negatively supercoiled. An interesting exception is the DNA in hyperthermic bacteria, which is positively supercoiled. For the numerous negatively supercoiled DNAs studied so far, the superhelicity mostly falls within a narrow range, with σ between -0.06 and -0.08.

Biological Effects of Supercoiling and Enzymes That Can Change DNA Supercoiling

To access the genetic information embedded within the double helix, most of the biological processes associated with critical functions of DNA involve unwinding or rewinding of the twin DNA strands. With a covalently closed circular DNA for which *Lk* stays constant, any change in *Tw* will be compensated by a change in *Wr* that is equal in magnitude but opposite in sign:

$$\Delta Tw = -\Delta Wr$$

This quantitative coupling between the DNA secondary structure and superhelical structure suggests that supercoiling can profoundly influence DNA structure and function. DNA with supercoils, either positive or negative, is thermodynamically less stable than its relaxed counterpart. For a negatively supercoiled DNA, any reactions associated with a reduction in the negative superhelical turns ($\Delta Wr > 0$) are energetically favored. These reactions will also be coupled with the unwinding of the DNA duplex because $\Delta Tw < 0$ if $\Delta Wr > 0$. Therefore negative DNA supercoiling facilitates the unwinding of DNA. In many instances, it has been demonstrated that replication, transcription, and recombination, all of which require the unwinding of DNA, are promoted by negative supercoiling. In an interesting corollary, DNA with positive supercoils will favor winding and disfavor unwinding of duplex structure (i.e., $\Delta Tw > 0$ if $\Delta Wr < 0$). It has been hypothesized that positive supercoiling found in some of the hyperthermophiles serves to stabilize the DNA double-helical structure in the extreme temperatures at which these organisms find home.

Nature has harnessed the use of DNA supercoiling for regulating the biological functions of DNA; it has also developed tools to modulate supercoiling. A ubiquitous class of enzymes, DNA topoisomerases, evolved to carry out the topological transformation in DNA. In order to break the hold of the topological constraint on closed circular DNA, these enzymes can make transient and reversible DNA breaks. There are two important features in these topoisomerase-mediated breaks in comparison with those made by nucleases. One is that a specific tyrosyl residue in the enzyme is joined covalently to the phosphate at the breakage site through a phosphodiester bond. Because this enzyme–DNA bridging bond is made at the expense of the neighboring DNA backbone bond, there is no significant energy change associated with the process of strand scission, thus assuring that the cleavage/religation is readily reversible. The enzyme-mediated DNA breakage is also accompanied by strand passage through the break or a rotation of the strand with the transient break around the intact strand. Both processes result in a change of DNA supercoiling or other topological transformation in DNA. Indeed, genetic experiments have demonstrated essential functions of these enzymes in the cell. These results also

underscore the importance of supercoiling in the biological functions of DNA.

He received a Ph.D. from the University of California at Berkeley and did his postdoctoral fellowship at the Stanford University Medical Center. His research has contributed to the discovery of new DNA topoisomerases and the unraveling of their biological functions.

DNA Topoisomerases: Type I

James J. Champoux
University of Washington, Seattle, Washington, USA

The large size of DNA molecules and the double-helical nature of DNA create unique topological problems during replication, transcription, recombination, and chromatin remodeling that are solved by a family of enzymes called DNA topoisomerases. Members of the type II subfamily of DNA topoisomerases alter the supercoiling of DNA and disentangle chromosomes by introducing temporary double-strand breaks into the DNA. Type I DNA topoisomerases, the subject of this review, manage DNA topology in the cell by transiently cleaving only one of the two DNA strands.

Reactions Catalyzed by Type I DNA Topoisomerases

To introduce a temporary single-strand break into duplex DNA, type I DNA topoisomerases must catalyze the cleavage and subsequent religation of a DNA strand. Since these two reactions occur without an external energy source such as ATP, cleavage cannot result from simple hydrolysis of a phosphodiester bond in the DNA. Instead, a covalent enzyme–DNA intermediate is generated that makes the religation step energetically feasible. The formation of the covalent intermediate involves nucleophilic attack by the O-4 atom of the active site tyrosine in the enzyme on a phosphodiester bond in the DNA to produce a phosphodiester bond between the tyrosine and the DNA and leave a free DNA hydroxyl end. DNA religation and release of the enzyme is the reverse reaction with the oxygen of the free DNA hydroxyl acting as the nucleophile. The type I enzymes display a loose preference for certain nucleotides in the vicinity of a cleavage site, and therefore a cleavage site typically occurs every 5–20 base pairs along the DNA.

Type I topoisomerases act on closed circular DNAs to change the number of times one strand winds around the other, a parameter referred to as the linking number of the DNA. Changes in the linking number are reflected in a reduction or an increase in the supercoiling of a plasmid DNA, a property that is most often measured by gel electrophoresis. In addition to altering the supercoiling of a plasmid DNA, many type I topoisomerases are capable of catalyzing a number of other transactions involving both single- and double-stranded DNAs. Most of these enzymes can catenate (interlock), decatenate, knot, and unknot single-stranded DNA circles. The same series of reactions can be carried out with duplex circular DNAs providing at least one of the circular molecules possesses a nick or gap. In some cases, the enzymes can facilitate the interwinding required for the renaturation of two complementary single-stranded circular DNAs, a reaction that could be important during homologous recombination. Interestingly, topoisomerase V, which has only been described in the hyperthermophilic archaeon *Methanopyrus kandleri*, possesses, in addition to the usual topoisomerase activity, an apurinic/apyrimidinic site-processing activity that would appear to implicate the enzyme in DNA repair. Finally, with certain unusual DNA substrates, a block to religation leads to permanent suicide cleavage and the enzyme remains covalently linked to the DNA.

Classification, Nomenclature and General Properties

Type I topoisomerases are classified into two structurally and mechanistically distinct subfamilies based on which DNA end becomes covalently attached to the enzyme during the cleavage reaction: type IA enzymes attach via a tyrosine phosphodiester linkage to the 5′ end of the DNA, whereas type IB enzymes attach to the 3′ end of the DNA. Table I lists the known type I DNA topoisomerases in the two subfamilies with their common names and origins. The common names have generally been assigned in the order of discovery using odd Roman numerals (even Roman numerals are similarly used for type II DNA topoisomerases). Type I enzymes with unusual properties or origins have been given unique names (reverse gyrase, poxviral topoisomerase, and mitochondrial topoisomerase). The recently described IB enzymes in some eubacteria are currently referred to as bacterial topoisomerases IB.

The three categories of type IA enzymes listed in Table I can be distinguished on the basis of the types of

TABLE I

Type I DNA Topoisomerases

Subfamily	Common name	Source	Structure
IA	Topoisomerase I	All eubacteria and some archaebacteria	Monomer
IA	Topoisomerase III	Some eubacteria and most eukaryotes	Monomer
IA	Reverse gyrase	All hyperthermophilic eubacteria and archaea	Monomer
IA	Reverse gyrase	Archaeon *Methanopyrus kandleri*	Heterodimer
IB	Topoisomerase I	Nucleus of all eukaryotes	Monomer
IB	Mitochondrial topoisomerase	Mitochondria of higher eukaryotes	Monomer
IB	Poxviral topoisomerase	All members of poxviridae family	Monomer
IB	Topoisomerase V	Archaeon *Methanopyrus kandleri*	Monomer
IB	Topoisomerase IB	Some eubacteria (see Table II)	Monomer
IB	Topoisomerase I	Trypanosomatids *Trypanosoma brucei* and *Leishmania donovani*	Heterodimer

reactions they catalyze. Topoisomerases I relax negative but not positive supercoils in plasmid DNAs; but since relaxation does not go to completion, some residual negative supercoils remain in the product. Topoisomerases III require hypernegatively supercoiled plasmid DNA as a substrate and again relaxation is incomplete. Interestingly, topoisomerases III are much more proficient than the topoisomerases I in DNA catenation and decatenation (see below). Reverse gyrases, which are only found in hyperthermophilic eubacteria and archaebacteria, introduce positive supercoils into plasmid DNAs at the expense of ATP hydrolysis. All of the type IA enzymes require Mg^{2+} and are monomeric with the exception of the reverse gyrase from the archaeon *Methanopyrus kandleri* which is a heterodimer.

The type IB DNA topoisomerases are capable of relaxing both positive and negative supercoils in a reaction that does not require ATP or divalent cations. The reactions go to completion to produce a completely relaxed set of plasmid DNA topoisomers. With the exception of the recently discovered heterodimeric topoisomerases I from trypanosomatids, all of the type IB enzymes are monomeric.

Type IA DNA Topoisomerases

Protein Domains

All type IA topoisomerases (Table I) share a highly conserved "cleavage/strand passage" domain that contains the active site tyrosine. This domain is also responsible for promoting the structural change in the DNA during the interval between the cleavage and religation reactions that results in a linking number change (see below) (Figure 1, red boxes). As indicated in Figure 1, all type IA enzymes contain a poorly conserved

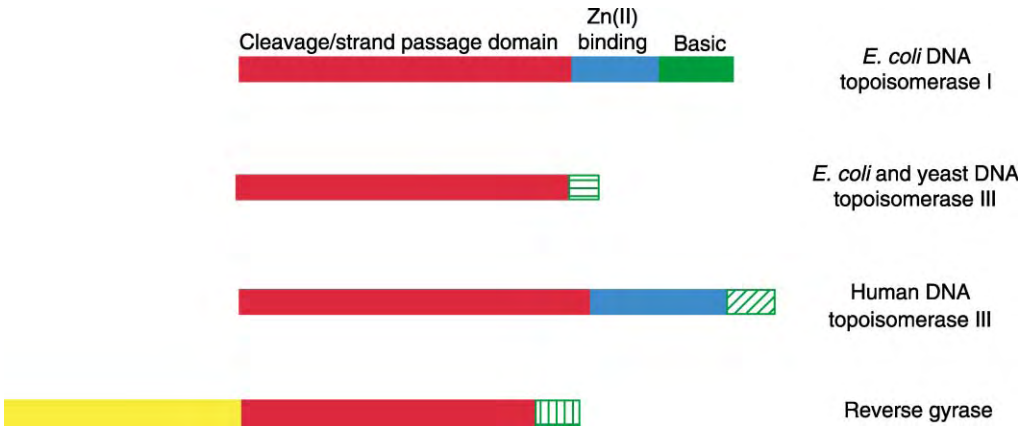

FIGURE 1 Domain structure and sequence relationships between type IA DNA topoisomerases. The domain structure of representative type IA topoisomerases is denoted by colored boxes. The names of the domains for the prototypic *E. coli* DNA topoisomerase I are given along the top. The cleavage/strand passage domains shared by all the IA enzymes are shown in red. Green is used to denote the basic C-terminal domains, but the different types of fill for these boxes indicate that these domains are poorly conserved. Some type IA enzymes contain a Zn(II) binding domain shown in blue. The helicase-like domain of reverse gyrase is shown in yellow.

basic C-terminal domain (solid or hatched green boxes) and some contain a Zn(II) binding domain as well (blue boxes). These latter two features appear to be important for the interaction of the enzyme with DNA. Finally, reverse gyrases contain an N-terminal domain, which resembles the ATPase domains of helicases (yellow box), and is connected to two domains that are structurally very similar to the cleavage/strand passage and basic domains of the typical type IA topoisomerases.

Crystal Structure of the Conserved Cleavage/Strand Passage Domain

The crystal structure of the cleavage/strand passage domain of *E. coli* DNA topoisomerase I shown in Figure 2 provides key insights concerning the substrate preference of the enzyme and the mechanism of DNA relaxation. Notably, the cleavage/strand passage domains of all type IA topoisomerases bear a strong resemblance to the *E. coli* structure. The hallmark of the crystal structure is a toroidal shape in which the diameter of the hole in the center of the torus is sufficient to accommodate either single- or double-stranded DNA.

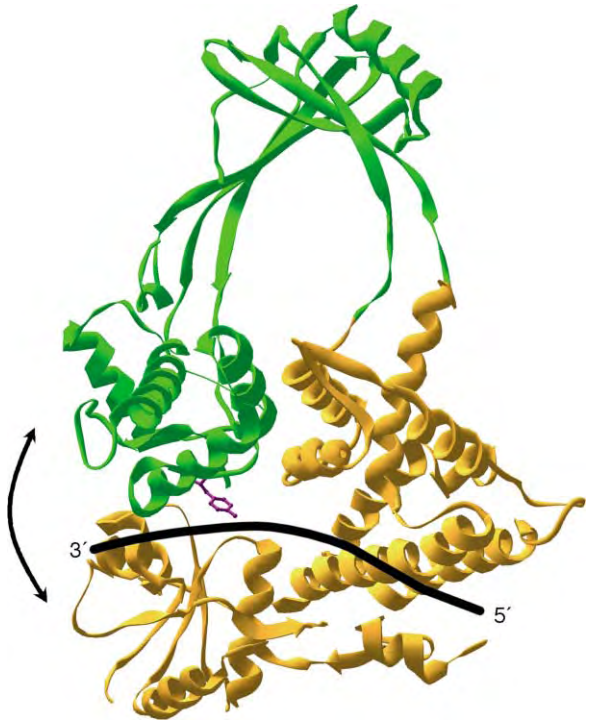

FIGURE 2 A ribbon diagram showing the crystal structure of the cleavage/strand passage domain of *E. coli* DNA topoisomerase I (pdb entry 1ecl) drawn with Swiss-Pdb Viewer software (Glaxo Wellcome Experimental Research). The approximate path of the bound single-stranded substrate DNA is indicated by the solid black line, and the active site tyrosine is shown in magenta. The two regions of the protein that move relative to each other (double-headed arrow) to open and close the torus during the strand passage reaction and to release the DNA are shown in green and orange.

The requirement for a negatively supercoiled substrate and the inability to completely relax negative supercoils is best explained by supposing that these enzymes will only bind an otherwise duplex DNA substrate if it contains a single-stranded region resulting from local unwinding of the helix. A plasmid DNA that is highly negatively supercoiled is energetically disposed toward helix unwinding, which explains why such a DNA is a good substrate for the enzyme. However, relaxation ceases when the negative supercoiling falls to a level below which there is insufficient energy to promote the required opening of the helix. As shown in Figure 2, a single strand of DNA (solid black line) binds to a narrow groove on the cleavage/strand passage domain of the enzyme in close proximity to the active site tyrosine (magenta).

Enzyme-Bridging Mechanism for Strand Passage

To change the linking number of a closed circular DNA during relaxation, one strand of DNA must pass through a break in the other strand. Knotting, catenation, and decatenation of either single or double-stranded DNAs similarly require such a strand passage event. The strand passage reaction for type IA topoisomerases occurs by what is referred to as an enzyme-bridging mechanism. Once the scissile DNA strand is cleaved, both DNA ends remain tightly associated with the enzyme; the 5′ end is bound covalently to the active site tyrosine and the 3′ end is bound noncovalently to the enzyme. To orchestrate strand passage, the enzyme undergoes a conformational change in which the top half of the protein containing the 5′ end of the cleaved strand (Figure 2, shown in green) lifts upward to generate a gate in the DNA through which another strand of DNA is passed. After strand passage, the broken strand is religated and the enzyme opens up a second time to release the strand that had been passed into the hole of the torus. A correlate of this model is that the linking number can only be changed in steps of one and this prediction has been verified biochemically.

This same scheme can explain how the enzyme can catenate or decatenate a DNA containing a nick or gap. However, it is unclear whether the DNA that passes through the temporary gate in the cleaved strand is captured in the hole of the torus before strand cleavage and is then passed out of the hole after cleavage or vice versa as described above.

Reverse Gyrase Mechanism

Despite the presence of a helicase-like ATPase domain in the N-terminal region of reverse gyrases, these enzymes

lack helicase activity when assayed under conditions that would require processive translocation along the DNA. Instead, the binding of the N-terminal domain to DNA is believed to simply unwind a region of the helix. Subsequently, in a reaction dependent on ATP, one of the two strands is cleaved and the other strand is passed through the resultant gate by the cleavage/strand passage domain present in the C-terminal half of the molecule. The key to positive supercoiling is that the strand passage event that occurs in the presence of ATP is directional such that the linking number of the DNA is increased and therefore the DNA ends up positively supercoiled. The structural basis for the unidirectional nature of the strand passage event remains unknown.

Type IB DNA Topoisomerases

Domain Structure and Sequence Conservation

Type IB DNA topoisomerases are present in the nucleus of all eukaryotic cells and the mitochondria of higher eukaryotes, as well as in at least one archaeon and some eubacteria (Table I). The typical eukaryotic type IB enzyme possesses the four domains shown in Figure 3. A highly charged and poorly conserved N-terminal domain (red box) is followed by the core domain (blue box), which binds DNA and contains most of the catalytic residues. The active site tyrosine is found in the C-terminal domain (yellow box) that is connected to the remainder of the protein by a poorly conserved linker region (orange box).

All of the other type IB enzymes share at least partial sequence and structural homology with the catalytically important core domain as can be seen from the color scheme in Figure 3 (blue boxes). Where present, the sequence of the mitochondrial enzyme is very similar to the nuclear enzyme with the exception of the N-terminal region (green box), which contains the organelle targeting signals. The eubacterial IB enzyme and the vaccinia topoisomerase are very similar to each other, but they lack most of the core domain as well as the conserved C-terminal domain that is characteristic of the other IB enzymes; instead, they share unique N-terminal and C-terminal regions (white and magenta boxes). The topoisomerase I found in the trypanosomatids is a heterodimer with one subunit containing the catalytic core (blue box) and the other subunit containing a region homologous to the C-terminal domain of the prototypic eukaryotic sequence (yellow box).

Crystal Structure of Human Topoisomerase I

Two views of the crystal structure of human topoisomerase I (missing the N-terminal domain) with a bound 22 base pair duplex oligonucleotide are shown in Figure 4. The protein is a bi-lobed structure that clamps completely around the DNA with the active site tyrosine (shown in black in Figure 4A) juxtaposed to the scissile phosphate. The linker region comprises the coiled-coil structure that protrudes conspicuously from the bottom portion of the enzyme and has an unknown function (Figure 4A). To release the DNA, the top half of the protein (shown in blue) must shift upward relative to the bottom half as indicated in Figure 4B by the double-headed arrow. Likewise, DNA binding requires that the protein clamp be in an open conformation. The region of

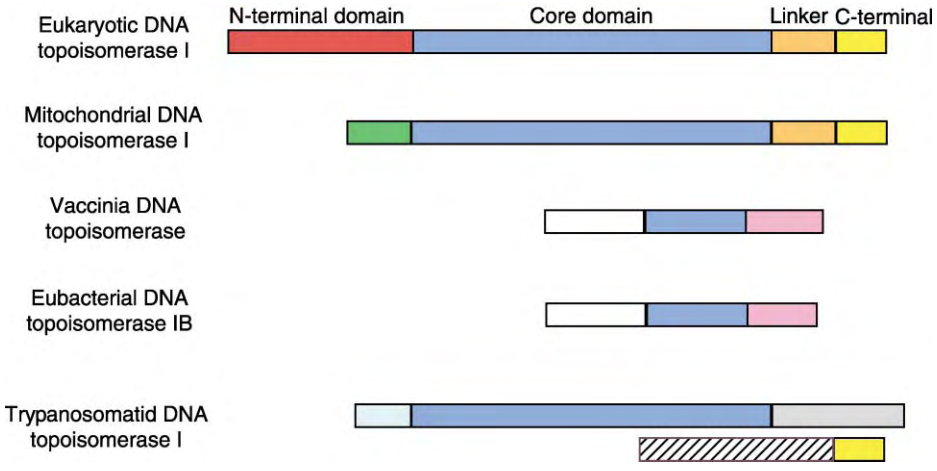

FIGURE 3 Domain structure and sequence relationships between type IB topoisomerases. The domain structure of the type IB topoisomerases from the indicated sources are denoted by colored boxes with similar domains aligned vertically. The names of the domains for the eukaryotic type IB topoisomerases are shown along the top. Regions that are similar in amino acid sequence share the same color; distinct sequences are assigned different colors. The two subunits of the heterodimeric topoisomerase I from trypanosomatids are shown with these same color conventions.

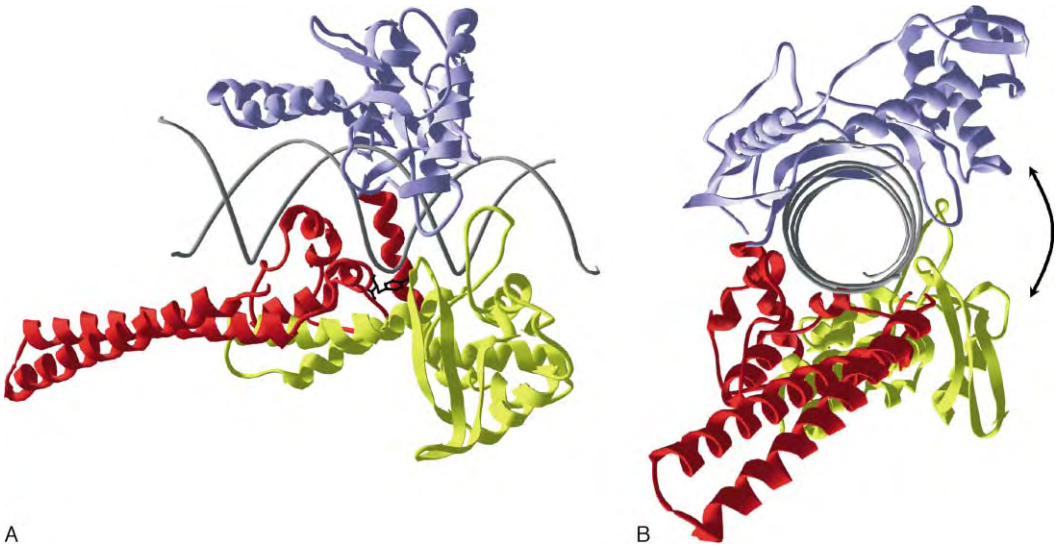

FIGURE 4 The ribbon diagrams show two views of the crystal structure of human topoisomerase I clamped around a 22 base pair duplex DNA, shown in gray (pdb entry 1a36). The top lobe of the enzyme is shown in blue and the bottom lobe is shown in red and yellow. The poxviral topoisomerase and the eubacterial topoisomerases IB are structurally very similar to the region of the bottom lobe, shown in yellow. The coiled-coil linker region in bottom lobe (in red) is most easily seen in the side view shown in (A). The active site tyrosine (in black) is shown in (A). Panel (B) shows a view of the structure looking down the axis of the DNA. The double-headed arrow in (B) indicates the nature of the conformational change that is required to open and close the clamp during binding and release of the DNA.

the human topoisomerase I structure shared by the poxviral and eubacterial IB enzymes corresponds to the portion of the core domain depicted in yellow in Figure 4. Tyrosine recombinases such as the bacteriophage λ and HP1 integrases, and cre recombinase are also structurally very similar to approximately this same region.

Catalysis

The co-crystal structure of human topoisomerase I with bound DNA reveals which amino acid residues in the protein are directly involved in catalysis. It is worth noting that the nucleophilic tyrosine O-4 does not appear to be activated for cleavage by general base catalysis, although a lysine residue acts as a general acid to protonate the leaving 5′ oxygen. The pentavalent transition state is stabilized by hydrogen-bonding interactions between three basic amino acid side chains and the scissile phosphate oxygens. An interaction between a lysine residue and the base of the nucleotide where cleavage occurs is also important for catalysis. Religation is likely to proceed by a pathway that is essentially the reverse of cleavage.

Rotational Mechanism for Strand Passage

Examination of the crystal structure of human topoisomerase I (Figure 4A) suggests that the strand passage reaction required to change the linking number of the DNA during DNA relaxation occurs by a rotational mechanism rather than by the enzyme-bridging mechanism described above for the type IA enzymes. However, there appears to be insufficient space within the confines of the enzyme to accommodate unrestricted rotation of the DNA. This feature of the structure suggests that the enzyme probably undergoes a conformational change after cleavage to open up the space downstream of the cleavage site to allow rotation. Unlike the enzyme-bridging model, a rotational mechanism places no *a priori* limit on the number of rotational events that can occur for each cycle of cleavage and religation. Indeed, in the case of vaccinia topoisomerase, five rotations of the DNA occur on the average between each cleavage and religation reaction.

Cellular Roles

Although much is yet to be learned about how the various topoisomerases collaborate to manage DNA topology in the cell, a partial picture has emerged based on work in bacteria and simple eukaryotes. Although the type II topoisomerases are not the subject of this review, the activities of these enzymes are briefly considered in the sections to follow for the sake of completeness. The type II enzymes are important for any cellular process that requires the passage of a region of duplex DNA through a double-strand break in the same or a different DNA molecule. The allocation of functions to

the known topoisomerases in setting the global levels of supercoiling, in transcription and in DNA replication, are discussed below.

Types of Supercoiling in Eukaryotic Versus Prokaryotic Cells

Two different situations lead to the supercoiling of DNA *in vivo*. First, DNA will assume a supercoiled configuration through an interaction with certain proteins or other cellular components. Alternatively, a closed domain of DNA (e.g., a closed circular DNA) will spontaneously supercoil if the linking number is not the same as the helical winding (referred to as twist) of the DNA helix. This latter type of supercoil is often referred to as torsionally strained supercoils. The chromosomal DNA of eukaryotes is wrapped into a protein-constrained solenoidal superhelix in nucleosomes and, except for the transient occurrence of torsionally strained supercoils associated with replication and transcription, is maintained in a relaxed state by DNA topoisomerases. However, in prokaryotes it appears that although some supercoils are constrained by virtue of an interaction with proteins as in eukaryotes, there exists, in addition, a fixed steady-state level of torsionally strained supercoiling generated by gyrases (see below).

Generation of Supercoiling Stress in Prokaryotes

Mesophilic Bacteria

The DNA in all mesophilic eubacteria and archaebacteria contains torsionally strained negative supercoils that are introduced by the type II enzyme called DNA gyrase. It appears that this steady-state level of negative superhelicity is required to facilitate helix opening during the initiation of DNA replication and transcription. To prevent the introduction of excess negative supercoils by the gyrase, these bacteria also contain one or two type IA DNA topoisomerases (topoisomerases I or III or both) to counteract the effects of DNA gyrase. The inability of the type IA enzymes to remove negative supercoils below a critical threshold level prevents these enzymes from negating the effects of DNA gyrase and is crucial for fine-tuning the negative supercoiling levels in these organisms. Some eubacteria also contain a type IB enzyme (Table II), which could also balance the effects of DNA gyrase; but the apparent ability of these enzymes to completely relax the DNA suggests that their activity would have to be regulated in some way. The exact role played by the bacterial topoisomerase IB and why this enzyme is only present in a subset of the mesophilic eubacteria remains unknown.

TABLE II

Occurrence of DNA Topoisomerase IB in Eubacteria

Known species possessing type IB topoisomerase	Examples of species lacking type IB topoisomerase
Mycobacterium avium	
Mycobacterium smegmatis	*Streptomyces coelicolor*
Cytophaga hutchinsonii	*Chlamydia trachomatis*
Agrobacterium tumefaciens	*Bacillus anthracis*
Bradyrhizobium japonicum	*Bacillus subtilis*
Mesorhizobium loti	*Clostridium tetani*
Sinorhizobium meliloti	*Mycoplasma pneumoniae*
Rhodobacter sphaeroides	*Listeria monocytogenes*
Novosphingobium aromaticivorans	*Staphylococcus aureus*
Bordetella parapertussis	*Streptococcus pneumoniae*
Burkholderia fungorum	*Streptococcus pyogenes*
Xanthomonas axonopodis	*Caulobacter crescentus*
Xanthomonas campestris	*Rickettsia conorii*
Pseudomonas aeruginosa	*Neisseria meningitidis*
Pseudomonas fluorescens	*Helicobacter pylori*
Pseudomonas putida	*Escherichia coli*
Pseudomonas syringae	*Yersinia pestis*
Deinococcus radiodurans	*Vibrio cholerae*
	Xylella fastidiosa
	Haemophilus influenzae
	Salmonella typhimurium
	Borrelia burgdorferi
	Treponema pallidum

Hyperthermophilic Bacteria

All hyperthermophilic eubacteria and archaebacteria possess a reverse gyrase that actively maintains positive supercoils in the chromosomal DNA. It appears this positive supercoiling is necessary to stabilize the DNA helix against denaturation at the high growth temperatures of these organisms. The mechanism for preventing excess positive supercoiling is not known, but it is likely that a type II enzyme that can relax positive supercoils (DNA gyrase or the archaeal topoisomerase VI) counteracts the effects of reverse gyrase to set the final steady-state level of positive supercoiling.

Transcription

During transcription, the movement of RNA polymerase along a DNA that is rotationally fixed transiently generates positive supercoils in front of the translocating polymerase and negative supercoils behind the polymerase (Figure 5A). The type IA enzymes present in all organisms relax the negative supercoils that accompany transcription, but the mechanism for the removal of the positive supercoils depends on the organism.

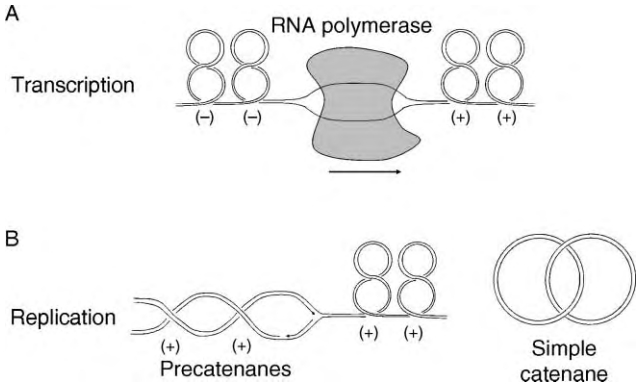

FIGURE 5 Topological transformations of DNA during transcription and replication. (A) The generation of positive supercoils (+) in front of and negative supercoils (−) behind a translocating RNA polymerase during transcription are depicted. (B) Replication fork movement in a closed domain results in an overwinding of the DNA ahead of the replication fork and the interwinding of the two daughter helices to form precatenanes behind the replication fork, as shown in (B). Any precatenanes remaining at the end of replication for a circular replicon will result in the catenation of the two daughter circular molecules. A simple catenane with a single interlink is also shown.

In prokaryotes, positive supercoils are relaxed by a type II enzyme such as DNA gyrase or in the archaea by topoisomerase VI, and in the case of select eubacteria (see Table II) probably by a combination of a type II enzyme and the type IB topoisomerase.

In eukaryotes, it is likely that the type IB DNA topoisomerase I relaxes the supercoils of both signs associated with transcription. Based on the known complete genome sequences, most eukaryotes, but not fungi or *Caenorhabditis elegans*, contain two distinct genes for type IB enzymes, one for the nuclear enzyme and a second for an enzyme that is imported into the mitochondrion to presumably function in transcription. In those eukaryotic organisms with only a single type IB enzyme, topoisomerase I likely plays a dual role, acting in both the nucleus and the mitochondrion.

DNA Replication

As the two DNA strands are separated during DNA replication, the DNA helix in front of the replication fork becomes at least transiently overwound or positively supercoiled (Figure 5B). This overwinding of the helix has been shown to be at least partially transmitted to the region behind the replication fork to cause an interwinding of the two daughter helices. These interwindings are referred to as precatenanes (Figure 5B), since in a circular replicon, if any remain at the end of replication, the two daughter circular molecules will be catenated. Resolution of the overwound structure of a replicating chromosome can be accomplished by relaxing positive supercoils in front of the fork, or by decatenating (or unlinking) the precatenanes behind the moving fork, or both.

As in transcription, positive supercoils can be removed in prokaryotes by a type II topoisomerase such as the DNA gyrase, the archaeal topoisomerase VI, or, for those eubacteria that have it, topoisomerase IB. Precatenanes can be resolved by a type II topoisomerase, most notably topoisomerase IV in eubacteria or topoisomerase VI in archaea. As long as gaps exist during discontinuous DNA synthesis, precatenanes can also be unlinked in some eubacteria either by topoisomerase IB (Table II) or by the potent type IA decatenating enzyme, topoisomerase III. Segregation of true catenanes lacking nicks or gaps in either of the two strands can only be accomplished by a type II enzyme.

In eukaryotes, the type IB topoisomerase relaxes the positive supercoils ahead of the replication fork and during synthesis can probably decatenate the precatenanes by acting at gaps in the DNA. However, most of the precatenanes and terminally interlinked or catenated structures are likely resolved by a type II topoisomerase. In mitochondria, replication-associated positive supercoils are relaxed by a type IB topoisomerase as described above for transcription. A mitochondrial type II topoisomerase and a type IA enzyme (topoisomerase III) are likely involved in unlinking precatenanes and catenated circular DNAs that occur during mitochondrial DNA replication.

Glossary

catenane Two interlocked circular DNA molecules in which the two duplexes are wound around each other one or more times.

catenate The process whereby two circular DNAs are interlocked to form a catenane. The unlocking of catenated DNAs is referred to as decatenation.

closed circular DNA Circular DNA in which both strands are intact.

DNA gyrase DNA topoisomerase that couples the hydrolysis of ATP to the introduction of negative supercoils into a closed circular DNA.

DNA supercoiling The coiling of the axis of a DNA molecule in three-dimensional space. Supercoiling may result from an interaction of the DNA with protein or from an inequality between the number of helical turns dictated by the structure of the DNA helix under a particular set of conditions (the twist of the DNA) and the linking number of the DNA.

linking number Topological property of a closed circular DNA that is a measure of the fixed interwinding of the two DNA strands.

precatenanes The interwinding of the two daughter duplexes behind a replication fork.

reverse gyrase DNA topoisomerase that couples the hydrolysis of ATP to the introduction of positive supercoils into a closed circular DNA.

scissile strand The strand of DNA that is cleaved by a type I topoisomerase.

topoisomerase Enzyme that changes the linking number of a closed circular DNA by temporarily breaking one (type I) or both (type II) of the strands of the DNA.

topoisomers Variants of a closed circular DNA that have different linking numbers.

torsionally strained supercoils Supercoils that result from an inequality between the number of helical turns dictated by the structure of the DNA helix under a particular set of conditions and the linking number of the DNA.

Biography

James J. Champoux is a Professor in the Department of Microbiology in the School of Medicine at the University of Washington. His research focuses on topoisomerases and reverse transcription. He holds a Ph.D. from Stanford University and carried out his postdoctoral work at the Salk Institute in San Diego, California. He discovered the eukaryotic type IB topoisomerase and was the first to show that the reaction proceeds through an enzyme–DNA covalent intermediate. He has been instrumental in elucidating the roles of the RNase H activity of reverse transcriptase in retroviral replication.

DNA Topoisomerases: Type II

Renier Vélez-Cruz and Neil Osheroff
Vanderbilt University School of Medicine, Nashville, Tennessee, USA

Although the genetic information of an organism is encoded by the linear array of DNA bases that make up its genome, the three-dimensional properties of the double helix dramatically affect how this information is expressed and passed from generation to generation. Some of the most important three-dimensional relationships in the genetic material are topological in nature, including DNA under- and overwinding, knotting, and tangling. The enzymes that modulate the topological properties of DNA are termed DNA topoisomerases. There are two classes of topoisomerases, type I and type II, which are defined by their reaction mechanisms. Type I topoisomerases alter DNA topology by creating a transient single-stranded break in the genetic material and facilitating controlled rotation of the double helix about (or strand passage through) the nick. Type II topoisomerases act by passing an intact double helix through a transient double-stranded break that they generate in a separate DNA segment. As a consequence of their reaction mechanisms, both classes of enzymes can regulate DNA under- and overwinding. However, because type II topoisomerases cut both strands of the double helix, they also are able to resolve knots and tangles in the genetic material. Type II topoisomerases are essential to all species. Beyond their critical physiological functions, these enzymes are the targets for some of the most important anticancer and antibacterial drugs in clinical use.

DNA Topology

The topological properties of DNA are defined as those that cannot be altered without breaking one or both strands of the double helix. Because DNA comprises two interwound nucleic acid strands and the genomes of all known organisms are very long or circular (or both), two distinct topological issues arise as a result of the genetic material. Proliferating cells must be able to cope with both of these in order to survive.

The first issue is related to the torsional stress on the double helix. The DNA from all species of eukaryotes and eubacteria is globally underwound ~5–10%. DNA under torsional stress is termed supercoiled (underwound molecules are negatively supercoiled and overwound molecules are positively supercoiled) because underwound or overwound DNA writhes about itself to form superhelical twists. Negative supercoiling puts energy into the genetic material and makes it easier to separate the two strands of the double helix for replication and transcription. Thus, DNA underwinding dramatically increases the rates of these two fundamental processes. In contrast, the movement of DNA tracking systems (such as replication forks and transcription complexes) through the double helix locally overwinds the DNA ahead of their actions. Because overwinding makes it much harder to pull apart the double helix, it blocks many essential cellular processes.

The second issue is related to the extreme length of genomic DNA. Nucleic acid knots (intramolecular) and tangles (intermolecular) are formed routinely during a variety of ongoing cellular processes including DNA recombination and replication. Both knots and tangles must be resolved in order for daughter chromosomes to segregate properly during meiosis and mitosis.

DNA Topoisomerases

Cells contain ubiquitous enzymes known as DNA topoisomerases that maintain the appropriate level of DNA supercoiling and remove knots and tangles from the genetic material. These enzymes modulate the topological structure of the genetic material by creating transient breaks in the backbone of DNA. There are two classes of topoisomerases that can be distinguished by the number of DNA strands that they cleave during their catalytic cycles. Type I enzymes create transient single-stranded DNA breaks, whereas type II enzymes create transient double-stranded breaks. To maintain genomic integrity during their DNA cleavage events, topoisomerases form covalent linkages between active-site tyrosyl residues and the newly generated DNA termini. These covalent protein-cleaved DNA complexes, known as cleavage complexes, are the hallmarks of all topoisomerases irrespective of enzyme classification. Because type I topoisomerases create single-stranded breaks in the genetic material, they can regulate DNA supercoiling. However, because type II topoisomerases generate double-stranded breaks in the DNA backbone, they can

resolve knots and tangles in addition to removing torsional stress from the genetic material.

Type II topoisomerases are essential to all eukaryotic and prokaryotic organisms. They are highly conserved among species, and the eukaryotic enzymes appear to be direct descendents of ancestral bacterial proteins.

Eukaryotic Type II Topoisomerases

The eukaryotic type II enzyme is called topoisomerase II. It was discovered in 1980 and is a member of the type IIA homology subfamily. Topoisomerase II can remove positive and negative superhelical twists from the double helix and can resolve DNA knots and tangles.

Enzyme Mechanism

Topoisomerase II interconverts different topological forms of DNA by the double-stranded DNA passage reaction depicted in Figure 1, which shows the products of each individual step. Briefly, it is proposed that topoisomerase II (1) binds two DNA segments, (2) creates a double-stranded break in one of the segments, (3) translocates the other DNA segment through the cleaved double helix, (4) rejoins (i.e., ligates) the cleaved DNA, (5) releases the translocated segment through a gate in the protein, and (6) closes the protein gate and regains the ability to start a new round of catalysis. The scissile bonds on the two strands of the double helix that are cut by topoisomerase II are staggered. Thus, the enzyme generates cleaved DNA molecules that contain four-base single-stranded ends at their 5′-termini. During its cleavage event, topoisomerase II covalently attaches to these newly generated 5′-termini.

Topoisomerase II requires two cofactors in order to carry out its catalytic double-stranded DNA passage reaction. First, it needs a divalent cation for all steps beyond enzyme-DNA binding (Figure 1, complex 1). Magnesium(II) appears to be the divalent cation that the enzyme uses *in vivo*. Second, topoisomerase II uses the energy of adenosine triphosphate (ATP) to drive the overall DNA strand passage reaction. Although ATP is not required for either DNA cleavage or ligation, the binding of this nucleoside triphosphate triggers DNA translocation (which converts complex 2 to complex 3)

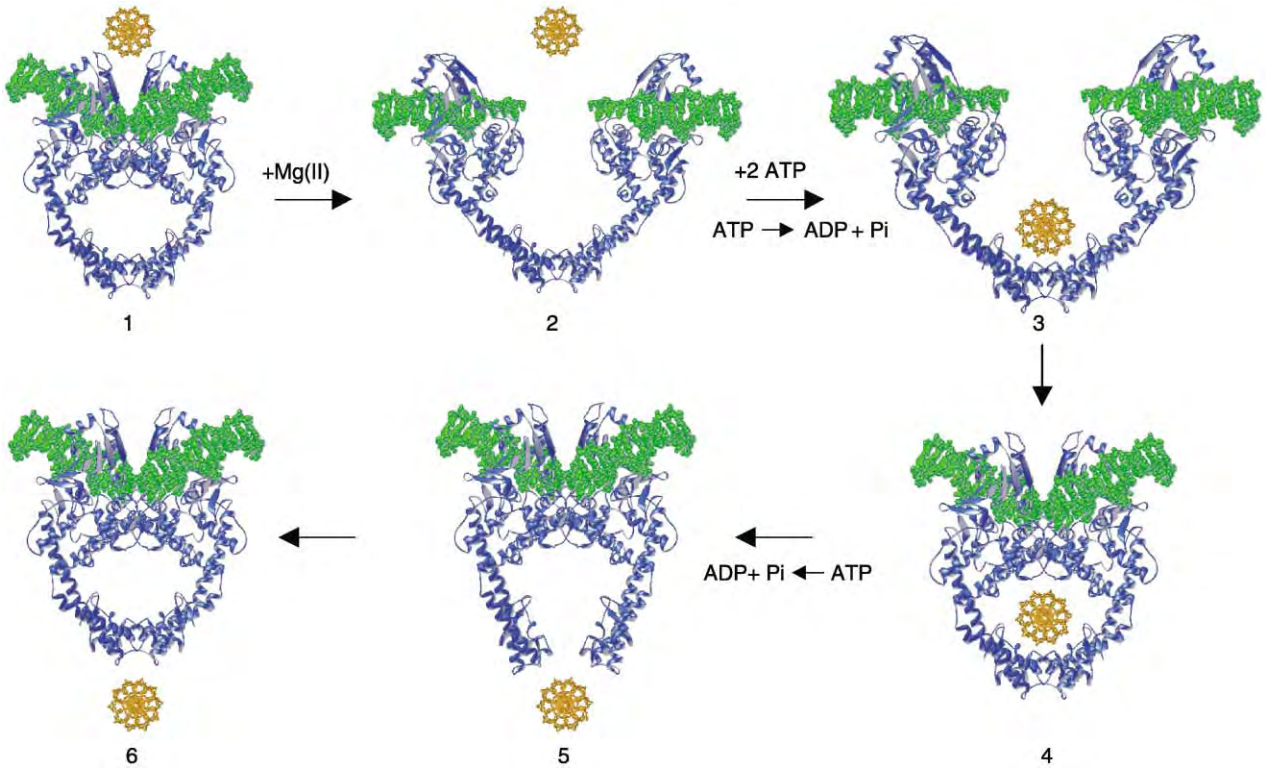

FIGURE 1 Catalytic cycle of type IIA topoisomerases. The complete double-stranded DNA passage reaction is shown as a series of discrete steps (the products of each step are shown). (1) Enzyme–DNA binding, (2) DNA cleavage (formation of cleavage complex), (3) double-stranded DNA passage, (4) DNA ligation, (5) gate opening and release of the translocated DNA helix, and (6) enzyme recycling. The protein (shown in blue) is based on the crystallographic structure of the catalytic core of yeast topoisomerase II. Modeled DNA helices are shown in green (horizontal) and orange (coming out of the plane of the paper). Structures are courtesy of Dr. James M. Berger, University of California, Berkeley.

and its hydrolysis to adenosine diphosphate (ADP) and inorganic phosphate (Pi) is necessary for enzyme recycling (which converts complex 5 to complex 6). Normally, topoisomerase II binds two molecules of ATP. Although hydrolysis of the cofactor is not a prerequisite for the strand passage event, it appears that this step proceeds more rapidly if it is preceded by hydrolysis of one of the bound ATP molecules.

Enzyme Domain Structures and Isoforms

Eukaryotic type II topoisomerases are homodimeric enzymes with protomer molecular masses ranging from ~160 to 180 kDa (depending on the species). On the basis of amino-acid-sequence comparisons with the bacterial type II enzyme, DNA gyrase, each enzyme monomer can be divided into three distinct domains (Figure 2). The N-terminal domain of the enzyme is homologous to the B-subunit of DNA gyrase (GyrB) and contains consensus sequences for ATP binding. The central domain is homologous to the A-subunit of DNA gyrase (GyrA) and contains the active-site tyrosyl residue that forms the covalent bond with DNA during scission. The C-terminal domain is not highly conserved and appears to have no corresponding region of homology with DNA gyrase. This variable region of the eukaryotic enzyme contains nuclear localization sequences as well as amino acid residues that are phosphorylated *in vivo*.

Although some eukaryotic species such as yeast and *Drosophila* appear to have only a single type II topoisomerase (i.e., topoisomerase II), vertebrates contain two closely related isoforms, topoisomerase IIα and β. These two isoforms share extensive amino acid sequence identity (~70%), but are encoded by separate genes (located at chromosomal bands 17q21–22 and 3p24 in humans, respectively) and can be distinguished by their protomer molecular masses (~170 and ~180 kDa, respectively).

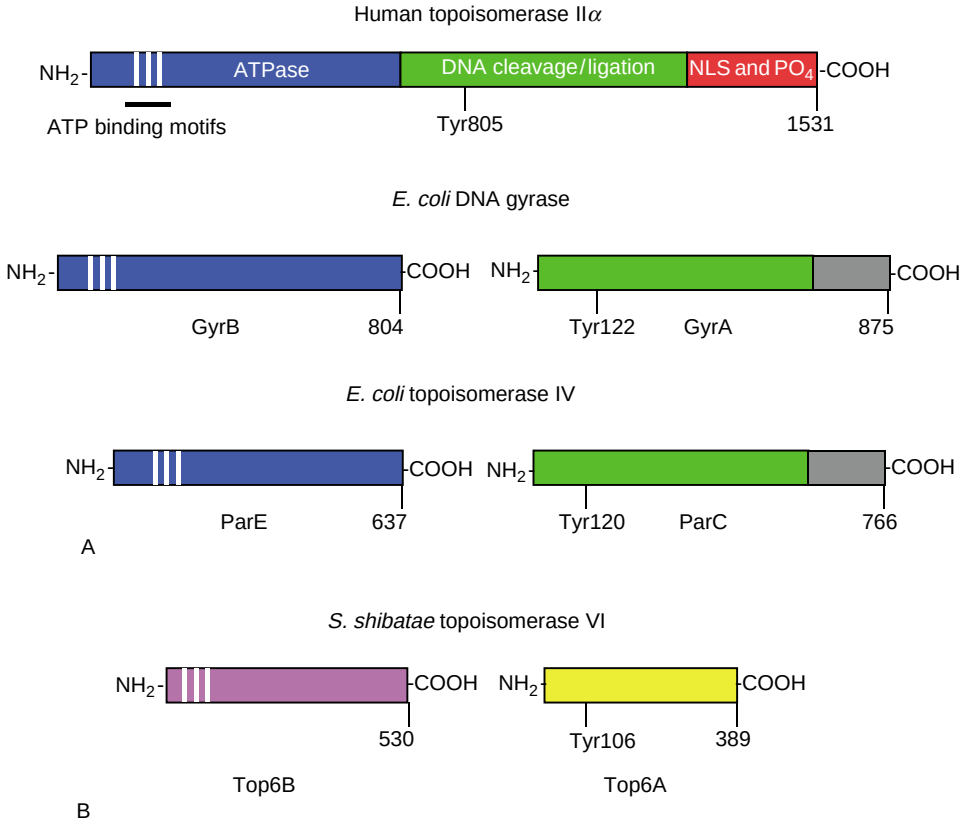

FIGURE 2 Domain structures of type II topoisomerases. (A) The domain structures of three type IIA topoisomerases: human topoisomerase IIα and bacterial (*Escherichia coli*) DNA gyrase and topoisomerase IV. Regions of homology among the enzymes are indicated by colors. The N-terminal (i.e., GyrB) homology domains contain the regions responsible for ATP binding and hydrolysis. The vertical white stripes represent the three conserved motifs of the Bergerat fold that define the ATP-binding domain. The central (i.e., GyrA) homology domains contain the active site tyrosyl residue (Tyr805 in human topoisomerase IIα) that forms the covalent bond with DNA during scission. For human topoisomerase IIα, the variable C-terminal domain contains nuclear localization sequences (NLS) and phosphorylation sites (PO_4). (B) The Top6A and Top6B subunits of the archaeal type IIB topoisomerase, *Sulfolobus shibatae* topoisomerase VI, shown for comparison.

Physiological Functions

Topoisomerase II plays a number of essential roles in eukaryotic cells and participates in virtually every major process that involves the genetic material. It unlinks daughter chromosomes that are tangled following replication and resolves DNA knots that are formed during recombination. It also helps to remove the positive DNA supercoils that are generated ahead of replication forks and transcription complexes. Topoisomerase II is required for proper chromosome condensation, cohesion, and segregation and appears to play roles in centromere function and chromatin remodeling. Finally, the type II enzyme is important for the maintenance of proper chromosome organization and structure, and it is the major nonhistone protein of the mitotic chromosome scaffold and the interphase nuclear matrix.

It is not obvious why vertebrate species possess two distinct topoisomerase II isoforms. Enzymological differences between topoisomerase IIα and β are subtle and the relationships between these isoforms are not well defined. Although either enzyme can complement yeast strains lacking topoisomerase II activity, topoisomerase IIα is essential for proliferating mammalian cells and its loss cannot be compensated by the β isoform. Topoisomerase IIβ appears to be dispensable at the cellular level, but is required for proper neural development in mice.

The specific cellular functions of topoisomerase IIα and β probably reflect their physiological regulation more than their enzymological characteristics. Topoisomerase IIα is regulated over both cell and growth cycles. Enzyme levels increase throughout the S-phase of the cell cycle and peak at the G_2-M boundary. Furthermore, this isoform is found almost exclusively in rapidly proliferating tissues. In contrast, the concentration of topoisomerase IIβ is independent of the cell cycle and this isoform is found in most cell types regardless of proliferation status. Taken together, these characteristics suggest that topoisomerase IIα is the isoform responsible for events associated with DNA replication and chromosome segregation, whereas topoisomerase IIβ is the isoform that probably functions in ongoing nuclear processes.

Prokaryotic Type II Topoisomerases

Eubacteria contain two distinct type II topoisomerases, DNA gyrase and topoisomerase IV. Both are members of the type IIA subfamily. In addition to these two enzymes, many archaeal species contain a third type II enzyme, topoisomerase VI. This last enzyme is a member of the type IIB subfamily.

DNA Gyrase

DNA gyrase was discovered in 1976. It was the first type II topoisomerase to be described and is the only one to retain its historical name (in the modern nomenclature, type II topoisomerases are denoted by even numbers). In contrast to the eukaryotic type II enzymes, DNA gyrase is comprised of two distinct subunits, GyrA and GyrB (molecular mass $\approx$96 kDa and 88 kDa, respectively) and is arranged as an A_2B_2 tetramer. GyrA contains the active site tyrosine used in DNA cleavage and ligation, and GyrB contains the binding site for ATP (Figure 2A).

In contrast to all other type II topoisomerases, DNA gyrase is the only enzyme that is capable of actively underwinding (i.e., negatively supercoiling) the double helix. It accomplishes this feat by wrapping DNA around itself in a right-handed fashion and carrying out its strand-passage reaction in a unidirectional manner.

The negative supercoiling activity of DNA gyrase far exceeds the ability of the enzyme to remove either knots or tangles from the genetic material. Consequently, the major physiological roles of DNA gyrase stem directly from its ability to underwind the double helix. DNA gyrase plays a critical role in opening DNA replication origins and removing positive supercoils that accumulate in front of replication forks and transcription complexes. In addition, this enzyme works in conjunction with the ω protein (a type I topoisomerase that removes negative supercoils from the double helix) to maintain the global balance of DNA supercoiling in bacterial cells.

Topoisomerase IV

Topoisomerase IV is an A_2B_2 tetramer that is comprised of two distinct subunits, ParC (molecular mass $\approx$88 kDa), and ParE (molecular mass $\approx$70 kDa), which are homologous to the A- and B-subunits of DNA gyrase (Figure 2B). (In gram-positive bacterial species, the subunits of topoisomerase IV are designated GrlA and GrlB, respectively.) It was known for several years that the ParC and ParE proteins were necessary for proper chromosome segregation in bacteria. However, it was not discovered until 1990 that these two subunits together constituted a type II topoisomerase.

The catalytic properties of topoisomerase IV can be distinguished from those of DNA gyrase in two important ways. First, although topoisomerase IV can remove positive and negative superhelical twists from DNA, it cannot actively underwind the double helix. Second, the ability of topoisomerase IV to resolve DNA knots and tangles is dramatically better than that of DNA gyrase. Because of these differences, the physiological roles of topoisomerase IV are distinct from those of DNA gyrase. The primary cellular functions of topoisomerase IV are to unlink daughter chromosomes following DNA replication and to resolve DNA knots

that are formed during recombination. Recently, it was found that topoisomerase IV removes positive supercoils from DNA more efficiently than it removes negative supercoils. This has led to speculation that the enzyme also may act ahead of DNA tracking systems to alleviate overwinding of the double helix. However, the precise role of topoisomerase IV in this process has yet to be defined.

Archaeal Topoisomerase VI

In 1997, a novel type II topoisomerase, topoisomerase VI, was discovered in hyperthermophilic archaeal species. This enzyme was designated as the first member of the topoisomerase IIB subfamily due to its lack of homology to previously identified type II enzymes.

Topoisomerase VI has two subunits, Top6A and Top6B (molecular masses ≈47 and 60 kDa, respectively), and is arranged as an A_2B_2 tetramer. Both subunits are considerably smaller than those of bacterial DNA gyrase or topoisomerase IV (Figure 2B). Although short regions of Top6B surrounding the ATP-binding domain are homologous to portions of GyrB, and Top6A contains an active-site tyrosine that is required for DNA cleavage, the primary structure of topoisomerase VI displays little similarity to the type IIA enzymes.

Archaeal topoisomerase VI appears to alter DNA topology by using a double-stranded DNA passage reaction like that described for other type II topoisomerases. During this reaction, it generates DNA breaks with 5′ overhangs that are covalently attached to its active-site tyrosyl residues. Topoisomerase VI relaxes positively and negatively supercoiled DNA, but cannot actively underwind the double helix. In addition, it can unlink (i.e., untangle) interwound double-stranded DNA circles.

The catalytic properties of topoisomerase VI differ from those of the type IIA enzymes in two significant aspects. First, topoisomerase VI requires ATP binding in order to cleave its DNA substrate. Second, in marked contrast to the type IIA enzymes (which produce four-base staggered ends during scission), topoisomerase VI-mediated DNA cleavage generates DNA termini that contain only two-base overhangs. Although the physiological functions of topoisomerase VI have yet to be determined, the enzyme is believed to play a role in unlinking daughter chromosomes following replication in archaeal cells.

With the exception of plants, no Top6B homologue has been identified in eukaryotic species. However, a Top6A homologue, Spo11, has been found in eukaryotes ranging from yeast to humans. Spo11 generates the double-stranded DNA breaks that initiate meiotic recombination. Like its topoisomerase relatives, Spo11 forms a covalent bond between an active-site tyrosyl residue and the 5′-DNA termini generated by its scission reaction. At the present time there is no evidence that Spo11 has topoisomerase (i.e., DNA strand passage) activity.

Type II Topoisomerases as Therapeutic Targets

In addition to their varied and critical physiological functions, the type IIA topoisomerases are targets for some of the most active anticancer and antibacterial drugs in clinical use. In contrast to most enzyme-targeted drugs, these agents do not act by robbing cells of an essential enzyme activity. Rather, drugs that target type II topoisomerases kill cells by dramatically increasing the concentration of covalent enzyme-cleaved DNA complexes (i.e., cleavage complexes) that are requisite intermediates formed during the double-stranded DNA passage reaction. Normally, cleavage complexes are present at low steady-state levels and are tolerated by cells. However, conditions that significantly increase either their concentration or lifetime trigger numerous mutagenic events.

The potential lethality of cleavage complexes rises dramatically when DNA tracking enzymes such as polymerases or helicases attempt to traverse the covalently bound topoisomerase roadblock in the genetic material. Such an action disrupts cleavage complexes and converts transient enzyme-mediated DNA breaks to permanent DNA breaks. These permanent breaks in the genome trigger the generation of chromosomal insertions, deletions, translocations, and other aberrations, and, when present in sufficient numbers, they initiate a series of events that culminates in cell death. Because the drugs that target type II topoisomerases convert these essential enzymes to potent cellular toxins that fragment the genome, they are referred to as topoisomerase poisons to distinguish them from drugs that act as catalytic inhibitors.

Anticancer Drugs

At the present time, six topoisomerase II-targeted anticancer agents (Figure 3A) are approved for use in the United States. Drugs such as etoposide and doxorubicin are front-line therapy for breast and lung cancers, as well as for a variety of leukemias, lymphomas, and germ-line malignancies. Approximately one-half of all cancer chemotherapy regimens contain drugs targeted to topoisomerase II. Moreover, every form of cancer that can be cured by systemic chemotherapy is treated with these agents.

Due to the high concentration of topoisomerase IIα in rapidly proliferating cells, this isoform probably is the major important target of anticancer therapy. However, circumstantial evidence suggests that the β-isoform also contributes to drug efficacy.

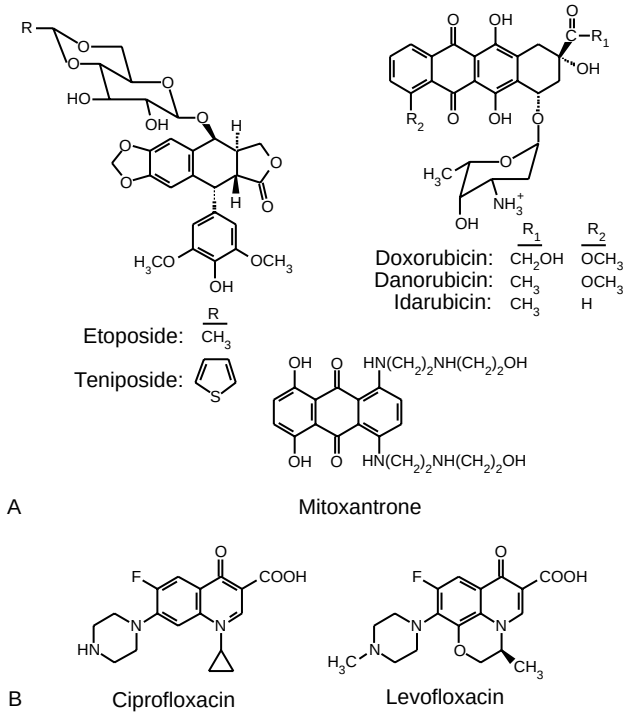

FIGURE 3 Structures of selected (A) anticancer drugs targeted to topoisomerase II and (B) antibacterial drugs targeted to DNA gyrase and topoisomerase IV.

Antibacterial Drugs

DNA gyrase and topoisomerase IV are the targets for quinolone-based antibacterial agents (Figure 3B). Quinolones are the most active and broad-spectrum antibacterial drugs currently available. Drugs such as ciprofloxacin are prescribed routinely for a wide variety of gram-negative bacterial infections, including gastrointestinal tract, respiratory tract, and bone and joint infections. Ciprofloxacin also is used to treat a number of sexually transmitted diseases as well as infection with anthrax. Newly developed quinolones, such as levofloxacin, display significant efficacy against gram-positive bacterial infections.

DNA gyrase is the primary cytotoxic target of quinolones in gram-negative bacteria. However, topoisomerase IV appears to be the more important target for many of these drugs in gram-positive species.

Glossary

adenosine triphosphate (ATP) A cofactor that supplies energy for many enzymatic processes.

cell cycle The process by which a cell grows, replicates its genome, and divides. The cell cycle is divided in four distinct phases: G_1, a growth phase; S, the phase in which the cell duplicates (i.e., synthesizes) its genetic material; G_2, a second growth phase in which the cell prepares to divide; and M, the phase in which the cell divides (i.e., mitosis).

DNA recombination The process by which the cell reorganizes its genetic material in order to repair certain forms of DNA damage (including double-stranded DNA breaks) or promote genetic diversity.

DNA replication The process by which the cell duplicates (i.e., synthesizes) its genetic material.

DNA supercoiling The underwinding (i.e., negative supercoiling) or overwinding (i.e., positive supercoiling) of the genetic material.

topoisomerase poison A drug that increases levels of topoisomerase-cleaved DNA complexes.

topology A field of mathematics that deals with relationships that are not altered by elastic deformation.

transcription The process by which the cell expresses its genetic material; the generation of messenger RNAs from a DNA template.

Neil Osheroff is a Professor in the Departments of Biochemistry and Medicine at the Vanderbilt University School of Medicine and holds the John G. Coniglio Chair in Biochemistry. His principal research interests are the fields of DNA topoisomerases, topoisomerase-targeted drugs, and DNA repair. He holds a Ph.D. in Biochemistry and Molecular Biology from Northwestern University and received his postdoctoral training in the Department of Biochemistry at the Stanford University School of Medicine. He has authored more than 170 articles and has contributed significantly to our understanding of the mechanism of action of type II topoisomerases and topoisomerase II poisons.

DNA Topoisomerases: Type III–RecQ Helicase Systems

Rodney Rothstein and Erika Shor
Columbia University College of Physicians and Surgeons, New York, USA

DNA helicases and topoisomerases belong to the category of proteins that physically manipulate and alter the structure of DNA molecules. DNA helicases are enzymes that separate the strands of double-stranded (ds) DNA molecules, thus catalyzing DNA unwinding. Topoisomerases transiently create breaks in a DNA strand(s), pass other strands through the broken strand(s), and reseal the breaks. Topoisomerase activity can change levels of DNA supercoiling or result in catenation (interlinking) or decatenation (unlinking) of two DNA molecules. Both DNA helicases and topoisomerases are key players in various DNA transactions, such as replication, transcription, and recombination. Different classes and families of helicases and topoisomerases have been identified based on their protein sequence conservation, substrate preference, directionality on DNA, and other properties. DNA helicases of the RecQ family have garnered much interest lately because of the involvement of three human RecQ helicase family members in genetic disorders characterized by genomic instability and cancer predisposition. RecQ helicases are evolutionarily conserved proteins found in organisms ranging from bacteria to humans. Interestingly, an association between RecQ-type helicases and type III topoisomerases has been observed throughout the evolutionary tree, suggesting that these two proteins act in concert to promote genomic stability.

Structure and Molecular Mechanisms

Topoisomerase III

Topoisomerase III belongs to the type IA topoisomerases (also known as type I-5′). This subfamily of topoisomerases acts on DNA that is negatively supercoiled (underwound) and/or contains single-stranded (ss) regions. The topoisomerase, which functions as a monomer, makes a break in a ssDNA region via a transesterification reaction between an active site tyrosine of the enzyme and a DNA phosphate group (Figure 1). A transient covalent linkage between the tyrosine and the 5′-phosphoryl group of the DNA is thus formed. After passage of other DNA strand(s) through the break, the reverse transesterification reaction leads to the rejoining of the DNA backbone. Topoisomerase III activity can result in relaxation/removal of negative supercoiling from DNA, (de)catenation and knotting of ss circular DNA molecules, and (de)catenation of ds DNA molecules that contain ss regions. Topoisomerase III does not require energy in the form of nucleoside triphosphates, such as ATP. Hence, the directionality of the topoisomerase III-driven reactions is toward the DNA conformation with the lowest free energy.

RecQ Helicases

The RecQ family of DNA helicases is defined by homology to the bacterial RecQ protein. Like other helicases, these proteins contain seven signature helicase motifs, including sequences that contain Walker A (required for ATP binding and hydrolysis) and B boxes. In addition to the core helicase motifs, all RecQ helicases share additional regions of homology not shared by other families of helicases.

The functional unit of a helicase is generally composed of a dimer or a hexamer that forms a ring around its substrate DNA. However, examples of monomeric helicases are also known. Whereas several early studies have indicated that RecQ-like helicases form hexamers, two recent studies suggest that DNA helicase activities *in vitro* of both *E. coli* RecQ and human BLM proteins are associated with a monomeric form of the protein. Thus, the composition of a functional unit of RecQ-like helicases is still being explored.

All RecQ-type helicases examined to date display $3' \rightarrow 5'$ directionality on DNA with respect to the strand to which the protein is bound (Figure 2A). *In vitro* substrate preference studies have indicated that these helicases can act on a variety of DNA structures, possibly reflecting the diversity of their *in vivo* activities. Among the structures that RecQ helicases can unwind are branched molecules, four-way dsDNA junctions, G-quartets, and D-loops (Figure 2B). ATP and Mg^{2++} are necessary cofactors for RecQ-driven reactions.

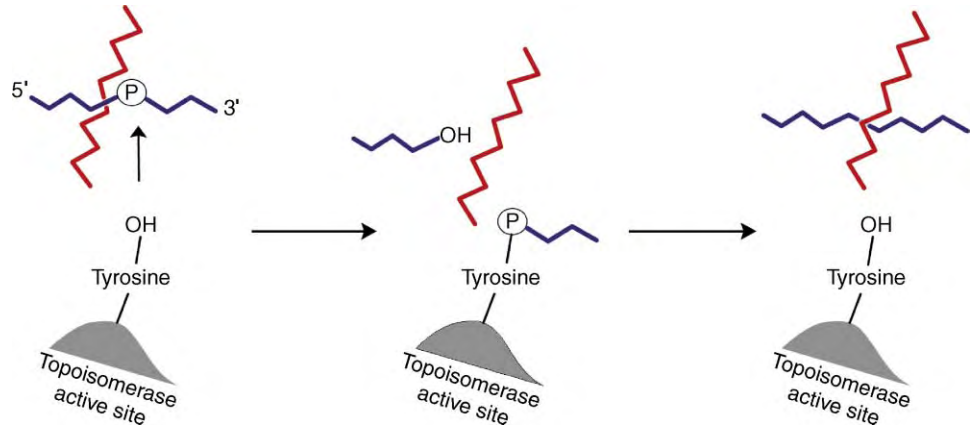

FIGURE 1 The mechanism of strand passage by a type IA topoisomerase. The topoisomerase makes a break in the blue strand by catalyzing a trans-esterification reaction between the tyrosine at the topoisomerase active site and a 5′ phosphate group of the DNA. Only the reacting phosphate is depicted as a P for clarity. The intact red strand is passed through the break, and a reverse trans-esterification reaction reseals the blue strand.

The RecQ Helicase–Topoisomerase III Connection

Physical Association

Two widely used model organisms, budding and fission yeast, each has one RecQ-like helicase and one topo III. In both organisms, the two proteins have been shown to physically interact with each other and/or to associate in cellular extracts. In human cells, the RecQ homolog BLM physically interacts with an isoform of topoisomerase III, Top3α, via the N-terminus of BLM. Mutation or deletion of BLM in human cells has several detrimental consequences on genome stability, including a marked increase in recombination between sister chromatids. Interestingly, cells expressing BLM protein that lacks its N-terminus and fails to interact with Top3α (but retains DNA unwinding activity) show increased levels of sister chromatid exchange, similar to cells that lack the entire BLM protein. This demonstrates that, in order to perform its role in suppressing recombination between sister chromatids, BLM needs to interact with Top3α *in vivo*, which supports other evidence that the two act as a complex with key roles in maintenance of genome stability.

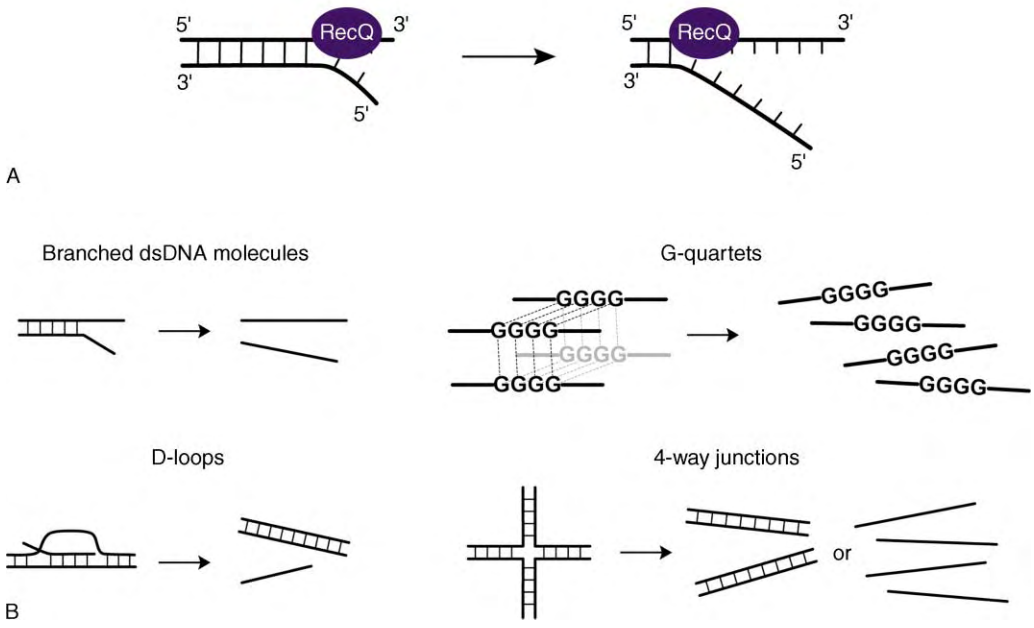

FIGURE 2 (A) RecQ helicases unwind DNA in the 3′ to 5′ direction with respect to the strand to which the helicase is bound. (B) Several of the known *in vitro* substrates of RecQ helicases before and after incubation with the protein.

Genetic Interactions in Yeast

As mentioned above, the genomes of both budding and fission yeast encode a single topoisomerase III gene. In both organisms, loss or mutation of the topo III protein is detrimental, resulting in slow growth or lethality. Concomitant loss of RecQ helicase function in mutants lacking topo III largely restores normal growth and viability. These genetic observations have led to the following model of RecQ–Topoisomerase III interaction *in vivo*. It is proposed that in wild-type cells, the activity of the RecQ helicase creates a DNA structure that is normally acted on and resolved by topo III. When topo III is inactivated, this structure is not processed properly and causes slow growth or lethality. In mutants lacking the RecQ helicase, this structure is not created, eliminating the need for a functional topo III. While this model is supported by genetic evidence, experimental data confirming the existence of such a DNA structure are lacking to date.

Combined Mode of Action

The genetic and physical interactions between RecQ-like helicases and type III topoisomerases in several organisms have prompted investigation and speculation regarding their combined mode of action. One possibility first put forth upon the discovery of the budding yeast RecQ homolog Sgs1 and its genetic and physical association with the budding yeast topo III was that the two proteins form a complex that functions like a eukaryotic reverse gyrase. A reverse gyrase is an enzyme found in several species of *Archaea*. A hallmark feature of the reverse gyrase protein is the presence of a type I topoisomerase-like domain and a helicase domain as part of the same polypeptide. *In vitro*, the enzyme introduces positive supercoiling into dsDNA molecules. This is thought to happen in the following manner. The helicase domain of reverse gyrase unwinds a region of dsDNA, creating local negative supercoiling on one side of the enzyme and local positive superoiling on the other. The topoisomerase domain relaxes the negative supercoiling, resulting in a net overall increase in positive supercoiling in the dsDNA molecule. However, despite the attractiveness of the hypothesis that the RecQ–topoIII complex resembles reverse gyrase, the few *in vitro* studies done on RecQ and topo III have not reported increased positive supercoiling as a result of the combined action of the two enzymes.

Another hypothesis regarding the role of the RecQ–topoIII complex suggests a role in catenation or decatenation of ds DNA molecules. This idea is supported by a study that examined the consequences of concerted action of bacterial RecQ and topo III in an *in vitro* system. It was shown that both bacterial and yeast topo III proteins are specifically stimulated by the bacterial RecQ helicase to fully catenate or decatenate (depending on the conditions of the reaction) covalently closed circular dsDNA molecules. *In vivo*, a decatenation activity may be used to separate such interlinked dsDNA substrates as sister chromatids following DNA replication or homologous chromosomes following mitotic or meiotic recombination. Their complete decatenation is essential for subsequent faithful chromosomal segregation, which in turn ensures accurate transfer of genetic material into daughter cells. On the other hand, a catenating activity may be used *in vivo* to suppress recombination, as DNA sequences that are highly catenated undergo fewer recombination events.

Cellular Roles of the RecQ–TopoIII Complex in DNA Metabolism

The Recombination Connection

Inactivation of a RecQ-type helicase or topoisomerase III generally causes a variety of detrimental consequences on the genomic integrity of an organism. One consequence that is shared by all organisms examined to date is an increase in genetic recombination. As mentioned above, hyper-recombination between sister chromatids is a hallmark of human cells expressing mutant versions of BLM protein. In budding yeast, inactivation of the RecQ homolog Sgs1 or of the topo III homolog Top3 leads to an increase in several kinds of recombination, such as recombination between tandemly repeated DNA sequences. In *E. coli*, inactivation of the *recQ* gene leads to an increase in illegitimate recombination (i.e., recombination between nonhomologous DNA sequences). These observations have suggested that RecQ helicases generally control or suppress recombination. This idea is supported by a series of genetic experiments with budding yeast and mirrored by observations in fission yeast. In these organisms, concomitant mutation of the RecQ family member and of another helicase, Srs2, causes extreme slow growth and frequent lethality. However, these defects are fully rescued by mutation of any of several proteins that perform homologous recombination. This indicates that in the absence of a functional homologous recombination pathway, deletion of the two helicases is no longer detrimental to the cell. This can be explained by proposing that in the absence of the two helicases, incorrectly regulated or uncontrolled recombination is responsible for the poor growth and increased lethality. Physical interactions between RecQ helicases and proteins that function in recombination add further support to the connection between the RecQ family and recombination. In both yeast and humans, a RecQ

family member was shown to physically interact with Rad51, a protein that performs key steps in homologous recombination, such as the invasion of a DNA duplex by a homologous single strand and subsequent branch migration. Also, biochemical activities of several RecQ helicases are consistent with a direct role in suppressing recombination. Human BLM and yeast Sgs1 proteins efficiently unwind or branch-migrate four way DNA junctions *in vitro* (Figure 2B). Interestingly, four-way junctions closely resemble the structure of an intermediate in genetic recombination, a Holliday junction. Another human RecQ homolog, WRN, unwinds D-loops, DNA intermediates formed by the first step of homologous recombination—the strand invasion of a duplex by a ssDNA molecule (Figure 2B). Thus, RecQ helicases may control recombination *in vivo* by disrupting recombination intermediates.

The Replication Connection

Several lines of evidence indicate that RecQ-like helicases and topo III function during DNA replication. Analyses of mRNA and protein levels of the budding yeast RecQ and topo III homologs have shown that expression of these genes fluctuates throughout the cell cycle, peaking during and right after the period of active DNA replication. Also, yeast mutants lacking the RecQ helicase or topo III are sensitive to chemicals that arrest DNA replication by depleting cellular pools of deoxynucleotide triphosphates (dNTP's)—the building blocks necessary to assemble new DNA molecules. For instance, wild-type fission yeast cells are able to resume normal replication after transient exposure to one such chemical, hydroxyurea, whereas mutants that lack the RecQ helicase fail to make the recovery. These observations indicate that the function of RecQ family proteins is especially important for cellular survival if DNA replication is stalled.

Whereas chemicals such as hydroxyurea can arrest the progress of DNA replication throughout the entire genome, occasional pausing in the progression of individual replication forks is thought to occur spontaneously in a high proportion of cells. Accordingly, proteins that are necessary for proper handling and eventual restart of these paused forks are required throughout DNA replication even in cells unchallenged by exogenous agents. Consistent with a role for RecQ helicases during normal cell cycle, analysis of human cells expressing mutant versions of BLM or WRN proteins has shown that these cells exhibit delayed replication progression and accumulate abnormal replication intermediates.

There are several non-mutually exclusive possibilities for the roles of RecQ family members during DNA replication. These proteins could physically manipulate or maintain replication fork structure. The importance of RecQ helicases for normal progression of DNA replication combined with their previously discussed roles in controlling recombination have led to the idea that these proteins function specifically to suppress recombination initiated at stalled replication forks. Also, RecQ helicases may be involved in replicating "difficult" regions of the genome, such as telomeres. Telomeric DNA is very GC-rich and may form alternative conformations, such as G-quartets (Figure 2B). Several RecQ homologs can unwind G-quartet DNA *in vitro*, and yeast RecQ homolog Sgs1 has been implicated in telomere maintenance *in vivo*. Alternatively, these proteins could detect fork stalling and signal to other molecules, resulting in recruitment of factors necessary for resumption of fork movement. Indeed, recent evidence suggests that some RecQ family members may be involved in DNA damage surveillance and signaling mechanisms called checkpoints. In particular, the budding yeast RecQ homolog Sgs1 has been shown to participate in such signaling mechanisms specific to DNA damage occurring during DNA replication.

RecQ Helicases and Human Disease

The human genome encodes five proteins that belong to the RecQ class of helicases. Mutations in three of these proteins, BLM, WRN, and RECQ4, cause genetic disorders: Bloom, Werner, and (at least a subset of) Rothmund–Thomson syndromes, respectively. Among other symptoms, Bloom syndrome patients exhibit short stature, immunodeficiency, impaired fertility, and a predisposition to a variety of cancers. At the cellular level, the syndrome is characterized by genomic instability, including hyper-recombination between sister-chromatids and homologous chromosomes. Werner and Rothmund-Thomson syndrome patients exhibit symptoms of premature aging, as well as a predisposition to certain types of cancer. Both syndromes are also characterized by increased genomic instability at the cellular level. Cells cultured from Werner syndrome patients exhibit an increase in illegitimate recombination, resulting in chromosomal deletions and translocations. Less is known about the cellular characteristics of the Rothmund–Thomson syndrome, but these cells also display increased chromosomal abnormalities.

Whereas no genetic disorder is known to result from mutation of a human topo III homolog, mouse knock-out strains have provided important information about the role of these proteins in higher eukaryotes. Deletion of the *TOP3α* gene, encoding one of the two isoforms of topo III in mice and humans, results in embryonic lethality, indicating that this protein has essential functions during development. Deletion of the other topo III isoform, *TOP3β*, does not result in lethality, but

causes a decrease in lifespan, reduced fertility, and increased incidence of aneuploidy. Thus, topo III-like proteins, similar to RecQ helicases, play important roles in mammalian development, aging, and chromosomal integrity.

Glossary

DNA recombination Exchange or transfer of genetic material between two DNA molecules, such as two chromosomes in the cell.

DNA replication The process of faithful copying of genetic information in a cellular genome prior to cell division. This is accomplished by separating the strands of duplex chromosomal DNA and synthesizing new DNA strands that are complementary to the parental strands.

replication fork Y-shaped DNA structure formed during DNA synthesis when the parental DNA strands are separated to provide a template for DNA replication.

sister chromatids The identical copies of a single chromosome produced after DNA replication.

supercoiling The topological state achieved by twisting a duplex DNA molecule around its axis.

telomere Region of DNA at the end of a linear chromosome.

Biography

Rodney Rothstein is a Professor of Genetics and Development at Columbia University College of Physicians and Surgeons in New York. His principal research interests are in the mechanisms of DNA recombination and the cellular response to DNA damage. He holds a Ph.D. from The University of Chicago and received postdoctoral training at the University of Rochester and Cornell University. He developed one-step gene disruption in yeast and is one of the authors of the double-strand break repair model. His laboratory discovered the first eukaryotic topoisomerase III gene family member and the first eukaryotic RecQ homolog, Sgs1.

Erika Shor, a senior graduate student in the Rothstein laboratory, studies the budding yeast RecQ and topoisomerase III family members.

Dopamine Receptors

Kim A. Neve
VA Medical Center, Portland, Oregon, USA

Dopamine receptors are rhodopsin-like seven transmembrane receptors (also called G protein-coupled receptors) that mediate the central and peripheral actions of dopamine. Dopamine receptors are most abundant in pituitary and brain, particularly in the basal forebrain, and are also found in the retina and peripheral organs such as the kidney. Stimulation of dopamine receptors modulates excretion of sodium by the kidney, and both cell division and hormone synthesis and secretion in the pituitary. Brain dopamine receptors regulate movement and locomotion, motivation, and working memory. Five subtypes of mammalian dopamine receptors have been identified that are divided into D1-like (D1, D5) or D2-like (D2, D3, D4) groups. The D1-like receptors couple primarily to the $G_{\alpha s}$ family of G proteins ($G_{\alpha s}$ and $G_{\alpha olf}$), whereas the D2-like receptors couple primarily to the $G_{\alpha i/o}$ family. Drugs that block D2 receptors are useful for the treatment of schizophrenia and other psychoses, while drugs that stimulate D1-like or D2-like receptors alleviate the motor symptoms that result from degeneration of dopamine-containing neurons in Parkinson's disease.

Introduction

Nobel prize-winning work by Arvid Carlsson and colleagues in 1958 first demonstrated that dopamine is a neurotransmitter, rather than being only an intermediate step in the synthesis of norepinephrine (noradrenaline), and a neurotransmitter that plays an important role in regulating motor behavior. The first pharmacological evidence for the existence of specialized receptors for dopamine was obtained five years later, but it was not until 1972 that the identification of dopamine-stimulated adenylate cyclase, the enzyme that converts ATP into the "second messenger" cyclic AMP, made possible the biochemical characterization of a dopamine receptor. Later that decade, further pharmacological and biochemical chacterization of dopamine receptors, including their division into D1 and D2 subtypes, was made possible by the development of radioisotopically labeled ligands, or radioligands, that bind to dopamine receptors with high affinity and selectivity. What might be considered the modern era of dopamine receptor research began with the determination of the DNA sequence and predicted protein sequence of the D2 dopamine receptor and the subsequent identification of additional dopamine receptor subtypes.

Dopamine Receptor Subtypes

Virtually all neurotransmitters and hormones activate multiple receptor subtypes—distinct classes of receptors that share relatively high affinity for a single neurotransmitter but that differ in structure, affinity for drugs, signaling, and distribution. It is common for the distribution of receptor subtypes to overlap, so that one organ or brain region may have multiple receptor subtypes for any neurotransmitter or hormone that is present.

D1-Like and D2-Like Receptor Subfamilies

Prior to the molecular cloning of dopamine receptors, they were divided into D1 and D2 subtypes on the basis of several criteria. D1 and D2 receptors have distinct pharmacological profiles; in particular, D2 receptors have high affinity for benzamide and butyrophenone antagonists such as sulpiride and spiperone, respectively, while D1 receptors have high affinity for benzazepine antagonists such as SCH23390. D1 receptors stimulate adenylate cyclase and cyclic AMP accumulation, while D2 receptors inhibit the enzyme. Finally, the D1 and D2 receptors are physically distinct. For example, there are tissues such as the anterior and intermediate pituitary gland that have an abundance of D2 receptors but no D1 receptors. Furthermore, it is possible to cause selective damage to cell bodies in the substantia nigra or in the neostriatum of the rat brain, using lesions that spare axons and axon terminals, and with these lesions to cause a preferential reduction in the abundance of D2 receptors (substantia nigra) or D1 receptors (neostriatum), thus demonstrating the differential localization of the subtypes on cell bodies and axon terminals in these brain regions. The molecular cloning of additional subtypes of dopamine receptors revealed the existence of

two receptor subfamilies, in each of which the subtypes share D1-like or D2-like characteristics.

Molecular Cloning of Dopamine Receptor Subtypes

Following the cloning of DNA encoding receptors determined to be identical to the pharmacologically characterized D1 and D2 receptors, several additional subtypes were identified in 1990–91. DNA sequence information was a new tool for classification of receptors, in that receptors belonging to the same subfamily are more similar in DNA and protein sequence. Thus, there are many amino acids that are common in D1 and D5 receptors (Figure 1A), but fewer that are shared among all the dopamine receptor subtypes (Figure 1B). D1 and D5 receptors are both D1-like receptors, whereas D2, D3, and D4 receptors belong to the D2-like receptor subfamily in terms of sequence identity and affinity for drugs.

Structural Characteristics of Dopamine Receptors

Most hormone and neurotransmitter receptors are integral membrane proteins that span the cell membrane at least once, so that one portion of the receptor lies outside the cell and another portion lies inside. Dopamine receptors all belong to the superfamily of proteins called 7-transmembrane receptors, because they traverse the membrane seven times, serpentine receptors because of the manner in which the wind back and forth across the membrane, or G protein-coupled receptors because most of the effects of neurotransmitter binding to the receptors are mediated by activation of G proteins. The superfamily of 7-transmembrane receptors includes receptors for light, odors, and calcium, in addition to most neurotransmitters. Although all dopamine receptors have seven membrane-spanning regions with four intracellular domains (loops 1–3 and the carboxy terminus) and four extracellular domains (the amino terminal extension and extracellular loops 1–3), the D1-like receptors have relatively short third intracellular loops and relatively long carboxy termini compared to the D2-like receptors (Figure 1).

As illustrated in Figure 1, the presence of specific amino acid residues at certain locations across receptor subtypes, or amino acid sequence homology, is highest within the membrane-spanning regions of 7-transmembrane receptors. This is primarily because maintaining the three-dimensional structure of a receptor so that it is relatively quiescent until activated by the binding of a neurotransmitter such as dopamine requires precise packing of the membrane-spanning alpha-helices and a network of interhelical bonds that constrain the movement of the helices. Random mutations in these regions would be often deleterious and selected against because of the relatively high likelihood of disrupting helix packing or interhelical bonds. Within a family of receptors for one neurotransmitter or for several structurally related neurotransmitters such as the catecholamines dopamine and norepinephrine (noradrenaline), sequence homology also reflects the conservation of amino acids that bind the neurotransmitter; for small molecule neurotransmitters such as dopamine, these amino acids are typically in the membrane-spanning helices, which form a water-accessible binding pocket within the membrane lipid bilayer.

Dopamine Receptor Subtype-Selective Drugs

D1 and D2 receptor-selective drugs have been very useful for differentiating between the behavioral and biochemical effects of D1-like or D2-like receptor stimulation. There are numerous commercially available potent and selective D2-like receptor agonists such as quinpirole and 7-OH DPAT, and antagonists such as spiperone and nemonapride (YM-09151-2). Although there are fewer D1-like receptor-selective drugs, the selective benzazepine antagonist SCH23390 and agonists such as SKF38393 and 6-chloro-APB (SKF82958) have been used to demonstrate that blockade or stimulation of D1-like receptors has significant behavioral consequences.

There is great interest in developing drugs that differentiate between D1 and D5 receptors or among the D2-like receptors, both as research tools and because of the possibility that selective blockade or stimulation of only one subtype will be a more effective treatment for a disease that is currently treated by blockade or stimulation of the D1-like or D2-like subfamily (Table I). It is still not possible to differentiate pharmacologically between D1 and D5 receptors, two subtypes with very similar sequence in the membrane-spanning helices (Figure 1A). On the other hand, the use of antagonists that are highly selective for only one of the three subtypes of the D2-like receptor subfamily, particularly for the D4 receptor, has demonstrated that dopamine binding to D3 or D4 receptors in rats has behavioral effects that are very different from D2 receptor-stimulated locomotor activation.

Dopamine Receptor Signaling

Most of the effects of dopamine receptors on cellular function are mediated by activation of heterotrimeric

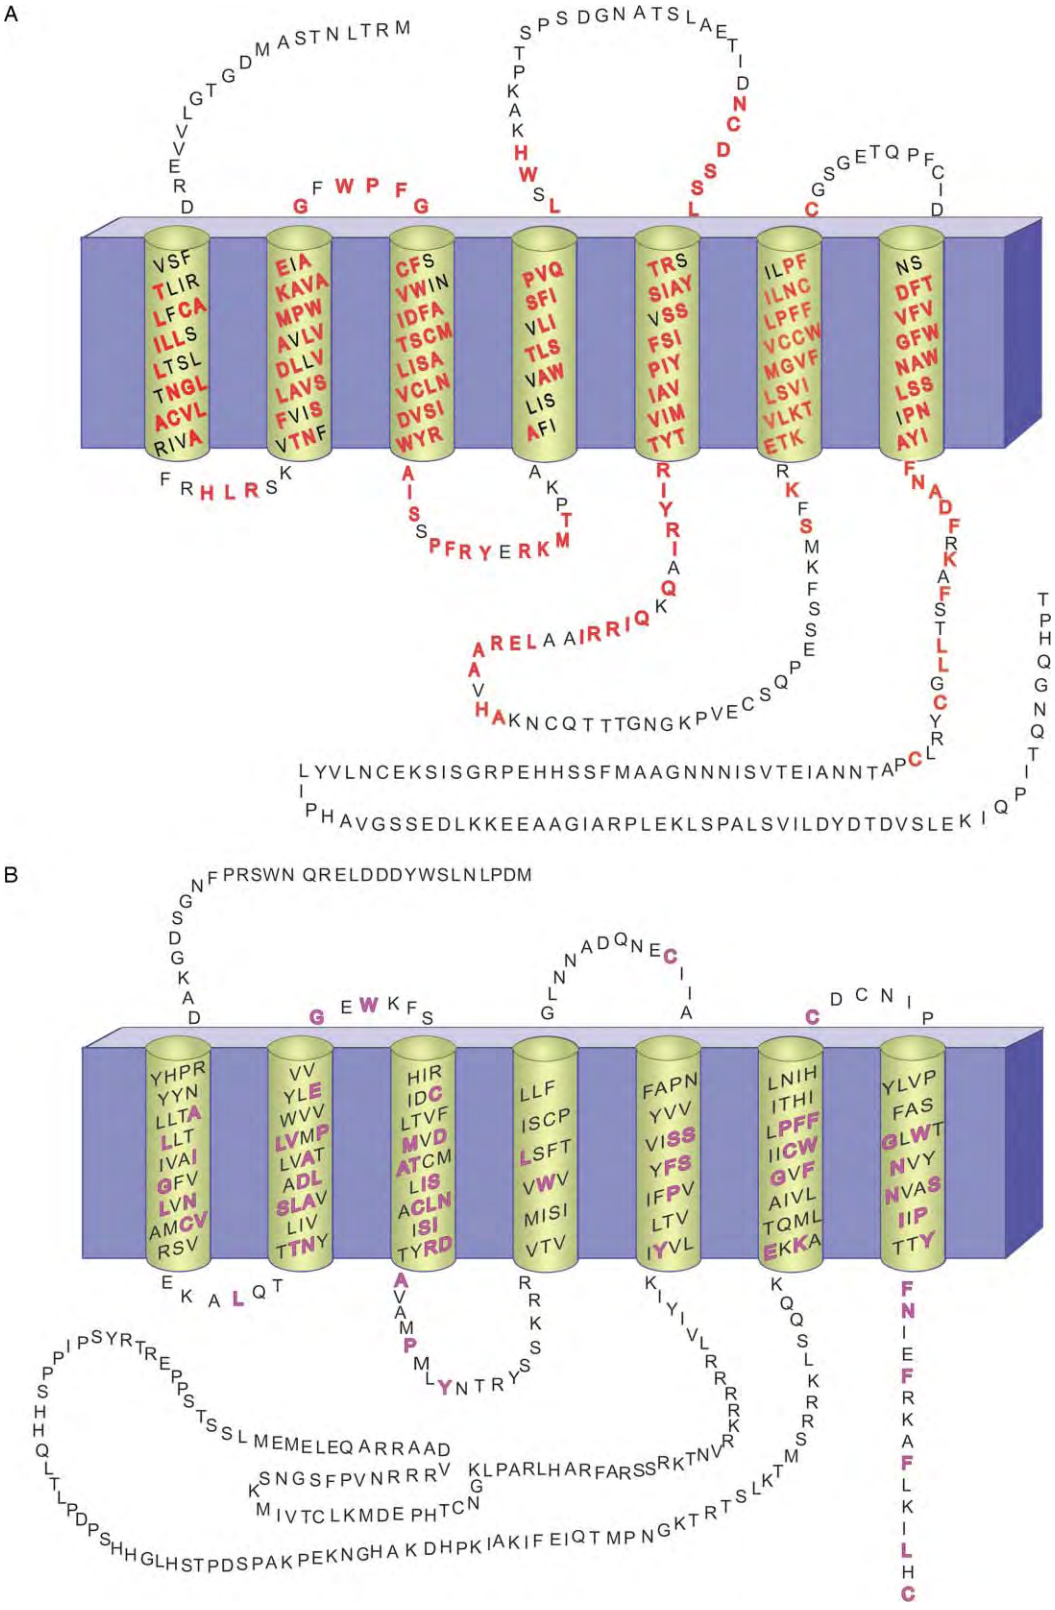

FIGURE 1 Predicted amino acid sequence and membrane-spanning segments of the D1 (A) and D2 (B) dopamine receptor subtypes. The figure is oriented so that the extracellular regions of each receptor are above the shaded transmembrane helices and the intracellular regions are below. Amino acids colored red (A) are shared between D1 and D5 receptors, whereas amino acids colored purple (B) are shared among all of the dopamine receptor subtype.

TABLE I

Features of Human Dopamine Receptor Subtypes

Type of feature	Dopamine receptor subtype				
	D1	**D5**	**D2**	**D3**	**D4**
Length (amino acids)	446	477	443[a]	400	387[b]
Introns in coding region	No	No	Yes	Yes	Yes
G protein coupling	$G\alpha_s/G\alpha_{olf}$	$G\alpha_s$	$G\alpha_{i/o}$	$G\alpha_{i/o}$	$G\alpha_{i/o}$
Agonists	SKF38393	SKF38393	Quinpirole	Quinpirole	Quinpirole
	6-Cl-APB	6-Cl-APB	7-OH-DPAT	7-OH-DPAT	7-OH-DPAT
				PD128907	PD168077
Antagonists	SCH23390	SCH23390	L-741,626	GR 103691	L-741,742
				U99194	L-745,870
Radioligands	[^{3}H]SCH23390	[^{3}H]SCH23390	[^{3}H]spiperone	[^{3}H]spiperone	[^{3}H]spiperone
	[^{125}I]SCH23982	[^{125}I]SCH23982	[^{3}H]YM-09151-2	[^{3}H]YM-09151-2	[^{3}H]YM-09151-2
				[^{3}H]7-OH-DPAT	
Localization[c]	Caudate-putamen, cerebral cortex, substantia nigra, parathyroid gland	Hippocampus, cerebral cortex	Caudate-putamen, substantia nigra, intermediate and anterior pituitary gland	Nucleus accumbens, olfactory tubercle	Cerebral cortex, hypothalamus, olfactory bulb
Splice variants	None	None	$D2_L/D2_S$	D3nf[d]	None
Allelic variants[e]	None	Leu88 → Phe	Val96 → Ala	Ser9 → Gly	Gly11 → Arg
		Ala269 → Val	Pro310 → Ser		12 bp repeat in exon 1
		Pro330 → Gln	Ser311 → Cys		21 bp deletion in exon 1
		Cys-335 → stop			13 bp deletion in exon 1
		Asn351 → Asp			Val194 → Gly
		Ser453 → Cys			48 bp repeat in exon 3

[a] Length of $D2_L$; $D2_S$ is 414 amino acids long.

[b] Length of the variant with two repeats (D4.2) although actual length depends on the number of repeat units, which varies from 2 to 10.

[c] Selected tissues and brain regions with relatively high expression of the subtype are listed.

[d] D3nf is a frame-shifted variant with D3 receptor sequence only through the fifth membrane-spanning helix. Although shorter truncated splice variants of D3 mRNA also exist, D3nf is the only one for which expression of the protein has been demonstrated.

[e] Only variants that alter the protein sequence are listed.

GTP-binding proteins called G proteins. Binding of dopamine to amino acids within the membrane-spanning helices of a dopamine receptor disrupts the interhelical bonds that hold the receptor in an inactive state. The resulting movement of one or more of the helices exposes amino acids on the cytoplasmic face of the membranes that bind to and activate G proteins. D1-like and D2-like receptor have very different signaling properties as a result of differential selection of G protein subtypes.

G Protein Coupling

Heterotrimeric G proteins are composed of α-, β-, and γ-subunits, and are generally named according to the subtype of G_α subunit. D1-like receptors that have been stimulated by dopamine or other D1 receptor agonists activate two G proteins that stimulate adenylate cyclase, $G_{\alpha s}$ and the closely related G protein $G_{\alpha olf}$ (Table I). (The latter G protein was first identified as mediating olfactory responses to receptors for odorants.) D2-like receptors activate the $G_{\alpha i}$ subtypes, named after their ability to inhibit adenylate cyclase, and the closely related G protein $G_{\alpha o}$. That these G proteins are substrates for ADP-ribosylation by cholera toxin, which persistently activates $G_{\alpha s}$, or pertussis toxin, which inactivates $G_{\alpha i/o}$, has contributed importantly to determining their role in dopamine receptor signaling.

Signaling Pathways

As suggested by their activation of G proteins that stimulate adenylate cyclase, most effects of D1-like receptor stimulation are mediated by increased levels of cyclic AMP and cyclic AMP-dependent protein phosphorylation. D1 receptor-stimulated protein phosphorylation alters the activity of other protein kinases, receptors, protein phosphatases, ion channels, and transcription factors. D2-like receptors inhibit the activity of adenylate cyclase via $G_{\alpha i}$. D2-like receptors also modulate many other signaling pathways, most of them as a result of the liberation of G protein $\beta\gamma$-subunits that occurs when 7-transmembrane receptors activate $G_{\alpha i/o}$ proteins. $G_{\beta\gamma}$-regulated pathways that are regulated by stimulation of D2-like receptors include several forms of adenylate cyclase, ion channels, phospholipase C, and mitogen-activated protein (MAP) kinases. Although the basic mechanism of activation of heterotrimeric G proteins by receptors is probably the same for all receptor-G protein combinations, for reasons that have not been determined, activation of other types of G proteins such as $G_{\alpha s}$ does not produce the same $G_{\beta\gamma}$-mediated signaling that is observed after receptor-mediated activation of $G_{\alpha i/o}$.

Distribution of Dopamine Receptors

The D1 and D2 dopamine receptors are overall the most abundant dopamine receptor subtypes. The D1 receptor is expressed most highly in brain, with lower expression in periperheral tissues such as the parathyroid gland, renal, mesenteric, and coronary vascular beds, and the kidney. Within the brain, the D1 receptor is most abundant in the caudate-putamen and other basal forebrain nuclei such as the nucleus accumbens, and is also found in the cerebral cortex and the substantia nigra *pars reticulata*. The D5 receptor is expressed at much lower levels in the same basal forebrain nuclei, the cerebral cortex, and hippocampus. The D2 receptor is expressed most highly in the intermediate pituitary gland, with abundant expression also observed in the anterior pituitary and in a number of brain regions including the caudate-putamen and other nuclei of the basal ganglia, the substantia nigra *pars compacta*, and the cerebral cortex. The D4 receptor is expressed in most of the same forebrain regions as the D2 receptor and in the cerebral cortex, albeit at a lower level. Whereas the D2 receptor is most abundant in dorsal areas of the striatum, the D3 receptor is also expressed in the basal forebrain but is more abundant in the ventral nuclei (nucleus accumbens, olfactory tubercle).

Dopamine Receptor Variants

Although there are only five mammalian dopamine receptor genes that give rise to D1–5 receptors, four of the genes produce multiple receptor variants (Table I). For example, the D2 receptor has two variants that result from alternative splicing of the RNA that is transcribed from the *DRD2* gene. The long form of the D2 receptor, $D2_L$, contains a 29-amino-acid insert encoded by an exon that is spliced out of the short form, $D2_S$. Recent evidence suggests that $D2_S$ and $D2_L$ might serve very different functions as autoreceptors that regulate dopamine release and as postsynaptic receptors that mediate the actions of dopamine on non-dopaminergic neurons, respectively. In contrast to splice variants that are derived from a single gene sequence and that are present in everybody, there are also dopamine receptor variants transcribed from distinct gene sequences, so that each individual expresses only one or two of the two or more existing variants. For example, there are at least 27 allelic variants of the human D4 receptor that have from 2 to 10 copies of an imperfectly repeated 48 nucleotide (16 amino acid) sequence in the third intracellular loop of the receptor. There is considerable interest in the possibility that these allelic variants also vary in functional characteristics.

Therapeutic Uses for Dopamine Receptor Agonists and Antagonists

By far the most common therapeutic purpose for drugs that act on dopamine receptors is the use of D2 receptor antagonists for the treatment of schizophrenia and other psychoses. D2-like receptor antagonists are also used for the treatment of nausea and vomiting, for delerium or dementia of unknown cause, and for symptomatic treatment of hyperactive movement disorders such as Tourette's syndrome and Huntington's disease. Dopamine receptor agonists alleviate the symptoms of Parkinson's disease, and are often used in combination with the dopamine precursor L-DOPA. The D2-like receptor agonist bromocriptine is used to treat hyperprolactinemia because of the inhibitory effect of anterior pituitary D2 receptors on prolactin secretion. When hyperprolactinemia results from a prolactin-secreting tumor, treatment with bromocriptine also decreases the size of the tumor. Dopamine or D1 agonists such as fenoldopam cause D1 receptor-mediated vasodilation, thus increasing glomerular filtration, renal blood flow, and sodium excretion, and are used to manage types of shock associated with loss of cardiac output and compromised renal function.

Glossary

affinity Term for how tightly a drug binds to a receptor, expressed as the concentration of drug that occupies half of the available receptors. High affinity means that a drug will bind at very low concentrations.

agonist A drug that binds to and activates a receptor. Dopamine is the endogenous agonist for dopamine receptors.

antagonist A drug that binds to a receptor without activating it, and thus prevents the binding of an agonist.

receptor A protein, usually associated with the cell membrane, that binds a neurotransmitter or hormone and initiates a biological response.

second messenger A chemical signal elicited by an activated receptor that transmits information within a cell. The extracellular neurotransmitter is the first messenger, and whereas some receptors transduce information about the neurotransmitter concentration into an electrical response, other receptors convert that information into altered abundance of an intracellular second messenger such as cyclic AMP.

He holds a Ph.D. from the University of California, Irvine and received his postdoctoral training at the University of Pennsylvania. His principal research interest concerns the structure and function of dopamine receptors, and he has worked extensively on determining how the responsiveness of the receptors is regulated by dopamine.

Dynactin

Trina A. Schroer
The Johns Hopkins University, Baltimore, Maryland, USA

Dynactin is a multi-subunit protein complex that links many components of cells to microtubules and microtubule-based motors. In addition to serving as an adapter that tethers and/or allows movement of cellular structures, dynactin also enhances the activity of some motors by increasing their processivity.

Overview of Dynactin Composition and Structure

Dynactin contains a total of 24 individual polypeptide subunits that are encoded by 11 different genes (Figure 1). The locations and nearest neighbors of most dynactin subunits have been identified using antibody labeling and biochemical analysis (Figure 2). Most of dynactin's mass is contained in a rod-like structure that is an octameric polymer of the actin-related protein, Arp1. The subunits p62, Arp11, p27, and p25 are organized into a disk-shaped complex that sits at one end of this polymer. The actin-capping protein (CapZ) α/β heterodimer is present at the other end of the Arp1 polymer. Dynactin also contains a single monomer of conventional cytoplasmic β-actin, the precise location of which has not been rigorously defined. The entire rod-like domain is thought to mediate interactions of dynactin with a wide variety of cellular structures.

The other prominent structural domain of dynactin is a flexible shoulder and arm complex that projects away from the Arp1 rod. This complex contains the largest dynactin subunit, $p150^{Glued}$, dynamitin (p50), and p24 in a stoichiometric ratio of 2:4:2. The projecting domain is where dynactin binds motors and microtubules.

Dynactin structure has been imaged in the electron microscope (EM) by a variety of methods, including negative-staining EM and scanning transmission EM. The most detailed information has been derived from platinum replicas of rotary shadowed, quick-frozen, deep-etched molecules. The dynactin structure obtained in this manner is the basis of the cartoon shown in Figure 2. Till the time of preparation of this entry, no high resolution structural information about dynactin as a whole or any of its individual subunits (aside from actin and CapZ) was available.

Dynactin Functions

Functions Associated with Dynein-Based Motility

Dynactin was first discovered as a large (20S) protein complex that copurified with the minus end-directed motor, cytoplasmic dynein. Dynactin was found to stimulate dynein's ability to translocate membrane vesicles *in vitro*. The name dynactin derives from its *dyn*ein-*act*ivating activity.

Adapter Function

An important function of dynactin is to serve as an "adapter" that allows cytoplasmic dynein to bind a variety of cargoes. This adapter function relies on dynactin's distinct dynein and cargo-binding domains. Dynein is the predominant minus end-directed motor activity in most cells and therefore virtually any subcellular structure or macromolecular complex that moves toward the cell center is translocated by dynein, usually in conjunction with dynactin. Dynein cargoes include membranous organelles such as the Golgi complex, the ER–Golgi intermediate compartment (ERGIC), endosomes, lysosomes, and mitochondria. Dynein can also move lipid droplets, aggresomes, viral capsids, and centrosome components toward the cell center.

Dynactin also contributes to the binding of dynein to large cellular structures such as centrosomes, mitotic spindle poles, chromosomes, the nucleus, and the plasma membrane. Dynein associates with centrosomes beginning in S-phase and remains at spindle poles during mitosis. Centrosomal dynactin is required for dynein binding. The persistent action of dynein at spindle poles is required for the retention and organization of microtubules. Dynactin is also required for proper binding of dynein to chromosome kinetochores, which is important for capture of spindle microtubules in prometaphase. Dynein may also power the lateral sliding of chromosomes along microtubules and contribute to attachment to microtubules that must undergo

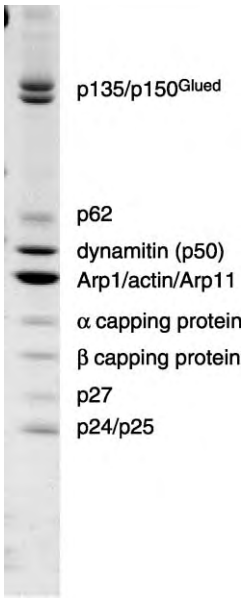

FIGURE 1 Dynactin composition. Dynactin's 11 distinct polypeptide subunits are shown on this Coomassie blue-stained, SDS polyacrylamide gel.

disassembly at their plus ends during prometaphase and anaphase. Just prior to mitosis, dynactin and dynein are recruited to the outer nuclear membrane. Dynein-driven movement of the nuclear envelope along microtubules pulls the entire centrosomal microtubule array toward the nucleus. This causes centrosomes to become closely associated with the nuclear surface and contributes to nuclear envelope rupture.

Dynein binds to the cell cortex via dynactin. As in the case of dynein bound to the nuclear envelope, the force exerted by cortical dynein "reels in" microtubules, pulling with them any structures to which they might be attached. This process can reorient the entire microtubule array and contributes to the long-range movements of nuclei that occur during mitosis and cellular morphogenesis.

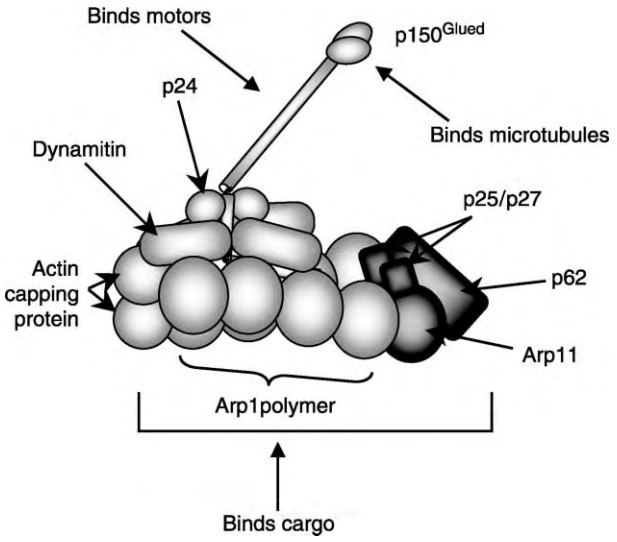

FIGURE 2 Subunit organization in dynactin. The three different binding domains are indicated. The precise location of conventional actin is unknown.

Processivity Enhancement

In the absence of dynactin, cytoplasmic dynein's two motor domains are able to travel only a very short distance along the microtubule lattice. Dynactin's $p150^{Glued}$ subunit provides a second set of microtubule binding sites that holds dynein in the vicinity of the microtubule. This low affinity binding allows dynein to move over longer distances, making it a more processive motor.

Interactions with other Motors

Dynactin may bind motors of the kinesin family to target them to cargoes and enhance processivity. Evidence exists suggesting that $p150^{Glued}$ binds Eg5/BimC, a plus end-directed motor that is localized at spindle poles where it contributes to microtubule organization. Membranous organelles that undergo dynamic bidirectional movements, such as late endosomes and pigment granules, must also be able to bind multiple motors. Dynactin on the surface of such membranes may be able to recruit both dynein and the heterotrimeric, plus end-directed motor, kinesin II (KIF3), thereby allowing bidirectional translocation.

Dynein-Independent Functions

Dynactin can support non-motile interactions of microtubules with cellular components in a manner that is independent of motor binding. This cross-linking function depends on dynactin's distinct microtubule and cargo-binding domains. Dynactin associates with microtubules at their plus ends, their minus ends, and along their length. At plus ends, dynactin may help control the rate of microtubule growth and shrinkage, perhaps by recruiting or working with other plus end-binding factors. Dynactin is also seen at sites where microtubule minus ends converge, such as centrosomes, at times when dynein is not. Centrosomal dynactin is required for microtubule anchoring at this site. Dynactin may interact with microtubule minus ends directly, or it might recruit other minus end-binding factors. Subunits of dynactin's cargo-binding domain are able to associate with a wide array of intracellular molecules and macromolecular complexes that are still being identified. This may allow dynactin to bind cellular components to microtubules transiently. This would prevent them from diffusing freely in cytosol and could cause them to be retained at particular sites within the cell, for example, in the cytoplasm rather than the nucleus.

Structure and Function of Individual Dynactin Subunits

Structure

Dynactin subunits can be grouped into four structural families: (1) proteins whose structures resemble actin (actin itself, plus the actin-related proteins Arp1 and Arp11) or actin-binding proteins (CapZ), (2) α-helical, elongated proteins (p150^{Glued}, dynamitin and p24), (3) β-helix proteins (p25 and p27), and (4) Cys/His RING/LIM domain proteins (p62).

Actin-Related or Actin-Binding Proteins

Dynactin contains three proteins of the actin superfamily: β-(cytoplasmic) actin, Arp1, and Arp11. Arp1 is quite similar (~65% identical) to conventional actin and is the only Arp that has been shown to assemble into filaments in vitro and hydrolyze ATP. Arp11 is less similar to actin but can copolymerize with actin and bind Arp1 *in vitro*. Sequence comparisons suggest that Arp11 is most divergent at its pointed end face. Arp11 has been localized to the pointed end of the Arp1 filament where it may bind Arp1 directly. The CapZ species found in dynactin contains the β_2 isoform only. Among the dynactin subunits, these five dynactin polypeptides are the most highly conserved between species.

α-Helical Proteins

The polypeptides p150^{Glued}, dynamitin and p24 are the least highly conserved of all the dynactin subunits, suggesting that their overall structures may play a more important role in dynactin function than their specific sequences. p150^{Glued} forms a parallel homodimer that is stabilized by two long coiled coils, one ~300 amino acids long and the other ~125 amino acids long (Figure 3). The 200 amino acid N-terminal domains comprise the globular heads found at the tip of the projecting arm. Only the N-terminal ~400 amino acids are exposed in the projecting arm, leaving the C-terminal two-thirds to associate with other dynactin subunits in the elastic shoulder that is associated with the Arp1 filament. The structural features of the central region and C terminus of p150^{Glued} have not yet been defined. The p150^{Glued} mRNA is spliced at multiple sites that are still being characterized. This may yield p150^{Glued} protein isoforms that exhibit differential binding to microtubules and other dynactin subunits.

Isolated dynamitin is an elongated tetramer, but it folds into a more compact structure when associated with other dynactin subunits. Dynamitin and p24 (2:1 stoichiometric ratio) associate stably with each other to form a complex that plays a critical role in dynactin integrity. Free dynamitin is able to displace endogenous dynamitin, p24 and p150 from the Arp1 filament. The location of dynamitin within the dynactin molecule has not been rigorously determined, but its known neighbors and general structural properties suggest that it is a major structural component of the shoulder.

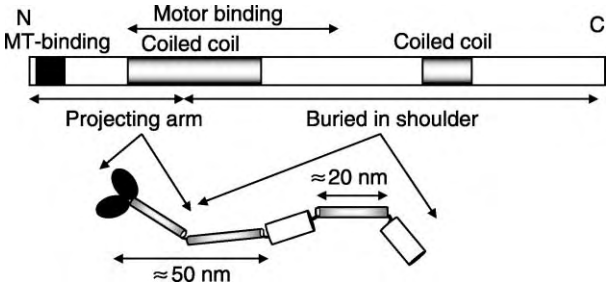

FIGURE 3 Two representations of the domain organization of p150^{Glued}. Top: A schematic of the primary sequence with predicted structural features and sites of known interactions indicated. Bottom: A cartoon illustrating the N-terminal globular heads and location and approximate lengths of the two coiled-coil domains. The structural features of the open boxed regions have not been determined.

β-Helix Proteins: p25 and p27

Dynactin contains one copy each of p27, p25, Arp11, and p62, which are closely associated in with each other. p27 and p25 are evolutionarily related and contain a polypeptide repeat motif that is characteristic of β-helical proteins. β-helix proteins are common in proteins from plants and pathogenic organisms, but rarer in animal cells. Most β-helices are elongated and possess an extended binding face or groove. The β-helices in p25 and p27 are predicted to be short, but the two proteins may associate with each other end-to-end to provide a longer-binding face. The unusually alkaline pI of the p25/p27 dimer suggests this part of dynactin may associate with acidic binding partners.

RING/LIM Domain Protein: p62

Very little is known about p62 structure, but it has been shown to associate with actin, Arp11, and Arp1. p62 contains a Cys/His-rich motif of the RING/LIM type that may chelate a metal ion and contribute to interactions with other dynactin subunits and/or other proteins. p62 contains a single consensus site for phosphorylation by cell cycle kinases (Cdks) that may govern its cell cycle-dependent binding to nuclei.

Binding Activities

Dynactin can interact with a wide variety of different cellular components. Its binding partners fall into three

classes: (1) microtubules, (2) motors, and (3) motile cargoes or non-motile subcellular docking sites. Each type of interaction is supported by a different part of the dynactin molecule (Figure 2).

Microtubule Binding

Microtubule binding is mediated by a CAP-Gly (i.e., cytoskeleton-associated protein that is glycine-rich) motif found in the N-terminal "head" domain of each $p150^{Glued}$ subunit (Figure 3). CAP-Gly motifs have been found in other microtubule binding proteins such as CLIP-170, Bik1 and the tubulin-folding cofactors, Factor B and E. The affinity of microtubule binding is regulated by phosphorylation, possibly at multiple sites. The ability of dynactin to bind microtubules with a range of affinities may allow it to work as either a processivity factor or a tethering molecule.

Motor Binding

$p150^{Glued}$ also contributes to motor binding. Its best-characterized binding partner is cytoplasmic dynein, but $p150^{Glued}$ has also been reported to interact with the kinesin family motors, Eg5 and kinesin II. Motors bind to the central portion of $p150^{Glued}$ (amino acids ~200–800; Figure 3). It is not known whether this element contains a single-motor-binding site or whether distinct sites bind different motors. In addition to $p150^{Glued}$, nearby dynactin subunits such as dynamitin and p24 may contribute to binding to cytoplasmic dynein and other motors.

Binding to other Cellular Components

Membranes Dynactin localizes to many cellular membranes, including the Golgi complex, ERGIC, endocytic pathway components, the nuclear envelope and the plasma membrane. All these interactions are thought to involve dynactin's Arp1 filament domain. Arp1 can associate with the actin-binding region of at least one spectrin isoform, which might provide a general mechanism for binding to the Golgi complex, nuclear envelope, and plasma membrane. Nuclear envelope binding also utilizes p62 and Arp11.

Other Cytoplasmic Structures The association of dynactin with lipid droplets, intracellular pathogens and cytoplasmic signaling complexes also appears to involve the Arp1 filament domain. The mechanisms for binding to most of these structures have not yet been defined. Cytoplasmic signaling complexes appear to bind dynactin via p27 and p25. These subunits are loosely associated with dynactin and may provide a mechanism for promoting transient and/or regulated interactions with a variety of cellular components.

Chromosomes Dynactin is bound to chromosome kinetochores during mitosis. As in the case of other structures that bind dynactin, kinetochore binding probably involves multiple dynactin subunits. One known contributor to this interaction is dynamitin, which binds the kinetochore component, ZW10, directly.

Glossary

centrosome A complex organelle located at the center of many cells that is the major site of microtubule nucleation and in some cells, focusing of minus ends.

dynein A massive, multisubunit mechanoenzyme that powers movement toward the minus ends of microtubules.

microtubule A 25 nm diameter hollow cytoskeletal polymer comprising 11–15 parallel protofilament strands of α/β tubulin heterodimers.

motor An ATPase that performs mechanical work as part of its ATP hydrolytic cycle.

processivity The ability of an enzyme to catalyze a reaction on multiple, successive subunits of a polymeric substrate.

Biography

Dr. Trina A. Schroer is a Professor in the Department of Biology at The Johns Hopkins University in Baltimore, Maryland. Her principal research interests are cytoarchitecture and subcellular motility, with a particular focus on the functions of the microtubule cytoskeleton and microtubule-based motors. She holds a Ph.D. from the University of California, San Francisco and received postdoctoral training at the Washington University School of Medicine. Dr. Schroer discovered dynactin as a postdoctoral fellow and has made significant contributions toward determining its composition, structure, and functions.

Dynein

K. Kevin Pfister
University of Virginia School of Medicine, Charlottesville, Virginia, USA

Dyneins are motor proteins that move along microtubules toward their minus ends. They are members of the AAA family of ATPases. Dyneins were first identified by Gibbons as the ATPases that are responsible for the propulsive flagella bending and he named them after the unit of force, the dyne. Many members of the dynein family have been found in organisms from yeast to humans. All dyneins are large protein complexes composed of one or more ~530 kDa polypeptides, known as heavy chains, and various accessory subunits from 10 to 150 kDa.

Characteristics of Dynein Complexes

Dyneins are found in many eukaryotes, including, fungi, worms, insects, and vertebrates, but analysis of *Arabidopsis* genome indicates that they are not found in plants. Dyneins are classified as either cytoplasmic or flagellar, and the flagellar dyneins are further divided into the outer arm and inner arm dyneins. Cytoplasmic dynein moves membranous organelles, kinetochores, and viruses along microtubules and assists in the assembly and function of the mitotic spindle. Cytoplasmic dynein is also responsible for retrograde axonal transport. The flagellar dyneins, also called axonemal dyneins, are the arms that project from the doublet axonemal microtubules of flagella and cilia. The flagellar dyneins generate the sliding force between outer doublet microtubules that is converted by other axonemal structures into the bending of cilia and flagella. The outer arms specify the flagellar beat frequency and the inner arms specify flagellar waveform. There is also a dynein responsible for the transport of protein complexes from the tip of cilia and flagella to their base that occurs between the axonemal microtubules and the flagellar membrane, known as intraflagellar transport.

Fungi, *Drosophila,*and mammals have provided the major sources and systems for the study of cytoplasmic dynein. The alga *Chlamydomonas*, which has two flagella, has been a useful model system for the study of flagellar dyneins. As many as ten different dynein complexes are found in animals and most of these are components of the flagella. Molecular genetic analyses indicate that genomes contain more than ten flagellar dynein heavy chain genes, one cytoplasmic dynein heavy chain gene, and the intraflagellar transport dynein heavy chain, which is most related to the cytoplasmic dynein heavy chain. Dynein complexes are composed of one, two, or three heavy chains, and each complex has various smaller accessory subunits (Tables I and II). Cytoplasmic dynein has two identical heavy chains. Flagellar outer arm dyneins have two or three different heavy chains depending on the species. Each flagella has many different inner arm dyneins. Inner arm dynein 1 has two different heavy chains, and there are at least six different inner arm dyneins each with one unique heavy chain.

The different dynein complexes hydrolyze MgATP at different rates, for example, the microtubule stimulated ATPase activity of cow brain cytoplasmic dynein is 0.3 μmol min^{-1} mg^{-1} and the activity of flagellar outer arm dynein is 2.0 μmol min^{-1} mg^{-1}. Different dynein complexes also move along microtubules at different rates. An *in vitro* motility assay is used to quantify the velocity of dynein-based movement by using computer-enhanced video microscopy. Dynein is attached to a glass coverslip and when microtubules are added the dynein motor domains bind the microtubules. In the presence of MgATP, the dynein moves microtubules across the coverslip with the microtubule-plus ends leading. Cytoplasmic dynein from bovine brain moves microtubules at the rate of ~1 μs^{-1} while sea urchin outer arm dynein moves microtubules at the rate of 3.5 μs^{-1}.

The Dynein Heavy Chain

The central component of the dynein complex is the heavy chain, an ~530 kDa polypeptide of that contains the ATP-binding and hydrolysis site and a microtubule-binding domain. Often the heavy chain alone is referred to as a dynein. The heavy chain is an AAA ATPase. The C-terminal two-thirds of the heavy chain, ~350 kDa, is necessary for ATP-dependent microtubule binding. This domain contains six sequential AAA domains, with

TABLE I

Composition of Cytoplasmic Dynein Complexes

	Cytoplasmic dynein	Intraflagellar transport dynein
Heavy chain	HC1a	HC1b
Number of heavy chains	2	nd (1?)
Intermediate chain[a]	IC74-1 IC74-2	n

n, none identified; nd, not determined.

[a] It is not known if the intermediate chains associate in the dynein complex as homodimers or heterodimers. The light intermediate chains associate in the dynein complex only as homoligomers.

[b] Each light chain family has at least 2 members.

~350 amino acid microtubule-binding region inserted between AAA domains 4 and 5. Consensus nucleotide-binding sites known as P loops are components of AAA domains 1 through 4, while AAA domains 5 and 6 lack consensus P loop motifs. The first P loop, P1, is the site of ATP binding and hydrolysis which generates force. In the presence of vanadate and inorganic phosphate, the heavy chains are cleaved by photolysis with ultraviolet light into two fragments at P1. The role of the other P loops is unknown although at least one of them binds nucleotide.

Structural analysis of the heavy chain indicates that the C-terminal motor portion forms a large globular domain known as the head (Figure 1). The head is made up of six or seven lobes arranged in a ring surrounding a central cavity. The individual AAA domains make six of the lobes. The microtubule binding region, two anti-parallel coiled coils separated by a globular region, projects from the head as a stalk. The N-terminal portion of the heavy chain extends from the head as a thin flexible stem across the head from the microtubule binding stalk. Two or three dynein heavy chains are often connected by their stems to form a common base. Most of the other subunits of the dynein complexes bind to the N terminus of the heavy chain at the base and they contribute to the motor protein's cargo-binding domain.

Cytoplasmic Dynein

The mammalian cytoplasmic dynein (Figure 1 and Table I) has a native molecular weight of 1.5×10^3 kDa. It is a homodimer of two identical heavy chains associated with two ~74 kDa intermediate chains, two to four ~55 kDa light intermediate chains (LIC) and three pairs of light chains, the Tctex1, roadblock, and LC8 families. The heavy chain of this dynein is encoded by a single gene, but two genes have been identified for the mammalian intermediate and light intermediate chains and for each of the three light chain families. Intermediate chain and light intermediate chain isoforms are also generated by mRNA alternative

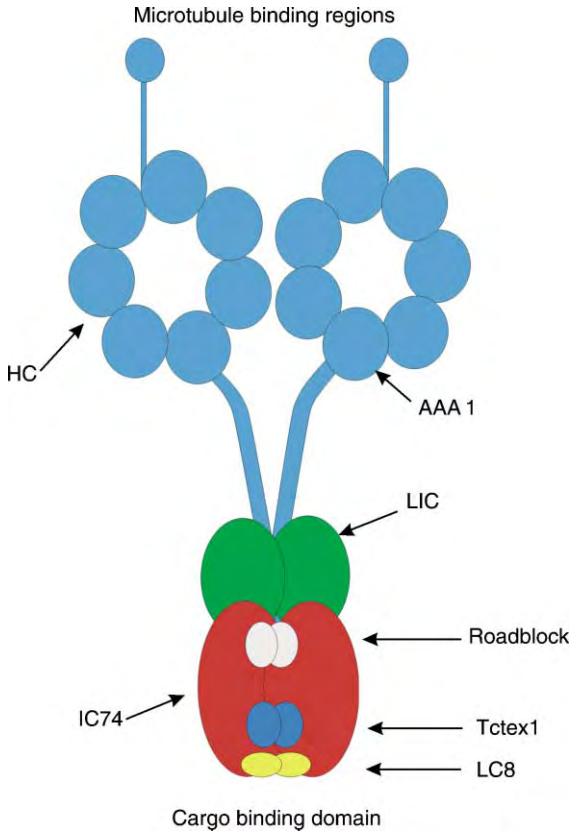

FIGURE 1 Model for the structure of cytoplasmic dynein. The two heavy chains, in light blue, have heads with six to seven lobes. A microtubule binding stalk projects from each head, and the N-terminal stem binds the light intermediate chains (LIC) and the intermediate chains (IC74). The three light chains bind the intermediate chain. The smaller subunits define the cargo-binding domain.

splicing. The heavy chain dimerization domain is a large portion of its N terminus. Also in this region are the overlapping binding sites for the light intermediate chains and the intermediate chains.

The intermediate chains play an important scaffold role in the structure of the cytoplasmic dynein complex. In addition to binding the heavy chains, the intermediate chain binds the three light chain families. It also binds other proteins including the p150 subunit of dynactin, a protein that links dynein to its cargo. The intermediate chain has seven WD domains at its C terminus, which are necessary for binding to the heavy chain. The intermediate chain N terminus is a region predicted to form a coiled coil followed by the alternative splicing regions. The binding site for the dynactin subunit, p150 contains the N-terminal coiled coil region and the next ~60 amino acids. The Tctex1 and LC8 light chains bind the intermediate chain N terminus near to the alternative splicing region, while the Roadblock light chain binds near the first of the WD domains.

Cytoplasmic dyneins have many functions in cells, including transporting many organelles. They are important for maintaining Golgi position near the centrosome, for endosome movement, and for nuclear migration. During mitosis, they assist in the assembly of spindle poles, are used by kinetochore to move along microtubules, and generate pulling forces from the cell cortex to separate the spindle poles. In axons, cytoplasmic dynein is essential for retrograde membrane-bounded organelle transport in fast transport and for the movement of microtubules and neurofilaments. Several viruses including Adenovirus, Herpes, and HIV also utilize cytoplasmic dynein to move along microtubules during the infection process. The cytoplasmic dynein cargo-binding domain is made up of the intermediate chains, light intermediate chains, and the three light chain families. The best-characterized protein responsible for linking dynein to cargo is the dynactin complex, it is important for dynein binding to kinetochores and most membrane-bounded organelles. Dynactin also increases the processivity of cytoplasmic dynein, the distance dynein travels along a microtubule before detaching. Cytoplasmic dynein binds liposomes, artificial lipid membranes, so it may bind directly to some membranes. Cytoplasmic dynein also transports individual proteins, which bind directly to the intermediate chains, light intermediate chains, or the light chains.

The cytoplasmic dynein heavy chain, light intermediate chain, and intermediate chain subunits are phosphorylated *in vivo*. Light intermediate chain phosphorylation is correlated with cell-cycle regulation of dynein binding to membrane-bounded organelles. Intermediate chain phosphorylation regulates dynein binding to the p150 subunit of dynactin.

In yeast deletion mutations of dynein subunits are not lethal, but mitosis is disrupted. Deletion of the cytoplasmic dynein heavy chain is lethal in multicellular organisms such as mouse and *Drosophila*. Non-lethal mutations of cytoplasmic dynein heavy and light chains lead to axonal pathfinding defects and other pleotrophic developmental defects in *Drosophila*, and mutations in the mouse heavy chain result in age-dependent progressive degeneration of motor neurons. Cytoplasmic dynein also binds to and is modulated by the lissencephaly disease protein, Lis1. Lissencephaly is characterized by defects in the organization of the cortical regions of the mammalian brain.

Flagellar Dyneins

Dyneins are the motor proteins that drive the bending of cilia and flagella. The flagellar dyneins are attached to the outer doublet microtubules of axonemes and generate the sliding force between neighboring outer doublet microtubules that is the basis for the propulsive bending of flagella that move cells through fluids.

The base of a flagellar dynein binds to one of the axonemal outer doublet microtubules, the A microtubule. The dynein head binds to the B microtubule of the neighboring outer doublet in an ATP-sensitive manner and utilizes the hydrolysis of ATP to push the B microtubule toward the tip of the axoneme. The arms are arranged in two rows along the microtubules, the outer and inner arms, and the dyneins in each row are different and have different functions. The outer arms specify the flagellar beat frequency and the inner arms specify waveform. While *Chlamydomonas* has fourteen flagellar dynein heavy chain genes, eight different flagellar dynein complexes have been purified from their flagella to date. There is one outer arm dynein complex and at least seven different inner arm complexes (Table II).

Outer Arm Dynein

The *Chlamydomonas* outer arm dynein is a heterotrimer of three different heavy chains, however in some species, such as sea urchin, the outer arm is a heterodimer. The outer arm dynein also has two different intermediate chains, and eight light chains. Outer arm dynein binds to the microtubule through the outer arm docking complex. The outer arm dynein light chains are well characterized. LC1 is a member of a leucine-rich repeat family, and unlike the other light chains, it binds to the motor domain of the gamma heavy chain, not to its N terminus. LC3 and LC5, are thioredoxin homologues. LC4 is involved in the regulation of dynein by Ca^{+2}. LC6 and LC8 are members of the LC8 family. There is also a roadblock light chain, LC7, and LC2 is Tctex2. Although they bind to different cargo, the intermediate chain and light chain subunits, which make up the cargo-binding domains of cytoplasmic dynein and outer arm dynein are closely related. The C termini of the intermediate chains, the region, which interacts with the heavy chains, are conserved between outer arm and cytoplasmic dynein complexes. However, the N termini of outer arm and cytoplasmic dynein are different and are thought to allow the binding to the different cargo. Both cytoplasmic dynein and outer arm dynein have light chains that are members of the Tctex family. The two complexes also have roadblock light chains and share identical LC8 light chains. LC8 is also a component of the two-headed inner arm dynein, and is thus associated with all dynein complexes that have more than one heavy chain.

Inner Arm Dynein

The inner arm dyneins are very heterogeneous (Table II). Inner arm dynein 1 has two different heavy chains, three different intermediate chains, and three light chains, including Tctex1 and LC8, both of which are also components of cytoplasmic dynein. The other six inner arm dyneins are organized into two groups. Each of the six dyneins has a single unique heavy chain and the heavy chains associate with two different sets of light chains. Three inner arm dynein heavy chains associate with actin and p28. The other three heavy chains associate with actin, an actin-related protein, and centrin. The functional significance the association of actin with these dyneins is unknown.

To convert from dynein-driven microtubule sliding to flagellar bending, the flagellar dyneins must be regulated. During flagellar bending, only a subset of the flagellar dyneins function at a time. The phosphorylation state of the inner arm dynein intermediate chain IC138 modulates this regulation. Genetic analysis has also identified several proteins that make up a dynein-regulatory complex, though the mechanism of the complex remains unknown.

Intraflagellar Transport Dynein

The intraflagellar transport dynein is encoded by a single unique heavy chain. To date a unique light intermediate chain is the only identified accessory subunit which binds to this heavy chain. This dynein moves protein complexes from the flagellar tip to the base in the space between the outer double microtubules and the flagellar membrane. It is most closely related to the cytoplasmic dynein heavy chain.

Biography

K. Kevin Pfister is an Associate Professor of Cell Biology at the University of Virginia School of Medicine. His current major research interest is the function of cytoplasmic dynein in axonal transport. His lab characterized the cytoplasmic dynein intermediate chains, and with Dr. S. King identified the cytoplasmic dynein light chains. He earned a Ph.D. from Princeton University and served as a postdoctoral fellow at the University of Texas Southwestern Medical Center.

Editors-in-Chief

William J. Lennarz

State University of New York at Stony Brook, Stony Brook, New York, USA

Section: Lipids, Carbohydrates, Membranes and Membrane Proteins

WILLIAM J. LENNARZ received his B.S. in Chemistry from Pennsylvania State University and a Ph.D. in Organic Chemistry from the University of Illinois. Subsequently he carried out postdoctoral work at Harvard with Konrad Bloch on fatty acid biosynthesis. In 1962 he was appointed Assistant Professor at Johns Hopkins in the Department of Physiological Chemistry. After promotion to Associate Professor in 1967, and full Professor in 1971, he remained at Hopkins until 1983. At that time, he was appointed Robert A. Welch Professor and Chair of the Department of Biochemistry and Molecular Biology at the University of Texas Cancer Center, M.D. Anderson Hospital. In 1989 he became a Leading Professor and Chair of the Department of Biochemistry and Cell Biology at SUNY at Stony Brook. In 1990 he founded and became Director of the Institute for Cell and Developmental Biology at Stony Brook.

Dr. Lennarz has served on many national and international committees. He has served as President of the Biochemistry Chairman's Organization, President of the American Society for Biochemistry and Molecular Biology and President of the Society for Glycobiology. He was a member of the Executive Committee of the International Union of Biochemistry and Molecular Biology for almost a decade.

He has presented special lectures at the University of Notre Dame, the NIH, the University of West Virginia, Johns Hopkins University, Florida State University, the University of California at San Diego, the University of Arkansas, Indiana University and the Medical College of Virginia.

He is a member of the National Academy of Sciences. The focus of his early work was on lipids and bacterial cell surfaces. More recent efforts have been in the structure, biosynthesis and function of cell surface glycoproteins. The biosynthesis studies initially were carried out in liver and oviduct, but these efforts now are focused in yeast. The functional studies have concentrated on the role of cell surface glycoproteins in fertilization and early development in the sea urchin and, more recently, the frog. For over 30 years Dr. Lennarz' research has been supported by federal sources, primarily the National Institutes of Health. Recently he was appointed Distinguished Professor and Chair of his department.

M. Daniel Lane

The Johns Hopkins University, School of Medicine, Baltimore, Maryland, USA

Section: Metabolism, Vitamins and Hormones

M. DANIEL LANE received B.S. and M.S. degrees in 1951 and 1953 from Iowa State University and a Ph.D. in 1956 from the University of Illinois. He was a Senior Postdoctoral Fellow with Professor Feodor Lynen at the Max-Planck Institute Fur Zellchemie in Munich. Following faculty positions at Virginia Polytechnic Institute and New York University School of Medicine, he joined the faculty at the Johns Hopkins University School of Medicine in 1969 and served as DeLamar Professor and Director of the Department of Biological Chemistry from 1978 to 1997. He is presently Distinguished Service Professor at Johns Hopkins. In 2002 he received an honorary degree, Doctor of Humane Letters, from Iowa State University.

Dr. Lane was elected to membership in the National Academy of Sciences (in 1987) and was elected as a Fellow of the American Academy of Arts and Sciences (in 1982) and of the American Society of Nutritional Sciences (in 1996). He received the Mead Johnson Award from the American Society for Nutritional Sciences in 1966 for his research on biotin-dependent enzymes and in 1981, the William C. Rose Award from the American Society for Biochemistry and Molecular Biology for his work on the insulin receptor. In 1990–1991 Lane served as President of the American Society of Biochemistry and Molecular Biology. He has presented many named lectureships (including the

Feodor Lynen Lecture in Germany in 1999) and served on numerous editorial boards including the Journal of Biological Chemistry and the Annual Reviews of Biochemistry. Currently he is Associate Editor for Biochemical and Biophysical Research Communications.

Dr. Lane has published 280 research papers in major scientific journals. His early work focused on various enzymatic CO_2 fixation reactions, notably the mechanisms by which the B-vitamin, biotin, functions in enzymes to catalyze carboxylation. Dr. Lane's work on the regulation of acetyl-CoA carboxylase, the key regulatory enzyme of fatty acid synthesis, led him to his present interests which are to understand the basic mechanisms of lipogenesis, adipogenesis and the consequence of aberrations in these processes, most notably obesity. Research currently underway in his laboratory focuses on: (1) the genes that signal stem cell "commitment" to the adipocyte lineage and subsequent differentiation into adipocytes, and (2) the mechanisms by which the region of the brain, known as the hypothalamus, monitors and controls the drive to eat.

Associate Editors

Ernesto Carafoli

Università degli Studi di Padova, Padova, Italy
Section: Bioenergetics

ERNESTO CARAFOLI earned his M.D. degree at the University of Modena in Italy in 1957. After postdoctoral studies in the Laboratory of Albert L. Lehninger at Johns Hopkins University in the mid 1960s he returned to his home institution in Italy where he worked until 1973, when he was appointed Professor of Biochemistry at the Swiss Federal Institute of Technology (ETH) in Zurich. He returned to Italy in 1998 as a Professor of Biochemistry at the University of Padova, where he now also directs the newly founded Venetian Institute of Molecular Medicine (VIMM).

Dr. Carafoli became interested in calcium as a signaling agent during his post-doctoral days at Johns Hopkins. When he arrived there his main interests were in mitochondrial bioenergetics and it was thus natural for him to expand them to the newly discovered area of mitochondrial calcium transport. He was involved in most of the early discoveries in the field, and he continued to work on mitochondria and calcium after his return to Italy and until he moved to the ETH. There his interests still remained focused on calcium, but the emphasis shifted to the proteins that transport it across membranes and to those that process its signal. His favorite object of study became the calcium pumps, especially that of the plasma membrane, an enzyme which is essential to the regulation of calcium homeostasis and thus to the well being of cells. His contributions on the enzyme, especially after he purified it in 1979, have helped establishing most of its properties and have clarified important problems of mechanism, regulation and structure.

Dr. Carafoli has authored or co-authored about 450 peer-reviewed articles and reviews, and has edited or co-edited about 20 books. He has served on the Editorial or Advisory Boards of several periodicals and has organized about 30 International Workshops and Symposia. He has been featured as a plenary or honorary lecturer at numerous events ranging from specialized Workshops to International Symposia and Congresses. Dr. Carafoli's honors and awards include several international prizes and medals, memberships in several Academies, and three honorary degrees.

Don W. Cleveland

University of California, San Diego, La Jolla, CA, USA
Section: Cell Architecture and Function

DON W. CLEVELAND has been a longstanding contributor to the elucidation of regulation of assembly of mitotic spindles and chromosome movement and how errors in these contribute to the chromosome loss characteristic of human tumors. He discovered the tubulin gene families encoding the major subunits of microtubules and the first mammalian example of control of gene expression through regulated RNA instability. He identified components required for microtubule nucleation and anchoring during spindle assembly. He identified the first human centromeric protein (CENP-B). He then discovered CENP-E, the centromere-associated, microtubule-motor that he showed to be essential for chromosome attachment and for activation and silencing of the mitotic checkpoint, the cell cycle control mechanism that prevents errors of chromosome segregation in mitosis.

Dr. Cleveland has also been a leading force in dissecting the disease mechanism for major human neurodegenerative disorders. He initially purified and characterized tau, the microtubule-associated protein that assembles aberrantly in human dementias including Alzheimer's disease and Pick's disease. He established that the extreme asymmetry of neurons acquired during development is achieved with a deformable array of interlinked neurofilaments, microtubules and actin. He showed that disorganization of neurofilament arrays caused selective death of motor neurons in mice and humans. He also demonstrated that neuronal death could also arise by a toxicity of mutant superoxide dismutase unrelated to its normal activity, thereby uncovering the mechanism underlying the major genetic form of amyotrophic lateral sclerosis. He showed that this toxicity could be

sharply ameliorated by lowering the content of neurofilaments.

Dr. Cleveland is currently Head, Laboratory for Cell Biology in the Ludwig Institute for Cancer Research and Professor of Medicine, Neurosciences and Cellular and Molecular Medicine at the University of California at San Diego. He is also the Editor of the Journal of Cell Biology and Current Opinion in Cell Biology.

Jack E. Dixon

University of California, San Diego School of Medicine,
La Jolla, CA, USA
Section: Protein/Enzyme Structure, Function, and Degradation

JACK E. DIXON earned his Ph.D. in Chemistry at the University of California, Santa Barbara in 1971 and did his postdoctoral training in Biochemistry at the University of California, San Diego.

Dr. Dixon is a pioneer and leader in the structure and function of the protein tyrosine phosphatases (PTPases). He demonstrated that the unique catalytic mechanism of the PTPases proceeds via a novel cysteine-phosphate intermediate. He discovered the first dual-specificity phosphatase, which led to the identification of the cell cycle protein, $p80^{cdc25}$, as a phosphatase. He also showed that the bacteria responsible for the plague or "black death" harbor the most active PTPase ever described. He and his colleagues went on to demonstrate that this PTPase gene product is essential for the pathogenesis of the bacteria. Dr. Dixon and his colleagues determined X-ray structures for both tyrosine and dual specificity phosphatases. Dr. Dixon also found that sequences outside of the PTPase catalytic domain could function to direct the subcellular localization of the PTPases and to restrict their substrate specificity. This is now a widely acknowledged regulatory paradigm for the PTPases. Recently, his laboratory demonstrated that the tumor suppressor gene, PTEN, which shares sequence identity with the PTPases, catalyzes the dephosphorylation of a lipid second messenger, phosphatidylinositol 3,4,5-trisphosphate (PIP3). This represents the first example of a PTPase dephosphorylating a lipid second messenger. PIP3 activates the protein kinase, AKT, which plays a critical role in controlling the balance between apoptosis and cell survival. The loss of the PTEN gene elevates PIP3 levels leading to constitutive activation by AKT and oncogenesis. Recently, Dr. Dixon in collaboration with Nikola Pavletich determined the X-ray structure of PTEN. Their structure–function studies explain the PIP3 substrate specificity of PTEN and also provide a rationale for many of the mutations seen in human cancers. Earlier in his career, Dr. Dixon adopted the tools of molecular biology as they became available in the 1970s, and his laboratory was among the first to use synthetic oligonucleotides to isolate and extensively characterize cDNAs encoding peptide hormones.

Dr. Dixon is Professor of Pharmacology, Cellular and Molecular Medicine and Chemistry and Biochemistry and Dean of Scientific Affairs at the University of California, San Diego. He is a member of the National Academy of Sciences, the Institute of Medicine and the American Academy of Arts and Sciences. Dr. Dixon was the recipient of the 2003 William C. Rose Award from the American Society for Biochemistry and Molecular Biology.

John H. Exton

Howard Hughes Medical Institute, Vanderbilt University School of Medicine, Nashvillie, TN, USA
Section: Signaling

JOHN H. EXTON was born and educated in New Zealand where he received his medical training and a Ph.D. in Biochemistry from the University of Otago in 1963. He did postdoctoral work at Vanderbilt University under Charles R. Park and Earl W. Sutherland, and became an Investigator of the Howard Hughes Medical Institute in 1968 and Professor of Physiology in 1970. He is presently Professor of Molecular Physiology and Biophysics, Professor of Pharmacology and a Hughes Investigator at Vanderbilt.

Dr. Exton's research initially focused on the changes in carbohydrate metabolism in liver during diabetes and treatment with various hormones using the perfused rat liver as the experimental system. His work concentrated on gluconeogenesis and identified the enzymatic reactions that were under control by insulin, epinephrine (adrenaline), glucagon and glucocorticoids, and demonstrated the importance of cyclic AMP in the regulation of these reactions. The role played by the supply of substrates, especially of alanine, was also shown.

Dr. Exton then turned his attention to the action of epinephrine (adrenaline) and demonstrated that many of its actions were not mediated by cyclic AMP but by calcium ions. This led to study of the breakdown of inositol phospholipids by phospholipase C that underlay the increase in calcium. Later this resulted in the discovery of G_q, a novel G protein that activated phospholipase C. Further studies demonstrated that agonists caused the breakdown of another phospholipid (phosphatidylcholine) by another phospholipase (phospholipase D). Current work is focused on the physiological role of phospholipase D.

Dr. Exton has authored over 350 scientific articles and is presently an Associate Editor of the Journal of Biological Chemistry. He has served on many scientific review groups and as a reviewer for many journals. He has won numerous awards, most notably the Lilly

Award of the American Diabetes Association, Fellow of the American Association for the Advancement of Science and election to membership in the National Academy of Sciences.

Paul Modrich

Duke University Medical Center, Durham, NC, USA
Section: Molecular Biology

PAUL MODRICH is an Investigator of the Howard Hughes Medical Institute and James B. Duke Professor of Biochemistry at Duke University Medical Center. He received his undergraduate degree from M.I.T. and his Ph.D. in Biochemistry from Stanford University. His current research addresses the mechanisms of DNA repair. He has served on the editorial boards of the Journal of Biological Chemistry, Biochemistry, Proceedings of the National Academy of Sciences, and DNA Repair. His honors include election to National Academy of Sciences and the Institute of Medicine, the Pfizer Award in Enzyme Chemistry, the General Motors Mott Prize in Cancer Research, and the Pasarow Foundation Award in Cancer Research.

Preface

Biological Chemistry is defined as the chemistry of the compounds and processes that constitute living organisms. The ultimate goal, of course, is to understand and define biology at a mechanistic level. This was aptly stated in an historical treatise on the founding of the *Journal of Biological Chemistry*, where John Edsall quoted a statement in a letter from J. L. Loeb (in Berkeley), "The future of biology lies with those who attack its problems from a chemical point of view." What was an emerging field in 1900 with its origins in physiology, nutrition and chemistry has broadened and expanded to include numerous other fields including mechanistic enzymology, molecular biology, structural biology, cell biology, genomics, proteomics, bioinformatics, metabolomics and others, that were not defined as discrete fields at that time.

Modern biochemistry (biological chemistry) began with the accidental discovery by Eduard Buchner in 1897 that a cell-free yeast extract could carry out fermentation of glucose to alcohol and CO_2 *in the absence of intact cells*. He named the dissolved substance responsible for this process zymase, the substance(s) we now refer to as enzymes. Importantly, Buchner recognized the significance of his discovery. This ended the dogma of the time, perpetuated by Pasteur, the concept of *vitalism*; i.e., that fermentation (and presumably other complex biological phenomena) required the action of intact cells. Thus, serendipity and a prepared mind ushered in a new era of discovery. Now it became possible to dissect complex physiological processes and to study them with preparations free of the constraints of intact cells. Once a metabolic pathway/process was established, it became possible to purify the enzymes, cofactors and substrates involved, to reconstitute the process with purified components and to characterize the components chemically. What followed was an information explosion in the field of biochemistry and progression through a series of trends, each "in vogue" in its time. The identification of the dietary essentials, the hunt for the vitamins/cofactors, the hormones, identification of metabolic pathways and the enzymes involved, oxidative phosphorylation, protein synthesis, molecular biology—each developed as a primary focus.

The need to associate chemistry with function came early and was evident in the naming of departments and journals. Over time names changed from Agricultural Chemistry to Physiological Chemistry to Biochemistry to Biological Chemistry. An example is the Department of Biochemistry at the University of Wisconsin, which began in 1883 as the Department of Agricultural Chemistry.

Where are we headed? We have reached the point where the borders of these areas have become blurred. What constitutes cell biology, molecular biology/genetics, developmental biology, physiology, immunology—ultimately reduces to chemistry. To understand these processes we must know what the molecules are and understand how they interact, i.e. the basic chemistry. That is what this encyclopedia is about.

The breadth of content of this encyclopedia aims to cover major topics of modern biochemistry, each authored by an expert in the area. We feel that the coverage is broad and we have been inclusive in choice of topics. The encyclopedia is a reference work encompassing four volumes containing over 500 articles with more than 750 authors or coauthors. Each article/topic covers an important area of the field which reflects the point of view of the authors. Together the articles cover virtually every aspect of biology for which we have "mechanistic" information. For those who wish to probe more deeply into a topic, references to further readings are included at the end of each article. The editorial board that made decisions on coverage consists of seven members, each an expert representing a major area in the field of biochemistry. A dedicated effort was made to provide coverage that is as complete as possible. The content is presented at a level that we hope will be interpretable to interested individuals with some background in chemistry and biology. It is intended for such individuals rather than specialists with extensive scientific backgrounds in specific areas. It is aimed at the generalist as opposed to the specialist.

Finally, we would like to single out Gail Rice and Dr. Noelle Gracy for their enormous contribution in putting this encyclopedia together. They, in fact, were a driving force that brought this major work to completion.

Notes on the Subject Index

Abbreviations used in subentries without explanation:

CoA	coenzyme A
DAG	diacylglycerol
ELISA	enzyme-linked immunosorbent assay
ERK	extracellular-signal regulated kinase
GlcNAC	N-Acetylglucosamine
HPLC	high-pressure liquid chromatography
IP_3	inositol 1,4,5-triphosphate
MAP	mitogen-activated protein
MMP	matrix metalloproteinase
mtDNA	mitochondrial DNA
NADPH	nicotinamide-adenine dinucleotide phosphate
PFK-2/ FBPase-2	6-phosphofructo-2-kinase/fructose-2,6-bisphosphatase
PI3K	phosphatidylinositol 3-kinase
PIP_2	phosphatidylinositol 4,5-bisphosphate
PIP_3	phosphatidylinositol-3,4,5-triphosphate
PPAR	peroxisome proliferator-activated receptor
RPLC	reversed-phase high-performance liquid chromatography

Volume 1

ABC Transporters, Pages 1-5, Andre Goffeau, Benoit De Hertogh and Philippe V. Baret

Abscisic Acid (ABA), Pages 6-11, Ramanjulu Sunkar and Jian-Kang Zhu

Actin Assembly/Disassembly, Pages 12-18, Henry N. Higgs

Actin-Capping and -Severing Proteins, Pages 19-26, Sankar Maiti and James R. Bamburg

Actin-Related Proteins, Pages 27-33, R. Dyche Mullins

Adenosine Receptors, Pages 34-39, Lauren J. Murphree and Joel Linden

Adenylyl Cyclases, Pages 40-45, Ronald Taussig

Adrenergic Receptors, Pages 46-50, David B. Bylund

Affinity Chromatography, Pages 51-56, Pedro Cuatrecasas and Meir Wilchek

Affinity Tags for Protein Purification, Pages 57-63, Joseph J. Falke and John A. Corbin

A-Kinase Anchoring Proteins, Pages 64-67, Lorene K. Langeberg and John D. Scott

Allosteric Regulation, Pages 68-73, Barry S. Cooperman

Alternative Splicing: Regulation of Fibroblast Growth Factor Receptor (FGFR), Pages 74-77, Mariano A. Garcia-Blanco

Alternative Splicing: Regulation of Sex Determination in Drosophila melanogaster, Pages 78-84, Jill K. M. Penn, Patricia Graham and Paul Schedl

Amine Oxidases, Pages 85-89, Giovanni Floris and Alessandro Finazzi Agro

Amino Acid Metabolism, Pages 90-95, Luc Cynober

Aminopeptidases, Pages 96-98, Ralph A. Bradshaw

Amyloid, Pages 99-104, Ronald Wetzel

Anaplerosis, Pages 105-110, Raymond R. Russell, III and Heinrich Taegtmeyer

Angiotensin Receptors, Pages 111-115, Tadashi Inagami

ara Operon, Pages 116-119, Robert F. Schleif

ARF Family, Pages 120-122, Gustavo Pacheco-Rodriguez, Joel Moss and Martha Vaughan

Aspartic Proteases, Pages 123-127, Ben M. Dunn

ATP Synthesis in Plant Mitochondria: Substrates, Inhibitors, Uncouplers, Pages 128-132, Kathleen L. Soole and R. Ian Menz

ATP Synthesis: Mitochondrial Cyanide-Resistant Terminal Oxidases, Pages 133-137, James N. Siedow

Autophagy in Fungi and Mammals, Pages 138-143, Daniel J. Klionsky and Ju Guan

B12-Containing Enzymes, Pages 145-151, Vahe Bandarian and Rowena G. Matthews

Bax and Bcl2 Cell Death Enhancers and Inhibitors, Pages 152-154, David L. Vaux

B-Cell Antigen Receptor, Pages 155-158, Thomas M. Yankee and Edward A. Clark

Bile Salts and their Metabolism, Pages 159-163, Ulrich Beuers and Thomas Pusl

Biliary Cirrhosis, Primary, Pages 164-169, Marshall M. Kaplan

Bioenergetics: General Definition of Principles, Pages 170-173, David G. Nicholls

Biotin, Pages 174-178, Steven W. Polyak and Anne Chapman-Smith

Biotinylation of Proteins, Pages 179-181, Ronald A. Kohanski

Bradykinin Receptors, Pages 182-185, Ronald M. Burch

Branched-Chain -Ketoacids, Pages 186-191, David T. Chuang

Brassinosteroids, Pages 192-197, Steven D. Clouse

Cadherin Signaling, Pages 199-204, David B. Sacks and Jonathan M. G. Higgins

Cadherin-Mediated Cell-Cell Adhesion, Pages 205-211, Frauke Drees and W. James Nelson

Calcitonin Gene-Related Peptide and Adrenomedullin Receptors, Pages 212-216, Debbie L. Hay, Alex C. Conner and David R. Poyner

Calcitonin Receptor, Pages 217-220, Samia I. Girgis, Niloufar Moradi-Bidhendi, Lucia Mancini and Iain MacIntyre

Calcium Buffering Proteins: Calbindin, Pages 221-225, Willi Hunziker and Igor Bendik

Calcium Buffering Proteins: ER Luminal Proteins, Pages 226-230, Jody Groenendyk and Marek Michalak

Calcium Oscillations, Pages 231-234, Marisa Brini

Calcium Sensing Receptor, Pages 235-240, Jacob Tfelt-Hansen and Edward M. Brown

Calcium Signaling: Calmodulin-Dependent Phosphatase, Pages 241-245, Claude Klee, Hao Ren and Shipeng Li

Calcium Signaling: Cell Cycle, Pages 246-249, Luigia Santella

Calcium Signaling: Motility (Actomyosin-Troponin System), Pages 250-255, Takeyuki Wakabayashi and Setsuro Ebashi

Calcium Signaling: NO Synthase, Pages 256-260, Zhi-Qiang Wang and Dennis J. Stuehr

Calcium Transport in Mitochondria, Pages 261-266, Rosario Rizzuto and Marisa Brini

Calcium Waves, Pages 267-269, Lionel F. Jaffe

Calcium, Biological Fitness of, Pages 270-273, Robert J. P. Williams

Calcium/Calmodulin-Dependent Protein Kinase II, Pages 274-280, Andy Hudmon and Howard Schulman

Calcium/Calmodulin-Dependent Protein Kinases, Pages 281-286, J. Robison and Roger J. Colbran

Calcium-Binding Proteins: Cytosolic (Annexins, Gelsolins, C2-Domain Proteins) , Pages 287-293, Joachim Krebs

Calcium-Modulated Proteins (EF-Hand), Pages 294-299, Robert H. Kretsinger

Calpain, Pages 300-306, Hiroyuki Sorimachi and Yasuko Ono

Carbohydrate Chains: Enzymatic and Chemical Synthesis, Pages 307-313, Thomas J. Tolbert and Chi-Huey Wong

Carnitine and -Oxidation, Pages 314-318, Janos Kerner and Charles L. Hoppel

Caspases and Cell Death, Pages 319-327, Don W. Nicholson, Pierluigi Nicotera and Gerry Melino

Cell Cycle Controls in G1 and G0, Pages 328-331, WengeShi and Steven F. Dowdy

Cell Cycle: Control of Entry and Progression Through S Phase, Pages 332-337, Susan L. Forsburg

Cell Cycle: DNA Damage Checkpoints, Pages 338-344, Jean Y. J. Wang

Cell Cycle: Mitotic Checkpoint, Pages 345-351, Tim J. Yen

Cell Death by Apoptosis and Necrosis, Pages 352-355, Pierluigi Nicotera

Cell Migration, Pages 356-361, J. Victor Small and Emmanuel Vignal

Cell-Matrix Interactions, Pages 362-366, Janet A. Askari and Martin J. Humphries

Centromeres, Pages 367-371, Beth A. Sullivan

Centrosomes and Microtubule Nucleation, Pages 372-376, Reiko Nakajima, Ming-Ying Tsai and Yixian Zheng

c-fes Proto-Oncogene, Pages 377-382, Thomas E. Smithgall and Robert I. Glazer

Chaperones for Metalloproteins, Pages 383-386, Valeria C. Culotta and Edward Luk

Chaperones, Molecular, Pages 387-392, Sue Wickner and Joel R. Hoskins

Chaperonins, Pages 393-398, Arthur L. Horwich, Wayne A. Fenton and George W. Farr

Chemiluminescence and Bioluminescence, Pages 399-404, Thomas O. Baldwin

Chemiosmotic Theory, Pages 405-412, Keith D. Garlid

Chemokine Receptors, Pages 413-418, Ann Richmond and Guo-Huang Fan

Chemolithotrophy, Pages 419-424, Alan B. Hooper

Chemotactic Peptide/Complement Receptors, Pages 425-429, Eric R. Prossnitz and Larry A. Sklar

Chlorophylls and Carotenoids, Pages 430-437, Hugo Scheer

Chloroplast Redox Poise and Signaling, Pages 438-445, John F. Allen

Chloroplasts, Pages 446-450, Nicoletta Rascio

Cholesterol Synthesis, Pages 451-455, Peter A. Edwards

Chromatin Remodeling, Pages 456-463, Eric Kallin and Yi Zhang

Chromatin: Physical Organization, Pages 464-468, Christopher L. Woodcock

Chromosome Organization and Structure, Overview, Pages 469-474, Elena Gracheva and Sarah C. R. Elgin

Coenzyme A, Pages 475-477, M. Daniel Lane

Collagenases, Pages 478-481, Kenn Holmbeck and Henning Birkedal-Hansen

Collagens, Pages 482-487, Darwin J. Prockop

Cyclic AMP Receptors of Dictyostelium, Pages 488-493, Dale Hereld and Peter N. Devreotes

Cyclic GMP Phosphodiesterases, Pages 494-500, Sharron H. Francis and Jackie D. Corbin

Cyclic Nucleotide Phosphodiesterases, Pages 501-505, Vincent C. Manganiello and Eva Degerman

Cyclic Nucleotide-Dependent Protein Kinases, Pages 506-511, Sharron H. Francis and Jackie D. Corbin

Cyclic Nucleotide-Regulated Cation Channels, Pages 512-515, Martin Biel and Franz Hofmann

Cysteine Proteases, Pages 516-520, David J. Buttle and John S. Mort

Cytochrome b6f Complex, Pages 521-527, Gunter A. Hauska and Thomas Schodl

Cytochrome bc1 Complex (Respiratory Chain Complex III), Pages 528-534, Bernard L. Trumpower

Cytochrome c, Pages 535-538, Hans Tuppy and Gunther Kreil

Cytochrome Oxidases, Bacterial, Pages 539-543, Peter Brzezinski and Pia Adelroth

Cytochrome P-450, Pages 544-549, Rita Bernhardt

Cytokines, Pages 550-555, Andrea L. Wurster and Michael J. Grusby

Cytokinesis, Pages 556-561, Masanori Mishima and Michael Glotzer

Cytokinin, Pages 562-567, Thomas Schmulling

Desmosomes and Hemidesmosomes, Pages 569-576, Rachel L. Dusek, Jonathan C. R. Jones and Kathleen J. Green

Detergent Properties, Pages 577-581, Darrell R. McCaslin

Diabetes, Pages 582-592, David W. Cooke

Diacylglycerol Kinases and Phosphatidic Acid Phosphatases, Pages 593-597, Stephen M. Prescott and Matthew K. Topham

Disulfide Bond Formation, Pages 598-602, Hiram F. Gilbert

DNA Base Excision Repair, Pages 603-608, Hilde Nilsen and Tomas Lindahl

DNA Damage: Alkylation, Pages 609-613, Anton B. Guliaev and B. Singer

DNA Glycosylases: Mechanisms, Pages 614-617, Daniel J. Krosky and James T. Stivers

DNA Helicases: Dimeric Enzyme Action, Pages 618-623, Timothy M. Lohman

DNA Helicases: HexamericEnzyme Action, Pages 624-631, Smita S. Patel

DNA Ligases: Mechanism and Functions, Pages 632-636, Alan E. Tomkinson and John B. Leppard

DNA Ligases: Structures, Pages 637-643, C. Kiong Ho, Mark Odell and Dimitar B. Nikolov

DNA Methyltransferases, Bacterial, Pages 644-651, Albert Jeltsch and Richard I. Gumport

DNA Methyltransferases, Structural Themes, Pages 652-659, Sanjay Kumar

DNA Methyltransferases: Eubacterial GATC, Pages 660-664, Martin G. Marinus

DNA Mismatch Repair and Homologous Recombination, Pages 665-670, Ivan Matic and Miroslav Radman

DNA Mismatch Repair and the DNA Damage Response, Pages 671-674, Guo-Min Li and Steven R. Presnell

DNA Mismatch Repair Defects and Cancer, Pages 675-681, Richard D. Kolodner

DNA Mismatch Repair in Bacteria, Pages 682-686, A-Lien Lu

DNA Mismatch Repair in Mammals, Pages 687-690, James T. Drummond

DNA Mismatch Repair: E. coli Vsr and Eukaryotic G-T Systems, Pages 691-693, Margaret Lieb

DNA Oxidation, Pages 694-697, Arthur P. Grollman and Dmitry O. Zharkov

DNA Photolyase, Pages 698-702, Carrie L. Partch and Aziz Sancar

DNA Polymerase, Eukaryotic α, Pages 703-707, Teresa S. -F. Wang

DNA Polymerase, Eukaryotic β, Pages 708-712, William A. Beard and Samuel H. Wilson

DNA Polymerase, Eukaryotic δ, Pages 713-715, Antero G. So and Kathleen M. Downey

DNA Polymerase, Eukaryotic ε, Pages 716-719, Yasuo Kawasaki and Akio Sugino

DNA Polymerase I, Bacterial, Pages 720-725, Catherine M. Joyce

DNA Polymerase II, Bacterial, Pages 726-728, Judith L. Campbell

DNA Polymerase III, Bacterial, Pages 729-733, Hisaji Maki

DNA Polymerases: Kinetics and Mechanism, Pages 734-739, Kenneth A. Johnson

DNA Replication Fork, Bacterial, Pages 740-744, Nancy G. Nossal

DNA Replication Fork, Eukaryotic, Pages 745-748, Lori M. Kelman, Jerard Hurwitz and Zvi Kelman

DNA Replication, Mitochondrial, Pages 749-752, David A. Clayton

DNA Replication: Eukaryotic Origins and the Origin Recognition Complex, Pages 753-760, Melvin L. DePamphilis and Cong-jun Li

DNA Replication: Initiation in Bacteria, Pages 761-766, Jon M. Kaguni

DNA Restriction and Modification: Type I Enzymes, Pages 767-771, David T. F. Dryden

DNA Restriction and Modification: Type II Enzymes, Pages 772-777, Darren M. Gowers and Stephen E. Halford

DNA Restriction and Modification: Type III Enzymes, Pages 778-781, Desirazu N. Rao and S. Srivani

DNA Secondary Structure, Pages 782-787, Albino Bacolla and Robert D. Wells

DNA Sequence Recognition by Proteins, Pages 788-793, Arabela A. Grigorescu and John M. Rosenberg

DNA Supercoiling, Pages 794-797, Tao-shih Hsieh

DNA Topoisomerases: Type I, Pages 798-805, James J. Champoux

DNA Topoisomerases: Type II, Pages 806-811, Renier Velez-Cruz and Neil Osheroff

DNA Topoisomerases: Type III-RecQ Helicase Systems, Pages 812-816, Rodney Rothstein and Erika Shor

Dopamine Receptors, Pages 817-822, Kim A. Neve

Dynactin, Pages 823-826, Trina A. Schroer

Dynein, Pages 827-831, K. Kevin Pfister

Volume 2

EF-G and EF-Tu Structures and Translation Elongation in Bacteria, Pages 1-5, Poul Nissen and Jens Nyborg

Eicosanoid Receptors, Pages 6-9, Richard M. Breyer and Matthew D. Breyer

Elastin, Pages 10-12, Judith Ann Foster

Endocannabinoids, Pages 13-15, Daniele Piomelli

Endocytosis, Pages 16-19, Julie G. Donaldson

Endoplasmic Reticulum-Associated Protein Degradation, Pages 20-23, Maurizio Molinari

Energy Transduction in Anaerobic Prokaryotes, Pages 24-30, Gottfried Unden

Enzyme Inhibitors, Pages 31-37, Vern L. Schramm

Enzyme Kinetics, Pages 38-44, Irwin H. Segel

Enzyme Reaction Mechanisms: Stereochemistry, Pages 45-50, Ming-Daw Tsai, Li Zhao and Brandon J. Lamarche

Epidermal Growth Factor Receptor Family, Pages 51-55, Denis Tvorogov and Graham Carpenter

ER/SR Calcium Pump: Function, Pages 56-60, Giuseppe Inesi

ER/SR Calcium Pump: Structure, Pages 61-65, Chikashi Toyoshima and Yuji Sugita

Exonucleases, Bacterial, Pages 66-72, Susan T. Lovett

F1-F0 ATP Synthase, Pages 73-79, Donata Branca

FAK Family, Pages 80-84, Steven K. Hanks

Fat Mobilization: Perilipin and Hormone-Sensitive Lipase, Pages 85-89, Constantine Londos and Alan R. Kimmel

Fatty Acid Oxidation, Pages 90-94, Horst Schulz

Fatty Acid Receptors, Pages 95-98, Christer Owman and Bjorn Olde

Fatty Acid Synthesis and its Regulation, Pages 99-103, Steven D. Clarke and Manabu T. Nakamura

Ferredoxin, Pages 104-106, Giuliana Zanetti and Vittorio Pandini

Ferredoxin-NADP+ Reductase, Pages 107-111, Giuliana Zanetti and Alessandro Aliverti

Fibroblast Growth Factor Receptors and Cancer-Associated Perturbations, Pages 112-117, Marko Kornmann and Murray Korc

Flavins, Pages 118-122, Barrie Entsch and David P. Ballou

Flippases, Pages 123-127, Charles J. Waechter

Focal Adhesions, Pages 128-133, Eli Zamir and Benjamin Geiger

Free Radicals, Sources and Targets of: Mitochondria, Pages 134-142, Alberto Boveris and Enrique Cadenas

Friedreich's Ataxia, Pages 143-145, Paul E. Hart and Anthony H. V. Schapira

G Protein Signaling Regulators, Pages 147-151, John H. Exton

G Protein-Coupled Receptor Kinases and Arrestins, Pages 152-157, Jeffrey L. Benovic

G12/G13 Family, Pages 158-161, Stefan Offermanns

GABAA Receptor, Pages 162-166, Richard W. Olsen and Gregory W. Sawyer

GABAB Receptor, Pages 167-170, S. J. Enna

Galectins, Pages 171-174, R. Colin Hughes

Genome-Wide Analysis of Gene Expression, Pages 175-180, Karine G. Le Roch and Elizabeth A. Winzeler

Gi Family of Heterotrimeric G Proteins, Pages 181-185, Maurine E. Linder

Giant Mitochondria (Megamitochondria), Pages 186-188, Bernard Tandler and Charles L. Hoppel

GlcNAc Biosynthesis and Function, O-Linked, Pages 189-192, Kaoru Sakabe and Gerald W. Hart

Glucagon Family of Peptides and their Receptors, Pages 193-196, Laurie L. Baggio and Daniel J. Drucker

Gluconeogenesis, Pages 197-203, Richard W. Hanson and Oliver E. Owen

Glucose/Sugar Transport in Bacteria, Pages 204-207, Lan Guan and H. Ronald Kaback

Glucose/Sugar Transport in Mammals, Pages 208-212, Silvia Mora and Jeffrey Pessin

Glutamate Receptors, Ionotropic, Pages 213-219, Derek B. Scott and Michael D. Ehlers

Glutamate Receptors, Metabotropic, Pages 220-223, P. Jeffrey Conn

Glutathione Peroxidases, Pages 224-228, Fulvio Ursini and Matilde Maiorino

Glycation, Pages 229-236, Suzanne R. Thorpe and John W. Baynes

Glycine Receptors, Pages 237-243, Bodo Laube and Heinrich Betz

Glycogen Metabolism, Pages 244-248, Peter J. Roach

Glycogen Storage Diseases, Pages 249-254, George H. Sack, Jr.

Glycogen Synthase Kinase-3, Pages 255-260, James R. Woodgett

Glycolipid-Dependent Adhesion Processes, Pages 261-265, Senitiroh Hakomori

Glycolysis, Overview, Pages 266-271, Robert A. Harris

Glycoprotein Folding and Processing Reactions, Pages 272-276, Armando J. Parodi

Glycoprotein-Mediated Cell Interactions, O-Linked, Pages 277-282, Robert S. Haltiwanger

Glycoproteins, N-Linked, Pages 283-292, Mark A. Lehrman

Glycoproteins, Plant, Pages 293-296, Carolyn J. Schultz

Glycosylation in Cystic Fibrosis, Pages 297-301, Andrew D. Rhim, Thomas F. Scanlin and Mary Catherine Glick

Glycosylation, Congenital Disorders of, Pages 302-307, Hudson H. Freeze

Glycosylphosphatidylinositol (GPI) Anchors, Pages 308-311, Anant K. Menon

Golgi Complex, Pages 312-315, Mark Stamnes

Gq Family, Pages 316-320, Wanling Yang and John D. Hildebrandt

Green Bacteria: Secondary Electron Donor (Cytochromes), Pages 321-324, Hirozo Oh-oka and Robert E. Blankenship

Green Bacteria: The Light-Harvesting Chlorosome, Pages 325-330, John M. Olson

Green Sulfur Bacteria: Reaction Center and Electron Transport, Pages 331-336, Gunter A. Hauska and Thomas Schodl

Gs Family of Heterotrimeric G Proteins, Pages 337-341, Susanne M. Mumby

Heat/Stress Responses, Pages 343-347, Davis T. W. Ng

Hematopoietin Receptors, Pages 348-353, Barbara A. Miller and Joseph Y. Cheung

Heme Proteins, Pages 354-361, Johannes Everse

Heme Synthesis, Pages 362-366, Gloria C. Ferreira

Hepatocyte Growth Factor/Scatter Factor Receptor, Pages 367-371, Selma Pennacchietti and Paolo M. Comoglio

Hexokinases/Glucokinases, Pages 372-377, Emile Van Schaftingen

Histamine Receptors, Pages 378-383, Stephen J. Hill and Jillian G. Baker

HIV Protease, Pages 384-387, Ben M. Dunn

HIV-1 Reverse Transcriptase Structure, Pages 388-392, Kalyan Das, Stefan G. Sarafianos, Eddy Arnold and Stephen H. Hughes

Homologous Recombination in Meiosis, Pages 393-397, Nancy M. Hollingsworth

HPLC Separation of Peptides, Pages 398-403, James D. Pearson

Imaging Methods, Pages 405-410, Gyorgy Szabadkai and Rosario Rizzuto

Immunoglobulin (Fc) Receptors, Pages 411-416, Mark Hogarth

Inorganic Biochemistry, Pages 417-420, Robert J. P. Williams

Inositol Lipid 3-Phosphatases, Pages 421-426, Gregory S. Taylor and Jack E. Dixon

Inositol Phosphate Kinases and Phosphatases, Pages 427-429, Stephen B. Shears

Insulin- and Glucagon-Secreting Cells of the Pancreas, Pages 430-435, Franz M. Matschinsky

Insulin Receptor Family, Pages 436-440, Paul F. Pilch and Jongsoon Lee

Integrin Signaling, Pages 441-445, Lawrence E. Goldfinger and Mark H. Ginsberg

Interferon Receptors, Pages 446-451, Christopher P. Elco and Ganes C. Sen

Intermediate Filament Linker Proteins: Plectin and BPAG1, Pages 452-457, Peter Fuchs and Gerhard Wiche

Intermediate Filaments, Pages 458-464, Kelsie M. Bernot and Pierre A. Coulombe

Intracellular Calcium Channels: cADPR-Modulated (Ryanodine Receptors), Pages 465-468, Antony Galione

Intracellular Calcium Channels: NAADP+-Modulated, Pages 469-472, Armando A. Genazzani and Marcella Debidda

Ion Channel Protein Superfamily, Pages 473-477, William A. Catterall

IP3 Receptors, Pages 478-481, Colin W. TaylorEdward Morris and Paula da Fonseca

Iron-Sulfur Proteins, Pages 482-489, Helmut Beinert

JAK-STAT Signaling Paradigm, Pages 491-496, Edward Cha and Christian Schindler

Keratins and the Skin, Pages 497-504, Pierre A. Coulombe and Kelsie M. Bernot

Ketogenesis, Pages 505-507, Janos Kerner and Charles L. Hoppel

Kinesin Superfamily Proteins, Pages 508-516, Nobutaka Hirokawa and Reiko Takemura

Kinesins as Microtubule Disassembly Enzymes, Pages 517-521, Susan L. Kline-Smith and Arshad Desai

Kinetic Isotope Effects, Pages 522-527, Justine P. Roth and Judith P. Klinman

lac Operon, Pages 529-534, Liskin Swint-Kruse and Kathleen S. Matthews

Lectins, Pages 535-540, Nathan Sharon and Halina Lis

Leptin, Pages 541-545, Thomas W. Gettys

LexA Regulatory System, Pages 546-550, Veronica G. Godoy, Penny J. Beuning and Graham C. Walker

Ligand-Operated Membrane Channels: Calcium (Glutamate), Pages 551-561, Elias K. Michaelis

Ligand-Operated Membrane Channels: GABA, Pages 562-566, F. Minier and Erwin Sigel

Light-Harvesting Complex (LHC) I and II: Pigments and Proteins, Pages 567-570, Stefan Jansson

Lipases, Pages 571-575, Howard L. Brockman

Lipid Bilayer Structure, Pages 576-579, Erwin London

Lipid Modification of Proteins: Targeting to Membranes, Pages 580-583, Marilyn D. Resh

Lipid Rafts, Pages 584-587, Deborah A. Brown

Lipoproteins, HDL/LDL, Pages 588-593, Fayanne E. Thorngate and David L. Williams

Low Barrier Hydrogen Bonds, Pages 594-598, Perry A. Frey

Luft's Disease, Pages 599-601, Salvatore DiMauro

Lysophospholipid Receptors, Pages 602-604, Gabor J. Tigyi

MDR Membrane Proteins, Pages 605-609, Nathan C. Rockwell

Meiosis, Pages 610-616, Neil Hunter

Melanocortin System, Pages 617-620, Roger D. Cone

Membrane Fusion, Pages 621-626, Joshua Zimmerberg and Leonid V. Chernomordik

Membrane Transport, General Concepts, Pages 627-630, Stanley G. Schultz

Membrane Transporters:Na+/Ca2+ Exchangers, Pages 631-636, Jonathan Lytton

Membrane-Associated Energy Transduction in Bacteria and Archaea, Pages 637-645, Gunter Schafer

Metabolite Channeling: Creatine Kinase Microcompartments, Pages 646-651, Uwe Schlattner and Theo Wallimann

Metalloproteases, Pages 652-656, David S. Auld

Metalloproteinases, Matrix, Pages 657-665, Hideaki Nagase and Gillian Murphy

Metaphase Chromosome, Pages 666-671, Sharron Vass and Margarete M. S. Heck

Methyl-CpG-Binding Proteins, Pages 672-675, David G. Skalnik

Microtubule-Associated Proteins, Pages 676-682, Nobutaka Hirokawa and Reiko Takemura

Mitochondrial Auto-Antibodies, Pages 683-688, Harold Baum

Mitochondrial Channels, Pages 689-692, M. Catia Sorgato and Alessandro Bertoli

Mitochondrial DNA, Pages 693-696, Gottfried Schatz

Mitochondrial Genes and their Expression: Yeast, Pages 697-702, Piotr P. Slonimski and Giovanna Carignani

Mitochondrial Genome, Evolution, Pages 703-708, B. Franz Lang, Dennis V. Lavrov and Gertraud Burger

Mitochondrial Genome, Overview, Pages 709-715, Douglas C. Wallace

Mitochondrial Inheritance, Pages 716-719, Eric A. Shoubridge

Mitochondrial Membranes, Structural Organization, Pages 720-724, Carmen A. Mannella

Mitochondrial Metabolite Transporter Family, Pages 725-732, Ferdinando Palmieri and Martin Klingenberg

Mitochondrial Outer Membrane and the VDAC Channel, Pages 733-736, Marco Colombini

Mitogen-Activated Protein Kinase Family, Pages 737-742, Hidemi Teramoto and J. Silvio Gutkind

Mitosis, Pages 743-747, Patricia Wadsworth and Nasser M. Rusan

mRNA Polyadenylation in Eukaryotes, Pages 748-752, Mary Edmonds

mRNA Processing and Degradation in Bacteria, Pages 753-757, Deborah A. Steege

Mucin Family of Glycoproteins, Pages 758-764, Juan Perez-Vilar and Robert L. Hill

Mucins in Embryo Implantation, Pages 765-769, Daniel D. Carson

Multiple Sequence Alignment and Phylogenetic Trees, Pages 770-774, Russell F. Doolittle

Muscarinic Acetylcholine Receptors, Pages 775-777, Neil M. Nathanson

Myosin Motors, Pages 778-781, Roy E. Larson

Volume 3

Natriuretic Peptides and their Receptors, Pages 1-5, Lincoln R. Potter

N-End Rule, Pages 6-10, Alexander Varshavsky

Neoglycoproteins, Pages 11-15, Y. C. Lee and Reiko T. Lee

Neuronal Calcium Signal, Pages 16-20, Hilmar Bading

Neuronal Intermediate Filaments, Pages 21-25, Ronald K. H. Liem

Neuropeptide Y Receptors, Pages 26-31, Eric M. Parker

Neurotensin Receptors, Pages 32-36, William Rostene, Patrick Kitabgi and Didier Pelaprat

Neurotransmitter Transporters, Pages 37-40, Aurelio Galli, Randy D. Blakely and Louis J. DeFelice

Neurotrophin Receptor Signaling, Pages 41-45, Jennifer J. Gentry and Bruce D. Carter

Nicotinamide Nucleotide Transhydrogenase, Pages 50-56, Jan Rydstrom

Nicotinic Acetylcholine Receptors, Pages 57-61, Nivalda O. Rodrigues-Pinguet and Henry A. Lester

Nitric Oxide Signaling, Pages 62-65, Michael A. Marletta

N-Linked Glycan Processing Glucosidases and Mannosidases, Pages 46-49, Linda O. Tremblay and Annette Herscovics

Non-Homologous End Joining, Pages 66-70, Penny A. Jeggo

Nonhomologous Recombination: Bacterial Transposons, Pages 71-79, Bao Ton Hoang and Michael G. Chandler

Nonhomologous Recombination: Retrotransposons, Pages 80-86, Siew Loon Ooi and Jef D. Boeke

Nuclear Compartmentalization, Pages 87-91, Kelly P. Smith and Jeanne B. Lawrence

Nuclear Envelope and Lamins, Pages 92-95, Bryce M. Paschal

Nuclear Factor kappaB, Pages 96-99, Thomas D. Gilmore

Nuclear Genes in Mitochondrial Function and Biogenesis, Pages 100-104, Alexander Tzagoloff and Carol L. Dieckmann

Nuclear Organization, Chromatin Structure, and Gene Silencing , Pages 105-108, Lori L. Wallrath, John R. Danzer, Oya Yazgan and Pamela K. Geyer

Nuclear Pores and Nuclear Import/Export, Pages 109-114, Anita H. Corbett

Nucleoid Organization of Bacterial Chromosomes, Pages 115-118, Charles J. Dorman

Nucleolus, Overview, Pages 119-122, Thoru Pederson

Nucleotide Excision Repair and Human Disease, Pages 123-129, James E. Cleaver

Nucleotide Excision Repair in Eukaryotes, Pages 130-133, Laura A. Lindsey-Boltz and Aziz Sancar

Nucleotide Excision Repair, Bacterial: The UvrABCD System, Pages 134-142, Bennett Van Houten and Lawrence Grossman

Nucleotide Excision Repair: Biology, Pages 143-147, Errol C. Friedberg

Olfactory Receptors, Pages 149-154, Sigrun I. Korsching

Oligosaccharide Analysis by Mass Spectrometry, Pages 155-160, Andrew J. Hanneman and Vernon N. Reinhold

Oligosaccharide Chains: Free, N-Linked, O-Linked, Pages 161-164, Tadashi Suzuki

Oncocytes, Pages 165-166, Bernard Tandler and Charles L. Hoppel

Opioid Receptors, Pages 167-171, P. Y. Law and Horace H. Loh

Ornithine Cycle, Pages 172-177, Malcolm Watford

Oxygenases, Pages 178-182, Osamu Hayaishi

P2X Purinergic Receptors, Pages 183-187, Annmarie Surprenant

P2Y Purinergic Receptors, Pages 188-191, George R. Dubyak

p53 Protein, Pages 192-195, Jamie Hearnes and Jennifer Pietenpol

p70 S6 Kinase/mTOR, Pages 196-200, Christopher G. Proud

Parathyroid Hormone/Parathyroid Hormone-Related Protein Receptor, Pages 201-207, Thomas J. Gardella

PCR (Polymerase Chain Reaction), Pages 208-210, Michael J. Brownstein

Pentose Phosphate (Hexose Mono Phosphate) Pathway, Pages 211-215, Bernard R. Landau

Pentose Phosphate Pathway, History of, Pages 216-225, John F. Williams

Peptide Amidation, Pages 226-230, Mark J. Niciu, Richard E. Mains and Betty A. Eipper

Periplasmic Electron Transport Systems in Bacteria, Pages 231-238, David J. Richardson, Gary Sawers and Rob J. M. Van Spanning

Peroxisome Proliferator-Activated Receptors, Pages 239-245, Mary C. Sugden, Edward A. Sugden and Mark J. Holness

Peroxisomes, Pages 246-250, Suresh Subramani

Phage Display for Protein Binding, Pages 251-255, Henry B. Lowman

Pheromone Receptors (Yeast), Pages 256-261, James B. Konopka and Jeremy W. Thorner

PHO Regulon, Pages 262-265, Bengt L. Persson

Phosphatidylinositol Bisphosphate and Trisphosphate, Pages 266-271, Alex Toker

Phosphatidylinositol-3-Phosphate, Pages 272-276, Joseph V. Virbasius and Michael P. Czech

Phosphofructokinase-2/Fructose Bisphosphatase-2, Pages 277-280, Daniel M. Raben

Phosphoinositide 3-Kinase, Pages 281-286, Khatereh Ahmadi and Michael Waterfield

Phosphoinositide 4- and 5-Kinases and Phosphatases, Pages 287-291, Shawn F. Bairstow, Matthew W. Bunce and Richard A. Anderson

Phosphoinositide-Dependent Protein Kinases, Pages 292-296, Nick R. Leslie and C. Peter Downes

Phospholipase A2, Pages 297-300, Timothy R. Smith and Edward A. Dennis

Phospholipase C, Pages 301-305, Fujio Sekiya, Yeun Ju Kim and Sue Goo Rhee

Phospholipase D, Pages 306-313, Mary M. LaLonde and Michael A. Frohman

Phospholipid Metabolism in Mammals, Pages 314-320, Claudia Kent

Phospholipid Synthesis in Yeast, Pages 321-325, Gil-Soo Han and George M. Carman

Photoreceptors, Pages 326-329, King-Wai Yau

Photosynthesis, Pages 330-335, Richard C. Leegood

Photosynthetic Carbon Dioxide Fixation, Pages 336-341, Matthew J. Paul

Photosystem I, Structure and Function, Pages 342-347, Petra Fromme

Photosystem I: FX, FA, and FB Iron-Sulfur Clusters, Pages 348-356, Mikhail L. Antonkine and John H. Golbeck

Photosystem II Light Harvesting System: Dynamic Behavior, Pages 357-362, Peter Horton and Alexander Ruban

Photosystem II: Assembly and Turnover of the D1 Protein, Pages 363-366, Eira Kanervo and Eva-Mari Aro

Photosystem II: Protein Components, Pages 367-374, James Barber

Photosystem II: Water Oxidation, Overview, Pages 375-380, Fabrice Rappaport and Pierre Joliot

Plant Signaling: Peptides, Pages 381-384, Clarence A. Ryan and Gregory Pearce

Plasma-Membrane Calcium Pump: Structure and Function, Pages 385-389, Emanuel E. Strehler

Plastocyanin, Pages 390-393, Elizabeth L. Gross

Platelet-Activating Factor Receptor, Pages 394-398, Katherine M. Howard and Merle S. Olson

Platelet-Derived Growth Factor Receptor Family, Pages 399-406, Marina Kovalenko and Andrius Kazlauskas

Polysialic Acid inMolecular Medicine, Pages 407-414, Frederic A. Troy, II

Porphyrin Metabolism, Pages 415-419, Mark Shepherd and Harry A. Dailey

Pre-tRNA and Pre-rRNA Processing in Bacteria, Pages 420-424, Sidney R. Kushner

Pre-tRNA and Pre-rRNA Processing in Eukaryotes, Pages 425-431, Hendrik A. Raue

Prions and Epigenetic Inheritance, Pages 432-436, Reed B. Wickner

Prions, Overview, Pages 437-440, Cedric Govaerts and Fred E. Cohen

Processivity Clamps in DNA Replication: Clamp Loading, Pages 441-446, Megan J. Davey and Mike O'Donnell

Propionyl CoA-Succinyl CoA Pathway, Pages 447-451, Wayne A. Fenton

Prostaglandins and Leukotrienes, Pages 452-456, William L. Smith and Robert C. Murphy

Proteases in Blood Clotting, Pages 457-463, John D. Kulman and Earl W. Davie

Proteasomes, Overview, Pages 464-468, Martin Rechsteiner

26S Proteasome, Structure and Function, Pages 469-473, Peter Zwickl and Wolfgang Baumeister

Protein Carboxyl Esterification, Pages 474-477, Shilpa G. Lalchandani and Jeffry B. Stock

Protein Data Resources, Pages 478-483, Philip E. Bourne

Protein Degradation, Pages 484-492, Tomo ari and Alfred L. Goldberg

Protein Folding and Assembly, Pages 493-499, David P. Goldenberg

Protein Glycosylation Inhibitors, Pages 500-503, Alan D. Elbein

Protein Glycosylation, Overview, Pages 504-509, Natasha E. Zachara and Gerald W. Hart

Protein Import into Mitochondria, Pages 510-515, Johannes M. Herrmann and Walter Neupert

Protein Kinase B, Pages 516-522, Bettina A. Dummler and Brian A. Hemmings

Protein Kinase C Family, Pages 523-526, Alexandra C. Newton

Protein N-Myristoylation, Pages 527-531, Erica Dutil Sonnenburg and Jeffrey I. Gordon

Protein Palmitoylation, Pages 532-535, Robert J. Deschenes

Protein Tyrosine Phosphatases, Pages 536-542, David J. Pagliarini, Fred L. Robinson and Jack E. Dixon

Proteinase-Activated Receptors, Pages 543-548, Kristina K. Hansen and Morley D. Hollenberg

Proteoglycans, Pages 549-555, Sara K. Olson and Jeffrey D. Esko

Pteridines, Pages 556-560, S. Colette Daubner and Paul F. Fitzpatrick

P-Type Pumps: Copper Pump, Pages 561-564, Ilia Voskoboinik and James Camakaris

P-Type Pumps: H+/K+ Pump, Pages 565-570, Jai Moo Shin and George Sachs

P-Type Pumps: Na+/K+ Pump, Pages 571-576, Peter L. Jorgensen

P-Type Pumps: Plasma-Membrane H+ Pump, Pages 577-581, A. Brett Mason and Carolyn W. Slayman

Purple Bacteria: Electron Acceptors and Donors, Pages 582-585, Evaldas Katilius and Neal W. Woodbury

Purple Bacteria: Photosynthetic Reaction Centers, Pages 586-594, C. Roy D. Lancaster

Pyridoxal Phosphate, Pages 595-599, David E. Metzler

Pyrimidine Biosynthesis, Pages 600-605, Monika Loffler and Elke Zameitat

Pyruvate Carboxylation, Transamination, and Gluconeogenesis, Pages 606-610, Sarawut Jitrapakdee and John C. Wallace

Pyruvate Dehydrogenase, Pages 611-615, Sam A. Johnson and James G. McCormack

Pyruvate Kinase, Pages 616-619, Kosaku Uyeda

Quinones, Pages 621-627, Giorgio Lenaz and Maria Luisa Genova

Rab Family, Pages 629-634, Mary W. McCaffrey and Andrew J. Lindsay

Ran GTPase, Pages 635-639, Mary Shannon Moore

Ras Family, Pages 640-644, Lawrence A. Quilliam

Recombination: Heteroduplexand Mismatch Repair in vitro, Pages 645-648, Leroy Worth

Recombination: Strand Transferases, Pages 649-653, Floyd R. Bryant

Recombination-Dependent DNA Replication, Pages 654-659, Kenneth N. Kreuzer

recQ DNA Helicase Family in Genetic Stability, Pages 660-664, Mary A. Risinger and Joanna Groden

Regulated Intramembrane Proteolysis (Rip), Pages 665-670, Jin Ye, Michael S. Brown and Joseph L. Goldstein

Respiratory Chain and ATP Synthase, Pages 671-675, David G. Whitehouse and Anthony L. Moore

Respiratory Chain Complex I, Pages 676-680, Ulrich Brandt

Respiratory Chain Complex II and Succinate: Quinone Oxidoreductases, Pages 681-687, C. Roy D. Lancaster

Respiratory Chain Complex IV, Pages 688-694, Hartmut Michel

Respiratory Processes in Anoxygenic and Oxygenic Phototrophs, Pages 695-699, Roberto Borghese and Davide Zannoni

Retinoblastoma Protein (pRB), Pages 700-703, Nicholas Dyson and Maxim Frolov

Retinoic Acid Receptors, Pages 704-707, Martin Petkovich

Reverse Transcriptase and Retroviral Replication, Pages 708-713, Laura Tarrago-Litvak, Marie-Line Andreola and Simon Litvak

Rho GTPases and Actin Cytoskeleton Dynamics, Pages 714-718, Priam Villalonga and Anne J. Ridley

Ribosome Assembly, Pages 719-724, John L. Woolford

Ribosome Structure, Pages 725-732, Brian T. Wimberly

Ribozyme Mechanisms, Pages 733-737, John Hsieh and Carol A. Fierke

Ribozyme Structural Elements: Group I Introns, Pages 738-742, Barbara L. Golden

Ribozyme Structural Elements: Hairpin Ribozyme, Pages 743-746, Adrian R. Ferre-D'Amare

Ribozymes and Evolution, Pages 747-752, Niles Lehman

RNA Editing, Pages 753-758, Charles E. Samuel

RNA Polymerase I and RNA Polymerase III in Eukaryotes, Pages 759-762, Robert J. White

RNA Polymerase II and Basal Transcription Factors in Eukaryotes, Pages 763-765, Joan Weliky Conaway and Ronald C. Conaway

RNA Polymerase II Elongation Control in Eukaryotes, Pages 766-769, David H. Price

RNA Polymerase II Structure in Eukaryotes, Pages 770-774, Patrick Cramer

RNA Polymerase Reaction in Bacteria, Pages 775-780, Arkady A. Mustaev and Alexander D. Goldfarb

RNA Polymerase Structure, Bacterial, Pages 781-784, Michael Anikin, Dmitri Temiakov and William T. McAllister

Volume 4

Secondary Structure in Protein Analysis, Pages 1-6, George D. Rose

Secretases, Pages 7-10, Robert L. Heinrikson

Secretory Pathway, Pages 11-16, Karen J. Colley

Selenoprotein Synthesis, Pages 17-21, August Bock

Septins and Cytokinesis, Pages 22-26, Makoto Kinoshita and Christine M. Field

Serine/Threonine Phosphatases, Pages 27-32, Thomas S. Ingebritsen

Serotonin Receptor Signaling, Pages 33-37, Paul J. Gresch and Elaine Sanders-Bush

Siglecs, Pages 38-40, Ajit Varki

Sigma Factors, Pages 41-44, John D. Helmann

Sliding Clamps in DNA Replication: E. coli -Clamp and PCNA Structure, Pages 45-47, Eric R. Goedken and John Kuriyan

Small GTPases, Pages 48-54, Adam Shutes and Channing J. Der

Somatostatin Receptors, Pages 55-60, Agnes Schonbrunn

Spastic Paraplegia, Pages 61-66, Elena Irene Rugarli and Andrea Ballabio

Spectrophotometric Assays, Pages 67-75, Britton Chance

Sphingolipid Biosynthesis, Pages 76-81, Martina Leipelt and Alfred H. Merrill

Sphingolipid Catabolism, Pages 82-87, Akira Abe and James A. Shayman

Spliceosome, Pages 88-92, Timothy W. Nilsen

Src Family of Protein Tyrosine Kinases, Pages 93-98, Jonathan A. Cooper

Starvation, Pages 99-110, Oliver E. Owen and Richard W. Hanson

Steroid/Thyroid Hormone Receptors, Pages 111-116, Ramesh Narayanan and Nancy L. Weigel

Store-Operated Membrane Channels: Calcium, Pages 117-122, Indu S. Ambudkar

Substrate Binding, Catalysis, and Product Release , Pages 123-126, W. Wallace Cleland

Sugar Nucleotide Transporters, Pages 127-129, Carlos B. Hirschberg

SUMO Modification, Pages 130-134, Frauke Melchior and Andrea Pichler

Superoxide Dismutase, Pages 135-138, Irwin Fridovich

Syk Family of Protein Tyrosine Kinases, Pages 139-145, Andrew C. Chan

T7 RNA Polymerase, Pages 147-151, Rui Sousa

Tachykinin/Substance P Receptors, Pages 152-157, Mark D. Richardson and Madan M. Kwatra

Taste Receptors, Pages 158-161, John D. Boughter, Jr. and Steven D. Munger

T-Cell Antigen Receptor, Pages 162-168, Andrea L. Szymczak and Dario A. A. Vignali

Tec/Btk Family Tyrosine Kinases, Pages 169-173, Shuling Guo and Owen N. Witte

Telomeres: Maintenance and Replication, Pages 174-179, Alessandro Bianchi and David Shore

Thyroid-Stimulating Hormone/Luteinizing Hormone/Follicle-Stimulating Hormone Receptors, Pages 180-186, Deborah L. Segaloff, Dario Mizrachi and Mario Ascoli

Tight Junctions, Pages 187-189, Shoichiro Tsukita

Title, Pages, Authors

Toll-Like Receptors, Pages 190-194, Himanshu Kumar, Kiyoshi Takeda and Shizuo Akira

Transcription Termination, Pages 195-199, Thomas J. Santangelo and Jeffrey W. Roberts

Transcriptional Silencing, Pages 200-203, Ann Sutton and Rolf Sternglanz

Transcription-Coupled DNA Repair, Overview, Pages 204-208, Isabel Mellon

Transforming Growth Factor-β Receptor Superfamily, Pages 209-213, Mark de Caestecker

Translation Elongation in Bacteria, Pages 214-223, Oliver Vesper and Knud H. Nierhaus

Translation Elongation in Eukaryotes, Pages 224-229, William C. Merrick and Anton A. Komar

Translation Initiation in Bacteria: Factors and Mechanisms, Pages 230-236, Cynthia L. Pon and Claudio O. Gualerzi

Translation Initiation in Eukaryotes: Factors and Mechanisms, Pages 237-241, Tatyana V. Pestova and Christopher U. T. Hellen

Translation Termination and Ribosome Recycling, Pages 242-246, Nadja Koloteva-Levin and Mick F. Tuite

Translesion DNA Polymerases, Eukaryotic, Pages 247-250, Alexandra Vaisman and Roger Woodgate

Trehalose Metabolism, Pages 251-255, Alan D. Elbein

Tricarboxylic Acid Cycle, Pages 256-262, Richard L. Veech

tRNA Synthetases, Pages 263-266, Karla L. Ewalt and Paul Schimmel

trp Operon and Attenuation, Pages 267-271, Paul Gollnick

Tubulin and its Isoforms, Pages 272-276, Eva Nogales

Tumor Necrosis Factor Receptors, Pages 277-283, Karen G. Potter and Carl F. Ware

Two-Dimensional Gel Electrophoresis, Pages 284-289, Gerhard Schmid, Denis Hochstrasser and Jean-Charles Sanchez

Two-Hybrid Protein-Protein Interactions, Pages 290-293, Ilya Serebriiskii and Erica A. Golemis

Tyrosine Sulfation, Pages 294-297, Denis Corbeil and Wieland B. Huttner

Ubiquitin System, Pages 299-303, Aaron Ciechanover and Michael H. Glickman

Ubiquitin-Like Proteins, Pages 304-307, Edward T. H. Yeh

UmuC, D Lesion Bypass DNA Polymerase V, Pages 308-312, Zvi Livneh

Uncoupling Proteins, Pages 313-318, Daniel Ricquier and Frederic Bouillaud

Unfolded Protein Responses, Pages 319-325, David Ron

Urea Cycle, Inborn Defects of, Pages 326-330, Marsha K. Fearing and Vivian E. Shih

Vacuoles, Pages 331-336, Christopher J. Stefan and Scott D. Emr

Vascular Endothelial Growth Factor Receptors, Pages 337-342, Kenneth A. Thomas

Vasopressin/Oxytocin Receptor Family, Pages 343-348, Michael J. Brownstein

V-ATPases, Pages 349-353, Michael Forgac

Vitamin A (Retinoids), Pages 354-359, Joseph L. Napoli

Vitamin B12 and B12-Proteins, Pages 360-366, Bernhard Krautler

Vitamin C, Pages 367-371, Robert B. Rucker and Francene Steinberg

Vitamin D, Pages 372-377, Hector F. DeLuca and Margaret Clagett-Dame

Vitamin D Receptor, Pages 378-383, Diane R. Dowd and Paul N. MacDonald

Vitamin E, Pages 384-388, Ute C. Obermuller-Jevic and Lester Packer

Vitamin K: Biochemistry, Metabolism, and Nutritional Aspects, Pages 389-393, J. W. Suttie

Vitamin K: Blood Coagulation and Use in Therapy, Pages 394-398, Matthew D. Stone and Gary L. Nelsestuen

Voltage-Dependent K+ Channels, Pages 399-404, Ramon Latorre and Francisco J. Morera

Voltage-Sensitive Ca2+ Channels, Pages 405-408, Harald Reuter

Voltage-Sensitive Na+ Channels, Pages 409-415, William J. Brammar

Von Hippel-Lindau (VHL) Protein, Pages 416-418, Ronald C. Conaway and Joan Weliky Conaway

XPV DNA Polymerase and Ultraviolet Damage Bypass, Pages 419-421, Alan R. Lehmann

X-Ray Determination of 3-D Structure in Proteins, Pages 422-428, Martha L. Ludwig

Yeast GAL1-GAL10 System, Pages 429-433, Dennis Lohr and Ralph Bash

Zinc Fingers, Pages 435-439, Mark Isalan

Lipids, Carbohydrates, Membranes and Membrane Proteins

Carbohydrate Chains: Enzymatic and Chemical Synthesis; Vol.1 - Pages 307-313, Thomas J. Tolbert and Chi-Huey Wong

Cell–Matrix Interactions; Vol.1 - Pages 362-366, Janet A. Askari and Martin J. Humphries

Detergent Properties; Vol.1 - Pages 577-581, Darrell R. McCaslin

Endocytosis; Vol.2 - Pages 16-19, Julie G. Donaldson

Flippases; Vol.2 - Pages 123-127, Charles J. Waechter

Galectins; Vol.2 - Pages 171-174, R. Colin Hughes

GlcNAc Biosynthesis and Function, O-Linked; Vol.2 - Pages 189-192, Kaoru Sakabe and Gerald W. Hart

Glycation; Vol.2 - Pages 229-236, Suzanne R. Thorpe and John W. Baynes

Glycolipid-Dependent Adhesion Processes; Vol.2 - Pages 261-265, Senitiroh Hakomori

Glycoprotein Folding and Processing Reactions; Vol.2 - Pages 272-276, Armando J. Parodi

Glycoprotein-Mediated Cell Interactions, O-Linked; Vol.2 - Pages 277-282, Robert S. Haltiwanger

Glycoproteins, N-Linked; Vol.2 - Pages 283-292, Mark A. Lehrman

Glycoproteins, Plant; Vol.2 - Pages 293-296, Carolyn J. Schultz

Glycosylation in Cystic Fibrosis; Vol.2 - Pages 297-301, Andrew D. Rhim, Thomas F. Scanlin and Mary Catherine Glick

Glycosylation, Congenital Disorders of; Vol.2 - Pages 302-307, Hudson H. Freeze

Glycosylphosphatidylinositol (GPI) Anchors; Vol.2 - Pages 308-311, Anant K. Menon

Ion Channel Protein Superfamily; Vol.2 - Pages 473-477, William A. Catterall

Lectins; Vol.2 - Pages 535-540, Nathan Sharon and Halina Lis

Lipases; Vol.2 - Pages 571-575, Howard L. Brockman

Lipid Bilayer Structure; Vol.2 - Pages 576-579, Erwin London

Lipid Rafts; Vol.2 - Pages 584-587, Deborah A. Brown

Lipoproteins, HDL/LDL; Vol.2 - Pages 588-593, Fayanne E. Thorngate and David L. Williams

MDR Membrane Proteins; Vol.2 - Pages 605-609, Nathan C. Rockwell

Membrane Fusion; Vol.2 - Pages 621-626, Joshua Zimmerberg and Leonid V. Chernomordik

Mucin Family of Glycoproteins; Vol.2 - Pages 758-764, Juan Perez-Vilar and Robert L. Hill

Mucins in Embryo Implantation; Vol.2 - Pages 765-769, Daniel D. Carson

Neoglycoproteins; Vol.3 - Pages 11-15, Y. C. Lee and Reiko T. Lee

N-Linked Glycan Processing Glucosidases and Mannosidases; Vol.3 - Pages 46-49, Linda O. Tremblay and Annette Herscovics

Oligosaccharide Chains: Free, N-Linked, O-Linked; Vol.3 - Pages 161-164, Tadashi Suzuki

Phospholipid Metabolism in Mammals; Vol.3 - Pages 314-320, Claudia Kent

Phospholipid Synthesis in Yeast; Vol.3 - Pages 321-325, Gil-Soo Han and George M. Carman

Prostaglandins and Leukotrienes; Vol.3 - Pages 452-456, William L. Smith and Robert C. Murphy

Protein Glycosylation Inhibitors; Vol.3 - Pages 500-503, Alan D. Elbein

Proteoglycans; Vol.3 - Pages 549-555, Sara K. Olson and Jeffrey D. Esko

Secretory Pathway; Vol.4 - Pages 11-16, Karen J. Colley

Siglecs; Vol.4 - Pages 38-40, Ajit Varki

Sphingolipid Biosynthesis; Vol.4 - Pages 76-81, Martina Leipelt and Alfred H. Merrill, Jr.

Sphingolipid Catabolism; Vol.4 - Pages 82-87, Akira Abe and James A. Shayman

Sugar Nucleotide Transporters; Vol.4 - Pages 127-129, Carlos B. Hirschberg

Trehalose Metabolism; Vol.4 - Pages 251-255, Alan D. Elbein

Metabolism, Vitamins and Hormones

Amino Acid Metabolism; Vol.1 - Pages 90-95, Luc Cynober

Anaplerosis; Vol.1 - Pages 105-110, Raymond R. Russell, III and Heinrich Taegtmeyer

Bile Salts and their Metabolism; Vol.1 - Pages 159-163, Ulrich Beuers and Thomas Pusl

Biliary Cirrhosis, Primary; Vol.1 - Pages 164-169, Marshall M. Kaplan

Branched-Chain -Ketoacids; Vol.1 - Pages 186-191, David T. Chuang

Carnitine and -Oxidation; Vol.1 - Pages 314-318, Janos Kerner and Charles L. Hoppel

Cholesterol Synthesis; Vol.1 - Pages 451-455, Peter A. Edwards

Diabetes; Vol.1 - Pages 582-592, David W. Cooke

Fat Mobilization: Perilipin and Hormone-Sensitive Lipase; Vol.2 - Pages 85-89, Constantine Londos and Alan R. Kimmel

Fatty Acid Oxidation; Vol.2 - Pages 90-94, Horst Schulz

Fatty Acid Synthesis and its Regulation; Vol.2 - Pages 99-103, Steven D. Clarke and Manabu T. Nakamura

Gluconeogenesis; Vol.2 - Pages 197-203, Richard W. Hanson and Oliver E. Owen

Glucose/Sugar Transport in Bacteria; Vol.2 - Pages 204-207, Lan Guan and H. Ronald Kaback

Glucose/Sugar Transport in Mammals; Vol.2 - Pages 208-212, Silvia Mora and Jeffrey Pessin

Glycogen Metabolism; Vol.2 - Pages 244-248, Peter J. Roach

Glycogen Storage Diseases; Vol.2 - Pages 249-254, George H. Sack, Jr.

Glycolysis, Overview; Vol.2 - Pages 266-271, Robert A. Harris

Hexokinases/Glucokinases; Vol.2 - Pages 372-377, Emile Van Schaftingen

Insulin- and Glucagon-Secreting Cells of the Pancreas; Vol.2 - Pages 430-435, Franz M. Matschinsky

Ketogenesis; Vol.2 - Pages 505-507, Janos Kerner and Charles L. Hoppel

Ornithine Cycle; Vol.3 - Pages 172-177, Malcolm Watford

Pentose Phosphate (Hexose Mono Phosphate) Pathway; Vol.3 - Pages 211-215, Bernard R. Landau

Pentose Phosphate Pathway, History of; Vol.3 - Pages 216-225, John F. Williams

Phosphofructokinase-2/Fructose Bisphosphatase-2; Vol.3 - Pages 277-280, Daniel M. Raben

Photosynthesis; Vol.3 - Pages 330-335, Richard C. Leegood

Photosynthetic Carbon Dioxide Fixation; Vol.3 - Pages 336-341, Matthew J. Paul

Porphyrin Metabolism; Vol.3 - Pages 415-419, Mark Shepherd and Harry A. Dailey

Propionyl CoA–Succinyl CoA Pathway; Vol.3 - Pages 447-451, Wayne A. Fenton

Pyruvate Carboxylation, Transamination, and Gluconeogenesis; Vol.3 - Pages 606-610, Sarawut Jitrapakdee and John C. Wallace

Pyruvate Dehydrogenase; Vol.3 - Pages 611-615, Sam A. Johnson and James G. McCormack

Pyruvate Kinase; Vol.3 - Pages 616-619, Kosaku Uyeda

Starvation; Vol.4 - Pages 99-110, Oliver E. Owen and Richard W. Hanson

Tricarboxylic Acid Cycle; Vol.4 - Pages 256-262, Richard L. Veech

Urea Cycle, Inborn Defects of; Vol.4 - Pages 326-330, Marsha K. Fearing and Vivian E. Shih

Vitamin A (Retinoids); Vol.4 - Pages 354-359, Joseph L. Napoli

Vitamin B12 and B12-Proteins; Vol.4 - Pages 360-366, Bernhard Krautler

Vitamin C; Vol.4 - Pages 367-371, Robert B. Rucker and Francene Steinberg

Vitamin D; Vol.4 - Pages 372-377, Hector F. DeLuca and Margaret Clagett-Dame

Vitamin E; Vol.4 - Pages 384-388, Ute C. Obermuller-Jevic and Lester Packer

Vitamin K: Biochemistry, Metabolism, and Nutritional Aspects; Vol.4 - Pages 389-393, J. W. Suttie

Vitamin K: Blood Coagulation and Use in Therapy; Vol.4 - Pages 394-398, Matthew D. Stone and Gary L. Nelsestuen

Cell Architecture and Function

Actin Assembly/Disassembly; Vol.1 - Pages 12-18, Henry N. Higgs

Actin-Capping and -Severing Proteins; Vol.1 - Pages 19-26, Sankar Maiti and James R. Bamburg

Actin-Related Proteins; Vol.1 - Pages 27-33, R. Dyche Mullins

Autophagy in Fungi and Mammals; Vol.1 - Pages 138-143, Daniel J. Klionsky and Ju Guan

Bax and Bcl2 Cell Death Enhancers and Inhibitors; Vol.1 - Pages 152-154, David L. Vaux

Cadherin-Mediated Cell–Cell Adhesion; Vol.1 - Pages 205-211, Frauke Drees and W. James Nelson

Caspases and Cell Death; Vol.1 - Pages 319-327, Don W. Nicholson, Pierluigi Nicotera and Gerry Melino

Cell Cycle Controls in G1 and G0; Vol.1 - Pages 328-331, WengeShi and Steven F. Dowdy

Cell Cycle: Control of Entry and Progression Through S Phase; Vol.1 - Pages 332-337, Susan L. Forsburg

Cell Cycle: DNA Damage Checkpoints; Vol.1 - Pages 338-344, Jean Y. J. Wang

Cell Cycle: Mitotic Checkpoint; Vol.1 - Pages 345-351, Tim J. Yen

Cell Migration; Vol.1 - Pages 356-361, J. Victor Small and Emmanuel Vignal

Centromeres; Vol.1 - Pages 367-371, Beth A. Sullivan

Centrosomes and Microtubule Nucleation; Vol.1 - Pages 372-376, Reiko Nakajima, Ming-Ying Tsai and Yixian Zheng

Chaperones for Metalloproteins; Vol.1 - Pages 383-386, Valeria C. Culotta and Edward Luk

Chaperones, Molecular; Vol.1 - Pages 387-392, Sue Wickner and Joel R. Hoskins

Chaperonins; Vol.1 - Pages 393-398, Arthur L. Horwich, Wayne A. Fenton and George W. Farr

Chromosome Organization and Structure, Overview; Vol.1 - Pages 469-474, Elena Gracheva and Sarah C. R. Elgin

Cytokinesis; Vol.1 - Pages 556-561, Masanori Mishima and Michael Glotzer

Desmosomes and Hemidesmosomes; Vol.1 - Pages 569-576, Rachel L. Dusek, Jonathan C. R. Jones and Kathleen J. Green

Dynactin; Vol.1 - Pages 823-826, Trina A. Schroer

Dynein; Vol.1 - Pages 827-831, K. Kevin Pfister

Endoplasmic Reticulum-Associated Protein Degradation; Vol.2 - Pages 20-23, Maurizio Molinari

Focal Adhesions; Vol.2 - Pages 128-133, Eli Zamir and Benjamin Geiger

Golgi Complex; Vol.2 - Pages 312-315, Mark Stamnes

Heat/Stress Responses; Vol.2 - Pages 343-347, Davis T. W. Ng

Inositol Lipid 3-Phosphatases; Vol.2 - Pages 421-426, Gregory S. Taylor and Jack E. Dixon

Intermediate Filament Linker Proteins: Plectin and BPAG1; Vol.2 - Pages 452-457, Peter Fuchs and Gerhard Wiche

Intermediate Filaments; Vol.2 - Pages 458-464, Kelsie M. Bernot and Pierre A. Coulombe

Keratins and the Skin; Vol.2 - Pages 497-504, Pierre A. Coulombe and Kelsie M. Bernot

Kinesin Superfamily Proteins; Vol.2 - Pages 508-516, Nobutaka Hirokawa and Reiko Takemura

Kinesins as Microtubule Disassembly Enzymes; Vol.2 - Pages 517-521, Susan L. Kline-Smith and Arshad Desai

Meiosis; Vol.2 - Pages 610-616, Neil Hunter

Metalloproteinases, Matrix; Vol.2 - Pages 657-665, Hideaki Nagase and Gillian Murphy

Microtubule-Associated Proteins; Vol.2 - Pages 676-682, Nobutaka Hirokawa and Reiko Takemura

Mitosis; Vol.2 - Pages 743-747, Patricia Wadsworth and Nasser M. Rusan

Myosin Motors; Vol.2 - Pages 778-781, Roy E. Larson

N-End Rule; Vol.3 - Pages 6-10, Alexander Varshavsky

Neuronal Intermediate Filaments; Vol.3 - Pages 21-25, Ronald K. H. Liem

Nuclear Compartmentalization; Vol.3 - Pages 87-91, Kelly P. Smith and Jeanne B. Lawrence

Nuclear Envelope and Lamins; Vol.3 - Pages 92-95, Bryce M. Paschal

Nuclear Pores and Nuclear Import/Export; Vol.3 - Pages 109-114, Anita H. Corbett

Peroxisomes; Vol.3 - Pages 246-250, Suresh Subramani

26S Proteasome, Structure and Function; Vol.3 - Pages 469-473, Peter Zwickl and Wolfgang Baumeister

Protein Glycosylation, Overview; Vol.3 - Pages 504-509, Natasha E. Zachara and Gerald W. Hart

Rho GTPases and Actin Cytoskeleton Dynamics; Vol.3 - Pages 714-718, Priam Villalonga and Anne J. Ridley

Septins and Cytokinesis; Vol.4 - Pages 22-26, Makoto Kinoshita and Christine M. Field

SUMO Modification; Vol.4 - Pages 130-134, Frauke Melchior and Andrea Pichler

Tight Junctions; Vol.4 - Pages 187-189, Shoichiro Tsukita

Transcriptional Silencing; Vol.4 - Pages 200-203, Ann Sutton and Rolf Sternglanz

Tubulin and its Isoforms; Vol.4 - Pages 272-276, Eva Nogales

Unfolded Protein Responses; Vol.4 - Pages 319-325, David Ron

Vacuoles; Vol.4 - Pages 331-336, Christopher J. Stefan and Scott D. Emr

Protein/Enzyme Structure Function and Degradation

Allosteric Regulation; Vol.1 - Pages 68-73, Barry S. Cooperman

Aminopeptidases; Vol.1 - Pages 96-98, Ralph A. Bradshaw

Amyloid; Vol.1 - Pages 99-104, Ronald Wetzel

Aspartic Proteases; Vol.1 - Pages 123-127, Ben M. Dunn

B12-Containing Enzymes; Vol.1 - Pages 145-151, Vahe Bandarian and Rowena G. Matthews

Biotin; Vol.1 - Pages 174-178, Steven W. Polyak and Anne Chapman-Smith

Biotinylation of Proteins; Vol.1 - Pages 179-181, Ronald A. Kohanski

Calpain; Vol.1 - Pages 300-306, Hiroyuki Sorimachi and Yasuko Ono

Chemiluminescence and Bioluminescence; Vol.1 - Pages 399-404, Thomas O. Baldwin

Coenzyme A; Vol.1 - Pages 475-477, M. Daniel Lane

Collagenases; Vol.1 - Pages 478-481, Kenn Holmbeck and Henning Birkedal-Hansen

Collagens; Vol.1 - Pages 482-487, Darwin J. Prockop

Cysteine Proteases; Vol.1 - Pages 516-520, David J. Buttle and John S. Mort

Disulfide Bond Formation; Vol.1 - Pages 598-602, Hiram F. Gilbert

Elastin; Vol.2 - Pages 10-12, Judith Ann Foster

Enzyme Inhibitors; Vol.2 - Pages 31-37, Vern L. Schramm

Enzyme Kinetics; Vol.2 - Pages 38-44, Irwin H. Segel

Enzyme Reaction Mechanisms: Stereochemistry; Vol.2 - Pages 45-50, Ming-Daw Tsai, Li Zhao and Brandon J. Lamarche

Flavins; Vol.2 - Pages 118-122, Barrie Entsch and David P. Ballou

Heme Proteins; Vol.2 - Pages 354-361, Johannes Everse

HIV Protease; Vol.2 - Pages 384-387, Ben M. Dunn

Kinetic Isotope Effects; Vol.2 - Pages 522-527, Justine P. Roth and Judith P. Klinman

Lipid Modification of Proteins: Targeting to Membranes; Vol.2 - Pages 580-583, Marilyn D. Resh

Low Barrier Hydrogen Bonds; Vol.2 - Pages 594-598, Perry A. Frey

Metalloproteases; Vol.2 - Pages 652-656, David S. Auld

Peptide Amidation; Vol.3 - Pages 226-230, Mark J. Niciu, Richard E. Mains and Betty A. Eipper

Phage Display for Protein Binding; Vol.3 - Pages 251-255, Henry B. Lowman

Prions, Overview; Vol.3 - Pages 437-440, Cedric Govaerts and Fred E. Cohen

Proteases in Blood Clotting; Vol.3 - Pages 457-463, John D. Kulman and Earl W. Davie

Proteasomes, Overview; Vol.3 - Pages 464-468, Martin Rechsteiner

Protein Carboxyl Esterification; Vol.3 - Pages 474-477, Shilpa G. Lalchandani and Jeffry B. Stock

Protein Degradation; Vol.3 - Pages 484-492, Tomo ari and Alfred L. Goldberg

Protein Folding and Assembly; Vol.3 - Pages 493-499, David P. Goldenberg

Protein N-Myristoylation; Vol.3 - Pages 527-531, Erica Dutil Sonnenburg and Jeffrey I. Gordon

Protein Palmitoylation; Vol.3 - Pages 532-535, Robert J. Deschenes

Pteridines; Vol.3 - Pages 556-560, S. Colette Daubner and Paul F. Fitzpatrick

Pyridoxal Phosphate; Vol.3 - Pages 595-599, David E. Metzler

Regulated Intramembrane Proteolysis (Rip); Vol.3 - Pages 665-670, Jin Ye, Michael S. Brown and Joseph L. Goldstein

Secretases; Vol.4 - Pages 7-10, Robert L. Heinrikson

Selenoprotein Synthesis; Vol.4 - Pages 17-21, August Bock

Substrate Binding, Catalysis, and Product Release; Vol.4 - Pages 123-126, W. Wallace Cleland

Two-Hybrid Protein–Protein Interactions; Vol.4 - Pages 290-293, Ilya Serebriiskii and Erica A. Golemis

Tyrosine Sulfation; Vol.4 - Pages 294-297, Denis Corbeil and Wieland B. Huttner

Ubiquitin System; Vol.4 - Pages 299-303, Aaron Ciechanover and Michael H. Glickman

Ubiquitin-Like Proteins; Vol.4 - Pages 304-307, Edward T. H. Yeh

Zinc Fingers; Vol.4 - Pages 435-439, Mark Isalan

Bioenergetics

ABC Transporters; Vol.1 - Pages 1-5, Andre Goffeau, Benoit De Hertogh and Philippe V. Baret

Amine Oxidases; Vol.1 - Pages 85-89, Giovanni Floris and Alessandro Finazzi Agro

ATP Synthesis in Plant Mitochondria: Substrates, Inhibitors, Uncouplers; Vol.1 - Pages 128-132, Kathleen L. Soole and R. Ian Menz

ATP Synthesis: Mitochondrial Cyanide-Resistant Terminal Oxidases; Vol.1 - Pages 133-137, James N. Siedow

Bioenergetics: General Definition of Principles; Vol.1 - Pages 170-173, David G. Nicholls

Calcium Buffering Proteins: Calbindin; Vol.1 - Pages 221-225, Willi Hunziker and Igor Bendik

Calcium Buffering Proteins: ER Luminal Proteins; Vol.1 - Pages 226-230, Jody Groenendyk and Marek Michalak

Calcium Oscillations; Vol.1 - Pages 231-234, Marisa Brini

Calcium Sensing Receptor; Vol.1 - Pages 235-240, Jacob Tfelt-Hansen and Edward M. Brown

Calcium Signaling: Calmodulin-Dependent Phosphatase; Vol.1 - Pages 241-245, Claude Klee, Hao Ren and Shipeng Li

Calcium Signaling: Cell Cycle; Vol.1 - Pages 246-249, Luigia Santella

Calcium Signaling: Motility (Actomyosin–Troponin System); Vol.1 - Pages 250-255, Takeyuki Wakabayashi and Setsuro Ebashi

Calcium Signaling: NO Synthase; Vol.1 - Pages 256-260, Zhi-Qiang Wang and Dennis J. Stuehr

Calcium Transport in Mitochondria; Vol.1 - Pages 261-266, Rosario Rizzuto and Marisa Brini

Calcium Waves; Vol.1 - Pages 267-269, Lionel F. Jaffe

Calcium, Biological Fitness of; Vol.1 - Pages 270-273, Robert J. P. Williams

Calcium/Calmodulin-Dependent Protein Kinase II; Vol.1 - Pages 274-280, Andy Hudmon and Howard Schulman

Calcium-Binding Proteins: Cytosolic (Annexins, Gelsolins, C2-Domain Proteins); Vol.1 - Pages 287-293, Joachim Krebs

Calcium-Modulated Proteins (EF-Hand); Vol.1 - Pages 294-299, Robert H. Kretsinger

Cell Death by Apoptosis and Necrosis; Vol.1 - Pages 352-355, Pierluigi Nicotera

Chemiosmotic Theory; Vol.1 - Pages 405-412, Keith D. Garlid

Chemolithotrophy; Vol.1 - Pages 419-424, Alan B. Hooper

Chlorophylls and Carotenoids; Vol.1 - Pages 430-437, Hugo Scheer

Chloroplast Redox Poise and Signaling; Vol.1 - Pages 438-445, John F. Allen

Chloroplasts; Vol.1 - Pages 446-450, Nicoletta Rascio

Cytochrome b6f Complex; Vol.1 - Pages 521-527, Gunter A. Hauska and Thomas Schodl

Cytochrome bc1 Complex (Respiratory Chain Complex III); Vol.1 - Pages 528-534, Bernard L. Trumpower

Cytochrome c; Vol.1 - Pages 535-538, Hans Tuppy and Gunther Kreil

Cytochrome Oxidases, Bacterial; Vol.1 - Pages 539-543, Peter Brzezinski and Pia Adelroth

Cytochrome P-450; Vol.1 - Pages 544-549, Rita Bernhardt

Energy Transduction in Anaerobic Prokaryotes; Vol.2 - Pages 24-30, Gottfried Unden

ER/SR Calcium Pump: Function; Vol.2 - Pages 56-60, Giuseppe Inesi

ER/SR Calcium Pump: Structure; Vol.2 - Pages 61-65, Chikashi Toyoshima and Yuji Sugita

F1–F0 ATP Synthase; Vol.2 - Pages 73-79, Donata Branca

Ferredoxin; Vol.2 - Pages 104-106, Giuliana Zanetti and Vittorio Pandini

Ferredoxin-NADP+ Reductase; Vol.2 - Pages 107-111, Giuliana Zanetti and Alessandro Aliverti

Free Radicals, Sources and Targets of: Mitochondria; Vol.2 - Pages 134-142, Alberto Boveris and Enrique Cadenas

Friedreich's Ataxia; Vol.2 - Pages 143-145, Paul E. Hart and Anthony H. V. Schapira

Giant Mitochondria (Megamitochondria); Vol.2 - Pages 186-188, Bernard Tandler and Charles L. Hoppel

Glutathione Peroxidases; Vol.2 - Pages 224-228, Fulvio Ursini and Matilde Maiorino

Green Bacteria: Secondary Electron Donor (Cytochromes); Vol.2 - Pages 321-324, Hirozo Oh-oka and Robert E. Blankenship

Green Bacteria: The Light-Harvesting Chlorosome; Vol.2 - Pages 325-330, John M. Olson

Green Sulfur Bacteria: Reaction Center and Electron Transport; Vol.2 - Pages 331-336, Gunter A. Hauska and Thomas Schodl

Heme Synthesis; Vol.2 - Pages 362-366, Gloria C. Ferreira

Intracellular Calcium Channels: cADPR-Modulated (Ryanodine Receptors); Vol.2 - Pages 465-468, Antony Galione

Intracellular Calcium Channels: NAADP+-Modulated; Vol.2 - Pages 469-472, Armando A. Genazzani and Marcella Debidda

IP3 Receptors; Vol.2 - Pages 478-481, Colin W. TaylorEdward Morris and Paula da Fonseca

Iron–Sulfur Proteins; Vol.2 - Pages 482-489, Helmut Beinert, Jacques Meyer and Roland Lill

Ligand-Operated Membrane Channels: Calcium (Glutamate); Vol.2 - Pages 551-561, Elias K. Michaelis

Ligand-Operated Membrane Channels: GABA; Vol.2 - Pages 562-566, F. Minier and Erwin Sigel

Light-Harvesting Complex (LHC) I and II: Pigments and Proteins; Vol.2 - Pages 567-570, Stefan Jansson

Luft's Disease; Vol.2 - Pages 599-601, Salvatore DiMauro

Membrane Transport, General Concepts; Vol.2 - Pages 627-630, Stanley G. Schultz

Membrane Transporters:Na+/Ca2+ Exchangers; Vol.2 - Pages 631-636, Jonathan Lytton

Membrane-Associated Energy Transduction in Bacteria and Archaea; Vol.2 - Pages 637-645, Gunter Schafer

Metabolite Channeling: Creatine Kinase Microcompartments; Vol.2 - Pages 646-651, Uwe Schlattner and Theo Wallimann

Mitochondrial Auto-Antibodies; Vol.2 - Pages 683-688, Harold Baum

Mitochondrial Channels; Vol.2 - Pages 689-692, M. Catia Sorgato and Alessandro Bertoli

Mitochondrial DNA; Vol.2 - Pages 693-696, Gottfried Schatz

Mitochondrial Genes and their Expression: Yeast; Vol.2 - Pages 697-702, Piotr P. Slonimski and Giovanna Carignani

Mitochondrial Genome, Evolution; Vol.2 - Pages 703-708, B. Franz Lang, Dennis V. Lavrov and Gertraud Burger

Mitochondrial Genome, Overview; Vol.2 - Pages 709-715, Douglas C. Wallace

Mitochondrial Inheritance; Vol.2 - Pages 716-719, Eric A. Shoubridge

Mitochondrial Membranes, Structural Organization; Vol.2 - Pages 720-724, Carmen A. Mannella

Mitochondrial Metabolite Transporter Family; Vol.2 - Pages 725-732, Ferdinando Palmieri and Martin Klingenberg

Mitochondrial Outer Membrane and the VDAC Channel; Vol.2 - Pages 733-736, Marco Colombini

Neuronal Calcium Signal; Vol.3 - Pages 16-20, Hilmar Bading

Nicotinamide Nucleotide Transhydrogenase; Vol.3 - Pages 50-56, Jan Rydstrom

Nuclear Genes in Mitochondrial Function and Biogenesis; Vol.3 - Pages 100-104, Alexander Tzagoloff and Carol L. Dieckmann

Oncocytes; Vol.3 - Pages 165-166, Bernard Tandler and Charles L. Hoppel

Oxygenases; Vol.3 - Pages 178-182, Osamu Hayaishi

Periplasmic Electron Transport Systems in Bacteria; Vol.3 - Pages 231-238, David J. Richardson, Gary Sawers and Rob J. M. Van Spanning

Phosphatidylinositol-3-Phosphate; Vol.3 - Pages 272-276, Joseph V. Virbasius and Michael P. Czech

Photosystem I, Structure and Function; Vol.3 - Pages 342-347, Petra Fromme

Photosystem I: FX, FA, and FB Iron–Sulfur Clusters; Vol.3 - Pages 348-356, Mikhail L. Antonkine and John H. Golbeck

Photosystem II Light Harvesting System: Dynamic Behavior; Vol.3 - Pages 357-362, Peter Horton and Alexander Ruban

Photosystem II: Assembly and Turnover of the D1 Protein; Vol.3 - Pages 363-366, Eira Kanervo and Eva-Mari Aro

Photosystem II: Protein Components; Vol.3 - Pages 367-374, James Barber

Photosystem II: Water Oxidation, Overview; Vol.3 - Pages 375-380, Fabrice Rappaport and Pierre Joliot

Plasma-Membrane Calcium Pump: Structure and Function; Vol.3 - Pages 385-389, Emanuel E. Strehler

Plastocyanin; Vol.3 - Pages 390-393, Elizabeth L. Gross

Protein Import into Mitochondria; Vol.3 - Pages 510-515, Johannes M. Herrmann and Walter Neupert

P-Type Pumps: Copper Pump; Vol.3 - Pages 561-564, Ilia Voskoboinik and James Camakaris

P-Type Pumps: H+/K+ Pump; Vol.3 - Pages 565-570, Jai Moo Shin and George Sachs

P-Type Pumps: Na+/K+ Pump; Vol.3 - Pages 571-576, Peter L. Jorgensen

P-Type Pumps: Plasma-Membrane H+ Pump; Vol.3 - Pages 577-581, A. Brett Mason and Carolyn W. Slayman

Purple Bacteria: Electron Acceptors and Donors; Vol.3 - Pages 582-585, Evaldas Katilius and Neal W. Woodbury

Purple Bacteria: Photosynthetic Reaction Centers; Vol.3 - Pages 586-594, C. Roy D. Lancaster

Pyrimidine Biosynthesis; Vol.3 - Pages 600-605, Monika Loffler and Elke Zameitat

Quinones; Vol.3 - Pages 621-627, Giorgio Lenaz and Maria Luisa Genova

Respiratory Chain and ATP Synthase; Vol.3 - Pages 671-675, David G. Whitehouse and Anthony L. Moore

Respiratory Chain Complex I; Vol.3 - Pages 676-680, Ulrich Brandt

Respiratory Chain Complex II and Succinate: Quinone Oxidoreductases; Vol.3 - Pages 681-687, C. Roy D. Lancaster

Respiratory Chain Complex IV; Vol.3 - Pages 688-694, Hartmut Michel

Respiratory Processes in Anoxygenic and Oxygenic Phototrophs; Vol.3 - Pages 695-699, Roberto Borghese and Davide Zannoni

Spastic Paraplegia; Vol.4 - Pages 61-66, Elena Irene Rugarli and Andrea Ballabio

Store-Operated Membrane Channels: Calcium; Vol.4 - Pages 117-122, Indu S. Ambudkar

Superoxide Dismutase; Vol.4 - Pages 135-138, Irwin Fridovich

Uncoupling Proteins; Vol.4 - Pages 313-318, Daniel Ricquier and Frederic Bouillaud

V-ATPases; Vol.4 - Pages 349-353, Michael Forgac

EF-G and EF-Tu Structures and Translation Elongation in Bacteria

Poul Nissen and Jens Nyborg
University of Aarhus, Aarhus, Denmark

The elongation cycle is the productive phase of protein biosynthesis. The genetic message in mRNA is a working transcript of a gene on DNA and it is translated one triplet codon at a time during this phase. Thereby, a specific amino acid sequence is synthesized and the final product represents a functional protein of the living cell. The translation is performed on the ribosome, which is a large complex of ribosomal RNA and ribosomal proteins. The ribosome is organized into two subunits, the large 50S subunit and the small 30S subunit. tRNA molecules provide amino acids for the protein biosynthesis and they are activated by the attachment to tRNA by an aminoacyl bond. During the elongation phase the ribosome is assisted by three elongation factors: (1) elongation factor Tu (EF-Tu), which brings to the ribosome amino-acylated tRNAs (aa-tRNAs) for decoding at the 30S subunit, (2) elongation factor G (EF-G), which assists the ribosome in translocating mRNA and tRNAs, and (3) elongation factor Ts (EF-Ts), which reactivates EF-Tu by exchanging its cofactor GDP for GTP. EF-Tu and EF-G are both G proteins that are active when GTP is bound as cofactor and inactive when GDP is bound. There is no nucleotide exchange factor for EF-G. The elongation phase and both EF-Tu and EF-G are surprisingly well preserved during evolution, for all living organisms. The proteins corresponding to EF-Ts are more complex in eukaryotes.

Elongation

The process by which the growing polypeptide on the ribosome is elongated by one amino acid according to the codon on mRNA involves the activities of the three elongation factors: EF-Tu, EF-Ts, and EF-G. EF-Tu in its active complex with GTP interacts with any aa-tRNA and prevents the spontaneous hydrolysis of the ester bond between the amino acid carboxyl acid moiety and the terminal 3′-ribose hydroxyls of the tRNA. EF-Tu in this so-called ternary complex interacts with the ribosome in its decoding activity where the correct match between the codon positioned in the decoding center of the 30S subunit and the anti-codon on tRNA is achieved. A signal is sent through as yet unknown routes to the 50S subunit, which reacts by inducing hydrolysis of GTP on EF-Tu at the GTPase center of the ribosome. EF-Tu in its GDP form undergoes a large conformational change and is released from the ternary complex and from the ribosome. The universal 3′-CCA end of tRNA is then free to swing into the peptidyl transferase center of the 50S subunit, where the formation of a new peptide bond between the growing polypeptide and the incoming amino acid is performed with the help of catalytic residues of the ribosomal RNA. The released EF-Tu:GDP is reactivated to EF-Tu:GTP with the help of the nucleotide exchange factor EF-Ts.

After peptidyl transfer the nascent polypeptide chain is attached to the incoming tRNA, with its anticodon still at the A site of the 30S subunit. It must be shifted to the P site together with the mRNA by exactly one codon. This is performed by EF-G in the translocation stage of elongation, where EF-G pushes the tRNA and the attached codon of the mRNA from the A site into the P site of the 30S subunit. After this the GTP of EF-G is hydrolyzed to GDP at the GTPase center of the ribosome, and EF-G:GDP is released. The high level of GTP in the cell and the relatively low affinity of GDP for EF-G is enough to ensure that EF-G reactivates into EF-G:GTP spontaneously, without the aid of a nucleotide exchange factor.

The ribosome has now completed one elongation cycle, and is left with a tRNA with its attached polypeptide in the P site of both the 50S and 30S subunits, and with the previous tRNA pushed into the E (exit) site. The ribosome exposes the next codon in the A site of the 30S subunit and is ready to receive the next cognate tRNA in its complex with EF-Tu:GTP.

Elongation Factor EF-Tu

EF-Tu has been the focus of structural studies for several decades. The name stems from early characterization of this factor as “translation factor unstable”. The biochemically most stable form is the biologically inactive EF-Tu:GDP, and was therefore the first form to be

structurally investigated. It was shown that EF-Tu consists of ~400 amino acids containing three domains (Figure 1). Domain 1 is a typical nucleotide binding domain with a central β-sheet surrounded by α-helices on both sides. This domain also contains all the consensus sequences now recognized as typical for a GTP-binding protein (G protein). Of these, there is a P-loop GXXXXGK(S/T) and a DXXG sequence motif also found in many ATP-binding proteins, where they are called Walker A and B motifs, respectively. Furthermore, there is a NKXD sequence motif involved in specific recognition of the G base of GTP, and a threonine residue in the so-called switch I region, which is now known to be involved in Mg^{2+} binding, and in the large conformational change of EF-Tu. A similar domain is found in all known G proteins, like the small GTPases (ras P21 or ran) and in the α-subunit of the heterotrimeric G proteins involved in cellular responses to external signals. The domain is therefore often referred to as the G domain. The remaining two domains, domain 2 and domain 3, of EF-Tu are both β-barrel structures and are in all known conformations of EF-Tu kept together as a single structural unit.

The biologically active form, EF-Tu:GTP, has been structurally determined with a nonhydrolyzable GDPNP nucleotide, where the O atom between the β- and γ-phosphate of GTP has been altered to the electronically similar NH group (Figure 1). The presence of the extra γ-phosphate in EF-Tu:GDPNP, when comparing to EF-Tu:GDP, has a dramatic effect on the overall conformation of the EF-Tu molecule. First of all, the γ-phosphate attracts the DXXG sequence motif, such that the peptide bond between the G residue and its preceding P residue is rotated by ~150°, and such that the NH group of this peptide bond makes a hydrogen bond with the γ-phosphate group. Like all G proteins, EF-Tu has switch regions of the G-domain that have significantly different structures in the GDP and GTP forms. The DXPGH motif of EF-Tu is at the beginning of its switch region II. This region in both the GDP and the GTP form includes an α-helix. However, between the two forms the helix is shifted by 4 residues along the sequence, and the position of its axis is therefore rotated by ~45°. As this helix is a major part of the interface towards domain 3 this change results in an overall rotation of the G-domain relative to domains 2 and 3 by ~90°. From biochemical studies, the histidine residue of the DXPGH motif of EF-Tu is known to be involved in the intrinsic GTPase activity of EF-Tu, and is presumably involved in stabilization of the transition state of GTP hydrolysis on the ribosome. Secondly, the presence of the γ-phosphate, and the shift in position of the proline residue of the DXPGH motif alters the conformation of the switch I region of EF-Tu such that its

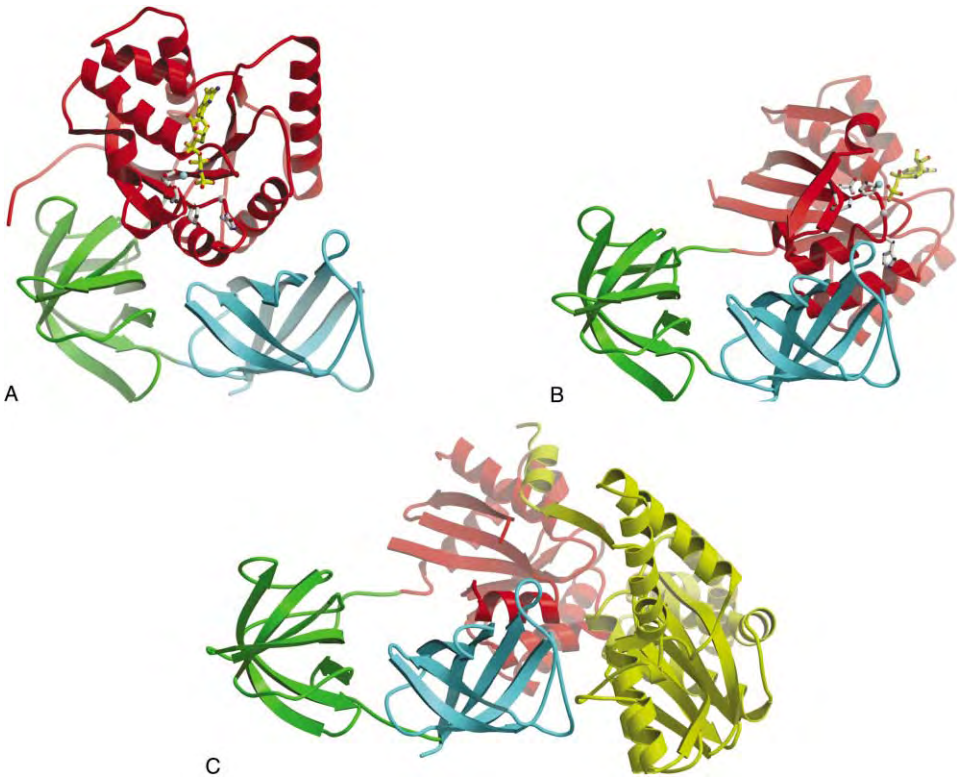

FIGURE 1 Structures of various forms of EF-Tu complexes: (A) EF-Tu:GDP, (B) EF-Tu:GTP, and (C) EF-Tu:EF-Ts. Domains of EF-Tu are colored: domain 1, red with nucleotides in yellow ball-and-stick where present; domain 2, green; domain 3, blue. EF-Ts is in yellow.

T residue becomes a ligand to the Mg^{2+} ion of the GTP form, and part of its secondary structure interchanges between a β-hairpin in the GDP form and an α-helix in the GTP form.

The structure of the complex between EF-Tu and its nucleotide exchange factor EF-Ts is also known. EF-Ts interacts with the G-domain of EF-Tu at the loops responsible for the nucleotide binding, and in many ways it alters the GDP binding pocket. Furthermore, EF-Ts interacts with the tip of domain 3 of EF-Tu in such a way that the G-domain and domain 3 are separated from each other. This separation represents an intermediate in the large conformational change of EF-Tu, and is also part of the catalysis of nucleotide exchange.

Elongation Factor EF-G

The structure of EF-G is known in its GDP-bound and in its nucleotide-free form (Figure 2). EF-G is much larger than EF-Tu and contains ~690 residues organized in five domains. The first domain of EF-G is the G-domain that has many similarities with the G-domain of EF-Tu in structure and in amino acid sequence. Apart from that, it contains an insert of ~90 residues (the G′-domain). The switch I region of EF-G in the GDP form is disordered. Domain 2 of EF-G is also similar to that of EF-Tu although it has a β-hairpin in the cleft between the G-domain and domain 2. The arrangement of the two domains in EF-G:GDP is like that of EF-Tu:GTP. Domains 3–5 have folds containing a small β-sheet with helices on one side only. This fold is very similar to that of some ribosomal proteins. Domain 4 contains an unusual left-handed $\beta-\alpha-\beta$ folding motif. Furthermore, this domain is more elongated and sticks out from the rest of the protein. It is known that the very tip of this domain is functionally important in translocation, as a histidine residue in the eukaryotic factor is modified into the unusual diftamide, and that ADP-ribosylation of this residue by difteria toxin blocks its function on the ribosome.

Despite numerous attempts by several research groups, it has not been possible to determine the structure of the biologically active EF-G:GTP. Studies by cryo-electron microscopy indicate that significant conformational changes occur when EF-G is bound on the ribosome.

The Ternary Complex of EF-Tu

Two structures have been determined of the ternary complex of EF-Tu (Figure 2). The first one was a complex between yeast Phe-tRNA and bacterial EF-Tu:GDPNP, while the second one was of bacterial Cys-tRNA and bacterial EF-Tu:GDPNP. The two are very similar and point to the fact that tRNAs are very similar in all organisms and that therefore the ternary complex is most likely to have the same general structures in all kingdoms of life. The large conformational change of EF-Tu from the GDP to the GTP form creates

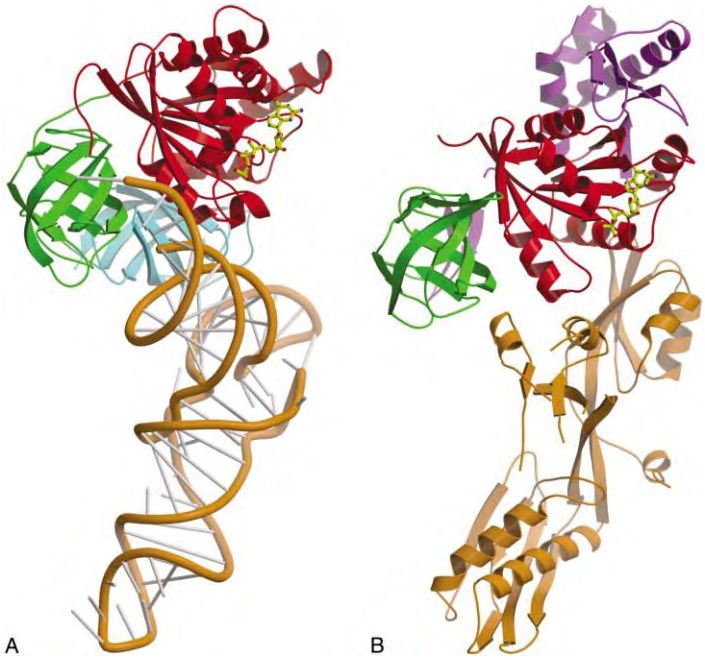

FIGURE 2 Structures of (A) the ternary complex of EF-Tu, and (B) EF-G:GDP. EF-Tu is colored as in Figure 1. The tRNA is in orange, domains 1 and 2 of EF-G are colored as for EF-Tu with an insert in domain 1 in magenta. Domains 3, 4, and 5 of EF-G are in orange.

a preformed binding surface for the tRNA. The structures of both tRNA and EF-Tu:GDPNP in the ternary complex are thus very similar to the structures of the free components. The universally conserved 3′-CCA end of tRNA is bound to a cleft between the G-domain and domain 2 of EF-Tu. This cleft as mentioned above is filled with a β-hairpin in EF-G. The terminal A base is recognized in a deep pocket on the surface of domain 2, while a pocket between the G-domain and domain 2 holds the amino acid attached to tRNA. The aminoacyl bond of the amino acid is recognized by main chain groups of EF-Tu in such a way that the amino group must be deprotonated in the complex. Other contacts involve general features of the tRNA structure.

The Structural Similarity of EF-G and the Ternary Complex

When the structure of the first ternary complex of EF-Tu was determined it was observed that its shape was very similar and points to that of the previously known EF-G:GDP (Figure 2). Domains 3, 4, and 5 of EF-G are thus a structural mimic of the tRNA of the ternary complex. The elongated domain 4 of EF-G directly mimics the anti-codon stem-and-loop of tRNA. There has been much speculation why this should be, and whether this would be a general phenomenon for parts of proteins known to interact with the A site of the ribosome. This does not seem to be the case according to recent results, and the simplest explanation of the mimicry is that the ternary complex has to interact with the ribosome after EF-G:GDP left the ribosome. Possibly, EF-G reshapes the ribosome into a form that is ready to interact with a ternary complex.

Action of Elongation Factors on the Ribosome

Electron microscopy of ribosomal particles in flash-frozen vitreous ice (cryo-EM) has revealed information on how elongation factors interact with the ribosome. The results obtained make use of the fact that some antibiotics interact specifically with the elongation factors on the ribosome. The antibiotic fusidic acid is thus known to interact with EF-G, while the antibiotic kirromycin interacts with the ternary complex of EF-Tu. Both antibiotics block the release of the target proteins on the ribosome after GTP hydrolysis has been induced. The antibiotics are believed to prevent conformational changes in the elongation factors that are needed for their release from the ribosome. The cryo-EM reconstructions of both EF-G and of the ternary complex on the ribosome reveal that they indeed occupy very similar positions and are found to have very similar shapes. The G-domain is seen to be very close to features of the 50S subunit that are very close to the GTPase-activating center of the ribosome. Domain 2 interacts with the 30S subunit such that the G-domain and domain 2 together fill the gap between ribosomal subunits.

The tip of domain 4 of EF-G and the tip of the anti-codon stem-and-loop of tRNA both reach into the decoding center of the 30S subunit. Thus, the similarity in the structures of EF-G:GDP and of the ternary complex of EF-Tu is reflected in their similar interaction with the ribosome.

Antibiotic Action on EF-Tu

A few families of antibiotics are known to interact directly with the function of EF-Tu. These families seem

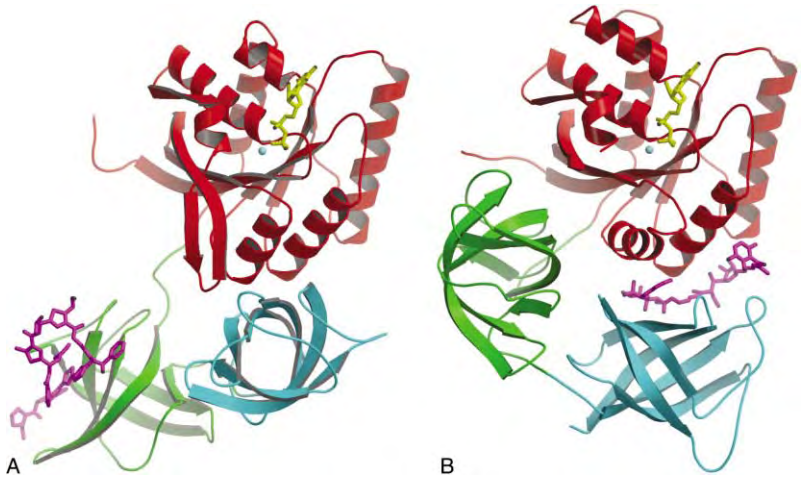

FIGURE 3 Structures of complexes of EF-Tu and antibiotics: (A) GE2770A bound to EF-Tu:GDP, and (B) aurodox bound to EF-Tu:GDP. Antibiotics are shown in magenta.

to fall into two functional groups. One group (examples are GE2270A and pulvomycin) prevents the formation of the ternary complex, while another group (examples kirromycin and enacyloxin IIa) prevents the release of EF-Tu from the ribosome. A structural complex of GE2270A with EF-Tu:GDP has been determined, and reveals that the antibiotic partly occupies the pocket on domain 2, which in the ternary complex accommodates the terminal A base. Furthermore, GE2270A stabilizes EF-Tu in the GDP-bound conformation and prevents the formation of the GTP-bound conformation. This structure thus explains how this group of antibiotics prevents the formation of a ternary complex of EF-Tu.

A structure of EF-Tu:GDP in complex with aurodox (a methylated version of kirromycin) shows the antibiotic in a cleft between the G-domain and domain 3, keeping the two together in a GTP-like form of EF-Tu although the nucleotide bound is GDP. This will explain how kirromycin blocks the release of EF-Tu from tRNA and from the ribosome upon GTP hydrolysis.

These results (Figure 3) may indicate that the conformations trapped by antibiotics are biologically relevant forms, which effectively can be blocked by inhibitors aimed at stopping protein biosynthesis in bacteria.

Glossary

anti-codon A triplet of bases on tRNA that by Watson–Crick base pairing can decode a codon.

codon A triplet of bases on mRNA that codes for one amino acid.

EF-G Translation factor controlled by GTP.

EF-Ts Translation factor (stable).

EF-Tu Translation factor (unstable).

G protein Protein whose action is controlled by GTP and GDP. The protein is active in its GTP-bound form, while hydrolysis of GTP into GDP inactivates the protein.

GDP Guanosine di-phosphate.

GTP Guanosine tri-phosphate.

mRNA Messenger ribonucleic acid containing the triplet codons, each specifying one amino acid.

ribosome Cellular particle that synthesizes proteins with the amino acid sequence given by the sequence of triplet codons of mRNA.

tRNA Transfer ribonucleic acid that carries on its 3′ CCA end an amino acid corresponding to its anti-codon.

Biography

Poul Nissen is an Associate Professor at the University of Aarhus, Denmark. His major scientific interest has been the structural investigation of the ternary complex of EF-Tu and of the large 50S ribosomal subunit and the transition state of its peptidyl transferase center. He received his Ph.D. in protein crystallography at the University of Aarhus, and spent his postdoctoral period at Yale University. He is now working on the yeast ribosome and membrane transport proteins. He is an EMBO Young Investigator and a Danish Research Council Ole Rømer Stipendiate.

Jens Nyborg is an Associate Professor at the University of Aarhus, Denmark. His major scientific interests have been the structural investigations of translation factors and of components of the innate immune system. He received his Ph.D. in crystallography on inorganic chemical compounds and spent his postdoctoral period at the Medical Research Councils Laboratory of Molecular Biology in Cambridge, UK. He is a member of the Royal Danish Academy of Sciences and Letters and EMBO.

Eicosanoid Receptors

Richard M. Breyer and Matthew D. Breyer
Vanderbilt University, Nashville, Tennessee, USA

Eicosanoids are the oxygenated metabolites of the 20-carbon polyunsaturated fatty acid arachidonic acid. These compounds are locally acting autacoids and are rapidly metabolized with a half-life of minutes to seconds. Once formed, eicosanoids exert their physiologic effects via interaction with specific receptors. The best characterized of these receptors belong to the superfamily of G protein-coupled receptors, although some eicosanoids are thought to interact with nuclear hormone receptors as well.

Eicosanoid Biosynthesis Pathways

The 5,8,11,14-eicosatrienoic acid, a 20-carbon polyunsaturated fatty acid with the trivial name arachidonic acid, is esterified in the lipid bilayer of cell membranes. Upon its enzymatic release by the action of phospholipase, free arachidonate is rapidly metabolized. Oxygenated metabolites of arachidonic acid are collectively known as the eicosanoids. These compounds are formed by the action of three distinct enzymatic pathways.

The Lipoxygenase (LO) Pathway

This pathway leads to the formation of the monoxygenated compounds such as hydroperoxytetraenoic acids (HPETEs), hydroxytetraenoic acids (HETEs), and trihydoxylated metabolites known as lipoxins via three principal enzymes: 5-LO, 12-LO, and 15-LO. The 5-HPETEs are substrates for the leukotriene synthases that lead to the formation of a series of key inflammatory mediators, the leukotrienes, including the unstable intermediate LTA_4, which is converted to the potent mediator LTB_4 and the cysteinyl leukotrienes LTC_4, LTD_4, and LTE_4. Sequential oxidation of arachidonic acid by the action of both 12-LO and 5-LO or 12-LO and 15-LO leads to the formation of the lipoxins LXA_4 and LXB_4. The lipoxins are structurally related to the leukotrienes, but appear to act through a distinct set of receptors and have very different actions *in vivo*. Finally, the 5-LO metabolite HPETE can be further metabolized to the 5-oxo ETE(5-oxo-6E,8Z,11Z,14Z-eicosatetraenoic acid), for which a unique receptor has recently been cloned.

The Cyclooxygenase (COX) Pathway

Cyclooxygenase metabolism leads to the production of the five principal prostanoids via two distinct isozymes, COX-1 and COX-2. Four of the principal prostaglandins, PGE_2, PGD_2, $PGF_{2\alpha}$, and PGI_2 are analogues of the 20-carbon unnatural fatty acid prostanoic acid, which is distinguished by its five carbon "prostane" ring group comprised of carbons five through eight. The fifth prostanoid, thromboxane, has an inserted ether oxygen and thus has a six-member ring structure and is an analogue of the unnatural fatty acid thrombanoic acid.

The Epoxygenase Pathway

Oxidation of arachidonic acid by the cytochrome P450 pathway leads to the formation of epoxytrienoic acids (EETs). Although physiologic effects have been attributed to these compounds no specific EET receptors have been identified to date.

Eicosanoid Action

As a class, eicosanoids mediate a wide array of physiologic effects including pain, inflammation, and modulation of smooth muscle tone. Many of these effects are receptor-mediated by cell surface G protein-coupled receptors (GPCRs). There is recent evidence that some PG metabolites can activate nuclear hormone receptors of the peroxisome-proliferation-activated receptor family (PPARs). In addition to the enzymatic products of arachidonic acid metabolism, prostanoid-like products resulting from nonenzymatic oxidation have also been described and designated isoprostanes. These products are structurally related to the COX-derived prostanoids, but are the product of non-enzymatically free radical oxidation. Isoprostanes are markers of oxidative stress and evidence suggests that these metabolites can also evoke receptor-mediated physiologic effects.

Receptors of Lipoxygenase Metabolites

The action of lipoxygenase metabolites of arachidonic acid is mediated by a distinct family of GPCRs. Six GPCRs have been identified that bind lipoxygenase metabolites of arachidonic acid: four leukotriene receptors designated BLT_1, BLT_2, $CysLT_1$, and $CysLT_2$ have been described, a lipoxin receptor designated ALX, and the receptor for 5-oxo ETE.

Leukotriene Receptors

The leukotriene receptors fall into two groups of structurally related GPCRs: the chemoattractant-like BLT receptors and the CysLT receptors, which are related to the family of nucleotide-binding receptors. Of the four cloned leukotriene receptors, BLT_1 and BLT_2 receptors have highest affinity for the leukotriene LTB_4 with BLT_1 binding LTB_4 with much higher affinity as compared to BLT_2. The BLT receptors are predominantly expressed in the peripheral blood including leukocytes, granulocytes, macrophages, and eosinophils. The $CysLT_1$ and $CysLT_2$ receptors in contrast each bind the cysteinyl leukotrienes LTC_4 and LTD_4 with high affinity. CysLT receptors are expressed in peripheral blood leukocytes, spleen, and lung as well in a number of other tissues at lower levels. The $CysLT_1$ receptor has been implicated as an important mediator in asthma, and antagonists of this receptor such as monteleukast have been used clinically in the treatment of asthma.

Lipoxin Receptors

The lipoxin A_4 receptor (ALX), is a member of the GPCR family of chemoattractant receptors, as are the BLT receptors discussed above. This receptor was identified as an orphan receptor cDNA sharing significant homology with the fMLP chemoattractant receptor and was designated FMLP-like receptor 1 (FPLR1). Subsequent identification of this receptor as a mediator of LXA_4 action resulted in its designation as the ALX receptor. Activation of this receptor mediates the anti-inflammatory actions of lipoxin LXA_4. Northern blot analysis of ALXR mRNA in mouse tissues demonstrates that the receptor is most highly expressed in neutrophils, lung, and spleen with lower levels detected in the liver and heart. Some actions of lipoxins cannot be accounted for by the ALXR, and the existence of other lipoxin receptors has been postulated, but existence of other lipoxin receptor cDNAs has not been confirmed.

The 5-Oxo-ETE Receptor

The orphan GPCR TG1019 and closely related R527 have been identified as receptors for 5-oxo-ETE. These receptors have no official designation at this time. These receptors have been shown to be highly expressed in the kidney and may mediate the observed hemodynamic effects of 5-oxo-ETE described in this tissue.

Prostaglandin (PG) Receptors

The local action of PGs depends in part, on activation of a family of specific GPCRs, designated EP for E-prostanoid receptors, FP, DP, IP, and TP receptors respectively, for the other prostanoids. The EP receptors are unique in that four receptors, designated EP1 through EP4, have been described for PGE_2 each encoded by a distinct gene. A second class of Prostaglandin D receptor designated chemoattractant receptor-homologous molecule expressed on Th2 cells (CRTH2) has been identified, which has no sequence homology to the remaining PG receptors. This receptor has been unofficially designated "DP2." Each of the other PGs has a single receptor, and taken together there are nine PG GPCRs, each encoded by distinct genes. Alternative mRNA splice variants have been cloned for the EP1, EP3, TP, and FP receptors. In each case, these splice variants generate receptor sequence diversity in the intracellular C-terminal tail of the receptor protein (Figure 1). Functionally, these splice variants appear to modulate the specificity of G protein coupling, as well as regulation of receptor desensitization by encoding alternate phosphorylation sites. Pharmacologically, the PG receptors are distinguished by their ligand-binding selectivity as well as the signal transduction pathway they activate. In general, PG receptors may have significant affinity for more than one prostanoid ligand. Moreover, multiple PG receptors are frequently coexpressed in a single cell type or tissue. COX activation and resulting PG production may lead to complex effects in the target tissue by activation of multiple PG receptor subtypes. Thus, a given PG ligand may elicit multiple, and at times apparently opposing, functional effects on a given target tissue. For example, prostaglandin receptors were initially characterized by their actions on smooth muscle, where they may lead to either smooth muscle contraction or relaxation. The vasodilator effects of PGE_2 have long been recognized in both arterial and venous beds. Smooth muscle relaxation by PGE_2 is, however, not uniformly observed, and PGE_2 is a potent constrictor in other smooth muscle beds, including trachea, gastric fundus, and ileum. Importantly, some structural analogues of PGE_2 are capable of reproducing the dilator effects of PGE_2, but are inactive on tissues where it is a constrictor. Conversely, analogues that reproduce the constrictor effects of PGE_2 may fail to affect tissues where PGE_2 is a dilator. The EP receptor mRNAs exhibit differential

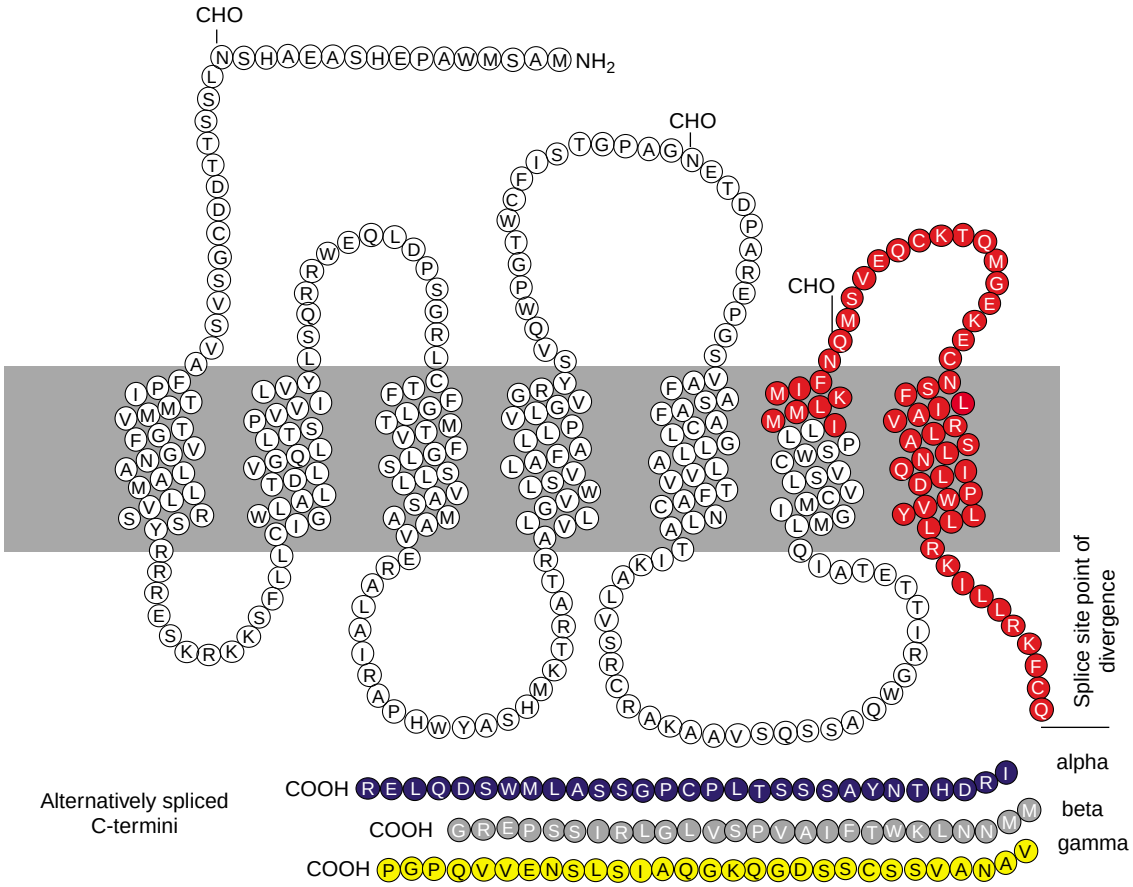

FIGURE 1 EP_3 receptor sequence of three mouse EP_3-receptor splice variants differing only in their intracellular carboxyl termini. The predicted amino acid sequences of each splice variant is represented by the one-letter amino acid code. Exons are color-coded. The common region is comprised of two exons (in white and red circles) which are spliced to three possible C-terminal tails. The carboxyl variable tails are designated alpha (blue), beta (gray), and gamma (yellow), each encoded by distinct exons.

expression in a number of tissues with distinct functional consequences of activating each receptor subtype. Functional antagonism among PGs can also be observed in platelet aggregation, where TXA_2 activation of the TP receptor causes platelet aggregation. Conversely, prostacyclin activates platelet IP receptors which opposes this platelet aggregation. Thus, the balance of PGs synthesized as well as the complement of PG receptors expressed determines the net effect of COX metabolism on platelet function.

PPARs

In addition to the GPCR-mediated effects there is evidence that prostaglandin metabolites are capable of activating some nuclear transcription factors. This action is exemplified by the cyclopentenone prostaglandins of the J-series, e.g., 15-deoxy -Δ12,14-PGJ_2 (15d-PGJ_2) which are derived from PGD_2. 15d-PGJ_2 activates a nuclear hormone receptor designated peroxisome proliferation activated receptor gamma (PPARgamma). There is also evidence that prostacyclin (PGI_2) also activates another member of this family designated PPARdelta. It is unclear whether the PGs represent true endogenous ligands of these receptors, as their affinity is generally in the micromolar range, which is two to three orders of magnitude lower than the nanomolar affinities observed for PGs at the GPCRs; nonetheless, these concentrations could be achieved in the intracellular environment.

Glossary

autacoid A class of physiologically active substances that act upon the cell that elaborated this compound or on adjacent cells.

cyclooxygenase (COX) Enzymes that catalyze the oxidation of arachidonic acid. Also known as PGH synthase. COX catalyzes two sequential reactions, a *bis* oygenase, or cycloxygenase, reaction leading to the formation of PGG_2 and a subsequent peroxidase activity at the C15 position leading to the conversion of PGG_2 to PGH_2.

eicosanoid Any of the collections of oxygenated metabolites of the 20-carbon fatty acid, 5,8,11,14-eicosatetranoic acid (arachidonic acid) that are the products of cyclooxygenase, cytochrome P450, lipoxygenase, and nonenzymatic pathways.

GPCRs G protein-coupled receptors. A class of integral membrane protein cell-surface receptors that change conformation upon binding cognate agonists. This conformational change causes the dissociation of heterotrimeric G proteins leading to the initiation of the signal transduction cascade.

leukotriene Monoxygenated metabolites of arachidonic acid formed by the action of the lipoxygenases.

nonsteroidal anti-inflammatory drugs (NSAIDs) A class of drugs that effect their action by inhibiting the activity of cyclooxygenase. They have potent analgesic, antipyretic, and anti-inflammatory properties.

prostanoids Oxygenated metabolites of the 20-carbon essential fatty acid arachidonic acid. They are analogues of the 20-carbon unnatural fatty acids, prostanoic, and thrombanoic acid, produced by the action of cyclooxygenase.

He holds an M.D. from Harvard University, and received his postdoctoral fellowship training at the University of Texas, Southwestern Medical Center in Dallas, Texas.

Elastin

Judith Ann Foster
Boston University School of Medicine, Boston, Massachusetts, USA

Elastin is a protein that exists as fibers in the extracellular spaces of many connective tissues. Elastin derives its name from its ability to act as an elastic band, i.e., to stretch and recoil with transient force. It is located throughout many tissues and organs of higher vertebrates and plays an important functional role in maintaining pressures associated with liquid and air flow in the cardiovascular and pulmonary systems. Elastogenic cells synthesize and secrete a soluble monomeric form of elastin into the extracellular space. The enzyme, lysyl oxidase, initiates cross-linking of the soluble monomers into insoluble fibers. Extracellular elastin associates closely with other proteins in the matrix including microfibrillar proteins and collagens. Once laid down in the matrix, the insoluble protein is very stable and resistant to degradation. Because of its critical role in the normal development and function of vital organs, impairment of elastin synthesis or proteolytic degradation of the insoluble fibers results in major clinical pathologies.

Composition and Primary Sequence

Elastin, as any protein, possesses a unique amino acid composition and a unique sequence of those amino acid residues along the polypeptide chain.

Amino Acid Composition

The soluble form of elastin, sometimes referred to as tropoelastin, contains a preponderance of uncharged and nonpolar amino acids. The polypeptide chain contains appropriately 850 amino acids and a molecular mass of 65–72 kDa. The actual size varies somewhat among different species. Glycine (33%), alanine (18%), proline (13%), valine (17%), and leucine (5%) residues represent 86% of the total amino acids. Prolyl hydroxylase converts 1–2% of the proline residues to hydroxyproline but it is unclear as to the significance of this cotranslational modification. There are ~36–38 lysine residues per molecule so the overall charge of monomer is basic with an isoelectric point over pH 10. Once lysyl oxidase deaminates the epsilon amino group of most lysine residues in the protein, the resulting semialdehydes undergo a series of aldol condensations and Schiff bases to form the desmosine cross-links. At this stage, the protein is irreversibly insoluble and any success in extracting soluble fragments requires cleavage of peptide bonds.

Amino Acid Sequence

Unlike the classical triple repeat of collagen wherein glycine residues occupy every third position of the triplet, elastin does not contain a uniform repeating structure. Instead, elastin contains two broad sequence motifs that accommodate much subdivision. Most lysine residues segregate together with alanine residues to create pairs of lysines separated by two or three alanine residues. These sequences exist within stretches of uncharged, nonpolar amino acid residues such as glycine, valine, and proline. The latter amino acid residues occur together with other nonpolar, hydrophobic, and polar residues, form tri, tetra, penta, and hexa repeats with not a single consistent motif. The carboxy terminal sequence is unique and highly conserved among different species. It contains the only cysteine residues within the molecule.

Isolation of Elastin

Insoluble Elastin

An early operational definition of elastin was that it represented the protein remaining after one extracted all other connective tissue proteins. Consequently, the insolubility of elastin serves as the basis for all isolation methods. Isolation procedures involve very harsh treatments such as autoclaving, extraction with hot alkali or strong denaturants, and exposure to cyanogen bromide or collagenases. Amino acid analysis of the material remaining insoluble after these treatments confirms the presence and homogeneity of the elastin.

Soluble Elastin

In vivo the conversion of soluble to insoluble elastin occurs rapidly making the isolation of soluble elastin very difficult. In order to isolate quantitative amounts of soluble elastin from a tissue, one must block the

conversion of the soluble to the insoluble form. Inhibition of the cross-linking enzyme, i.e., lysyl oxidase, is the most effective approach for isolating intact elastin monomers. Since lysyl oxidase is a copper-dependent enzyme that is specific for lysine residues it can be inhibited by removing copper or adding a noncompetitive inhibitor. In practice, this involves rendering an animal copper deficient by dietary restriction or by adding β-aminopropionitrile, a lathyrogen, to the diet of young animals. The procedure for isolating soluble elastin is based primarily on its unique solubility in organic solvents.

The Elastin Gene

Gene Structure

The single copy, elastin gene spans ~35–40 kb of DNA but only 7% of the sequences represent exons that are transcribed into the mRNA. The huge amount of intron sequences in the gene (19:1, intron to exon) makes this one of the most disperse genes reported. The short exon sequences (less than 190 bp) encode separate cassettes for the nonpolar and lysine/alanine residues of the protein. Many of the intron sequences encode elastin-like sequences.

Gene Promoter

The elastin gene promoter contains features of a constitutively expressed (housekeeping) gene. It lacks a classic TATA box, is very GC rich (67%), has two CAAT boxes and possesses multiple transcription start sites. There are also several Sp1 sites as well as a cryptic GC box and several consensus AP2 sequences within the proximal promoter. In addition, consensus sequences for glucocorticoid, TPA-inducible, and CRE response elements reside in the distal promoter regions.

Elastin Gene Expression

Elastin mRNAs

Transcription of the elastin gene results in multiple mRNAs. The multiple forms all possess a size in the 24S range arising from alternate splicing of several different exons. All of the transcripts contain ~3.5 kb that includes a large untranslated 3′ region of ~1.0 kb in addition to the polyA tail.

Elastin Protein Isoforms

Translation of multiple mRNA results in different isoforms of soluble elastin that reflect insertion of different exons sequences. Although there is variance in the presence of isoforms dependent on cell type and age, the function of the different variations of soluble elastin is still not clear. There is speculation that different isoforms play a major role in the early phase of elastic fiber assembly by providing interactive sites for specific binding to other components of the extracellular matrix.

Regulation of Elastin Gene Expression

The expression of elastin is high in developing tissues and through early growth to maturity. In the adult animal, elastin synthesis is very low and its reinitiation occurs only in normal injury/repair situations or in some pathological conditions. Many studies have focused on understanding how elastin expression is regulated in development and disease conditions. The results show that expression is regulated at both the transcriptional and posttranscriptional levels.

Transcriptional Regulation

Many studies have shown that elastin expression in developing pulmonary and cardiovascular tissues is controlled primarily at the transcriptional level. These results have been confirmed in transgenic animals carrying the transgene with a reporter driven by the elastin promoter and by *in vitro* tissue transfections of the same reporter gene. In addition, primary cultures of elastogenic cells demonstrate that elastin transcription plays a major role in the action of elastin modulators such as basic fibroblast growth factor and insulin-like growth factor. Putative *cis*-acting elements in the 5′ flanking region of the gene have been broadly defined through transient transfections of various cell types with a series of deletion reporter constructs. Of the *cis*-acting elements identified within the elastin promoter, few have been functionally shown to convey an increase in elastin transcription. In fact, the majority were found to be repressors. These latter observations suggest that a possible route to increase elastogenesis is to block the repressor complex from binding via the disruption of the receptor and/or ligand binding, as well as blocking the resultant signal pathway.

Posttranscriptional Regulation

Studies on the expression of elastin in cultures of elastogenic cells challenged with biologically significant factors show that elastin mRNA stability is important in regulating expression especially in the adult animal.

Biography

Dr. Judith Ann Foster is currently a Professor of Biochemistry at Boston University School of Medicine. She has held faculty positions at the Utah University School of Medicine, the University of Georgia and served as the Chairperson of the Biology Department at Syracuse University. She has been studying elastin for the last 30 years. She began her work on characterizing soluble elastin and the regions of cross-link formation and progressed to examining the biosynthesis and expression of elastin in lung and aortic cells. Dr. Foster has spent the last decade studying the regulation of elastin gene transcription.

Endocannabinoids

Daniele Piomelli
University of California, Irvine, California, USA

The endocannabinoids are a family of biologically active lipids that bind to and activate cannabinoid receptors, the G protein-coupled receptors targeted by Δ^9-tetrahydrocannabinol in marijuana. The term encompasses several derivatives of arachidonic acid, which are generated on demand by neurons and other cells in response to physiological or pathological stimuli. The two best-characterized endocannabinoids are anandamide (arachidonoylethanolamide) and 2-arachidonoylglycerol (2-AG). Others are noladin ether (2-arachidonoyl glyceryl ether) and virodhamine (O-arachidonoyl ethanolamine).

Synthesis

Anandamide

Anandamide is produced from the hydrolysis of an N-acylated species of phosphatidylethanolamine (PE), called N-arachidonoyl-PE. This reaction is initiated by activating neurotransmitter receptors and/or by elevating intracellular levels of Ca^{2+} ions and is probably catalyzed by phospholipase D. The anandamide precursor, N-arachidonoyl-PE, is present at low levels in nonstimulated cells, but its formation can be stimulated by Ca^{2+} and occurs simultaneously with that of anandamide. N-arachidonoyl-PE synthesis is catalyzed by membrane-bound N-acyltransferase, which has been partially purified. (See Figures 1 and 2.)

2-Arachidonoylglycerol

In brain neurons, 2-AG formation is probably initiated by the activation of phospholipase C, which cleaves membrane phospholipids (e.g., phosphatidylinositol-4,5-bisphosphate) at the proximal phosphate ester bond, producing 1,2-diacylglycerol. This intermediate is broken down by diacylglycerol lipase to yield 2-AG and free fatty acid. Another pathway of 2-AG release might involve the hydrolytic cleavage of a phospholipid at the *sn*-1 position of the glycerol backbone, catalyzed by phospholipase A_1. This reaction yields a *sn*-2 lysophospholipid, which can be further hydrolyzed to produce 2-AG (Figure 3). Finally, 2-AG might be formed by hormone-sensitive lipase acting on triacylglycerols or by lipid phosphatases acting on lysophosphatidic acid. However, as these enzymes preferentially target lipids enriched in saturated or monounsaturated fatty acids, they are unlikely to play a role in the synthesis of a polyunsaturated species such as 2-AG.

Physiological Regulation of Endocannabinoid Synthesis

Anandamide

Anandamide synthesis is initiated by intracellular Ca^{2+} rises and/or by activation of G protein-coupled receptors. For example, activation of vanilloid receptors elevates intracellular Ca^{2+} levels and stimulates anandamide synthesis in rat sensory neurons in culture. In addition, activation of dopamine D_2-receptors enhances anandamide release in the brain striatum of the rat *in vivo*. The molecular steps involved in these effects have not yet been clarified.

2-Arachidonoylglycerol

2-AG formation is also linked to intracellular Ca^{2+} rises. For example, in freshly dissected slices of rat hippocampus, electrical stimulation of the Schaffer collaterals (a glutamatergic fiber tract that projects from CA3 to CA1 neurons) produces a fourfold increase in 2-AG levels, which is prevented by the Na^+ channel blocker tetrodotoxin or by removing Ca^{2+} from the medium. It is notable that anandamide levels are not changed by the stimulation, suggesting that the syntheses of 2-AG and anandamide can be independently regulated. This idea is supported by the fact that activation of D_2 receptors, a potent stimulus for anandamide release in the rat striatum, has no effect on striatal 2-AG levels.

Deactivation

In the brain and other tissues, anandamide and 2-AG are rapidly eliminated through a two-step process consisting of uptake into cells and enzymatic hydrolysis.

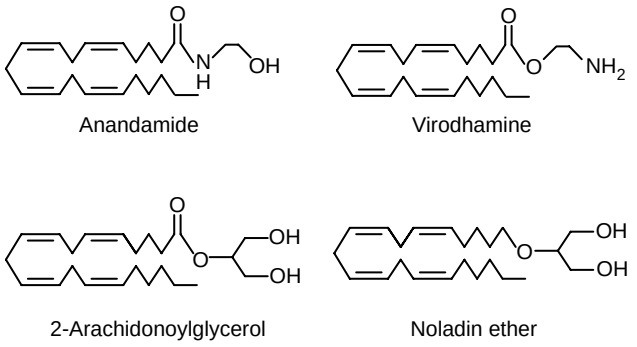

FIGURE 1 Chemical structures of the endocannabinoids anandamide (arachidonoylethanolamide), 2-arachidonoylglycerol (2-AG), noladin ether, and virodhamine.

The two endocannabinoids share a functionally similar transport mechanism, but they follow distinct routes of intracellular degradation.

Transport into Cells

The transport of anandamide and 2-AG into neurons and astrocytes is structurally specific, displays classical saturation kinetics, and is selectively inhibited by compounds such as N-(4-hydroxyphenyl)-arachidonamide (AM404). The putative transporter involved has not yet been identified, but transport has been shown to be Na^+-independent, which is suggestive of a facilitated diffusion mechanism.

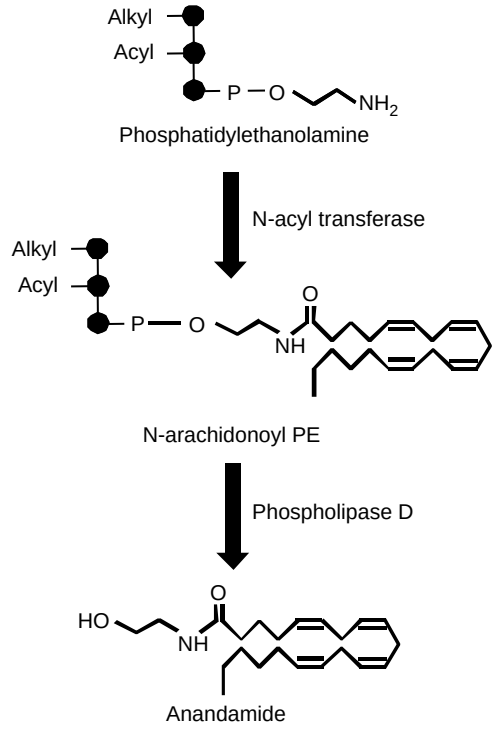

FIGURE 2 Anandamide biosynthesis. PE, phosphatidylethanolamine.

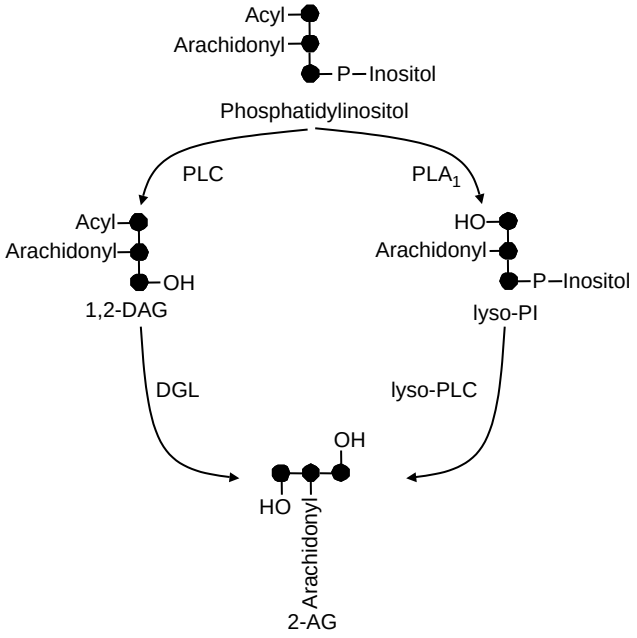

FIGURE 3 2-AG biosynthesis. 1,2,-DAG, 1,2- diacylglycerol; DGL, diacylglycerol lipase; PL, phospholipase.

Intracellular Hydrolysis

Inside cells, anandamide is metabolized by fatty acid amide hydrolase (FAAH), a membrane-bound intracellular serine hydrolase that also cleaves oleoylethanolamide, an endogenous satiety factor, and other lipid amides. Hydrolysis of 2-AG is catalyzed instead by monoglyceride lipase (MGL), a cytosolic serine hydrolase that converts 2- and 1-monoglycerides into fatty acid and glycerol. The contribution of other lipases to 2-AG degradation cannot be excluded at present.

Cannabinoid Receptors

The endocannabinoids regulate the function of multiple organs and tissues of the body. These regulatory effects are primarily mediated by two G protein-coupled receptors: CB_1 and CB_2. CB_1 is highly expressed in the central nervous system, but is also present at lower levels in a variety of peripheral tissues. By contrast, CB_2 is mostly found in immune cells such as lymphocytes. Both subtypes are linked to G_i/G_o proteins and can initiate signaling events typical of these transducing proteins, which include inhibition of adenylyl cyclase activity, opening of K^+ channels, closing of Ca^{2+} channels, and stimulation of protein kinase activities. Nevertheless, CB_1 and CB_2 are structurally different (they have only 44% sequence homology), which has allowed the development of subtype-selective ligands such as the CB_1 antagonist SR141716A (rimonabant) and the CB_2 antagonist SR144528. There is evidence for the

existence of at least two additional cannabinoid-sensitive sites in the brain and vasculature, which remain however uncharacterized.

Functions

In broad terms, the endocannabinoids are considered paracrine mediators, substances that act on cells near their sites of synthesis without entering the bloodstream. For example, they are formed by circulating leukocytes and platelets during hypotensive shock and induce the vascular relaxation that accompanies this phenomenon by activating CB_1 receptors on the surface of smooth muscle cells. Similar paracrine actions occur in the brain, where the endocannabinoids mediate a localized signaling mechanism through which neurons modify the strength of incoming inputs. The endocannabinoids are generated by neuronal depolarization and travel backward across the synapse to regulate the release of neurotransmitters from neighboring axon terminals, a process called retrograde signaling.

Glossary

arachidonic acid Common name for eicosatetraenoic acid (eicosatetraenoic acid, $20{:}4\Delta^{5,8,11,14}$), an essential fatty acid that serves as metabolic precursor for eicosanoids and endocannabinoids.

axon terminal Specialized structure of a neuron that secretes neurotransmitters.

G proteins Heterotrimeric proteins with GTPase activity that link the occupation of certain cell surface receptors to cellular responses.

neurotransmitter Substance secreted by a neuron at a synapse.

phospholipase A group of enzymes that catalyze the hydrolysis of phospholipids at their glycerol ester (PLA) of phosphodiester (PLC, PLD) bonds.

protein kinase Enzyme that transfers a phosphate group from ATP to a protein.

stereospecific numbering (sn) A convention on how to designate the stereochemistry of glycerol-based lipids. When the glycerol moiety is drawn with the secondary hydroxyl to the left, the carbons are numbered 1,2,3 from top to bottom.

striatum A subcortical brain structure involved in the control of movement, habit learning, and the rewarding properties of drugs of abuse.

synapse Specialized junction between the ending of the presynaptic neuron and the dendrite, cell body, or axon of a postsynaptic neuron.

vanilloid receptor A receptor channel permeable to monovalent cations and activated by heat, acid, and capsaicin, the active ingredient of chili peppers.

Biography

Daniele Piomelli is a Professor in the Department of Pharmacology at the University of California, Irvine. His principal research interest is in the field of lipid signaling, including the endocannabinoids. He holds a doctorate in pharmacy from the University of Naples (Italy) and a Ph.D. in pharmacology from Columbia University, New York. He served as postdoctoral fellow at the Rockefeller University, New York, and worked at the INSERM, Paris, and at the Neurosciences Institute in La Jolla, California. He is a member of the American College of Neuropsychopharmacology.

Endocytosis

Julie G. Donaldson
National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland, USA

Endocytosis is a process carried out by all eukaryotic cells that involves the invagination of the cell surface membrane and constricted closure to form a vesicle that enters the cell interior. Included in the internalized vesicle are extracellular fluid and plasma membrane proteins and lipids. Endocytosis enables the cell to take up extracellular nutrients, remove activated receptors from the cell surface, and turnover cell surface proteins and lipids. Endocytosis is also used for the removal of extracellular debris such as dead cells and bacteria, and as a cellular port of entry for infectious bacteria and viruses. Endocytosis can be broadly divided into pinocytosis (cell drinking) and phagocytosis (cell eating) (Figure 1). There are several types of pinocytosis. The best-characterized type is that involving endocytosis of vesicles coated on the cytoplasmic surface with a protein called clathrin. Phagocytosis involves ingestion of particles by extension and wrapping of plasma membrane around the particle, bringing it into the cell. After internalization, the endocytosed material meets different fates: degradation, recycling back to the cell surface, or routing to other destinations within the cell.

Clathrin-Mediated Endocytosis

Endocytosis that is associated with clathrin coating enables certain plasma membrane proteins to be concentrated and efficiently internalized (Figure 1A). The transferrin receptor and low-density lipoprotein (LDL) receptor are cell surface proteins that are internalized by this mechanism, carrying iron-loaded transferrin protein and cholesterol-bearing LDL particles bound to these receptors into the cell. The clathrin coat that assembles on these structures forms a distinctive basket-like structure that can be visualized by electron microscopy. The polymerization of the clathrin coat is believed to facilitate changes in membrane curvature, deformation of the surface membrane, and formation of the vesicle. Once the vesicle has separated from the cell surface (fission), the clathrin coat is rapidly shed and then reutilized for additional endocytic events. Clathrin-coated pits cover 2% of the plasma membrane and since they are believed to have a lifetime of ~1 min, ~2% of the cell surface membrane is internalized each minute in the average cell. Clathrin-mediated endocytosis accounts for the bulk of pinocytosis in most cells. Clathrin assembly onto membrane requires the prior binding of a set of cytosolic adaptor proteins onto the plasma membrane.

Adaptor Proteins

The clathrin adaptor protein 2 complex (AP2) is composed of four different cytosolic proteins that bind to specific lipids and proteins at the plasma membrane and to clathrin, thus initiating clathrin assembly at distinct sites along the cell surface. There are three additional AP complex proteins in cells that associate with other cellular membranes such as the Golgi complex where they also facilitate clathrin assembly. One of the subunits of AP2 specifically binds to tyrosine-based, amino acid sorting signals in the cytoplasmic regions of plasma membrane proteins. The transferrin receptor contains such a tyrosine signal that sorts transferrin receptor into forming clathrin-coated PM vesicles enabling the transferrin receptor to be efficiently and rapidly internalized into cells. The ability to concentrate specific surface cargo proteins into clathrin-coated pits is the hallmark of clathrin-mediated endocytosis (Figure 2). There are other amino acid sorting signals that allow for rapid internalization via clathrin endocytosis including paired leucine and/or isoleucine residues. Plasma membrane proteins that contain these sorting sequences are continually brought into cells by clathrin-mediated endocytosis. Some hormone receptors such as the β2-adrenergic receptor lack these sorting sequences and do not appreciably enter clathrin-coated vesicles in the absence of hormonal stimulation. However, when the receptor is activated by a hormone, a special adaptor protein called β-arrestin binds to the receptor, allowing the receptor–arrestin complex to associate with AP2 and be rapidly internalized by the clathrin-dependent pathway.

Dynamin

The final step in endocytosis is membrane fission that allows the vesicle to detach from the cell surface. A GTP-binding protein called dynamin facilitates this process

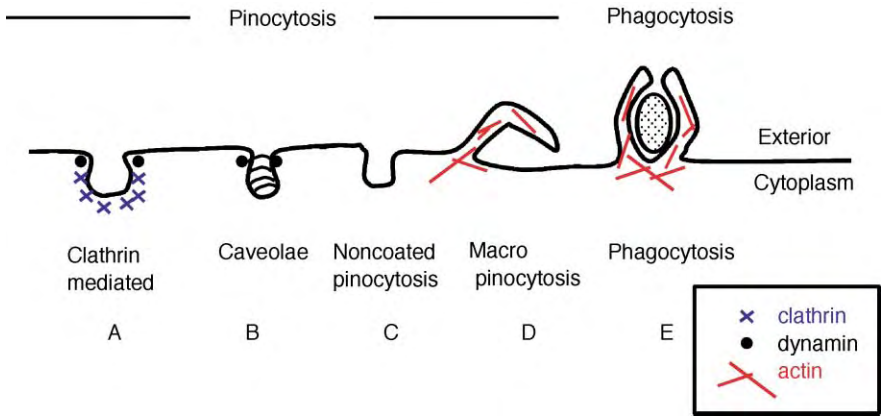

FIGURE 1 Types of endocytosis. Features of the various types of endocytosis (pinocytosis and phagocytosis) are shown. (A) Clathrin-mediated pinocytosis is associated with a cytosolic coat of clathrin (X) and uses dynamin (black spots) for vesicle fission. (B) Caveolae are flask-shaped structures coated with caveolin that also use dynamin for vesicle fission. (C) Non-coated pinocytosis involves invagination of membrane that does not have a recognizable protein coat. (D) Macropinocytosis is associated with cell surface actin-dependent protrusions and forms by fusion of the protruding membrane back onto the cell surface. (E) Phagocytosis is a process that is stimulated by an extracellular particle that induces actin-dependent cell extensions to envelope the particle.

by assembling into ring-like structures and constricting at the necks forming clathrin-coated vesicles. Mutations in dynamin, originally described for *Drosophila melanogaster* mutants, freeze clathrin-forming vesicles at the constricted state and the vesicles are not released. All clathrin-mediated and some other types of endocytosis are dependent upon the function of dynamin. Dynamin also associates with other factors that may facilitate the fission process. Rearrangements in membrane lipids and changes in lipid composition also contribute to the changes in membrane curvature required for vesicle budding and vesicle fission.

Clathrin-Independent Endocytosis

Several other types of pinocytosis have been identified that are not associated with clathrin coats. We know less about the mechanisms of these processes and how they are regulated. Plasma membrane proteins that lack the

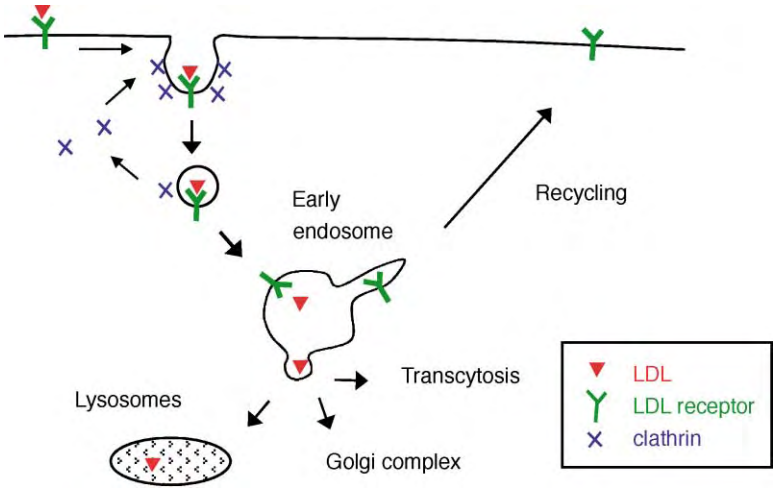

FIGURE 2 Itinerary of internalized cell surface receptors and vesicle contents. Shown here is the pathway followed by internalized LDL bound to the LDL receptor. Cell surface–LDL receptor binds to LDL and is sorted into forming clathrin-coated vesicles at the plasma membrane. After vesicle fission, the clathrin coat is rapidly released from the vesicle so it can assemble again onto the plasma membrane. The vesicle membrane then fuses with the early endosome, a membrane compartment that serves as a sorting station for membrane proteins and lipids. The low pH of the early endosome causes release of LDL from its receptor. The LDL particle and other molecules present in the fluid portion of the early endosome can then be routed to lysosomes for degradation. The LDL receptor enters regions of the early endosome that break off and carry these receptors and membrane back to the plasma membrane. Some membrane proteins leave the early endosome and are transported to other regions of the plasma membrane (transcytosis) or to the Golgi complex.

cytoplasmic amino acid sequences specifying association with AP2 and clathrin, can be endocytosed into cells by these processes.

Caveolae

Some proteins associate with cholesterol and glycosphingolipid-enriched regions of the plasma membrane referred to as membrane raft domains. In many cells, especially in endothelial cells that line blood vessels, these raft domains are present in flask-shaped invaginations of the plasma membrane. These flask-shaped invaginations are called caveolae (caves), and the cytoplasmic coat protein associated with these structures that give them their distinctive shape is called caveolin (Figure 1B). Caveolar endocytosis is dependent upon dynamin and is used as an endocytic mechanism for the transport of materials across endothelial cells. Interestingly, simian virus 40 stimulates caveolar endocytosis and enters many types of cells through this mechanism. Finally, there are cells that lack caveolin and hence caveolae and yet endocytose proteins that associate with membrane raft domains.

Noncoated Endocytosis and Macropinocytosis

Plasma membrane proteins and lipids are also observed in invaginations budding from the membrane that lack any identifiable protein coat (Figures 1C and 1D). This process may or may not require dynamin function depending upon the cell type. Although this process may account for a smaller fraction of cell-surface endocytosis than clathrin-mediated endocytosis, it can be greatly stimulated when cells get activated and form membrane ruffles and protrusive structures. In this case, the membrane ruffle can fuse with the plasma membrane forming a large, macropinosome that internalizes a large amount of surrounding fluid. Dendritic cells of the immune system are very active in macropinocytosis as a means of sampling foreign material in the extracellular fluid. Macropinosome formation is actin dependent. Some bacteria, notably *Salmonella typhi*, stimulate host cells to form membrane ruffles and macropinosomes, and then use these structures as a port of entry into the cells.

Phagocytosis

In lower eukaryotes, such as protozoa, this process of particle ingestion is used for nutrient uptake. However, in mammals phagocytosis is observed in specialized cell types, namely, macrophages and neutrophils that ingest bacteria and dead cells and degrade them. When a macrophage encounters a bacterium that has been coated with antibodies generated by the immune system, cell surface receptors that recognize the Fc portion of the antibodies get activated. This stimulates changes in the macrophage actin cytoskeleton and leads to the extension of membrane around the bacteria, and final closure of the structure through membrane fusion (Figure 1E). Macrophages are also active in phagocytosing senescent-red blood cells and other cells that have undergone programmed cell death. It is believed that macrophages can detect alterations on the cell surface of the senescent cell, such as appearance of a phospholipid on the outer surface that is normally present only on the cytoplasmic side of the plasma membrane. After phagocytosis, the resulting phagosome usually fuses with lysosomes and membrane-bound organelles that contain hydrolytic enzymes that degrade the bacteria. However, some bacteria such as *Mycobacterium tuberculosis*, can actively prevent the fusion of the phagosome with lysosomal membranes, and hence escape degradation.

Fate of Internalized Membrane and Content

After endocytosis, the endocytic vesicle usually fuses with a membrane-bound structure called the early endosome (Figure 2). The early endosome accepts newly endocytosed material and serves as a sorting station that directs incoming proteins and lipids to their final destination. The early endosomal membrane contains a special membrane lipid, phosphatidylinositol 3-phosphate that recruits cytosolic proteins onto these membranes and facilitates the fusion of incoming vesicles with the early endosome. The interior, lumenal environment of the early endosome is moderately acidic (pH 6.5–6.0). The low pH facilitates the sorting process, releasing bound proteins from their receptors and sorting membrane proteins and lipids into different domains. A good example of how low pH serves this function is the itinerary of the transferrin receptor that carries iron-saturated transferrin into the cell. The acidic environment of the early endosome causes the release of iron from transferrin. The iron is then transferred across the membrane into the cytosol, while the transferrin bound to the transferrin receptor is recycled back to the cell surface via membrane carriers that are released from the early endosome. Another example of this sorting of incoming material is the fate of internalized LDL particles bound to the LDL receptor (shown in Figure 2). LDL is released from the receptor in the early endosome and is transferred with other lumenal material to late endosomes and lysosomes. There the LDL is degraded, causing cholesterol

release inside the cell. Meanwhile, the LDL receptor returns to the cell surface to carry out additional rounds of endocytosis. For the transferrin and LDL receptors, endocytosis is a mechanism for delivery of iron and LDL into the cell. By contrast, for signaling receptors, such as those activated by hormones and growth factors, endocytosis is generally used to halt the signaling process by removal of the receptor from the cell surface. An exception to this is the recent observation that the epidermal growth factor (EGF) receptor may require endocytosis for some signaling functions.

Endocytosed membrane proteins can be transported to different locations in the cell (Figure 2). Some membrane proteins are sorted into vesicles that fuse to another region of the plasma membrane, a process called transcytosis. Mucosal immunoglobulins such as IgA are transcytosed across intestinal epithelia via IgA receptors that ferry IgA from the basal (serosal) side to the apical (mucosal) surface of the epithelia. Other proteins leave the early endosome in vesicles that fuse with membranes adjacent to the *trans* side of the Golgi complex.

Regardless of how a membrane is brought into the cell, it must be balanced by addition of membrane back to the plasma membrane. This is accomplished by endosomal-membrane recycling and also through the contribution of newly synthesized membranes from the secretory pathway. The cell has to regulate and coordinate the flux of membrane into and out of the cell to maintain cell surface area and for proper localization of important cell surface receptors.

Julie G. Donaldson is a Senior Investigator in the Laboratory of Cell Biology in the National Heart, Lung, and Blood Institute at the National Institutes of Health in Bethesda, Maryland. Her research interests are in understanding the mechanisms and regulation of endosomal and secretory membrane traffic in the cell. She holds a Ph.D. from the University of Maryland and was a Postdoctoral Fellow in the National Institute of Child Health and Human Development prior to her current position.

Endoplasmic Reticulum-Associated Protein Degradation

Maurizio Molinari
Institute for Research in Biomedicine, Bellinzona, Switzerland

For proper functioning, a protein has to fold into a characteristic three-dimensional structure and may have to form a multimeric complex. The endoplasmic reticulum (ER) provides an environment optimized for the folding and assembly of proteins that will then be secreted (hormones, antibodies, pancreatic enzymes, etc.), or displayed at the plasma membrane (receptors, channels, etc.), or that reside in intracellular compartments such as the lysosomes and the Golgi. Only native proteins leave the ER to be transported along the secretory pathway to their final destination. A quality control system is in place to prevent forward transport of polypeptides for which folding and assembly have failed. To prevent their accumulation in the lumen of the ER, a series of events regulated by luminal and cytosolic components, and collectively named ER-associated protein degradation (ERAD) ensures that terminally misfolded polypeptides are transferred into the cytosol to be degraded by the 26S proteasome. This article summarizes recent advances in understanding how malfolded glycoproteins are cleared from the ER lumen of mammalian cells.

Protein Synthesis and Folding in the ER

In mammalian cells, secreted proteins are expressed by ribosomes attached at the cytosolic face of the endoplasmic reticulum (ER) at an average synthesis rate of three to five amino acids per second. Nascent chains are translocated into the ER lumen and most of them become N-glycosylated upon addition of pre-assembled, branched oligosaccharides (N-glycans) at asparagines in Asn–Xaa–Ser/Thr sequons. The highly hydrophilic N-glycans preserve the solubility of yet unstructured chains likely to expose hydrophobic, aggregation-prone patches. Moreover, they are the ligands of calnexin and calreticulin, two lectin chaperones that make nascent chains accessible to ERp57. ERp57 is an oxidoreductase that catalyzes the formation of disulfide bonds, a rate-limiting step of the folding process peculiar for proteins expressed in the ER. As thoroughly reviewed by Armando Parodi and Ari Helenius, calnexin, calreticulin and ERp57, together with the sugar-processing enzymes glucosidase I and II and UDP-glucose:glycoprotein glucosyltransferase (GT) compose the calnexin/calreticulin cycle, a chaperone network that assists folding and quality control of glycoproteins.

The kinetics and the efficiency of the folding process are highly variable and depend on the substrate protein considered, and on the cell type where folding occurs. Somewhat surprisingly, the folding of heterologous proteins may be faster and significantly more efficient compared to the maturation of cell-self proteins. So it may take only ten minutes for a viral glycoprotein (e.g., influenza virus hemagglutinin) to complete the folding and oligomerization processes and to leave the ER with an efficiency approaching 100%. On the other hand, it may take several hours before ~20% of the cystic fibrosis channel (CFTR) expressed in the ER lumen becomes native and leaves the compartment. About 80% of the wild-type CFTR is produced just to be degraded, a fate probably shared with a significant fraction of any cellular protein. In some cases, degradation may actually start even before the synthesis of a given polypeptide has been completed. This has no consequences for cell viability and ER-associated protein degradation (ERAD) actually plays an important regulatory role, as shown by Randy Hampton for the HMG-CoA reductase, a rate-limiting enzyme for production of sterols and a variety of essential isoprenoids, whose intracellular level is controlled, at least partially, by regulated degradation.

Folding efficiency may drop substantially, and can be the cause of impaired cell, organ, and/or organism viability when genetic mutations occur that change or delete amino acids in polypeptides (e.g., deletion of phenylalanine at position 508 of the CFTR). If the mutated protein cannot fold properly, it will not fulfill the quality control standard for ER exit and will eventually become a substrate of the ERAD machinery.

Diseases Related to Failure of Protein Folding and Quality Control in the ER

An increasing number of strongly debilitating human diseases has been ascribed to defective protein folding and quality control. Together with cystic fibrosis, one could mention the hereditary lung emphysema and liver failure caused by alpha1-antitrypsin deficiency, diabetes mellitus caused by retention and degradation from the ER of mutant insulin receptors, familial hypercholesterolemia (low-density lipoprotein receptor), osteogenesis imperfecta (type I procollagen), retinitis pigmentosa, and several neurodegenerative diseases. In these so-called "conformational diseases," mutated proteins that do not acquire their native structure are diverted to ERAD. If their disposal is not efficient, they accumulate intra- or extracellularly triggering severe damages to cells and tissues. In some cases, such as the hereditary lung emphysema caused by alpha1-antitrypsin deficiency (alpha1-antitrypsin is the principal blood-borne inhibitor of the destructive neutrophil elastase in the lungs), the lack-of-function phenotype observed at the level of patient's lungs is accompanied by a gain-of-toxic-function phenotype at the level of the patient's liver because the mutated protein accumulates in the ER of hepatocytes.

Degradation of Aberrant Proteins Expressed in the ER: The Mannose Timer

But how are polypeptides recognized as being "non-native," retained in the ER, and targeted for ERAD? The mechanisms, better known for glycoproteins and named GERAD for glycoprotein ERAD by Rick Sifers, are summarized in the following paragraphs.

The quality control machinery of the ER checks the structure and not the function of newly synthesized proteins. Therefore, function-competent proteins can be retained in the ER and destroyed because they are structurally imperfect, as exemplified by the case of the ΔPhe508 CFTR.

The modification of N-glycans can determine the fate of newly synthesized glycoproteins. Glycans are added as preassembled units composed of two N-acetyl-glucosamine, nine mannose, and three glucose residues. Two glucoses are removed in a matter of seconds after addition of the N-glycan to nascent chains. In the minutes following the synthesis of a glycoprotein, the number of glucoses on N-glycans can vary from zero to one in response to the counteracting enzymatic activities of glucosidase II and GT. These modifications control cycles of dissociation from/association with the lectin chaperones, calnexin and calreticulin (as described in Armando Parodi's review). How long newly synthesized proteins are retained in the calnexin/calreticulin cycle depends on their rate of folding. N-glycans of native glycoproteins are inaccessible to GT; they are therefore not re-glucosylated so that mature proteins exit the folding cycle, leave the ER, and are transported along the secretory pathway.

In this model, proteins unable to fold properly persist in the calnexin/calreticulin cycle. To prevent accumulation of aberrant polypeptides in the ER, the terminally misfolded polypeptides have to be released from the calnexin/calreticulin cycle and targeted for degradation. After several unsuccessful folding attempts, N-glycans become substrates of ER-resident mannosidases. Therefore, long retention in the ER as signaled by a reduced number of mannose residues on N-glycans is a clear symptom of a problematic folding. It has originally been proposed by Helenius in 1994 that a timer based on mannose cleavage exists in the ER that decides when it is time to stop folding attempts and to divert unlucky polypeptides for degradation. The timer function that mannosidase activities play during ER quality control is supported by findings which show that cleavage of mannoses from the N-glycans has to take place for GERAD to proceed (as first shown by Green and then elucidated by Sifers, mannosidase inhibitors interfere potently and specifically with GERAD). It is conceivable that GERAD candidates are subjected to folding attempts and remain shielded from the degradation machinery while in the calnexin/calreticulin cycle. Accordingly, the degradation of glycoproteins is usually preceded by a lag phase whose length is determined by the retention of the GERAD candidates in association with the ER lectins.

Distinct ER Chaperone Networks are Involved in the GERAD Process

Involvement of at least two distinct chaperone networks (the calnexin/calreticulin cycle and the BiP/PDI system) has been shown (by the groups of Rick Sifers and Maurizio Molinari) to regulate degradation of GERAD candidates in mammalian cells. Interestingly, misfolded glycoproteins remain in the calnexin/calreticulin cycle when degradation is blocked by mannosidase inhibitors; they are released from the lectin chaperones to remain trapped in the BiP/PDI system, in the lumen of the ER when the proteasome activity is specifically shut down. These data show that the two chaperone networks work sequentially and offer the appealing view that GERAD

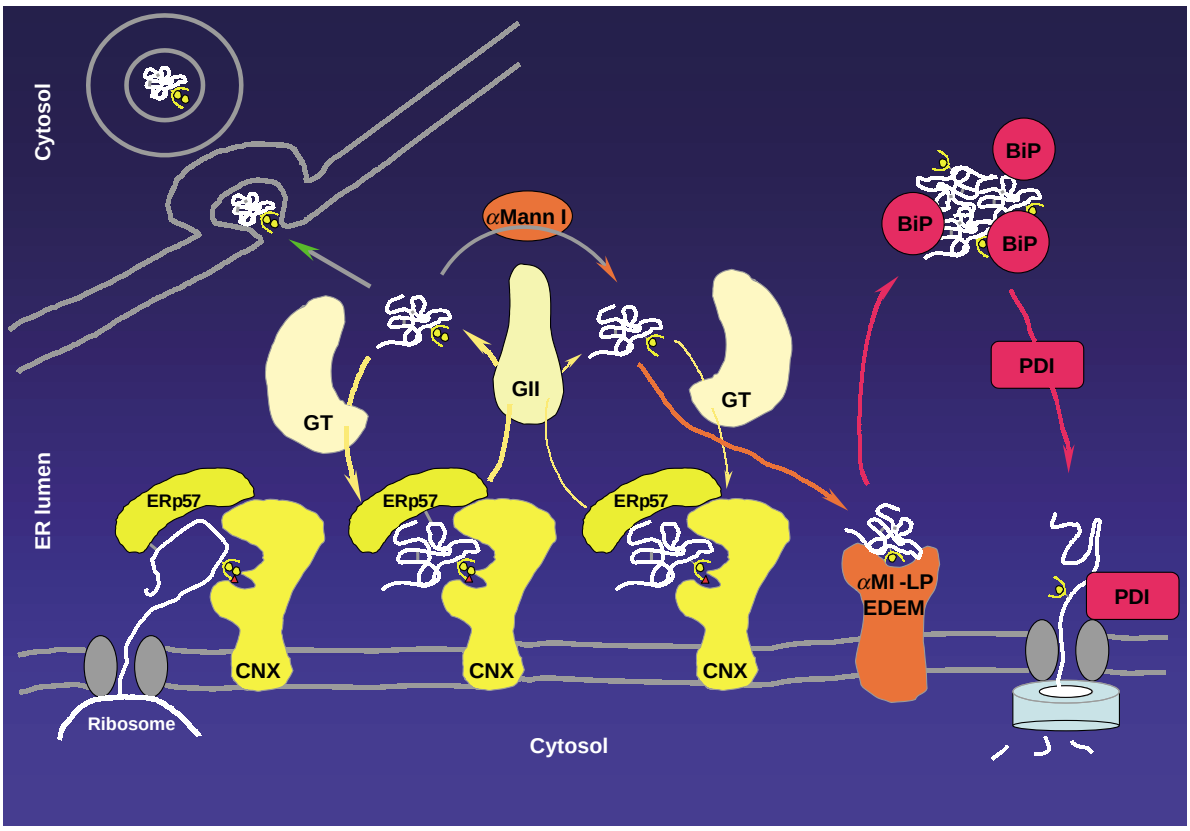

FIGURE 1 The GERAD mechanism can be divided into four steps. First, the GERAD candidate is subjected to folding attempts in the calnexin cycle. Second, the folding-incompetent protein is extracted from the calnexin cycle by the concerted activity of a mannose-trimming enzyme (the ER α-mannosidase I) and a mannose-binding lectin (EDEM). Third, the aberrantly folded polypeptide has to be unfolded (e.g., the wrong disulfide bonds formed during the folding attempts have to be reduced) in order to (fourth) allow dislocation of the GERAD candidate across the ER membrane to be degraded by the proteasome.

candidates are first subjected to folding attempts in the calnexin/calreticulin cycle (lag between synthesis and degradation onset) to be then transferred into the BiP/PDI system that would regulate unfolding and dislocation of the aberrant polypeptide into the cytosol for proteasome-mediated degradation (Figure 1).

A Role for a Mannose-Binding Lectin in GERAD

Mechanistically, the sequential cleavage of mannoses affects the retention of the aberrant protein in the calnexin/calreticulin cycle by decreasing the capacity of glucosidase II and GT to further re- and de-glucosylate the sugar moiety associated with a misfolded chain. Moreover, at least one mannose-binding lectin (EDEM for ER degradation enhancing alpha mannosidase-like protein) is present in the ER lumen and is involved in recognition of aberrant proteins carrying N-glycans with a reduced number of mannose residues, and in deviating them from the folding into the GERAD machinery. The role of EDEM as an acceptor of misfolded glycoproteins released from the calnexin/calreticulin cycle has been recently elucidated by the groups of Kazuhiro Nagata and Maurizio Molinari. It has actually been shown that the intracellular level of EDEM regulates kinetics of the GERAD process by determining the permanence of misfolded proteins in the calnexin cycle. Importantly, as shown by Kazutoshi Mori, the level of EDEM is adapted to the cargo load of the ER, so as to ensure, at any time, optimal disposal of wastes produced during secretory protein synthesis and to prevent processes, which may ultimately lead to cell death through intracellular accumulation of malfolded proteins. Whether EDEM represents the last acceptor of ERAD candidates before their dislocation into the cytosol for proteasome-mediated degradation, or if EDEM regulates the transfer of GERAD candidates from the folding into the unfolding cycles driven by the ER lectins and by the BiP/PDI system, respectively, remains an open question.

Glossary

calnexin and calreticulin Calnexin is a nonglycosylated, type I protein of the ER membrane with 573 amino acids. Most of them are in the lumen of the ER and comprise a glucose-binding site for transient association with folding substrates and a P-domain for noncovalent association with the co-chaperone ERp57; 89 residues are cytosolic and contain a RKPRRE ER-retention sequence. Calreticulin is the soluble homologue of calnexin; it has 400 amino acids with a KDEL ER-retrieval sequence.

EDEM *E*R *d*egradation *e*nhancing α-*m*annosidase-like protein is a type II glycoprotein of the ER membrane that shares sequence homology with ER mannosidases. It has, however, no enzymatic activity possibly because it lacks two cysteines conserved in all active mannosidases. The intracellular level of EDEM is increased in response to accumulation in the lumen of the ER of misfolded proteins.

ERAD ER-associated protein degradation (also GERAD for glycoproteins), the processes leading to recognition of misfolded proteins present in the ER lumen and their dislocation into the cytosolic compartment for proteasome-mediated destruction.

quality control The capacity of cells to distinguish and retain in the ER lumen to be eventually targeted for degradation, proteins that have structural defects.

Biography

Maurizio Molinari obtained a Ph.D. from the ETH in Zurich, Switzerland, under the guidance of Ernesto Carafoli in 1995. He then performed two postdoctoral training periods in the group of Cesare Montecucco (University of Padua, Italy), and in the group of Ari Helenius (ETH, Zurich). Since October 2000 he has been Group Leader at the Institute for Research in Biomedicine in Bellinzona, Switzerland. His research interests are in the characterization of the mechanisms of folding and degradation of proteins expressed in the endoplasmic reticulum of mammalian cells.

Energy Transduction in Anaerobic Prokaryotes

Gottfried Unden
Johannes-Gutenburg-Universität Mainz, Mainz, Germany

Many prokaryotes (bacteria and archaea) are able to grow in the absence of molecular O_2. In the absence of O_2 metabolic energy can be gained by the catabolic reactions of fermentation, anaerobic respiration, anoxygenic photosynthesis, decarboxylation of dicarboxylic acids, or electrogenic transport of substrate and product molecules. Many of the reactions are unique for prokaryotes. Anaerobic metabolism is essential for many biotopes which are permanently or occasionally anoxic. The bacteria responsible for anaerobic metabolism and mineralization are either strictly anaerobic and restricted to anaerobic biotopes, or facultatively anaerobic, using either aerobic or anaerobic metabolism depending on the O_2 supply. The facultative bacteria switch between aerobic and anaerobic metabolism by using molecular O_2 sensors, which control the expression of aerobic or anaerobic metabolic systems mostly at the transcriptional level.

ADP Phosphorylation Driven by Chemical Coupling or by the Membrane Potential

Synthesis of ATP by fermentation relies on substrate level phosphorylation, whereas the other reactions for anaerobic energy conservation use a membrane potential as the coupling device between energy-supplying and energy-consuming reactions, in particular ADP phosphorylation (Figure 1). Phosphorylation of ADP for generation of ATP requires a free energy ($\Delta G_0'$) of $\sim +50\ \mathrm{kJ\ mol^{-1}}$ under cellular conditions. This amount of free energy has to be supplied in fermentation by one chemical reaction and direct coupling. In the metabolic systems using the membrane or proton potential (Δp) as the coupling device (Figure 1), the energy-supplying reaction on the other hand has to supply only $12-17\ \mathrm{kJ\ mol^{-1}}$ per reaction which is the amount required for translocating 1 H^+ (or Na^+) across the membrane. Three or four H^+ are then used to drive ADP phosphorylation. Therefore, storing the free energy in a membrane potential is favorable for anaerobic catabolic processes which often provide only small amounts of free energy.

The overview will demonstrate, by examples, the functioning of anaerobic metabolism of prokaryotes, in particular fermentation and reactions using a membrane potential for coupling between energy-supplying and energy-consuming reactions.

Fermentation

Typical habitats for fermentation are sediments in freshwater, sewage fermenters, or the digestive tract of vertebrates and insects. Fermentation means growth in the absence of external electron acceptors or light. ADP is phosphorylated under these conditions by substrate level phosphorylation, or direct chemical coupling, without involvement of membranes or membrane potential. Most common substrates for fermentative metabolism are sugars and amino acids. The substrates are first degraded in an oxidative part of metabolism yielding pyruvate or related compounds plus NAD(P)H. For oxidation of the sugars, most bacteria use the glycolytic (Embden–Meyerhof–Parnas, EMP) pathway to pyruvate (glucose + $2NAD^+$ + 2ADP + 2 $P_i \rightarrow$ 2pyruvate + 2NADH + $2H^+$ + 2ATP). Some bacteria use the phosphoketolase (modified pentose-phosphate) pathway (glucose + $3NAD(P)^+$ + ADP + P_i + HSCoA → pyruvate + acetyl-CoA + 3NADH + $3H^+$ + 1ATP) for pyruvate formation, whereas the Entner–Doudoroff (or 2-keto-3-deoxy-6-P-gluconate, KDPG) pathway (glucose + $2NAD(P)^+$ + ADP + $P_i \rightarrow$ 2pyruvate + 2NAD(P)H + $2H^+$ + 1ATP) is found only rarely in anaerobic bacteria.

In simple fermentations pyruvate is used as the electron acceptor for reoxidation of the NAD(P)H formed in sugar oxidation, yielding lactate or ethanol as the fermentation products. In more complicated fermentation reactions (mixed acid fermentation, butyrate fermentation, and others), pyruvate is further oxidized yielding acetate and additional ATP. In these

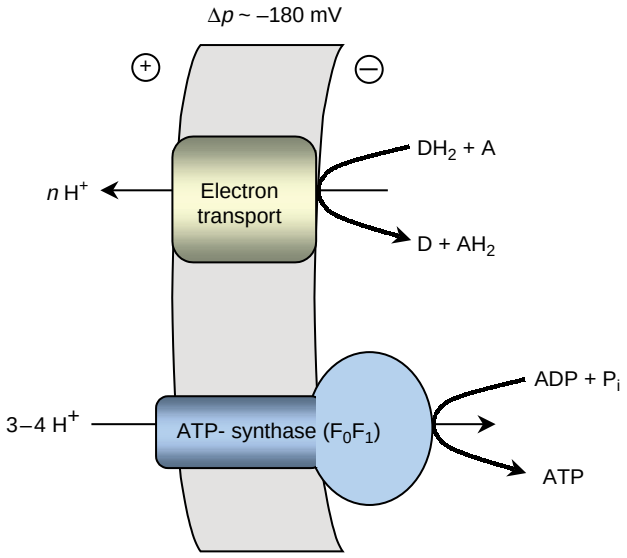

FIGURE 1 Generation of a proton potential (Δp) by translocation of protons across a cytoplasmic membrane by anaerobic respiration and coupling to ADP phosphorylation by ATP synthase. DH_2, electron donor; A, electron acceptor.

pathways butyrate or ethanol (plus acetate) can be obtained as fermentation products among others.

Typical fermentation products derived from sugars and amino acids are carboxylic acids (formate, acetate, propionate, butyrate, and lactate), alcohols (ethanol, 2-propanol, *n*-butanol, and 2,3-butandiol), but also polyols (glycerol, erythritol, and mannitol), CO_2, and H_2 (Table I). The well-known fermentation reactions of this type are homo- and heterofermentative lactic acid, propionic acid, butyric acid, mixed acid, or ethanolic fermentations which are named according to the major or characteristic products (Table I). The ATP yields of the fermentation reactions are generally in the range of 1–3 ATP mol^{-1} of hexose (compared to up to 38 ATP mol^{-1} glucose in aerobic metabolism).

The most important primary or energy-conserving reactions in fermentation are the oxidation of aldehyde to carbonates (thioester formation by glyceroaldehyde-3-phosphate dehydrogenase), the oxidative decarboxylation of α-ketoacids (thioester formation by pyruvate-ferredoxin oxidoreductase), and phosphoroklastic cleavage of ketuloses (acetyl-phosphate formation by phosphoketolase) which are all located in the oxidative part of fermentative metabolism. Reductive desamination of amino acids (acetyl-phosphate formation by glycine reductase) is an example for an energy-conserving reaction in the reductive branch of Stickland fermentation. The energy-rich products obtained from these reactions are then used finally for the phosphorylation of ADP yielding ATP.

Organic matter (polysaccharides, proteins, fats, and monomers derived thereof) can be mineralized in the absence of electron acceptors to methane and CO_2 by interaction of fermenting and methanogenic prokaryotes. The primary fermenters degrade sugars and amino acids to propionate, butyrate, succinate, lactate, acetate, alcohols, CO_2, H_2, and NH_3. H_2, CO_2, and acetate are converted by homoacetogenic and methanogenic prokaryotes to methane and CO_2. Alcohols and fatty acids (short chain fatty acids such as propionate, up to C_{18}), on the other hand, are degraded by secondary fermenters to methane and CO_2. The secondary fermenters are synthrophic bacteria which convert alcohols, fatty acids, and aromatic compounds such as benzoate to H_2, CO_2, and acetate. Secondary fermentation is an endergonic process under standard conditions (e.g., butyrate + $2H_2O \rightarrow$ 2acetate + $H^+ + 2H_2$; $\Delta G_0' = +48.2$ kJ mol^{-1} butyrate) and becomes only exergonic in the presence of syntrophic prokaryotes which consume H_2 to keep it at very low levels. By this the reaction becomes exergonic under environmental conditions ($\Delta G_{env} = -18$ kJ mol^{-1} butyrate) enabling growth of the bacteria. Acetate, H_2, and CO_2 are metabolized by methonogenic archaea and the homoacetogenic bacteria finally to methane and CO_2. In this way fatty acids, alcohols, and aromatic compounds are mineralized yielding CO_2 and methane as the final products.

TABLE I

Fermentation Products of Sugars (Primary Fermentations)

Fermentation (pathway for sugar degradation)	Products per mol glucose (ATP yield per glucose)	Bacterium or microorganism
Lactic acid, homof ermentative (EMP)	2 lactate (+2ATP)	*Lactobacillus lactis*
Lactic acid, heterof ermentative (PK)	1 lactate + 1 ethanol + $1CO_2$ (+1ATP)	*Leuconostoc*
Propionic acid (EMP)	2 propionate (+2–3ATP)	*Propionibacterium*
Butyric acid (EMP)	1 butyrate + $2CO_2$ + $2H_2$ (+3ATP)	*Clostridium butyricum*
Mix acid (EMP)	1 acetate + 1 ethanol + 2 formate (+3ATP)	*Escherichia coli*
Ethanolic (ED)	2 ethanol + $2CO_2$ (+1ATP)	*Zymomonas mobilis*
Ethanolic (EMP)	2 ethanol + $2CO_2$ (+2ATP)	*Saccharomyces cerevisiae* (yeast)

EMP, Embden–Meyerhof–Parnas pathway (glycolysis); PK, phosphoketolase pathway; ED, Entner–Doudoroff pathway.

Fermentation reactions are used on a large scale for preparation of food and beverages. The fermentation reactions and products improve food (nutritional) quality, taste, and durability. For this purpose mainly primary fermentation reactions such as ethanol (beverages), lactic acid (dairy products, vegetables, sour dough), propionic acid fermentation (cheese), and others are used. Solvent production (ethanol, propanol, butanol, and acetone) by Clostridia also depend on type I fermentations. Biotechnological processes for microbiological production of amino acids, citrate, and others, on the other hand, rely on an overflow metabolism of central pathway and anabolic reactions.

Electron Transport Phosphorylation in Anaerobic Respiration

Anaerobic respiration is able to generate an electrochemical proton potential ($\Delta p \sim -0.18$ V) over the membrane which is driven by the oxidation of an electron donor by an (mostly externally added) electron acceptor. The free energy of the redox reaction is converted to and conserved in a proton potential (Figure 1). The proton potential then drives phosphorylation of ADP and formation of ATP by ATP synthase. The Δp generating respiratory chain and the Δp consuming ATP synthase are thus coupled only by the Δp. The free energy of the redox reaction of the respiratory chain under standard conditions and pH 7 is directly related to the difference in the redox potentials of the electron donors and acceptors ($\Delta E_0'$), the Faraday constant ($F = 96.5 \times 10^3$ J mol^{-1} V^{-1}) and the number of participating electrons (n):

$$\Delta G_0' = -nF\Delta E_0'$$

Figure 2 gives a selection of important electron donors and acceptors used by prokaryotes in anaerobic respiration and the corresponding midpoint potentials. The $\Delta E_0'$ value sets the maximal (theoretical) amount of electrons (H^+/e ratio) which can be translocated across the membrane for the given Δp value (-0.18 V):

$$(H^+/e)_{max} = \Delta E_0'/\Delta p$$

The actual H^+/e ratio generally is lower than the calculated value due to lower coupling efficiency, and since some electron transport enzymes lack coupling mechanisms for H^+ translocation. From the above equations it follows that the minimal amount of free energy required for translocation of 1 H^+ across membranes ($\Delta p = -180$ mV) amounts to -17.4 kJ mol^{-1}. Thus free energy as low as $\Delta G_0' = -17$ kJ mol^{-1} can be conserved in a membrane potential by anaerobic respiration (or other Δp generating reactions) compared to $\Delta G_0'$ value of ~ -50 kJ mol^{-1} required in substrate level phosphorylation. Therefore storage of free energy in a membrane potential allows use of energy-supplying reaction with low $\Delta G_0'$ values, since 3–4 translocated H^+ or Na^+ ions are equivalent to phosphorylation of one ADP. This coupling mechanism is of particular significance for reactions of anaerobic metabolism which are only weakly exergonic.

In anaerobic respiration a large number of different electron acceptors can be used, including S^0, CO_2, sulfate, fumarate, nitrate, tetrachlorethen, and Fe^{3+} (Figure 2). The free energy, and thus the ATP yields, are distinctly lower than in aerobic respiration due to the more negative redox potentials (and thus $\Delta E_0'$ values) of the electron acceptors. Most of the anaerobic respiratory systems are composed of two enzymes, a dehydrogenase and a terminal reductase. The enzymes are linked by diffusible low molecular redox mediators (quinones). In anaerobic respiration menaquinone (MK, a lipophilic naphtoquinone derivative with $E_0' = -80$ mV) replaces ubiquinone (Q, a lipophilic benzoquinone derivative with $E_0' = +110$ mV) from aerobic respiratory chains. Figure 3 gives a schematic presentation on the topology and arrangement of enzymes in fumarate and nitrate respiration with formate as the electron donor. The biochemistry and energetics of the enzymes have been studied in detail, and the structures of the enzymes have been solved by X-ray cristallography. Each of the enzymes is anchored in the membrane with a hydrophobic anchor protein, which contains the active site for the lipophilic quinone. The second active site for the hydrophilic substrates formate, fumarate, or nitrate, is located in the cytoplasmic or periplasmic protrusions of the enzymes.

In formate:fumarate reductase respiration the enzymes catalyze the following reactions:

Formate dehydrogenase :

$$\text{Formate} + \text{MK} + 2H^+_{in} \rightarrow CO_2 + \text{MKH}_2 + 2H^+_{ex}$$

Fumarate reductase :

$$\text{Fumarate} + \text{MKH}_2 + 2H^+_{in} \rightarrow \text{succinate} + \text{MK} + 2H^+_{in}$$

Formate : fumarate reduction :

$$\text{Formate} + \text{fumarate} + 2H^+_{in} \rightarrow \text{Succinate} + CO_2 + 2H^+_{ex}$$

The overall reaction of formate : fumarate respiration results in the release of $2H^+$ at the periplasmic, and consumption of $2H^+$ at the cytoplasmic side of the membrane resulting in a H^+/2e ratio of 2, which is due to the action of formate dehydrogenase. The enzyme has the

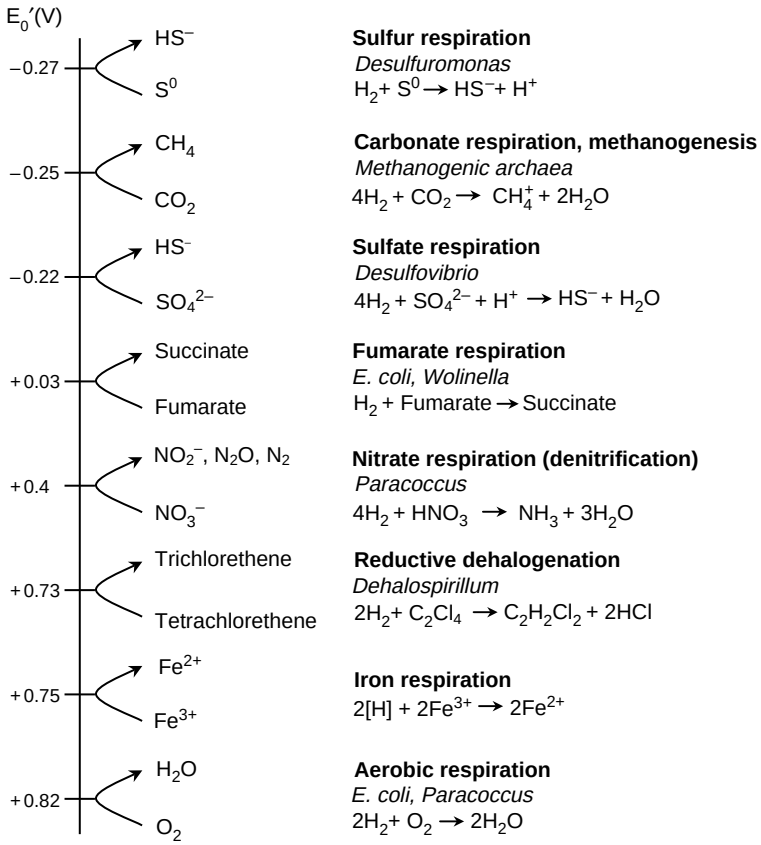

FIGURE 2 Important electron acceptors of anaerobic respiration by prokaryotes. The scheme gives the redox potentials of the redox pairs, the type of respiration, the metabolic balance using H_2 as the electron donor and examples for prokaryotes catalyzing the reaction. The free energy of the reaction can be calculated from $\Delta G_0' = -nF\Delta E_0'$, and is for example for fumarate respiration (H_2 + fumarate → succinate) $\Delta G_0' = -87$ kJ mol^{-1}.

active sites for formate oxidation and menaquinone reduction on opposite sides of the membrane, and translocates $2e^-$ from the formate to the quinone site, resulting in an overall translocation of two charges across the membrane (without actual translocation of H^+) and generation of Δp. Many anaerobic respiratory enzymes generate Δp in the same way. This mechanism of Δp generation has to be distinguished from proton-pumping redox enzymes, such as cytochrome *c* oxidase, which transfer protons across the membrane in a reaction, which is driven by a redox reaction (proton pump).

In fumarate reductase the protons are released (menaquinol site) and consumed (fumarate site) finally on the same (cytoplasmic) side of the membrane. The reaction therefore is not electrogenic and does not contribute to the formation of Δp, and fumarate reductase functions only as an electron sink. The overall $H^+/2e^-$ ratio of formate fumarate reduction is 2 (2 from formate dehydrogenase, 0 from fumarate reductase). These findings are in agreement with the energetics of the overall formate fumarate reduction, and of the partial reactions. The big difference in the redox potentials of the electron donor formate and of the electron acceptor menaquinone of formate:menaquinone reductase ($\Delta E_0' = -340$ mV) allows generation of a proton potential (max. H^+/e^- ratio ≤ 1.9). For fumarate reductase $\Delta E_0'$ is much lower ($\Delta E_0' = -110$ mV) which is not sufficient for generation of a proton potential in agreement with the scheme of Figure 3. In the same way other terminal reductases such as nitrite reductase from *Wolinella succinogenes* function as electron acceptors without contributing directly to Δp production.

Formate–nitrate respiration is catalyzed by an electron transport chain consisting of formate dehydrogenase and nitrate reductase:

Formate dehydrogenase:

$$\text{Formate} + \text{MK} + 2\text{H}^+_{\text{in}} \rightarrow \text{CO}_2 + \text{MKH}_2 + 2\text{H}^+_{\text{ex}}$$

Nitrate reductase:

$$\text{Nitrate} + \text{MKH}_2 + 2\text{H}^+_{\text{in}} \rightarrow \text{Nitrite} + \text{MK} + \text{H}_2\text{O} + 2\text{H}^+_{\text{ex}}$$

Formate:nitrate reduction:

$$\text{Formate} + \text{nitrate} + 4\text{H}^+_{\text{in}} \rightarrow \text{nitrite} + \text{CO}_2 + 4\text{H}^+_{\text{ex}}$$

For quinol:nitrate reduction with nitrate ($E_0' = +430$ mV) as the electron acceptor, $\Delta E_0'$ amounts to -510 mV with

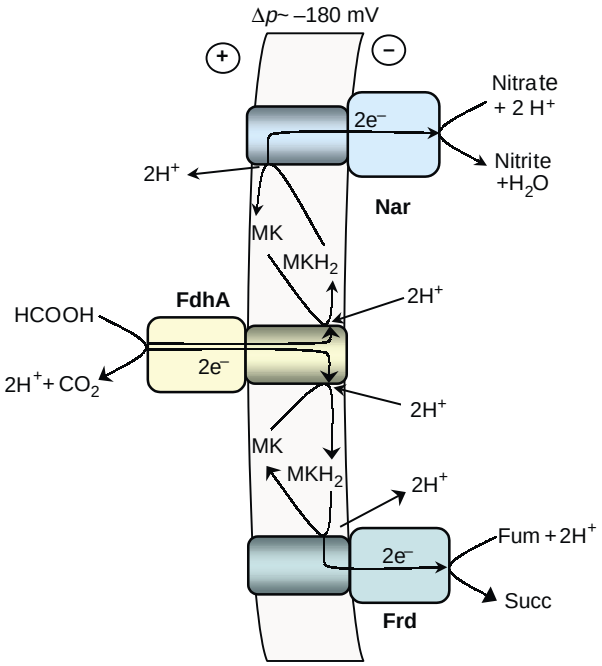

FIGURE 3 Formate–fumarate and formate–nitrate respiration. The figure shows topology and reactions of formate dehydrogenase (formate:quinol reductase), fumarate reductase (quinol:fumarate reductase) and nitrate reductase (quinol:nitrate reductase). Note the topology of the active sites for formate, fumarate, nitrate, and the quinones, the release and consumption of H^+ at the active sites, and transmembrane transfer of electrons in formate dehydrogenase and nitrate reductase. Frd, fumarate reductase; Nar, Nitrate reductase; Fdh, formate dehydrogenase. Examples of this type of fumarate respiration are found in *E. coli* and *Wolinella* of the nitrate respiration in *E. coli*.

menaquinol, or to -350 mV with ubiquinol as the electron donor, which allows conservation of the redox energy in a proton potential (Figure 3). Accordingly, the enzyme functions as a redox half-loop very similar to (but mirror-inverted) formate dehydrogenase, resulting in the translocation of two positive charges across the membrane (inside to outside).

A similar organization is found for many anaerobic respiratory chains, which are composed of one respiratory dehydrogenase and terminal reductase each, and which are linked by the quinones. In this way a large number of different respiratory dehydrogenases and terminal reductases can be linked to each other in branched respiratory chains.

Decarboxylation of Dicarboxylic Acids

Some anaerobic bacteria grow at the expense of decarboxylation of dicarboxylic acids such as oxaloacetate or succinate. The free energy of this reaction amounts to ~ -20 kJ mol^{-1} and is used for translocation of one Na^+ across the membrane by a membraneous decarboxylase as the energy-conserving reaction. The sodium motive force generated in this way can be used to drive secondary substrate transport, flagella, motility, or for phosphorylation of ADP if the bacteria contain an Na^+ potential-driven ATP synthase. The Na^+-dependent ATP synthase is very similar in function and composition to H^+-translocating F_1F_0-ATP synthase. In this way 3–4 decarboxylation reactions are required for phosphorylation of one ADP. *Propionigenium modestum* grows by conversion of succinate to propionate, including decarboxylation of methylmalony-CoA by a membraneous decarboxylase (Figure 4). Succinate is converted to methylmalonyl-CoA which is then decarboxylated in a reaction coupled to Na^+ translocation. The enzyme in addition consumes one H^+ from the periplasmic side of the membrane for the formation of propionyl-CoA + CO_2. Thus, the free energy of decarboxylation is used for generating an electrochemical Na^+ potential. The decarboxylation represents an intramolecular redox reaction producing an oxidized (CO_2) and a reduced (propionate) product. The reaction, however, does not comprise electron transport and depends only on the membraneous decarboxylase for generation

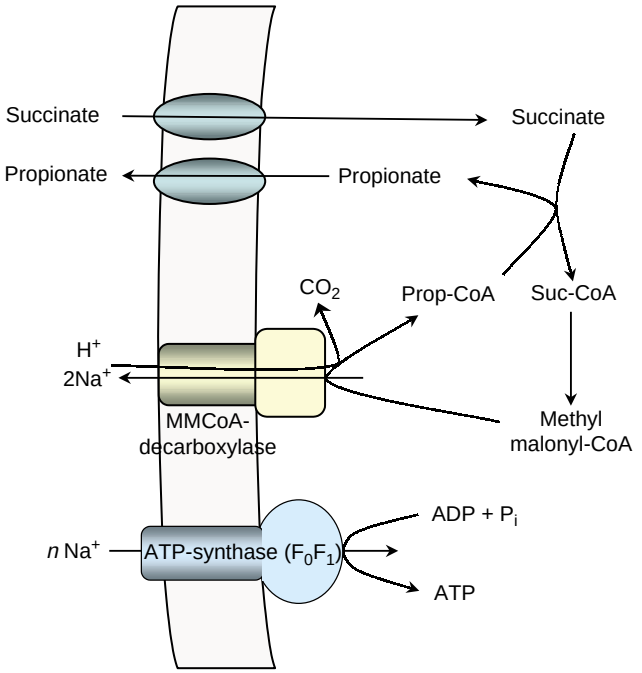

FIGURE 4 Anaerobic growth on succinate by *P. modestum* (succinate + $H_2O \rightarrow$ propionate + CO_2; $\Delta G_0' = -21$ kJ mol^{-1}) and generation of an Na^+ potential by decarboxylation. The membraneous methylmalony-CoA decarboxylase couples decarboxylation to translocation of $2Na^+$ ions over the membrane. H^+ for the decaroxylation reaction is derived from the outside.

of the electrochemical potential. In *Klebsiella*, an enterobacterium closely related to *Escherichia coli*, a membraneous Na^+ translocating decarboxylase of this type (oxaloacetate decarboxylase) is part of citrate fermentation and decarboxylates oxaloacetate yielding pyruvate which can be further converted to acetate + formate. In citrate fermentation ATP is formed in addition by substrate level phosphorylation, or a H^+ potential is generated in respiratory pathways. Therefore, the ATP synthase of *Klebsiella* is H^+ dependent, and the Na^+ potential is used mainly for secondary substrate transport.

Generation of a H^+-Potential by Transport of Charged Substrate and Product Molecules

Some bacteria use the (electrogenic) transport of substrate and product molecules for the generation of a proton potential. *Oxalobacter formigenes* and lactic acid bacteria like *Lactococcus lactis* or *Oenococcus oeni* are able to generate a proton potential by decarboxylation of the dicarboxylic acids oxalate or malate. The decarboxylation is catalyzed by cytoplasmic enzymes, and the free energy of the reaction is not directly stored in a membrane potential as in the membraneous decarboxylases. In *Oxalobacter* oxalate^{2-} is taken up by an electrogenic antiport with formate, the end product of the pathway (Figure 5). Decarboxylation of activated oxalate (oxalyl-CoA) produces CO_2 and consumes one H^+. The antiport of the dianionic oxalate against the monoanionic formate generates an electrical gradient (outside positive), and consumption of $1H^+$ by the decarboxylation generates a ΔpH (alkaline inside). The resulting proton potential is then used to drive ADP phosphorylation by a H^+-ATP synthase.

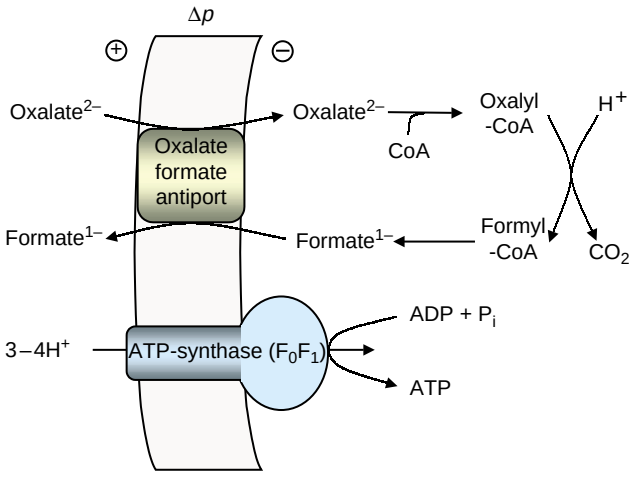

FIGURE 5 Anaerobic growth on oxalate by *Oxalobacter formigenes* (oxalate → formate + CO_2; $\Delta G_0' = -27$ kJ mol^{-1}) and generation of a H^+ potential by electrogenic oxalate^{2-}/formate^{1-} antiport and decarboxylation of oxalate by a cytoplasmic (H^+ consuming) decarboxylase.

Decarboxylation of malate by lactic acid bacteria (malolactic fermentation: malate^{2-} + H^+ → lactate$^-$ + CO_2) uses a similar mechanism of energy conservation. In *Lactococcus lactis* malate^{2-} is taken up and converted by a cytoplasmic decarboxylase to lactate$^-$ + CO_2, consuming H^+ as a cosubstrate. Malate^{2-} and lactate$^-$ are transported by an electrogenic antiporter generating an electrical potential (outside positive), and H^+ consumption in the cytoplasm during decarboxylation generates a ΔpH value (inside alkaline). The proton potential can be used for driving ADP synthesis by a membraneous ATP synthase.

Anoxygenic Photosynthetic Prokaryotes

Anoxygenic photosynthetic bacteria use only one photosystem for converting light energy into an electrochemical proton potential which is then used for driving ADP phosphorylation. Anoxygenic photosynthetic bacteria are found in three different phylogenetic groups which contain different photosynthetic systems: the purple bacteria, the green phototrophic bacteria with the subgroups of green sulfur bacteria (Chlorobiaceae) and *Chloroflexus*, and the gram-positive Heliobacteria. The three groups show differences in the type of photosynthetic reaction center, photosynthetic electron transfer and the electron donors used, pigments, and the pathway for CO_2 fixation. In anoxygenic photosynthesis, light is used to raise electrons to a more electronegative redox potential and to feed the electrons into a cyclic electron transport to generate a proton potential. The cyclic electron transport systems contain only one reaction center in contrast to oxygenic photosynthesis in cyanobacteria, green algae, or plants. The archaeon *Halobacterium salinarum*, on the other hand, contains a proton pump which is directly driven by light to translocate protons over the membrane without involvement of a photosynthetic electron transport. In contrast to the photosynthetic bacteria using chlorophyll containing proteins for photosynthesis and energy conversion, *Halobacterium* contains bacteriorhodopsin with retinal as a chromophor for light absorption and conversion to an electrochemical proton potential.

Enzyme Inhibitors

Vern L. Schramm
Albert Einstein College of Medicine, Yeshiva University, Bronx, New York, USA

Enzymes catalyze the chemical reactions necessary for life. They typically increase chemical reaction rates by factors of 10^{10}–10^{15}. The first step to initiate catalysis is binding the reactant molecules into the catalytic sites to form the Michaelis complex. In most enzymes, a conformational change occurs to enclose the reactants tightly in the enzyme and to make contacts between reactants and the enzyme that will achieve the transition state and subsequently form products. The enzyme then relaxes to open the catalytic site and release products. Enzyme inhibitors prevent enzymes from their catalytic function by interfering with any step in this catalytic cycle. Four common types of enzyme inhibitors are given as follows:

1. catalytic site inhibitors that compete with the substrate for formation of the Michaelis complex, traditionally called competitive inhibitors;

2. inhibitors that alter formation of the Michaelis complex and full expression of catalytic potential are called noncompetitive inhibitors;

3. covalent inhibitors that form a Michaelis complex followed by a chemical reaction with the enzyme to form a stable and inactive complex, often called mechanism-based inhibitors or "suicide inhibitors"; and

4. transition-state analogue inhibitors that resemble the unstable reactant complex at the transition state of the reaction.

Reversible Catalytic-Site Inhibitors

Reactant and Product Analogues

Molecules with shape and charge similar to the substrate or products may bind to the catalytic site similar to the normal reactants. When they are bound, substrate cannot bind and the enzyme is prevented from catalyzing the reaction. The relative affinity of these competing molecules for the catalytic site and their abundance relative to substrate will determine if they prevent substrate binding (Figures 1 and 2). Thus, if reactants and inhibitors bind with equal affinity, at equal concentrations, the enzyme catalytic site will be equally occupied with reactants and inhibitor resulting in 50% inhibition. This relationship is described in quantitative terms by the competition between an inhibitor (I) and a reactant (A) for a simple enzyme with one reactant by the equation: $v = (k_{cat})(A)/(K_m + A(1 + I/K_i))$, where v is the enzymatic reaction rate, k_{cat} is the maximum catalytic rate of the enzyme, K_m is related to the binding affinity between enzyme and substrate, defined as the concentration of substrate to achieve 50% of k_{cat} in the absence of inhibitor, and K_i is the dissociation constant for the enzyme–inhibitor complex, defined by the equation: $K_i = (E)(I)/(EI)$, and A and I are reactant and inhibitor concentrations. Diagrams of substrate and product inhibition illustrate the mutually exclusive or "competitive" inhibition relative to the catalytic site (Figure 2). Complete graphical and mathematical analyses of enzyme inhibition cases are available.

Bisubstrate Mimics

Many enzymatic reactions combine two different molecules at the catalytic site to transfer a chemical group between them. An example is the enzyme adenylate kinase that transfers the terminal phosphoryl group of ATP to AMP to generate two molecules of ADP (Figure 3). The catalytic site must accommodate ATP and AMP at the same time in preparation for group transfer. The bisubstrate mimic for the adenylate kinase reaction is chemically similar to ATP combined with AMP to make a bisubstrate molecule called AP_5A (Figure 3). Such molecules compete for both substrate sites, since they prevent either substrate from binding by competition for the same sites. Bisubstrate mimics can bind tightly to the enzyme since connected molecules bind with affinity equal to the product of the affinity of the individual molecules. For example, if individual dissociation constants (K_i values) for ATP and AMP are both 10^{-4} M, the dissociation constant for the bisubstrate mimic would be expected to be related to the product of these constants or $10^{-4} \times 10^{-4}$ M $= 10^{-8}$ M.

Transition-State Analogues

A special class of competitive inhibitors resembles the reactant molecule at the very point where it

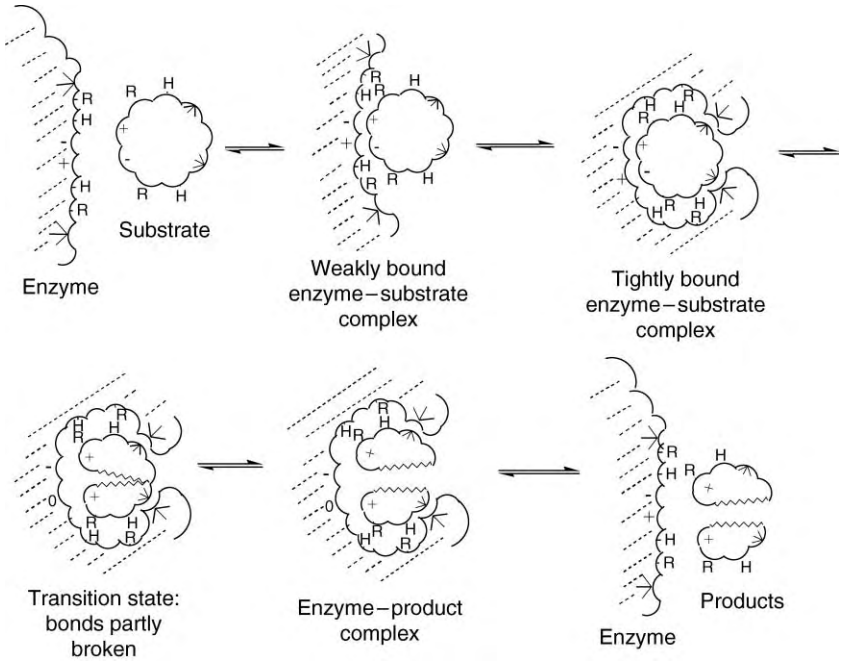

FIGURE 1 A schematic for the steps in enzyme-catalyzed reactions. In the first step diffusion causes collision between the substrate and an open catalytic site. The weakly bound enzyme–substrate complex causes the protein to close to form the tightly bound enzyme–substrate complex. Hydrogen bonds (H–R), ionic bonds (+ −), and hydrophobic interactions (><) in this closed complex at the transition state are shown. Following bond changes, the enzyme–product complex relaxes to release product and regenerate the original form of the enzyme to repeat the cycle.

crosses the chemical energy equivalence point of bond breaking/bond making called the transition state. These inhibitor molecules must be chemically stable, but have close similarity to the unstable transition state. Based on the theory of transition-state stabilization for enzyme-catalyzed reactions, the perfectly designed transition-state analogue is capable of binding to the enzyme by the factor: K_i for transition state inhibitor $= K_m$/catalytic rate enhancement. Since enzymatic catalytic rate enhancements are typically 10^{10}–10^{15}, perfectly designed transition-state inhibitors can bind 10^{10}–10^{15} times better than substrate. These incredibly large affinities have been rarely achieved. It is impossible to match the nonequilibrium bond lengths and partial charges present at the precise moment of the transition state with chemically stable molecules. However, incorporation of even modest similarities between the actual transition-state and transition-state analogues can achieve binding affinities 10^5–10^7 times that of reactants, and this improvement is adequate to achieve inhibition of the targeted enzymes in biological systems.

Enzymatic Transition States

This point of the chemical reaction is often the most energetic point in the reaction cycle, and therefore the rarest and the most difficult to detect. The exact shape and charge of the substrate molecule at the moment of the transition state is of great interest, since chemically stable molecules that resemble the substrate molecule at the transition state bind extremely tightly to the enzyme, as discussed above. This concept was proposed early in the history of biochemistry by Linus Pauling, and was formalized several decades later by Richard Wolfenden. An example of the substrate, enzyme-stabilized transition state and a transition analogue for purine nucleosidase phosphorylase is shown (Figure 4). These inhibitors commonly bind to the catalytic sites of enzymes millions of times more tightly than the substrates. Many of the antibiotics isolated in nature have been found to be transition-state analogues. Recently, molecules designed to be transition-state analogues are being tested in medical applications such as anticancer agents. Transition-state inhibitors compete at the catalytic site and cause the enzyme to fold into its tightly binding mode and keep it closed for long times, preventing catalysis (see Figure 1).

Design of Transition-State Analogues

Both the shape and charge of reactant molecules change as they reach the transition state (see Figure 1). The structure of the transition state can be experimentally measured by using kinetic isotope effects, combined with computational chemistry to locate the enzymatic

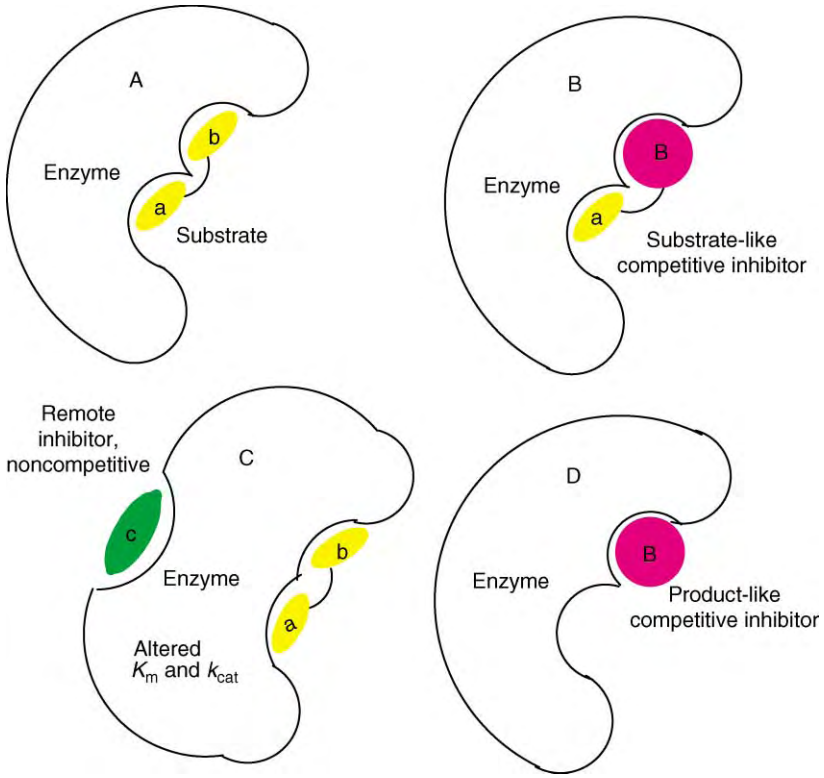

FIGURE 2 Enzyme A is a normal Michaelis complex with substrate a–b at the catalytic site (yellow). The bond to be broken by the enzyme connects a and b. The substrate-like competitive inhibitor (pink, enzyme B) has a difference in the B part of the bound molecule and is not a substrate but competes directly for a–b at the catalytic site. Since this is a competition, large amounts of a–b will displace a–B. A noncompetitive inhibitor binds to influence catalysis but does not directly compete for the catalytic site. There are many variants of noncompetitive inhibition and binding at a remote site to change features of the catalytic site is one example (green in enzyme C). Competitive inhibitors can also be product-like as shown in enzyme D (pink).

transition state. The electron distribution at the van der Waals surface of a molecule is called its molecular electrostatic potential surface. This can be described for substrate and transition states for enzyme reactions provided the transition-state structure is known, and can also be established for proposed inhibitor molecules. Electrostatic matches to the transition state make powerful inhibitors by capturing some of the transition-state energy usually applied to catalysis (Figure 4).

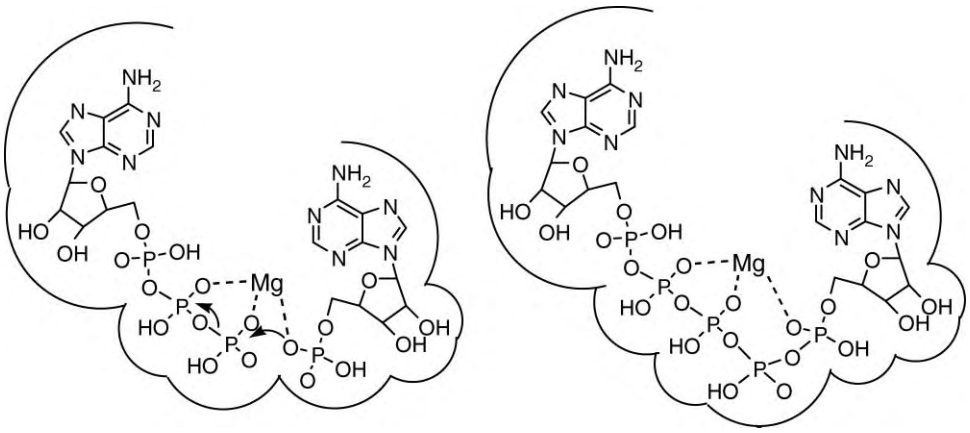

FIGURE 3 The Michaelis complex for adenylate kinase (ATP + AMP → 2ADP) is shown on the left with the arrows indicating electron flow for the phosphoryl group transfer. The inhibited complex with adenosyl–pentaphosphate–adenosine (A–P5–A) is on the right. The bisubstrate inhibitor competes for both ATP- and AMP-binding sites. Ionic charges are omitted for clarity and the ribosyl groups are all β-D-ribose in stereochemistry.

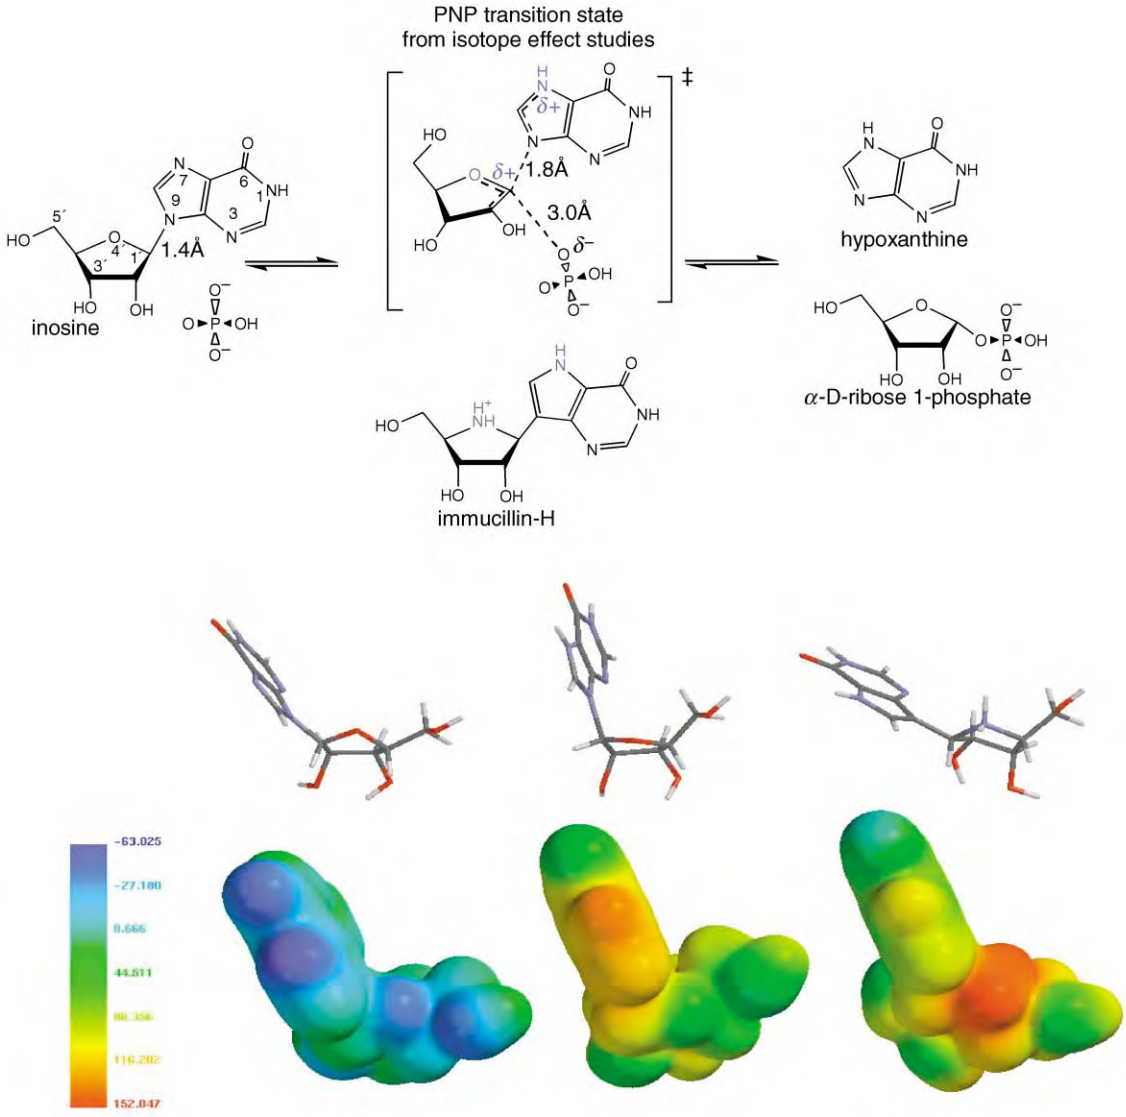

FIGURE 4 The reaction catalyzed by bovine purine nucleoside phosphorylase (PNP), transition-state structure, and a transition-state analogue inhibitor (immucillin-H). Novel features of the transition state are protonation at N7 and the partial positive charge on the ribosyl group. Both are represented in the inhibitor, shown in blue. Immucillin-H binds approximately 1 million times more tightly to PNP than does the substrate inosine. Shown below are the electronic van der Waals surfaces of inosine (left), transition state (middle), and Immucillin-H (right). Note the electrostatic similarity between transition state and Immucillin-H. Reproduced with permission of Elsevier Ltd., from Vern, L. Schramn. Development of transition state analogues of purine nucleoside phosphorylase as anti-T-cell agents. (2002) *Biochem. Biophys. Acta* **1587**, 107–117.

Natural Product Transition-State Analogues

Many antibiotics isolated from natural sources are transition-state inhibitors. One example is an antibiotic formed in the culture medium of *Streptomyces antibioticus* that is apparently made as an agent of microbial warfare between species of soil organisms. R-Coformycin binds to the catalytic sites of adenine nucleoside and nucleotide deaminases millions of times tighter than the reactant molecules. The transition-state structure for deaminase enzymes has been solved and the similarity of transition-state analogue and transition state is greater than either to the substrate (Figure 5).

Noncatalytic Site Inhibitors

Noncatalytic site inhibitors include all inhibitors binding at sites other than the catalytic site. These inhibitor molecules can cause several different types of enzymatic inhibition, both competitive inhibition and noncompetitive inhibition. The reason for this diversity arises by inhibitor binding distant to the catalytic site but, in so doing, changing the enzyme conformation to prevent proper function of the enzyme either in binding its substrate or in formation of the products.

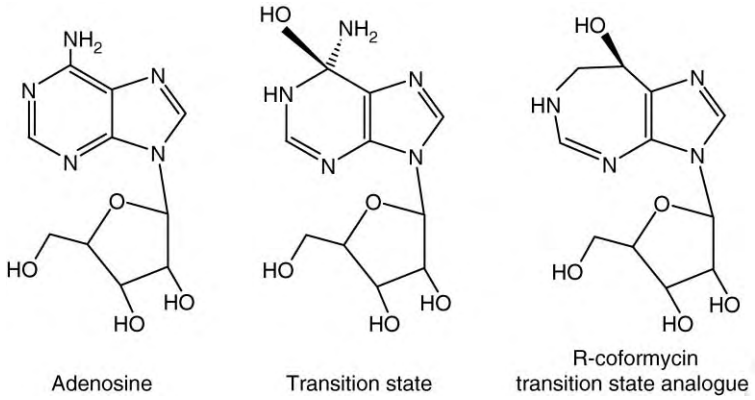

FIGURE 5 Reactant (adenosine), transition state, and transition-state analogue inhibitor for adenosine deaminase. R-Coformycin is a natural product transition state analogue inhibitor that binds 10 million times tighter to adenosine deaminase than does adenosine.

Prevent Catalytic-Site Binding

An inhibitor may bind remote from the catalytic site to change the protein conformation to cause mutual exclusion between reactant binding at the catalytic site and inhibitor binding at the remote site. For this interaction, kinetic analysis of the type shown above will be kinetically indistinguishable from competitive inhibition. The surfaces of proteins contain highly irregular and charged surfaces that interact with specific molecules. Current practice of testing libraries of diverse chemical compounds against a specific enzyme to find any type of interaction that can cause inhibition often discovers this class of inhibitor.

Prevent Subunit Formation

Most enzymes have multiple protein subunits that must interact to provide a functional catalytic unit. An example is the ribonucleotide diphosphate reductase required to form deoxynucleotides for the biological production of DNA. During cellular protein synthesis of these enzymes, the protein subunits are formed separately and must then combine to make the functional catalyst. In the cell, these subunits are thought to separate and recombine many times, providing an opportunity to insert an inhibitory molecule in the protein interface between subunits. Selection of such molecules from chemical libraries or designing them from known protein–protein interfaces prevents formation of the active enzyme molecule in the cell. Inhibitors of this type have been designed for ribonucleotide diphosphate reductase and show promise in this new area of specific inhibitor design.

Prevent Conformational Change for Catalysis

A related inhibitor type is one binding remote from the catalytic site to prevent an enzymatic conformational change that is required for catalysis. Most enzymes require protein motion to close the catalytic site prior to formation of the transition state. These loop or domain motions involve physical motion of segments of the proteins, often over relatively large distances. A consequence of the motion is to position amino acid residues in the catalytic site where they are required for catalysis. An inhibitor that binds outside the catalytic site and prevents this protein motion required for catalysis will provide complete loss of enzyme function without blocking access of reactants to the catalytic site. As knowledge of the protein surfaces becomes more complete, it will be increasingly possible to design molecules that act in these novel inhibitory roles.

Mechanism-Based Inhibitors

Mechanism-based enzymatic inhibitors are designed to be stable molecules that resemble the substrate. They bind at the catalytic site of the target enzyme and are converted by the enzyme to a chemically reactive form that covalently reacts with the catalytic site of the enzyme. This covalent intermediate of enzyme inhibitor differs from normal catalytic intermediates by its chemical stability and long lifetime. Trapping the enzyme in a stable covalent complex blocks the catalytic site from normal interaction and provides long-term inhibition of the enzyme. Mechanism-based inhibitors are in broad use in biology, and our example of this chemical inhibitor logic is in the pathway of polyamines (Figure 6).

Polyamine Synthesis

The polycationic polyamines are essential counterions for DNA replication in dividing cells. The first step in

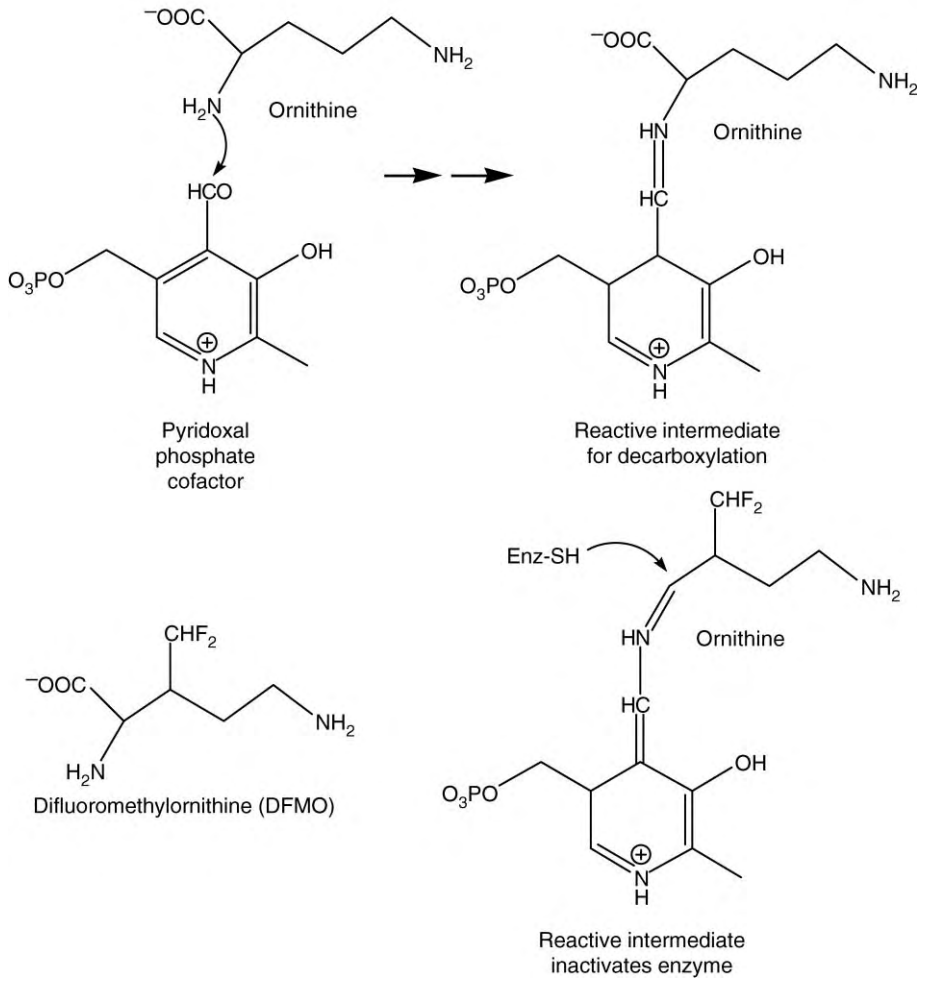

FIGURE 6 Covalent suicide inhibition of ornithine decarboxylase by DFMO. In the normal reaction, the enzymatic cofactor, pyridoxal phosphate, forms a Schiff base favoring decarboxylation of ornithine. With DMFO, the same steps occur but decarboxylation generates a reactive difluoro-conjugated imine. A nearby cysteine nucleophile reacts to form a stable, inactive enzyme.

polyamine synthesis is catalyzed by ornithine decarboxylase which uses a transient covalent intermediate to the enzymatic cofactor pyridoxal phosphate. Difloromethylornithine (DFMO) is decarboxylated in similar fashion to orinithine, but the reaction creates a highly reactive intermediate that reacts with a nearby group on the enzyme to form a stable covalent intermediate, resulting in an inactive ornithine decarboxylase. It therefore stops polyamine biosynthesis. It has been used as an anticancer agent and an antibiotic against *Trypanosoma* species that cause sleeping sickness. Specificity is provided by the binding of DFMO only to the target enzyme and long biological action is provided by the stable covalent interaction with the enzyme. These are features of most mechanism-based enzyme inhibitors. Care is needed that chemical reactivity causing enzymatic inactivation is revealed only to the target enzyme.

Other Mechanism-Based Inhibitors

Many of the common antimetabolites are mechanism-based inhibitors. Thus, certain insecticides form covalent interactions with the catalytic site of enzymes involved in insect neurotransmission. Deprenyl is a drug used to treat Parkinson's disease and mental depression by increasing brain dopamine levels. It functions by suicide inhibition at the catalytic site of monamine oxidase, the enzyme that degrades dopamine.

Conclusion

The intricate steps in enzymatic action can be disrupted in numerous ways, each causing inhibition of catalytic steps. Enzymes have evolved to function in the presence of the complex mixture of normal cellular components, but inhibitors can be designed to specifically target a

single enzyme of the thousands that function in coordination in a normal cell.

Biography

Vern Schramm received his Ph.D. at the Australian National University, John Curtain School of Medical Research in 1968. In the Department of Biochemistry at the Temple University School of Medicine (1971), he began to apply isotope effects to the study of enzymatic transition states. At the Albert Einstein College of Medicine in 1987, he began a systematic program of solving enzymatic transition states by kinetic isotope effects. Enzymatic transition-state information is then applied to the design of transition-state analogue inhibitors. The inhibitors are applied to biomedical problems.

Enzyme Kinetics

Irwin H. Segel
University of California, Davis, California, USA

Enzymes are protein catalysts that accelerate the rates at which reactions approach equilibrium. *Enzyme kinetics* is the branch of biochemistry that deals with a quantitative description of this process, mainly, how experimental variables affect reaction rates. The variables that are studied include the concentrations of the enzyme, substrates (reactants), products, inhibitors, activators, the pH, temperature, and ionic strength. A complete kinetic analysis (together with complementary studies of equilibrium ligand binding, isotope exchange, covalent modification of amino acid side chains, etc.) can disclose most of the functional characteristics of a particular enzyme. These include (1) the specificities and affinities of the ligand subsites, (2) the order in which substrates bind and products leave, (3) the enzyme species that are intermediates in the overall reaction, (4) the magnitudes of component rate constants, (5) the possible identities of active-site residues, (6) the mode of action of an inhibitory drug, and (7) how the enzyme might be regulated *in vivo*. Enzyme kinetics combined with related approaches can show how the functional properties of a mutant or "engineered" enzyme compare to those of its wild-type parent. Many of the equations of enzyme kinetics are also applicable to other saturable biological processes, e.g., membrane transport and receptor–ligand interactions.

Unireactant Enzymes and the Michaelis–Menten Equation

By the mid- to late 1800s, most of the laws governing the effect of reactant concentrations on the rates of chemical reactions were known. But enzyme-dependent reactions did not always follow these simple rate laws. In 1902, Victor Henri proposed the first useful equation for an enzyme-dependent reaction. Henri's equation took into account the known properties of enzymes, including that (1) an enzyme was highly specific for a particular substrate (or class of substrates), (2) substrates often protected an enzyme from inactivation by heat, and (3) a plot of initial velocity versus substrate concentration was hyperbolic. (These properties all pointed to the participation of an enzyme–substrate complex.) Subsequent workers, including Michaelis and Menten (1913), Van Slyke and Cullen (1914), and Briggs and Haldane (1925) confirmed and/or extended Henri's equation, which is derived below.

The Rapid Equilibrium Assumption

The following assumptions and procedures led Henri and others to the relationship between substrate concentration and reaction rate, which is now known as the Michaelis–Menten equation:

1. The overall reaction occurs in two steps, as shown below:

$$\mathrm{E} + \mathrm{S} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{ES} \xrightarrow{k_2} \mathrm{E} + \mathrm{P}. \qquad (1)$$

This sequence recognizes that the enzyme is not consumed in the reaction, but rather, is a recycling catalyst. The first step is the rapid equilibration of the free enzyme, E, and the free substrate, S, to form an ES complex. This is followed by the unidirectional, rate-limiting decomposition of ES to E + P. The rapid equilibrium between E, S, and ES is maintained throughout the course of the reaction. (This condition requires that $k_{-1} >> k_2$.) The equilibrium is described by the dissociation constant, K_s of the ES complex:

$$K_s = [E][S]/[ES] = k_{-1}/k_1. \qquad (2)$$

Equation (2) allows the concentration of the ES complex to be expressed in terms of the concentration of free E, free S, and K_s:

$$[ES] = [S][E]/K_s. \qquad (3)$$

2. At any time, the total enzyme, $[E]_t$ is present as either free E or as the ES complex. Thus, the mass balance (conservation) equation is

$$[E]_t = [E] + [ES]. \qquad (4)$$

The total substrate is also distributed between the free and complexed species:

$$[S]_t = [S] + [ES]. \qquad (5)$$

However, for most enzyme-dependent reactions that are studied *in vitro*, the enzyme is present at a very low (catalytic) level (i.e., $[E]_t << [S]_t$), so that the

maximum $[ES]$ that can form will be much smaller than the $[S]_t$ added. Consequently, it can be assumed that the free S concentration is essentially identical to the total added S (i.e., $[S] \approx [S]_t$). This assumption is not valid for many enzymes inside the cells, where $[E]_t$ may be in the same range as $[S]_t$.

3. The instantaneous or "initial" rate, $\mathrm{d}[P]/\mathrm{d}t$ or $-\mathrm{d}[S]/\mathrm{d}t$ (usually indicated as "v" for "velocity"), is proportional to the concentration of the ES complex:

$$v = k_2[ES]. \tag{6}$$

4. It is assumed that the accumulating product has no effect on the reaction. That is, the P concentration remains close to zero throughout the course of the reaction, or P has no affinity for the enzyme.

5. The final velocity equation is obtained by dividing eqn. (6) by eqn. (4) and substituting for $[ES]$ from eqn. (3):

$$\frac{v}{[E]_t} = \frac{k_2[ES]}{[E] + [ES]} \quad \text{or} \quad v = \frac{k_2[E]_t \dfrac{[S][E]}{K_S}}{[E] + \dfrac{[S][E]}{K_S}} \tag{7}$$

$k_2[E]_t$ is defined as V_{max} because when all the enzyme is in the ES form, the observed velocity will be maximal. This substitution and canceling $[E]$ in eqn. (7) yields the final Michaelis–Menten equation:

$$v = \frac{V_{max} \dfrac{[S]}{K_s}}{1 + \dfrac{[S]}{K_s}} = \frac{V_{max}[S]}{K_s + [S]}. \tag{8}$$

The Steady-State Assumption

By the 1920s, researchers realized that the rapid equilibrium assumption was too restrictive and would not be valid for enzymes where the ES complex proceeds on to E + P much faster than it dissociates back to E + S. In such cases, E, S, and ES would not attain equilibrium. In 1925, Briggs and Haldane offered a more general method for deriving velocity equations that did not require a rapid equilibrium assumption. Their *steady-state* approach recognized that under most assay conditions, $[E]$ and $[ES]$ would attain certain levels very quickly after mixing E and S, but that the concentrations of these enzyme species would change very little thereafter. In other words, for the duration of the assay, the rate at which ES is formed (from E + S) remains identical to the rate at which it decomposes (back to E + S, plus forward to E + P). Similarly, the rate at which E is produced from ES equals the rate at which E is used to form ES. Scheme (1) is still applicable, but now rate constants for individual steps must be taken into account. Applying the steady-state assumption we can write

$$\mathrm{d}[ES]/\mathrm{d}t = 0 \quad \text{or} \quad k_1[E][S] = (k_{-1} + k_2)[ES] \tag{9}$$

and

$$\mathrm{d}[E]/\mathrm{d}t = 0 \quad \text{or} \quad (k_{-1} + k_2)[ES] = k_1[E][S]. \tag{10}$$

Solving either equation for $[ES]$ yields

$$[ES] = k_1[E][S]/(k_{-1} + k_2) \quad \text{or} \quad [ES] = [S][E]/K_m \tag{11}$$

where in the latter expression, the three rate constants are combined into a single kinetic constant, K_m, as shown below:

$$K_m = (k_{-1} + k_2)/k_1. \tag{12}$$

The initial velocity, v, at any $[S]$ still equals $k_2[ES]$. So, proceeding as described earlier, but substituting for $[ES]$ from eqn. (11), we obtain

$$v = \frac{V_{max}[S]}{K_m + [S]}. \tag{13}$$

Thus, the velocity equation is the same as that derived for rapid equilibrium conditions, except that the constant in the denominator (now called a Michaelis constant) is more complex than a simple dissociation constant. The Briggs–Haldane approach is more general than the rapid-equilibrium approach because it makes no assumptions about the relative magnitudes of the various rate constants. If $k_2 \ll k_{-1}$, K_m reduces to k_{-1}/k_1, which is equivalent to the simpler K_s.

Equation (13) is valid throughout the experimental [S] range provided that the rate of P formation is measured before [S] changes appreciably. (In practice, substrate use should be restricted to less than 5% (or at most 10%) of $[S]_t$.) When $[S] \ll K_m$, eqn. (13) reduces to $v = V_{max}[S]/K_m = k[S]$, i.e., the reaction is *first order* with respect to $[S]$ with a rate constant equivalent to V_{max}/K_m. When $[S] >> K_m$, v is essentially constant at V_{max} and independent of $[S]$. (The reaction is *zero order* with respect to $[S]$.)

A More Realistic Unireactant Reaction Sequence

Equation (1) contains the minimum number of steps that must be considered in the description of a uni–uni (one substrate, one product) reaction. A more realistic scheme takes into account the conversion of enzyme-bound S to enzyme-bound P (before P is released) and the reversibility of each step as shown below:

$$\mathrm{E} + \mathrm{S} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \mathrm{ES} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \mathrm{EP} \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} \mathrm{P} + \mathrm{E}. \tag{14}$$

A steady-state treatment of the above reaction sequence once again yields the familiar Michaelis–Menten equation when $[P] = 0$, except that now

$$K_m = \frac{k_{-1}k_3 + k_{-1}k_{-2} + k_2k_3}{k_1(k_2 + k_{-2} + k_3)} \tag{15}$$

and

$$V_{max} = \frac{k_2k_3[E]_t}{k_2 + k_{-2} + k_3}. \tag{16}$$

So, in the absence of other information, the rate constant compositions of the two kinetic constants, K_m and V_{max}, are not usually known. But regardless of its makeup, K_m is a valuable characteristic because it is equivalent to the substrate concentration that yields half-maximal velocity. V_{max} is not a true constant because it depends on the enzyme concentration. However, $V_{max}/[E]_t$, expressed as moles of S converted to P per second per mole of enzyme active site (which reduces to per second, or s^{-1}) is the *catalytic rate constant* (or *turnover number*) of the enzyme, k_{cat}. The ratio k_{cat}/K_m has been used to compare the action of an enzyme on a series of related substrates. The higher the value of this *specificity constant*, the better the substrate. If an enzyme is evolutionarily perfected so that the catalytic and product release rate constants are very much larger than any of the reverse first-order rate constants, the ratio k_{cat}/K_m reduces to k_1, the second-order rate constant for the interaction of E and S to form ES. In aqueous solution, this constant has a maximum, diffusion-limited value of $\sim 10^9\ M^{-1}\ s^{-1}$. Many enzymes have k_{cat}/K_m values that approach this maximum.

Reversible Reactions

In the presence of both the substrate and product, the net steady-state velocity is given by the difference between the forward and reverse rates of any step, e.g.,

$$v = k_2[ES] - k_{-2}[EP] \tag{17}$$

or

$$\frac{v}{[E]_t} = \frac{k_2[ES] - k_{-2}[EP]}{[E] + [ES] + [EP]}. \tag{18}$$

After substituting for $[ES]$ and $[EP]$ and grouping rate constants into kinetic constants, the equation is

$$v = \frac{V_{max,f}\dfrac{[S]}{K_{mS}} - V_{max,r}\dfrac{[P]}{K_{mP}}}{1 + \dfrac{[S]}{K_{mS}} + \dfrac{[P]}{K_{mP}}} \tag{19}$$

where $V_{max,f}$ and $V_{max,r}$ are the forward and reverse maximal velocities, respectively; K_{mS} and K_{mP} are the Michaelis constants of S and P, respectively. Equation (19) can also be written as

$$v = \frac{V_{max,f}[S]}{K_{mS}\left(1 + \dfrac{[P]}{K_{mP}}\right) + [S]} - \frac{V_{max,r}[P]}{K_{mP}\left(1 + \dfrac{[S]}{K_{mS}}\right) + [P]} \tag{20}$$

which shows that in this unireactant process, P acts as a competitive inhibitor of the forward reaction and S acts as a competitive inhibitor of the reverse reaction. (In reactions catalyzed by multireactant enzymes, individual products might be competitive, uncompetitive, or noncompetitive with respect to different substrates.)

The Velocity Curve and its Linear Forms

Figure 1 shows the typical hyperbolic dependence of the velocity of an enzyme-catalyzed reaction on the substrate concentration. The kinetic constants, K_m and V_{max}, can be obtained by fitting the v versus $[S]$ data directly to the Michaelis–Menten equation using an appropriate computer application. Alternatively, K_m and V_{max} can be obtained by plotting the data in a linear form such as $1/v$

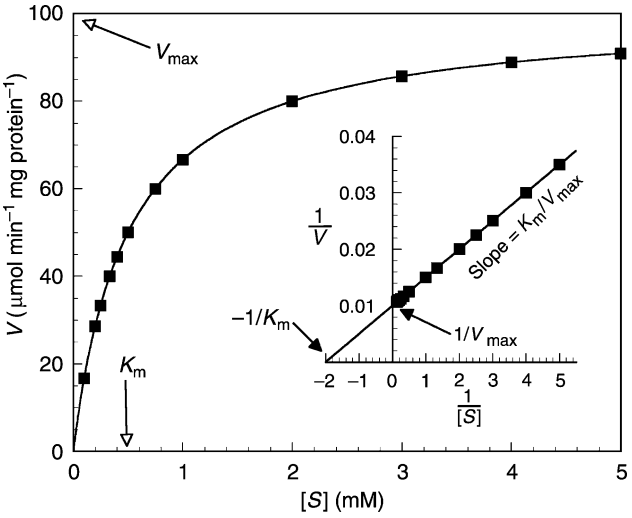

FIGURE 1 Theoretical plot of initial velocity versus substrate concentration in the absence of the product for an enzyme with a K_m of 0.5 mM and a V_{max} of 100 μmol min^{-1} mg^{-1} protein. The $[S]$ at which v is 50% of V_{max} (i.e., $[S]_{0.5}$) is equivalent to K_m. The curvature of the plot is the same for all enzymes obeying Henri–Michaelis–Menten kinetics, regardless of the absolute values of the kinetic constants. For example, the ratio of substrate concentration that yields 90% of V_{max} ($[S]_{0.9}$) to that yielding 10% of V_{max} ($[S]_{0.1}$) is always 81. Similarly, the $[S]_{0.75}/[S]_{0.5}$ ratio is always 3. Note that V_{max} is difficult to determine visually. But a computer-assisted fit to $v = Vmax^*[S]/(Km + [S])$ will return both V_{max} and K_m. (Inset) Double-reciprocal plot of the data. A wide range of substrate concentrations is needed to construct both the primary plot and the double-reciprocal plot because $[S]$ values that are evenly spaced on one plot do not space evenly on the other.

versus $1/[S]$ (usually called the Lineweaver–Burk or double-reciprocal plot), $v/[S]$ versus v (usually called the Scatchard plot), v versus $v/[S]$, or $[S]/v$ versus $[S]$. The most popular of these is the double-reciprocal plot, which is based on the linear transformation of the Michaelis–Menten equation shown below.

$$\frac{1}{v} = \frac{K_m}{V_{max}}\frac{1}{[S]} + \frac{1}{V_{max}}. \quad (21)$$

A major advantage of a linear plot is that data obtained at several different fixed concentrations of a second ligand (e.g., a cosubstrate, product, inhibitor, or activator) can be displayed simultaneously and the resulting slope and intercept characteristics used to diagnose the kinetic mechanism or the mode of inhibition or activation.

Multireactant Enzymes

Common Mechanisms

Most enzymes catalyze reactions between two or more substrates to yield two or more products. The substrates bind to the enzyme either in a random manner or in a compulsory order. Similarly, product release is random in some cases, and ordered in others. Mechanisms in which catalysis occurs only after two (or more) substrates are brought together on the enzyme are called "sequential." Some enzymes catalyze the formation and release of a product before all the substrates have bound. For example, an enzyme might capture a substrate, A, and retain part of that molecule (sometimes as a covalent adduct with the enzyme) releasing the rest of the molecule as product P. Only then does substrate B bind and combine with the part of A that was left on the enzyme to form product Q, which then leaves. This type of substituted enzyme or "ping-pong" mechanism is common for transaminases; the amino group of substrate A is left temporarily on the enzyme. A reaction catalyzed by a terreactant (three-substrate) enzyme might proceed by a combination of sequential and ping-pong steps. The order of addition of substrates and release of products is called the *kinetic mechanism*. Four bireactant examples are shown in Figure 2.

Velocity Equations for Some Bireactant Mechanisms

In some cases, different kinetic mechanisms are described by different velocity equations. (See standard enzyme kinetics texts for the procedures used to derive these equations.) Consequently, it is sometimes possible to distinguish between mechanisms from the characteristics of the double-reciprocal plots. For example, the velocity equation for an ordered bireactant mechanism under steady-state conditions in the absence of products is

$$v = \frac{V_{max}[A][B]}{K_{ia}K_{mB} + K_{mB}[A] + K_{mA}[B] + [A][B]} \quad (22)$$

where K_{mA} and K_{mB} are the Michaelis constants of the two substrates and K_{ia} is the simple dissociation constant of the EA complex. (Velocity equations for multireactant mechanisms often contain both types of constants.) When $[A]$ is varied at different fixed concentrations of B, the velocity dependence can be written in the form of the Michaelis–Menten equation:

$$v = \frac{V_{max}[A]}{K_{mA}\left(1 + \frac{K_{ia}K_{mB}}{K_{mA}[B]}\right) + [A]\left(1 + \frac{K_{mB}}{[B]}\right)}. \quad (23)$$

Or, in double reciprocal form:

$$\frac{1}{v} = \frac{K_{mA}}{V_{max}}\left(1 + \frac{K_{ia}K_{mB}}{K_{mA}[B]}\right)\frac{1}{[A]} + \frac{1}{V_{max}}\left(1 + \frac{K_{mB}}{[B]}\right). \quad (24)$$

When $[B]$ is varied at different fixed concentrations of A, the equations are

$$v = \frac{V_{max}[B]}{K_{mB}\left(1 + \frac{K_{ia}}{[A]}\right) + [B]\left(1 + \frac{K_{mA}}{[A]}\right)} \quad (25)$$

and

$$\frac{1}{v} = \frac{K_{mB}}{V_{max}}\left(1 + \frac{K_{ia}}{[A]}\right)\frac{1}{[B]} + \frac{1}{V_{max}}\left(1 + \frac{K_{mA}}{[A]}\right). \quad (26)$$

At a fixed concentration of one substrate, e.g., A, the velocity dependence on the concentration of substrate B can also be described by a simplified form of eqn. (25):

$$v = \frac{V_{max,app}[B]}{K_{mB,app} + [B]} \quad (27)$$

where the *apparent constants* are related to the true or limiting constants as shown below.

$$V_{max,app} = \frac{V_{max}}{\left(1 + \frac{K_{mA}}{[A]}\right)} \quad \text{and} \quad K_{mB,app} = \frac{\left(1 + \frac{K_{ia}}{[A]}\right)}{\left(1 + \frac{K_{mA}}{[A]}\right)}. \quad (28)$$

In other words, the experimentally determined "K_m" and "V_{max}" depend on the concentration of the co-substrate and will not equal the limiting values unless that concentration is infinitely high ("saturating"). In practice, the limiting kinetic constants are obtained from appropriate replots of the slopes and $1/v$-axis intercepts

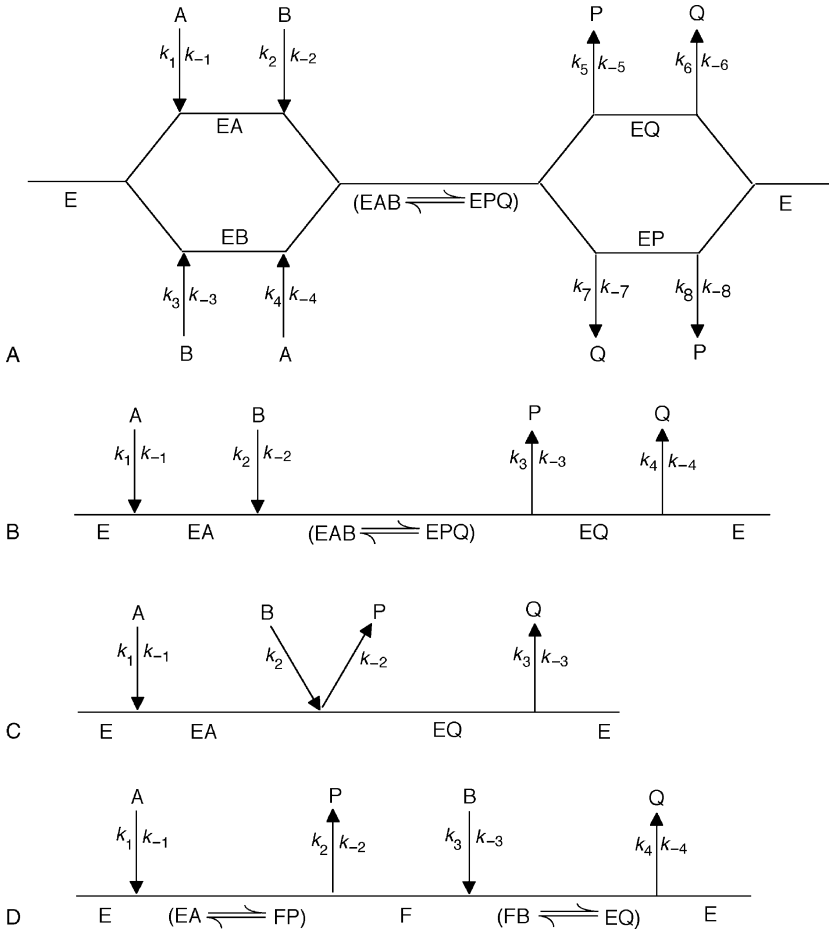

FIGURE 2 Four common kinetic mechanisms for bireactant enzymes shown in the Cleland shorthand notation. Substrates are indicated above a horizontal line as A, B, C, etc., in the order in which they add to the enzyme. Products are indicated as P, Q, R, etc., in the order in which they dissociate from the enzyme. Arrows are shown pointing in a single direction, but all the reactions are reversible. Rate constants for each reversible reaction are shown alongside of the arrows. For computer-based derivations of the velocity equation, it is usually more convenient to indicate all rate constants with positive subscripts (odd numbers for the forward steps; even numbers for the reverse direction). The various enzyme species present in the mechanism are placed below the horizontal line (in sequence of their formation). Species that are interconverted by a unimolecular step are usually grouped together within parentheses. (A) Random mechanism, (B) ordered mechanism, and (C) Theorell–Chance mechanism. The last is a limiting case of an ordered mechanism in which the EAB + EPQ central complex does not account for a significant fraction of the total enzyme in the steady state. (D) Ping-pong mechanism where stable enzyme form F may be a covalent adduct of E with the part of substrate A left behind.

of the double-reciprocal plots. (The former is a replot of $K_{m,app}/V_{max,app}$; the latter is a replot of $1/V_{max,app}$.) For example, the replots for the family of $1/v$ versus $1/[B]$ plots at different fixed $[A]$ are described by the following linear equations:

$$\text{int} = \frac{K_{mA}}{V_{max}}\frac{1}{[A]} + \frac{1}{V_{max}} \tag{29}$$

$$\text{slope} = \frac{K_{mB}K_{ia}}{V_{max}}\frac{1}{[A]} + \frac{K_{mB}}{V_{max}}. \tag{30}$$

V_{max}, K_{mA}, K_{mB}, and K_{ia} can be determined from the intercepts of the replots.

The equations for the substituted enzyme (ping-pong) bireactant mechanism in the absence of products is

$$v = \frac{V_{max}[A][B]}{K_{mB}[A] + K_{mA}[B] + [A][B]}. \tag{31}$$

When $[A]$ is varied at different $[B]$, the Michaelis–Menten and double reciprocal equations are

$$v = \frac{V_{max}[A]}{K_{mA} + \left(1 + \dfrac{K_{mB}}{[B]}\right)} \tag{32}$$

and

$$\frac{1}{v} = \frac{K_{mA}}{V_{max}}\frac{1}{[A]} + \frac{1}{V_{max}}\left(1 + \frac{K_{mB}}{[B]}\right). \qquad (33)$$

The equations for varied $[B]$ at different $[A]$ are symmetrical to those shown for varied $[A]$. Figure 3 shows the families of $1/v$ versus $1/[A]$ plots for an ordered and a ping-pong mechanism. In both mechanisms different fixed $[B]$ values affect the vertical-axis intercepts. In the ordered mechanism, changing $[B]$ also affects the slopes of the $1/v$ versus $1/[A]$ plots. But in the ping-pong mechanism, changing the fixed $[B]$ has no effect on the slopes. (Note that eqns. (24) and (33) predict these effects.) The absence of a slope effect is often sufficient to identify the ping-pong mechanism. But the presence of both slope and intercept effects (as shown in Figure 3A) is not sufficient to diagnose the mechanism as ordered because in the absence of products, a steady-state ordered, a Theorell–Chance, and a rapid-equilibrium random mechanism all have the same velocity equation. Consequently, the double-reciprocal plot patterns of the three different mechanisms are the same. Additional measurements are needed to distinguish between these mechanisms. Product inhibition studies can be informative. For example, in a steady-state ordered mechanism, one of the products (P, the first to dissociate from the enzyme) is noncompetitive with respect to both substrates, but in a Theorell–Chance and random mechanism, each product is competitive with at least one substrate. Dead-end inhibition studies may also be useful. For example,

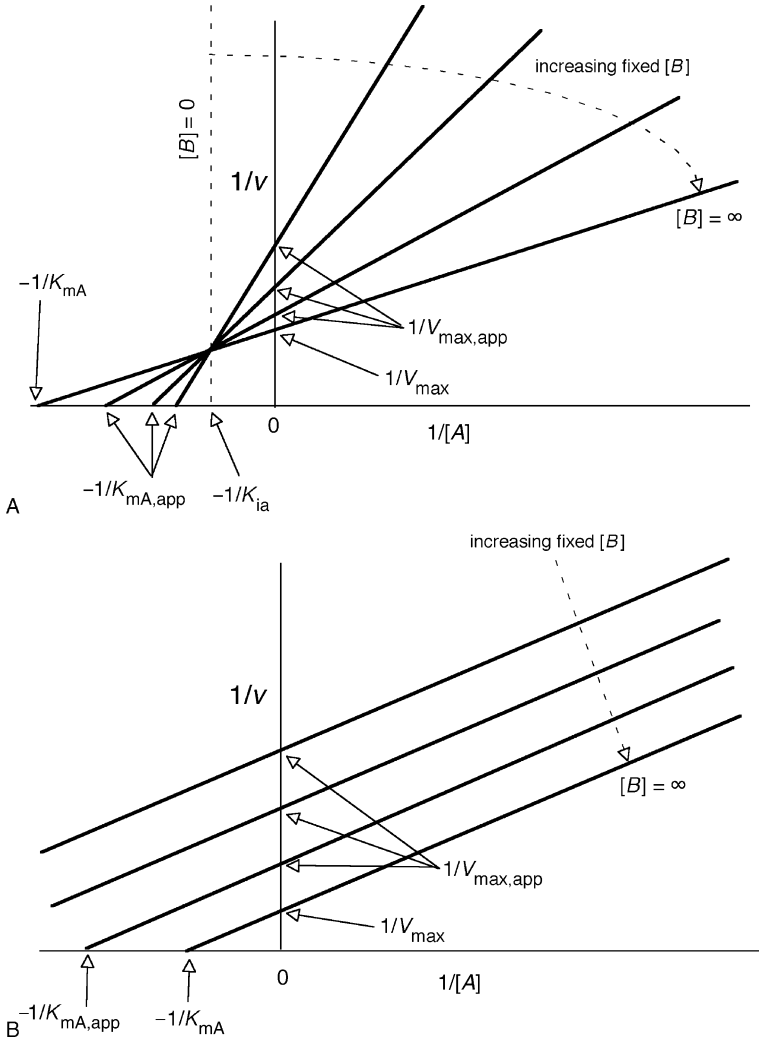

FIGURE 3 Double-reciprocal plots of $1/v$ versus $1/[A]$ at different fixed concentrations of B. A is called the varied substrate; B is called the changing fixed substrate. (A) A sequential mechanism. The plots could be for a steady-state ordered, Theorell–Chance, or a rapid-equilibrium random mechanism. (B) Ping-pong mechanism. For the above mechanisms, the plots of $1/v$ versus $1/[B]$ at different fixed $[A]$ have the same appearance as for varied $1/[A]$. The limiting kinetic constants, K_{mA}, K_{mB}, K_{ia}, V_{max}, etc., are obtained by replotting the slopes and/or $1/v$-axis intercepts of the double-reciprocal plots against the reciprocal of the changing fixed substrate concentration.

a nonreactive analogue that is competitive with B will be uncompetitive with A in the ordered and Theorell–Chance mechanisms, but noncompetitive with A in the random mechanism. (This assumes that the inhibitor forms an EAI complex in the Theorell–Chance mechanism and mimics substrate B completely in the random mechanism by binding to both E and EA.)

Cleland's Slope and Intercept Rules

W. W. Cleland has presented a series of rules for predicting the effect of changing the fixed concentration of a co-substrate or product on the slopes and vertical-axis intercepts of $1/v$ versus 1/[varied substrate] plots. The slope and intercept effects are predicted separately and then combined to deduce the appearance of the double-reciprocal plot family. Conversely, the slope and intercept patterns can help to diagnose the kinetic mechanism. The rules are as follows.

Intercept Effect

A changing fixed substrate or product will cause an intercept effect if it and the varied substrate combine with different enzyme forms. Exceptions: an intercept effect will not be seen for a changing fixed ligand that adds to the enzyme before the varied substrate under rapid-equilibrium conditions, or in a Theorell–Chance "hit-and-run" sequence between a substrate and the immediately released product (B and P in Figure 2C).

Slope Effect

A changing fixed substrate or product will cause a slope effect if it and the varied substrate combine with the same enzyme form, or with different forms that are "reversibly connected" in the upstream or downstream direction. Two enzyme forms will not be reversibly connected if either (1) a product release step occurs between them and that product is at zero concentration in the assay solution, or (2) a substrate addition step occurs between the two enzyme forms and that substrate is present at a saturating concentration. Both the upstream and downstream directions must be blocked to eliminate reversibility.

A product will have no effect on slopes or intercepts if the steady-state level of the enzyme form with which it combines is zero because of saturation with a competitive substrate.

Similar rules predict the slope and intercept effects produced by dead-end inhibitors.

Biography

Irwin H. Segel is a Professor in the Section of Molecular and Cellular Biology at the University of California, Davis. His major research interests are in the structure–function relationships of the inorganic sulfate activating enzymes, ATP sulfurylase and APS kinase. He received his Ph.D. from the University of Wisconsin and did postdoctoral research at the Centre National de la Recherche Scientifique in Marseille. He is a Fellow of the American Association for the Advancement of Science.

Enzyme Reaction Mechanisms: Stereochemistry

Ming-Daw Tsai, Li Zhao and Brandon J. Lamarche
The Ohio State University, Columbus, Ohio, USA

Stereochemistry **is the facet of chemistry concerned with the three-dimensional properties of molecules. The history of stereochemistry began in 1815 when Jean-Baptiste Biot discovered that some molecules are capable of rotating the plane of polarized light. Louis Pasteur suggested in 1850 that this phenomenon could be attributed to the stereochemical properties of molecules. In the subsequent 150 years it has come to be understood that stereochemistry is all-important in biology, where a molecule's structure and function are inextricably related. Though synthetic chemists are increasingly adept at controlling the stereochemistry of chemical reactions, enzymes – nature's catalysts – remain the paradigm for stereochemical control. Stereochemical analysis of enzymatic reactions can therefore yield information about the mechanism of enzyme action. That is the focus of this entry.**

Explanation of Stereochemical Terms

Figure 1 uses chemical structures to illustrate key stereochemical terms. *Stereomers* (or stereo isomers) are molecules that have the same molecular formula and the same order of attachment of atoms, but they differ in the way their atoms are oriented in space. Any molecule that cannot be superimposed on its mirror image is said to be *chiral*. Though chirality can result from a number of molecular properties, it is usually due to the presence of one or more carbon or phosphorus atoms, called chiral centers, which are surrounded by four unique substituents. Chiral molecules are classified as either *enantiomers* (stereoisomers that are mirror images of each other) or *diastereomers* (stereoisomers that are not mirror images of each other).

Configuration specifies how substituents are oriented around a chiral center and is determined by the *R*–*S* notation system, where *R* and *S* refer to the Latin terms *rectus* (right) and *sinister* (left). To assign *R*/*S* configuration, a priority rating is given to each substituent at a chiral center using the following rules: Priority is first assigned on the basis of atomic number with highest priority given to the atom with the highest atomic number. When identical atoms are directly attached to the chiral center, the next atoms on the substituent are compared, until a difference is noted. Once priority has been established, the molecule is oriented so that the lowest priority substituent is pointing away from the viewer. The direction of rotation observed when moving from the highest to lowest priority will now be either clockwise or counterclockwise and the configuration is designated *R* or *S*, respectively.

An atom that is attached to two unique substituents and two identical substituents is said to be prochiral. The two identical groups at a prochiral center can be designated as pro-*R* and pro-*S* following a prochirality rule. As shown in Figure 1C, the pro-*R* hydrogen (H_R) is the one that leads to R configuration if it is given a higher priority than the other hydrogen atom. When a chiral center or prochiral center is phosphorus instead of carbon, a subscript p is added (i.e., R_P, S_P, pro-R_P, pro-S_P).

Stereoselectivity, Stereospecificity, and Stereochemical Course of Enzymatic Reactions

If exposed to a racemic mixture of substrates, most enzymes utilize one enantiomer or diastereomer preferentially. In reactions where chemistry is occurring at a prochiral center, an enzyme is also likely to act on just one of the two available enantiotopic or diastereotopic groups. The enzyme is said to be *stereoselective* in both cases.

Enzymatic reactions are almost always *stereospecific*, which means that they convert one stereoisomer of substrate to one stereoisomer of product. For substitution reactions, *stereochemical course* refers to the change (or lack thereof) in configuration at the reaction center in a stereospecific reaction. While *retention* means the new group occupies the same position as the

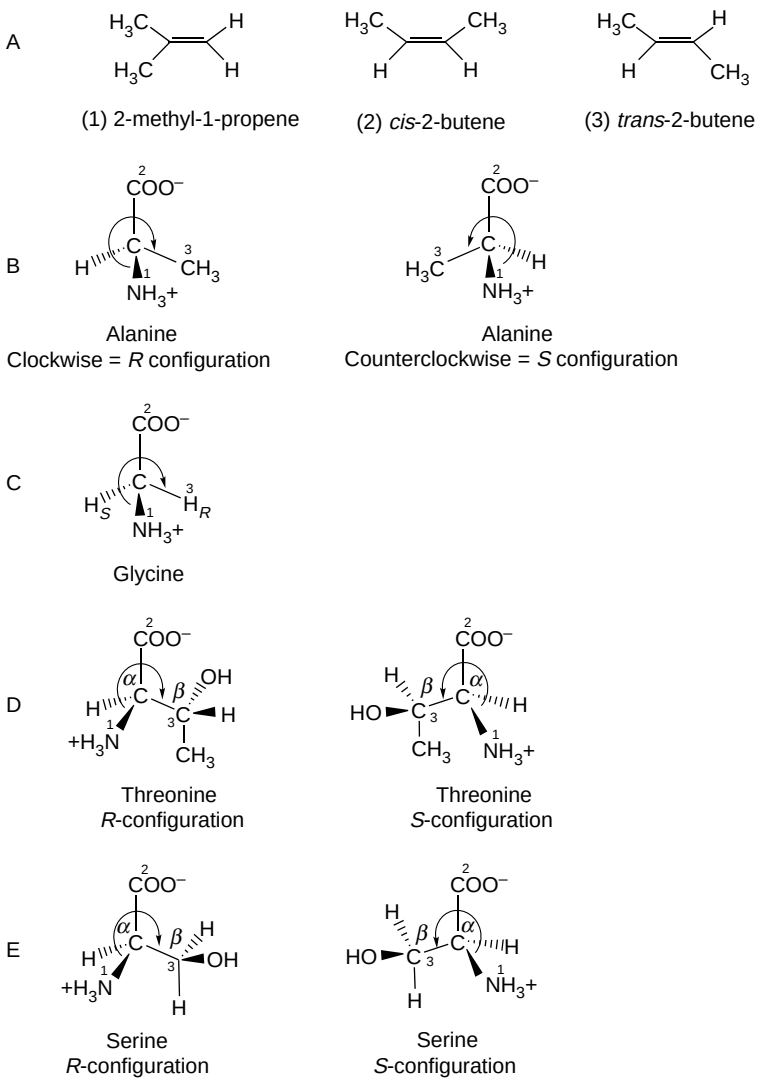

FIGURE 1 Demonstration of stereochemical terms using structures. (A) Though molecules 1, 2, and 3 have the same molecular formula, only 2 and 3 are stereoisomers. Molecule 1 has a different pattern of bonding (i.e., a different linkage of atoms) and is therefore a structural isomer of molecules 2 and 3. (B) Alanine stereoisomers are *enantiomers* since they are mirror images of each other. Note that the different configuration of substituents about the central carbon makes it impossible to superimpose the two isomers. (C) Glycine is *achiral* and therefore does not have stereoisomers. However, the central carbon is a prochiral center since it can be converted to a chiral center by replacing one of the two hydrogens with a different group. The two hydrogens are said to be *enantiotopic* since the separate replacement of each hydrogen results in a pair of enantiomers. (D) The two stereoisomers of threonine shown are diastereomers, i.e., stereo isomers that are not complete mirror images of each other. Note that this pair of molecules results by altering the configuration at C_α while leaving the configuration at the C_β unmodified. (E) Serine contains a chiral center at C_α and a prochiral center at C_β. Unlike glycine, the two hydrogen atoms at the prochiral center of serine are *diastereotopic* groups since the separate replacement of each hydrogen results in a pair of diastereomers.

displaced group, *inversion* means it occupies the opposite position. If the reaction is non-stereospecific, it leads to racemization, with both isomers being formed at a ratio close to 1:1. Note that an *R*-substrate does not necessarily give an *S*-product in an inversion reaction, since the priority of the substituents at the reaction center can be altered on going from substrate to product. Also note that there is a steric course (inversion or retention) even when the displacement occurs at a prochiral center or a pro-prochiral center (a methyl group or phosphoryl group). The three hydrogen atoms of a methyl group and the three oxygen atoms of a phosphoryl group are homotopic and cannot be differentiated from one another by an enzyme. In these cases, there is no issue of stereoselectivity, only steric cause. Experimentally, pro-prochiral centers can be made chiral via isotope substitution, which in turn allows elucidation of the steric course of the reaction as illustrated in Figures 2B and 2C.

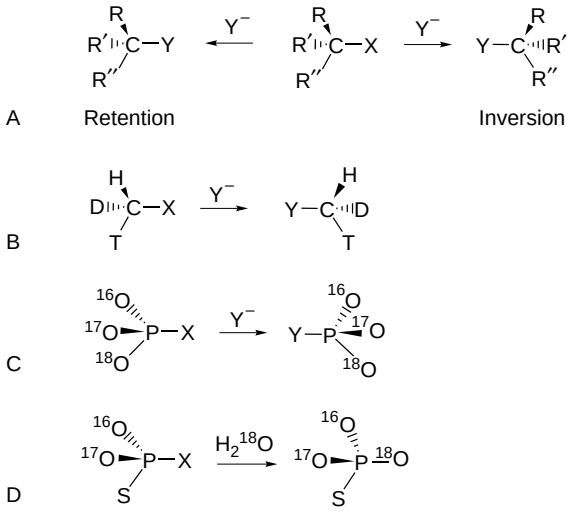

FIGURE 2 Illustration of possible steric courses of enzymatic reactions and application of isotope substitutions to elucidate the steric course. Steric courses shown in B, C, and D are inversion, inversion, and retention, respectively.

In addition to the use of oxygen isotopes, an oxygen atom at a prochiral or pro-prochiral center can also be replaced by a sulfur atom. These phosphorothioate analogs have found broad applications in the study of diverse biological systems. The stereochemical course of phosphatases, which convert a phosphomonoester to inorganic phosphate, have been deciphered in this manner, as illustrated in Figure 2D.

Key steps in conducting stereochemical experiments are the synthesis of isomers of chiral substrates and/or substrate analogs and the analysis of a compound's stereochemical configuration before and after being processed by an enzyme. Since different substrate analogs are required for each enzyme studied, and since isotopes are frequently used, these studies are particularly challenging.

Pioneering Study: Alcohol Dehydrogenase (ADH)

Yeast alcohol dehydrogenase (ADH) catalyzes the reversible transfer of a hydrogen atom between a molecule of ethanol and a molecule of the coenzyme nicotinamide-adenine dinucleotide (NAD^+). By use of deuterated ethanol or coenzyme, ADH was shown to abstract the pro-*R* hydrogen of ethanol and adding it to the *re* face of NAD^+, as illustrated in Figure 3.

Analysis of Steric Course to Probe an Enzymatic Reaction Pathway

In nonenzymatic reactions, a bimolecular S_N2 reaction leads to inversion of configuration of the chiral carbon, while a unimolecular S_N1 reaction generates a planar carbonium ion that reacts randomly at each face to generate a racemic product. In enzymatic reactions, however, the steric course is usually an inversion for both types of mechanisms, since the carbonium ion is not free to rotate within the active site. Thus, an inversion of steric course can be used to conclude that the reaction involves an odd number of displacements (most likely single displacement), whereas retention can be used to conclude that the reaction involves an even number of displacements (most likely two displacements involving an E–S intermediate).

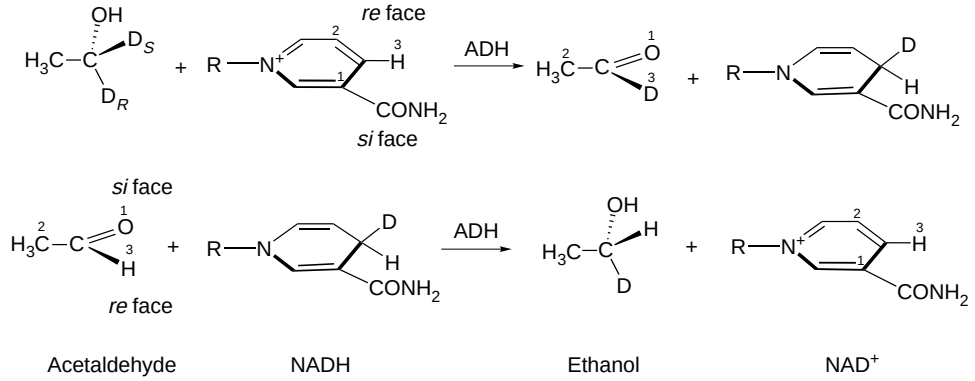

FIGURE 3 Stereochemistry involved in the reaction catalyzed by yeast alcohol dehydrogenase (ADH). In the forward reaction, the pro-*R* hydrogen of ethanol is transferred to the *re* face of NAD^+ to give NADH and acetaldehyde. In the reverse reaction, the pro-*R* hydrogen of NADH is transferred to the *re* face of acetaldehyde. The numbers 1, 2, and 3 designate the priorities of the substituents at the sp^2 carbon. The *re* and *si* faces of NADH are diastereotopic faces (since "R" includes stereocenters) whereas those of acetaldehyde are enantiotopic faces.

Phosphoryl transfer reactions are described by different terminology, where dissociative and associative mechanisms generally correspond to S_N1 and S_N2, respectively. The associative mechanism can be executed via in-line or adjacent mechanisms. In the adjacent mechanism, the nucleophile enters on the same side as the leaving group, generating a pentavalent intermediate with trigonal bipyramidal geometry. However, for the reaction to proceed, both the nucleophile and the leaving group must occupy apical positions. Therefore, pseudorotation – rearrangement of substituents about the reaction center such that the leaving group shifts from an equatorial to an axial position – must occur before the leaving group can be expelled. Except when the adjacent mechanism appears likely, the steric course of the reaction is also used to obtain information about the number of phosphoryl transfers.

Information about an enzyme's steric course is very useful for elucidating the reaction pathway as illustrated by the following example: mammalian phosphatidylinositol-specific lipase C (mPI-PLC) catalyzes the simultaneous formation of 1,2-cyclic phosphate (IcP) and inositol phosphate (IP) from phosphatidylinositol (DPPI). Two reaction schemes, sequential and parallel, can account for this behavior (Figure 4). Examination of the steric course of the mPI-PLC catalyzed reaction, where inversion of configuration at the phosphate center of IcP and retention of configuration at the phosphate center of IP were found, led to the conclusion that the reaction pathway is sequential.

Stereoselectivity Can Probe Metal–Nucleotide or Enzyme–Substrate Interactions at the Transition State

Enzymes catalyze reactions by stabilizing the transition state. Knowledge of enzyme substrate interactions at the transition state is therefore requisite for understanding the mechanism of enzyme action. Though structures of enzyme–substrate complexes are useful, they can only provide information about ground state interactions. Since enzymatic stereoselectivity is a consequence of steric and electronic constraints within the enzyme active site at the transition state, stereochemical studies can provide information about catalytic interactions that is often unattainable via structural work alone.

Since there are numerous points of contact between an enzyme and its substrate throughout a reaction pathway, stereoselectivity alone is often not sufficient for providing information about a particular enzyme–substrate interaction. However, this difficulty is circumvented by employing substrate analogs in conjunction with stereochemical analysis. For example, most enzymes that utilize ATP prefer one isomer of ATPαS or ATPβS over the other. Such R_P/S_P (or S_P/R_P) stereoselectivity can be caused by phosphate–metal-ion interactions, phosphate–enzyme interactions, or both types of interactions. A reversal (or a dramatic change) of stereoselectivity in the presence of an

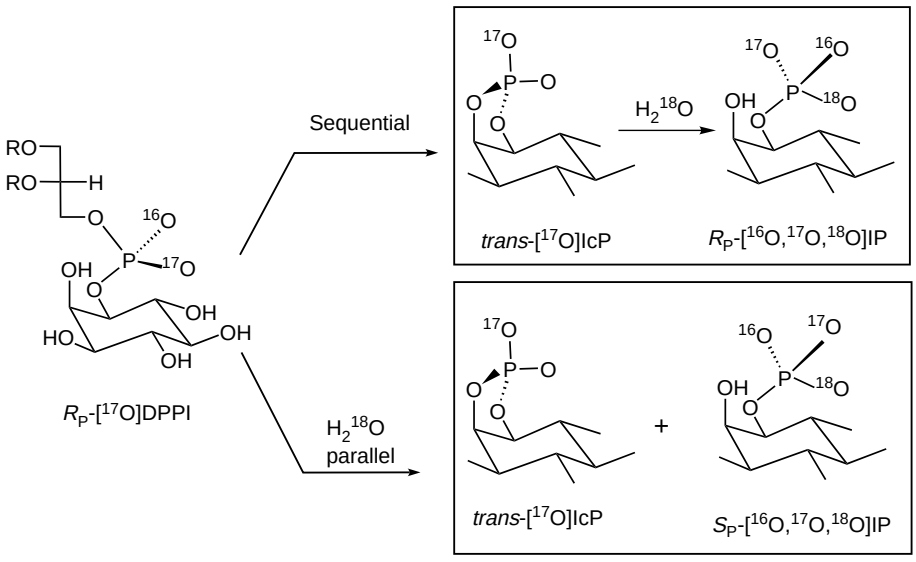

FIGURE 4 Proposed sequential and parallel mechanisms for the formation of IcP and IP catalyzed by mPI-PLC. In the sequential mechanism, intramolecular attack by the axial ring hydroxyl forms the cyclic intermediate (IcP), which is then broken down by hydrolysis ($H_2^{18}O$) to give R_P-[^{16}O, ^{17}O, ^{18}O] IP. In the parallel mechanism, intramolecular attack by the axial ring hydroxyl and direct water ($H_2^{18}O$) attack gives S_P-[^{16}O, ^{17}O, ^{18}O] IP, respectively.

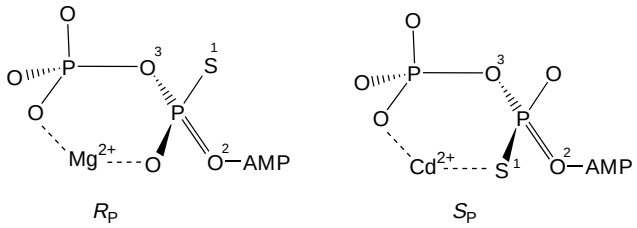

FIGURE 5 Metal–nucleotide interactions showing that substitution of Mg^{2+} by Cd^{2+} leads to a change in the stereoselectivity of AK from R_P-ATPβS to S_P-ATPβS.

"unnatural" metal ion or upon mutating an active site residue provides strong evidence that the metal ion or mutated residue interacts with that particular phosphate moiety. Studies of adenylate kinase (AK) described below further illustrate this point.

AK catalyzes the reversible phosphoryl transfer reactions: $Mg^{2+} \cdot ATP + AMP \leftrightarrow Mg^{2+} \cdot ADP + ADP$. Of the R_P and S_P isomers of ATPβS shown in Figure 5, AK prefers the S_P isomer by a factor of 9 in the presence of Mg^{2+}. However, this stereoselectivity is reversed (R_P isomer is preferred by a factor of 10) when Mg^{2+} is substituted by Cd^{2+}. Since Cd^{2+} preferentially coordinates sulfur over oxygen, which is opposite to the ligand preference of Mg^{2+}, the switch of stereospecificity upon Cd^{2+} substitution is strong evidence for direct coordination of the metal ion by the pro-*S* oxygen of the

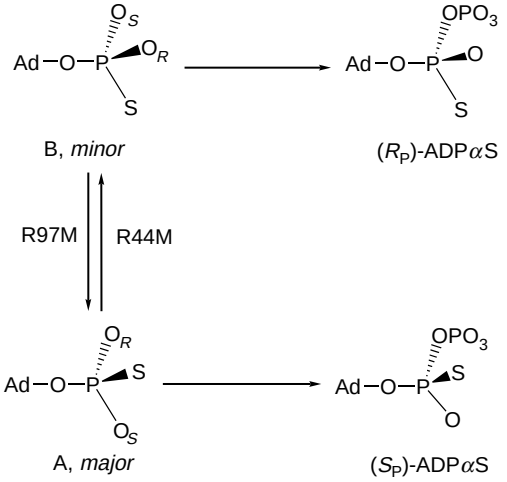

FIGURE 6 Enhancement and reversal of adenylate kinase stereoselectivity by site-directed mutagenesis (Ad, adenosine). In the reaction catalyzed by WT protein, phosphate is preferentially attached to the pro-*R* oxygen of AMPS. The R97M and R44M mutations enhance and reverse this stereoselctivity, respectively. This provides strong evidence that R97 and R44 interact with the phosphate moiety of AMP at the transition state. A and B represent two "conformers" of AMPS when bound to the active site of the enzyme.

β-phosphate of ATP. Additional mechanistic information for AK was derived using active site mutants. Wild type AK catalyzes the stereoselective conversion of AMPS to S_P-ADPαS. Such stereoselectivity could be achieved by restricting orientation of the P–S and P–O bonds at the active site as shown in Figure 6. Experimental results demonstrated that the stereoselectivity of this reaction is further enhanced by the R97M mutant, but is completely reversed in the reaction catalyzed by the R44M mutant. These results indicate that the conformational equilibrium of the AMPS substrate in the active site is perturbed in both mutants, suggesting that the Arg97 and Arg44 residues interact with the phosphate moiety of AMPS.

Glossary

enzyme-catalyzed reaction Usually stereospecific; many of them are also stereoselective. The stereochemical property of an enzymatic reaction is useful in elucidating its reaction mechanism.

stereoselectivity The ability of an enzyme to choose from two or more possible stereoisomers as a preferred substrate, to choose from two enantiotopic groups or from two diastereotopic groups, or to produce one stereoisomer as a preferred product when more than one stereoisomeric products are possible.

stereospecificity The ability of an enzyme to convert a particular stereoisomeric substrate to a specific stereoisomeric product. For a substitution reaction, the stereochemical course of a stereospecific reaction can be retention or inversion.

Biography

Ming-Daw Tsai is a Professor in the Departments of Chemistry and Biochemistry at The Ohio State University. Dr. Tsai's overall research interest lies at the interface between chemistry and biology, in particular, the structure–function relationship of enzymes and proteins. He holds a Ph.D. in Medicinal Chemistry from Purdue University.

Li Zhao holds a Ph.D. in Chemistry from The Ohio State University. Her research focus has been the catalytic mechanism of Phosphatidylinositol-specific lipase C.

Brandon J. Lamarche earned a B.Sc. in Chemistry from Westmont College. In 1999 he started doctoral work in the Department of Chemistry at The Ohio State University. His research interests involve the enzymology of DNA repair.

Epidermal Growth Factor Receptor Family

Denis Tvorogov and Graham Carpenter
Vanderbilt University School of Medicine, Nashville, Tennessee, USA

The physiological state of a single cell in a multicellular organism is generally determined by different extracellular signals presented to the cell. Many of these extracellular signals transduce their cellular response by recognizing and activating a receptor with intrinsic tyrosine kinase activity. Among these is the epidermal growth factor receptor family, also known as the ErbB family of receptors.

Receptors and Ligands

The ErbB family is comprised of four receptor tyrosine kinases: ErbB-1 (also known as an epidermal growth factor [EGF] receptor), ErbB-2, ErbB-3, and ErbB-4. These receptors are thought to mediate signal for cell proliferation, differentiation, migration, or apoptosis. Deregulated expression or mutational activation of ErbB receptors, especially ErbB-1 and ErbB-2, has been found in numerous types of human cancer.

Eleven different EGF-like growth factors, which directly activate ErbB receptors, have been identified: EGF, transforming growth factor alpha (TGF-α), amphiregulin, heparin-binding-EGF (HB-EGF), epiregulin, betacellulin, epigen, and the neuregulins (NRG-1, NRG-2, NRG-3, NRG-4) also known as heregulins. ErbB receptors are subgrouped by their ligand-binding properties. ErbB-1 recognizes EGF, TGF-α, amphiregulin, HB-EGF, epiregulin, epigen, and betacellulin. ErbB-3 binds NRG-1 and NRG-2. ErbB-4 binds NRG-1–4, betacellulin, epiregulin, and HB-EGF (Figure 1). As yet no ligand has been identified for ErbB-2, but significant data suggest that ErbB-2 serves as a coreceptor for all other ErbBs. The binding of a ligand with an ErbB receptor induces the formation of homodimers and heterodimers, particularly with ErbB-2. Dimerization is a mechanism to provoke receptor autophosphorylation and thereby stimulate the intrinsic tyrosine kinase activity of the receptors.

The Structure of ErbB Receptors

The domain structure of the ErbB receptors consists of an extracellular ligand-binding domain, a single transmembrane (TM) domain, and an intracellular region (Figure 1). The extracellular domains of all ErbB receptors are highly glycosylated and are subdivided into four subdomains, termed I, II, III, and IV. Domains II and IV are cysteine-rich regions, and are highly conserved among the ErbBs. Domains I and III cooperate to form a growth factor-binding site as demonstrated by the crystal structure of the extracellular region of the ErbB-1 receptor with EGF and TGF-α. These data further indicate that growth factor binding induces conformational changes in subdomain II, which leads to dimerization through a direct receptor:receptor interaction.

The TM domain of each ErbB receptor contains 20–25 amino acid residues forming five loops of α-helical structure, and probably plays a passive role in signal transduction. This conclusion is based on experiments with ErbB-1 receptors containing a mutated TM region. Different forms of the ErbB-1 receptor with extended or shortened TM regions were able to bind EGF and dimerize. Alterations generated within the TM domain did not prevent receptor autophosphorylation.

The intracellular domain of ErbB receptors contains a tyrosine kinase domain and autophosphorylation sites (Figure 1). The tyrosine kinase domain is highly conserved among all four ErbB receptors; however, the ErbB-3 has a defective tyrosine kinase domain due to several residue changes. ErbB-3, therefore, must dimerize with a kinase competent receptor (ErbB-2 is preferred) to form a signaling competent complex.

Binding of ligand to an ErbB receptor provokes autophosphorylation of multiple tyrosine residues within the carboxy-terminal domain. Together with adjacent residues each phosphotyrosine residue serves as a receptor docking site for proteins involved in

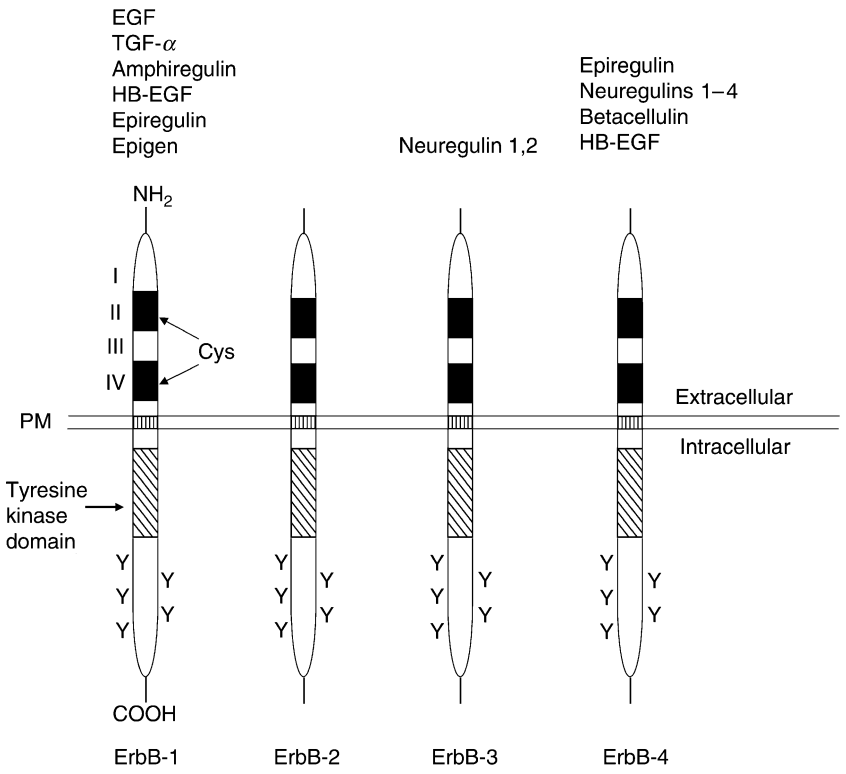

FIGURE 1 Structure of ErbB receptors. Each receptor contains an extracellular region bearing with cysteine-rich domains (Cys, filled), a single TM domain (vertical hatched), and a cytoplasmic region consisting of a tyrosine kinase domain (diagonal hatched) and tyrosine residues (Y) on the C-terminal domain which can be phosphorylated by the tyrosine kinase domain. The ErbB-3 receptor has a deficient tyrosine kinase domain (diagonal hatched with a cross). The ligands which bind to these receptors are listed above each receptor.

downstream signaling events (Figure 2). The association between tyrosine phosphorylated sequences and each signaling protein is facilitated by the presence of either an Src homology 2 (SH2) or a phosphotyrosine binding (PTB) domain in the signaling protein. The specificity of the interaction of any given ErbB receptor with an SH2 or PTB domain-containing protein is determined by the exact amino acid sequences surrounding the phosphorylated tyrosine residue, as well as sequences within each SH2 or PTB domain. Generally, receptor docking of these proteins is a prerequisite for tyrosine phosphorylation of these signaling proteins by the receptor and the activation of signal transduction pathways that cooperate to produce cellular responses.

FIGURE 2 Subsets of signaling proteins activated by each ErbB receptor.

ErbB Receptor Substrates

ErbB receptors are involved in the initiation of a variety of cell responses, such as proliferation, differentiation, or cell locomotion, which require changes in gene expression, intracellular Ca^{2+} level, protein and lipid phosphorylation, and other intracellular conditions. Therefore, every activated ErbB receptor interacts with a battery of proteins involved in different signal intracellular pathways. Different ErbB receptors associate with overlapping subsets of intracellular proteins to activate subsets of the same downstream signaling pathways (Figure 2). The list of signaling partners for each ErbB receptor is not entirely determined and most data have been obtained from experiments with the ErbB-1 (or EGF) receptor. Proteins that interact with activated ErbB receptors can be categorized according to

their signaling properties: enzymes participating in phosphatidylinositol metabolism, such as phospholipase Cγ1 and the regulatory subunit of phosphatidylinositol 3-kinase; protein kinases, such as Src; phosphatases, such as Shp1 and Shp2; adaptor proteins, such as Cbl, Shc, Grb2, Nck; and transcription factors, such as STATs. As shown in Figure 2. the signaling pathways activated by the four ErbB receptors frequently overlap. How signaling pathways are actually integrated to provoke a cellular response, such as proliferation, is unknown.

Receptor-Mediated Endocytosis

A second consequence of ligand binding to ErbB receptors is an initiation of rapid receptor-mediated endocytosis (Figure 3). During this process ligand–receptor complexes cluster in cell-surface clathrin-coated pits, which subsequently become intracellular clathrin-coated endosomes. The clathrin coat is then removed to produce early endosomes and this compartment matures to form multivesicular bodies. There are two fates for internalized receptor. First, receptors may undergo recycling, from early endosomes or from multivesicular bodies, to the plasma membrane. Multivesicular bodies become late endosomes and then primary lysosomes where receptor and ligand degradation occurs. Hence, a receptor may be degraded or recycled following the endocytic pathway. Under most circumstances the degradation route is kinetically favored.

Interestingly, only ErbB-1 receptors have been shown to be rapidly internalized following ligand binding. Other ErbB receptors are endocytosis impaired or demonstrate only a very slow endocytotic rate. Experiments with chimeric receptors containing the ErbB-1 extracellular domain and different ErbB-2, ErbB-3, ErbB-4 cytoplasmic regions show extremely low rates of internalization. These data suggest that the structure of the ErbB cytoplasmic domains determines whether or not a given ErbB receptor will be rapidly internalized by clathrin-coated pits. It also has been shown that ErbB-1 tyrosine kinase activity is necessary for ligand-dependent receptor trafficking into clathrin-coated pits and subsequent internalization.

There are two different points of view regarding the significance of endocytosis for growth factor receptor signal transduction. One view is that endocytosis serves as a desensitization mechanism by removing the receptors from the plasma membrane and degrading the activated receptors in the lysosome. Indeed, introduction of a truncated form of EGF receptor that retains kinase activity is internalization defective and leads to enhanced mitogenic responses and cellular transformation after treatment with EGF. A second viewpoint is that positive signaling occurs during endocytosis. It has been shown that EGF receptors in endosomes retain bound EGF, are authophosphorylated, and are able to activate some intracellular signaling pathways. This suggests that receptor-mediated endocytosis may serve as a mechanism for spatial redistribution of activated EGF receptors and transduction of signals.

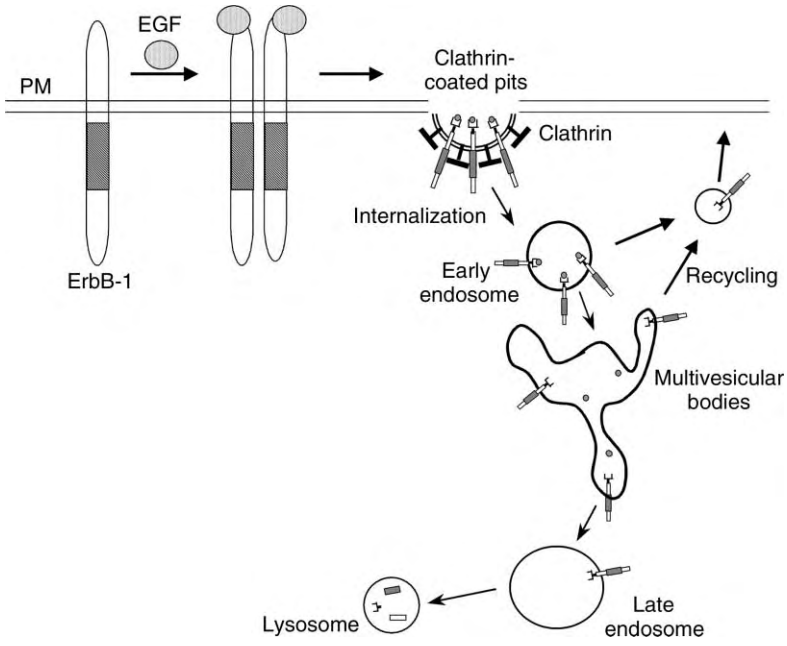

FIGURE 3 Schematic representation of ErbB-1 receptor trafficking following EGF binding.

Targeting ErbB Receptors in Cancer Therapy

During the past several years it has become clear that deregulated signaling from ErbB receptors is involved in cancer development. Among the ErbB receptors, the overexpression or abnormal activation of ErbB-1 or ErbB-2 is most often observed in epithelial carcinomas and glioblastomas. There are three possible mechanisms by which an ErbB pathway may be hyperactivated: ligand overproduction, receptor overexpression, or mutation to produce activated receptors in the absence of a growth factor. Expression of ErbB-1 or its ligand has been reported in over 80% of head and neck squamous cell carcinomas, while its overexpression occurs in breast carcinomas and its mutational activation occurs in glioblastomas. Overexpression of the ErbB-2 receptor is common in breast cancer, ~25% of invasive ductal breast cancers have overexpressed ErbB-2 due to gene amplification. The level of ErbB-2 overexpression correlates with tumor size and its spread to lymph nodes. Breast cancers with ErbB-2 overexpression have a poorer prognosis and are more resistant to chemotherapy. Among all ErbB ligands, the role of TGF-α in human cancer is most characterized. Co-overexpression of TGF-α and ErbB-1 has been found in several types of carcinomas, and overproduction of TGF-α in lung and colon tumors coexpressing ErbB-1 correlates with poor prognosis.

In general, there are two different but related approaches to inhibit Erb-B-mediated signaling in human tumors and both are now in clinical trials. These include monoclonal antibodies and tyrosine kinase selective inhibitors. Several ErbB-1-specific antibodies against the extracellular region of receptor have been developed. The mechanism of inhibiting the activity of the receptor involves antibody binding to the receptor and masking the ligand-binding site. This prevents ligand-binding and receptor activation. Additionally the antibody may enhance receptor internalization and degradation. It is also possible that the antibody marks cells that express an increased level of ErbB-1 and targets them for destruction by the immune system. A humanized antibody to ErbB-2 termed Herceptin has been validated for clinical use and represents one of the first successes of biotechnology in clinical settings. Herceptin slows the proliferation rate of breast cancer cells overexpressing ErbB-2, by increasing the percentage of the cell population in G0/G1 or quiescent states of the cell cycle.

Low-molecular-weight inhibitors are another strategy used *in vivo* to suppress hyperactivated ErbB signaling in human tumors. These compounds competitively inhibit ATP binding at the tyrosine kinase active site and thereby block proliferation. One of these compounds, Iressa, has been cleared for clinical use.

Conservation of ErbB Receptor Signaling during Evolution

ErbB signaling is present not only in mammalians, but also in less-developed organisms such as the nematode *Caenorhabditis elegans* and the fruitfly *Drosophila melanogaster.* The nematode has one EGF-like ligand (Lin-3) and one ErbB-like receptor (Let23). These components are required for correct development in the nematode. In the fruitfly the ErbB signaling network consists of four EGF-like ligands (Vein, Gurken, Spitz, and Argos) and one EGF-like receptor (*Drosophila* EGF receptor – DER). Argos is a unique ligand as it acts negatively to inhibit receptor signaling. In *Drosophila*, ErbB signaling is also required for several developmental pathways. Interestingly, many of the signaling elements found downstream of the mammalian EGF receptor are highly conserved in the nematode and fruitfly. Hence, this growth factor signaling system has been highly conserved throughout millions of years of evolution.

ER/SR Calcium Pump: Function

Giuseppe Inesi
University of Maryland School of Medicine, Baltimore, Maryland, USA

The sacro-endoplasmic reticulum Ca^{2+} ATPase (SERCA) utilizes ATP for active transport of cytosolic Ca^{2+} into membrane bound intracellular compartments. Intracellular storing of Ca^{2+} by SERCA is an integral part of signaling mechanisms for a large number of cellular functions. The catalytic and transport cycle of SERCA includes formation of a phosphorylated enzyme intermediate and protein conformational changes, leading to vectorial translocation of Ca^{2+} across the membrane.

ATP Use for Ca^{2+} Transport

The sarcoendoplasmic reticulum calcium ATPase (SERCA) is the Ca^{2+} pump of intracellular membranes. The pump plays a prominent role in numerous cytosolic signaling mechanisms that require the sequestration of intracellular Ca^{2+}. The SERCA pump was first noted in a microsomal fraction of rabbit skeletal muscle homogenates, which was found to prevent activation of glycerinated muscle fibers or isolated contractile models upon the addition of ATP. The microsomes were then identified with vesicular fragments of sarcoplasmic reticulum (SR), and the relaxing effect was attributed to sequestration of Ca^{2+} from the medium through active transport by a membrane-bound ATPase. cDNA cloning identified three gene products (SERCA 1, SERCA2, and SERCA3) with two to three splice variants for each primary transcript. The related isoforms display specific tissue distribution, functional roles, and regulatory mechanisms.

The SR vesicles obtained from skeletal muscle contain a high quantity of Ca^{2+} ATPase (SERCA1A isoform), which accounts for approximately 50% of the total protein and which is densely spaced within the plane of the membrane (Figure 1). These vesicles provide a very useful experimental system inasmuch as they allow parallel measurements of ATPase activity and Ca^{2+} transport, as well as control of the ionic environment in compartments delimited by the native membrane. For this reason, they have been used extensively in biochemical and structural studies to clarify the mechanism of ATP use for Ca^{2+} transport.

Steady-State Behavior

Active transport of Ca^{2+} into the lumen of SR vesicles occurs with a stoichiometric ratio of two Ca^{2+} per hydrolyzed ATP under optimal steady-state conditions. Acetyl phosphate or *p*-nitrophenyl phosphate can be used as substrate by the enzyme instead of ATP, although with lesser kinetic competence. The maximal levels of ATP-dependent Ca^{2+} uptake by the vesicles is increased by Ca^{2+} binding to a native acidic protein, calsequestrin, in the lumen of the vesicles. It can also be increased by complexation with anions such as oxalate or phosphate in the lumen of the vesicles.

Independent of the substrate, the ATPase has a strict requirement for Ca^{2+} activation. In fact the enzyme is activated by medium containing free Ca^{2+} within the micromolar range and is inhibited by lumenal free Ca^{2+} in the millimolar range. This indicates that ATP is used to change the affinity and orientation of the Ca^{2+}-binding sites, resulting in a three-orders-of-magnitude Ca^{2+} gradient across the membrane. Furthermore, in reconstituted ATPase preparations that are deprived of pathways for passive leakage, it was shown that Ca^{2+} transport is accompanied by H^+ countertransport at a 1:1 ratio and that the pump is electrogenic.

Considering these functional features, the free energy required for active transport of Ca^{2+} into the vesicles can be defined, at first approximation, as:

$$\Delta G = RT \ln\left(\left[Ca^{2+}_{in}\right]/\left[Ca^{2+}_{out}\right]\right) + zF\Delta V$$

where $[Ca^{2+}_{in}]$ and $[Ca^{2+}_{out}]$ refer to the Ca^{2+} concentration in the lumen of the vesicles and in the outer medium, z is the electrical charge of the transported species, R and F are the gas and Faraday constants, respectively, and ΔV is the transmembrane electrical gradient. The free-energy requirement, estimated in this manner, provides a satisfactory match of the experimentally observed gradients with the chemical potential of ATP.

The Partial Reactions of the Catalytic and Transport Cycles

The Ca^{2+} ATPase catalytic cycle includes a phosphorylated intermediate formed by covalent transfer of the

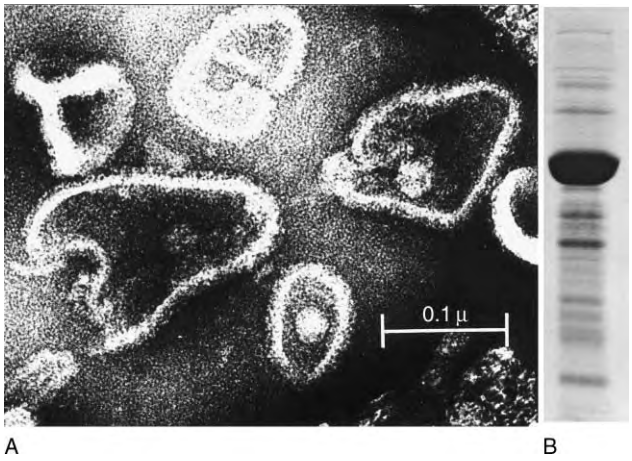

FIGURE 1 Structural characterization of SR vesicles. (A) Negatively stained SR vesicles, obtained from rabbit skeletal muscle, are visualized by electron microcopy. The densely spaced granules on the surface of the membrane correspond to Ca^{2+} ATPase molecules. (B) Electrophoretic analysis demonstrating that the Ca^{2+} ATPase separates as a prominent band that accounts for the major portion of the membrane protein. Adapted from Scales, D. and Inesi, G. (1976). Assembly of ATPase protein in sarcoplasmic reticulum membranes. *Biophys. J.* **16**, 735–751, with permission from the Biophysical Society.

ATP terminal phosphate to an aspartyl residue (Asp351) at the catalytic site. Phosphoryl transfer requires activation by the same Ca^{2+} concentration as ATP hydrolysis, indicating that enzyme activation by Ca^{2+} must occur early in the catalytic cycle. In fact, cooperative binding of two Ca^{2+} per ATPase in the absence of ATP, with an apparent K_d in the micromolar Ca^{2+} range, was demonstrated by direct equilibrium measurements (Figure 2A).

The sequence of partial reactions making up the catalytic cycle was unveiled by transient-state experiments showing that addition of ATP to SR vesicles preincubated with micromolar Ca^{2+} is followed by the rapid formation of phosphorylated intermediate and vectorial displacement of two bound Ca^{2+} per ATPase. These initial events are then followed by hydrolytic cleavage of inorganic phosphate (Pi) after a time lag (Figure 2B). On the other hand, the ATPase cycle is highly reversible, as demonstrated by ATP synthesis coupled to the Ca^{2+} efflux from loaded vesicles. The partial reactions of the reverse cycle were further clarified by the finding that, in the absence of bound Ca^{2+}, the enzyme can be phosphorylated with Pi to yield ADP-insensitive phosphoenzyme (E-P). This phosphoenzyme can then be made ADP-sensitive by the addition of millimolar Ca^{2+}, whereupon it reacts with ADP to form ATP.

These functional findings have been attributed to a mechanism based on the interconversion of two enzyme states. One state (E_1), stabilized by Ca^{2+} binding, has the Ca^{2+} sites in high affinity and cytosolic orientation.

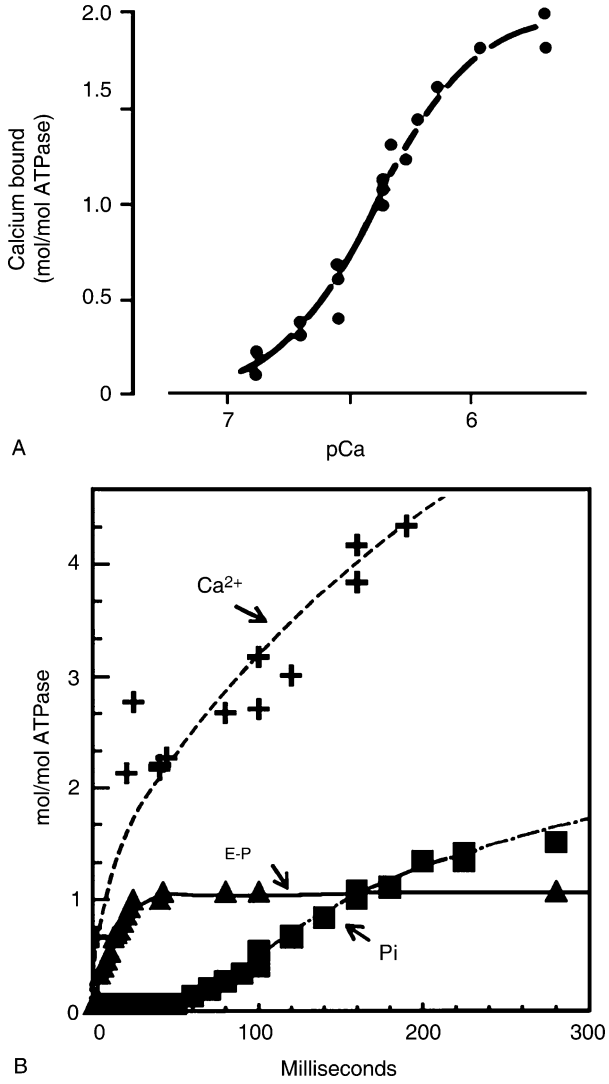

FIGURE 2 Functional characterization of SR vesicles. (A) Calcium binding at equilibrium in the absence of ATP, demonstrating cooperative binding of two Ca^{2+} per ATPase. Chem.* 255, 3025–3031 with permission from The American Society for Biochemistry & Molecular Biology. (B) Rapid enzyme phosphorylation and inward displacement of the two bound Ca^{2+} upon addition of ATP. Hydrolytic cleavage of inorganic phosphate (Pi) occurs after a lag period. E-P, phosphoenzyme. From Inesi, G., Watanabe, T., Coan, C., and Murphy, A. (1978). The mechanism of sarcoplasmic reticulum ATPase. *Ann. N.Y. Acad. Sci.* **402**, 515–534 with permission.

The alternate state (E_2), stabilized by enzyme phosphorylation, has the Ca^{2+} sites in low affinity and lumenal orientation. A more explicit view of the coupling mechanistic can be obtained by considering a minimal number of partial reactions and their equilibrium constants, as follows:

$$H_2E + 2Ca^{2+}_{out} \equiv E{\cdot}Ca_2 + 2H^+_{out} \qquad (10^{12}\ M^{-2}) \quad (1)$$

$$E{\cdot}Ca^{2+} + ATP \equiv ATP{\cdot}E{\cdot}Ca_2 \qquad (10^{5}\ M^{-1}) \quad (2)$$

$$ATP{\cdot}E{\cdot}Ca_2 \equiv ADP{\cdot}E{\cdot}P{\cdot}Ca_2 \quad (1.0) \qquad (3)$$

$$ADP{\cdot}E{\cdot}P{\cdot}Ca_2 \equiv E - P{\cdot}Ca_2 + ADP \quad (10^{-4}\,M) \qquad (4)$$

$$E - P{\cdot}Ca_2 + 2H^+_{in} \equiv H_2E{-}P + 2Ca^{2+}_{in} \quad (10^{-6}\,M^2) \qquad (5)$$

$$H_2E{-}P \equiv H_2E{\cdot}Pi \quad (1) \qquad (6)$$

$$H_2E{\cdot}Pi \equiv H_2E + Pi \quad (10^{-2}\,M) \qquad (7)$$

where the equilibrium constants (listed after each reaction) relate to conditions allowing constant temperature (25 °C) and pH (7.0).

In the reaction sequence given, the initial high-affinity binding (reaction 1) of two Ca^{2+} activates the enzyme, permitting the use of ATP and the formation of a phosphorylated intermediate (reactions 2–4). In turn, enzyme phosphorylation destabilizes and changes the vectorial orientation of the bound Ca^{2+}, thereby increasing the probability of its dissociation into the lumen of the vesicles (reaction 5). Note that the equilibrium constant for the enzyme phosphorylation by ATP is nearly 1, indicating that the free energy of ATP is conserved by the enzyme and used to change the Ca^{2+}-binding characteristics. Finally, the phosphoenzyme undergoes hydrolytic cleavage and releases Pi (reactions 6 and 7) before entering another cycle. The reaction sequence shows clearly that the direct mechanistic device for translocation of bound Ca^{2+} is enzyme phosphorylation rather than hydrolytic cleavage of Pi.

The Coupling Mechanism

Free-Energy Use

Because the catalytic and transport cycles are likely to include conformational transitions, it should be noted that such transitions are coupled intrinsically with the chemical reactions subjected to experimental measurement and that their influence is reflected by the equilibrium constants just listed. In fact, the standard free energies ($-RT \ln K$) of the partial reactions add up to the standard free energy of ATP hydrolysis (γ-phosphate), as expected. Most interestingly, the standard free-energy diagram for the partial reactions reveals that the chemical potential of ATP does not manifest itself in the phosphoryl transfer or hydrolytic cleavage reactions (K_4 and K_6 near 1) but rather in the drastic reduction of the enzyme affinity for Ca^{2+} (compare K_1 to $1/K_5$). We can, then, write that, under standard conditions:

$$\Delta G = nRT \ln\left(K_a^{\text{CaE-P}}/K_a^{\text{CaE}}\right) \qquad (8)$$

per n calcium ions (2 in our case) transported per cycle, and where the equilibrium constant (listed after the reaction) relates to conditions allowing constant temperature (25 °C and pH 7.0). $K_a^{\text{CaE-P}}/K_a^{\text{CaE}}$ are the association constants of the enzyme for Ca^{2+} in the ground state and following activation by ATP. With reference to the reaction scheme given previously, the two relevant constants are K_1 and $1/K_5$. Note that, as written in the scheme and in the forward direction of the cycle, the equilibrium constant for reaction 1 is Ka, while it is Kd for reaction S.

It is then apparent that the basic coupling mechanism of catalysis and transport consists of the mutual destabilization of Ca^{2+} and phosphorylation sites. Analysis of the amino acid sequence, electron microscopy of ordered ATPase arrays, and diffraction patterns obtained from three-dimensional crystals have shown that the SERCA enzyme is a 100-kDa protein, folded into a membrane-bound region, an extramembranous (cytosolic) region, and a short stalk between them. The membrane-bound region includes 10 helical segments (M1, …, M10) and the calcium-binding domain. On the other hand, the extramembranous region, or headpiece, comprises the nucleotide-binding (N) domain and a phosphorylation (P) domain, in addition to a smaller actuator (A) domain. It is clear that the Ca^{2+}-binding domain and the catalytic domain are separated by a large distance (~ 50Å). Therefore, the interconversion of cation-binding and phosphorylation potentials requires a long-range intramolecular linkage, rendered possible by protein conformational changes. It is, then, useful to relate the binding and covalent reactions to conformational changes that may occur through the catalytic and transport cycles.

Ca^{2+} Binding and Catalytic Activation

Binding of two calcium ions per ATPase molecule is an absolute requirement for enzyme activation. The cooperative character of binding is consistent with a sequential binding mechanism to two interdependent sites (I and II). Spectroscopic studies provided early suggestions of Ca^{2+}-induced conformational effects, accounting for binding cooperativity and enzyme activation. A detailed characterization of the large conformational changes produced by Ca^{2+} binding was recently obtained by high-resolution diffraction studies.

The functional role of the Ca^{2+}-induced conformation change lies in its absolute requirement for enzyme activation, rendered possible by the long-range intramolecular linkage. The requirement for Ca^{2+} involves both ATP use for phosphoenzyme formation in the forward direction of the cycle and the formation of ATP upon addition of ADP to

phosphoenzyme formed with Pi in the reverse direction of the cycle. Activation is not obtained by Ca^{2+} occupancy of the first binding site only but requires the occupancy of the second site, which may then be considered a Ca^{2+} trigger point for enzyme activation. Ca^{2+}-binding affects directly the M4, M5, and M6 transmembrane helices and is then transmitted to the extramembranous region, resulting in the large displacement of the headpiece domains and catalytic activation. Single mutations of several residues in the segments connecting the Ca^{2+}-binding region with the phosphorylation domain, such as M4, M5, and the M6–M7 loop, interfere with the phosphorylation reactions.

Nucleotide Binding and Substrate-Induced Conformational Fit

Nucleotide protection of the ATPase from digestion with proteinase and the mutational analysis of this phenomenon suggest that ATP binding produces a conformational change that includes repositioning of the A domain, concomitant with approximation of the N and P domains to match the molecular geometry of ATP. This substrate effect appears similar to the approximation of nucleotide binding (fingers) and catalytic (palm) domains that occurs in DNA polymerases. Although ATP is likely to form an initial complex with Mg^{2+} due to the cation-binding property of the nucleotide, ATP and Mg^{2+} reach the catalytic site through a random mechanism. Accordingly, the initial nucleotide binding at the substrate site does not include Mg^{2+}, even though the subsequent phosphoryl transfer and hydrolytic reactions require Mg^{2+}. The stabilization provided by Mg^{2+} to the transition state, relative to that of the enzyme–substrate complex, is of definite kinetic advantage.

Phosphoryl Transfer and Hydrolytic Cleavage

The Ca^{2+} ATPase mechanism includes a covalent intermediate, general acid–base catalysis and metal ion assistance. The covalent intermediate is formed through an attack on the electrophilic ATP terminal phosphate by a nucleophilic carboxylate group (D531) within the catalytic site. The phosphoenzyme intermediate reacts, then, with water to yield Pi.

It is useful to consider the Ca^{2+} ATPase catalytic mechanism in the light of the phosphorylserine phosphatase (PSPase), due to a remarkable structural and functional analogy and the high definition available for the PSPase catalytic intermediates. Based on this analogy, and on ATPase mutational analysis, it appears that the terminal phosphate of ATP comes in close proximity to Asp351, stabilized by neighboring residues such as K352, T353, G626, K684, and N706. Mg^{2+} is then coordinated by D703, T353, D351, and phosphate oxygen, participating in the transition state and in all subsequent steps. Furthermore, T353 is likely to serve as a general acid for proton donation to the leaving ADP. The same residue then acts as a general base, extracting a proton from nucleophilic water for hydrolytic cleavage of the phosphoenzyme.

Interconversion of Phosphorylation and Ca^{2+}-Binding Potentials

The specific step related to interconversion of phosphorylation and Ca^{2+}- binding potentials is often referred to as the $E_1P{\cdot}Ca_2 \rightleftharpoons E_2P{\cdot}Ca_2$, to indicate the transition of an intermediate of high phosphorylation potential and high Ca^{2+} affinity to an intermediate of low phosphorylation potential and low Ca^{2+} affinity. The functional and structural information described so far indicates that small conformational changes occurring in concomitance with ATP use at the catalytic site (phosphorylation trigger point) are amplified and transmitted to the Ca^{2+}-binding domain through a long-range relay mechanism. The inversion of phosphoryl oxygen atoms during the transition state of the phosphorylation reaction and the displacement of residues interacting with these oxygen atoms may be the triggering perturbation. This is then followed by large motions of the headpiece domains, which are transmitted to the Ca^{2+}-binding domain in the membrane-bound region. Accordingly, the ability of headpiece domains to chemically cross-link changes drastically as they are displaced by intermediate reactions of the catalytic cycle.

In conclusion, the transduction mechanism relies on a long-range linkage of transmembrane helices and cytosolic domains, whereby large-scale and mutually exclusive motions are triggered by Ca^{2+} binding at one end and ATP use at the other. This is rendered possible by the ability of the protein to use free energy derived from binding and phosphorylation reactions. The cycle proceeds forward to Ca^{2+} release or in reverse to ATP synthesis, depending on the concentrations of ligands, substrate, and products.

Physiological Regulation and Experimental Inhibitors

The SERCA2 isoform of cardiac muscle is subject to physiological regulation by phospholamban (PLB), a 22-kDa pentameric protein undergoing reversible association and dissociation. The PLB monomer

interacts with the ATPase at the level of both the membrane-bound and extramembranous regions of the enzyme. In the presence of PLB, the ATPase activation curve is displaced to a higher Ca^{2+} concentration range. The velocity at nonsaturating Ca^{2+} concentrations is thereby reduced, although the maximal velocity at saturating Ca^{2+} concentrations remains unchanged. This inhibition is reversed when PLB undergoes phosphorylation catalyzed by cAMP and calmodulin-dependent kinases. The phosphorylation-dependent relief of inhibition by PLB is related to the physiological mechanism whereby adrenergic stimuli increase Ca^{2+} storing by SR and improve the contractile performance of the heart muscle *in vivo*. Another small protein, sarcolipin, appears to regulate the Ca^{2+} ATPase in skeletal muscle.

Thapsigargin (TG), a plant-derived sesquiterpene lactone, is a very potent and specific SERCA inhibitor. Although TG is not likely to be a physiologic inhibitor, it is nevertheless an extremely useful experimental tool. TG interferes with all partial reactions of the catalytic cycle and induces stabilization of ordered ATPase arrays, suggesting a general effect on the enzyme. Mutational and structural studies indicate that the TG-binding site resides in a cavity delimited by the M3, M5, and M7 helices near the cytosolic surface of the membrane. It is likely that the presence of TG in this cavity confers structural stabilization to the enzyme, thereby preventing conformational responses to Ca^{2+} binding and phosphorylation reaction, as required for the progression of the catalytic cycle.

Biography

Giuseppe Inesi is a Professor in and Chair of the Department of Biochemistry at the University of Maryland, School of Medicine, Baltimore. His research interest is the mechanism of Ca^{2+} transport by Ca^{2+} ATPase, including kinetic and equilibrium characterizations, protein biochemistry, and mutational analysis. He received an M.D. at the University of Modena, and a Ph.D. at the University of Bologra (Italy). He participated in the initial recognition of Ca^{2+} ATPase and has made major contributions to its characterization.

ER/SR Calcium Pump: Structure

Chikashi Toyoshima and Yuji Sugita
University of Tokyo, Tokyo, Japan

The structures of the Ca^{2+}-ATPase of skeletal muscle sarcoplasmic reticulum (Sarco(Endo)plasmic Reticulum Calcium ATPase 1, SERCA 1) have been determined to 2.4Å resolution for the Ca^{2+}-bound form ($E1Ca^{2+}$, PDB entry code: 1SU4) and to 3.1Å for the unbound (but thapsigargin(TG) bound) form (E2(TG), PDB entry code: 1IWO). Detailed comparison of these two structures reveals that very large rearrangements of the transmembrane helices take place accompanying Ca^{2+} dissociation and binding and that they are mechanically linked with equally large movements of the cytoplasmic domains. Such domain movements are thermal in nature and used efficiently for rearranging various domains to alter the functional properties (e.g., affinity for Ca^{2+}) of the ion pump.

Overall Description of the Structure

Ca^{2+}-ATPase is a tall molecule, ~150Å high and 80Å thick, and comprises a large cytoplasmic headpiece, transmembrane domain made of ten (M1–M10) α-helices, and small lumenal domain (Figure 1). The cytoplasmic headpiece consists of three domains, designated as A (actuator), N (nucleotide binding), and P (phosphorylation) domains. They are widely split in the presence of Ca^{2+} but gather to form a compact headpiece in the absence of Ca^{2+}. The A-domain is connected to M1–M3 helices, and the P-domain to M4 and M5 helices. The N-domain is a long insertion between two parts of the P-domain. The M5 helix runs from the lumenal surface to an end of the P-domain and works as the "spine" of the molecule. On the lumenal side, there are only short loops connecting transmembrane helices, except for the loop of ~40 residues connecting the M7 and M8 helices. The distance between the Ca^{2+}-binding sites and the phosphorylation site is larger than 50Å. For the phosphoryl transfer from ATP to Asp351 to take place, the N-domain has to approach the P-domain even closer than that observed in the E2(TG) form.

The orientations and positions of atomic models with respect to the lipid bilayer are determined from crystallographic constraints and illustrated in Figure 1, in which the models are positioned in the bilayer of dioleoylphosphatidylcholine generated by molecular dynamics calculation. The orientations were found to be the same as in the original crystals. The coordinates of the aligned models can be downloaded from the author's web site (http://www.iam.u-tokyo.ac.jp/StrBiol/models).

Organization of the Transmembrane Domain

Transmembrane Helices

As expected from the amino acid sequence, SERCA1 has ten (M1–M10) transmembrane α-helices, two of which (M4 and M6) are partly unwound for efficient coordination of Ca^{2+}. M6 and M7 are far apart and are connected by a long cytosolic loop that runs along the bottom of the P-domain. The amino acid sequence is well conserved for M4–M6 but not for M8 even within the members of closely related P-type ATPases, such as Na^+K^+- and H^+K^+-ATPases. M7–M10 helices are in fact lacking in bacterial-type I P-type ATPases, and are apparently specialized for each subfamily. Nevertheless, M5 and M7 are packed very tightly at Gly770 (M5) and Gly841 (M7) and Gly845 (M7), forming a pivot for the bending of M5. The M7–M10 helices appear to work as a membrane anchor.

Details of the Ca^{2+}-Binding Sites

It is well established that SR Ca^{2+}-ATPase has two high-affinity transmembrane Ca^{2+}-binding sites and the binding is cooperative. X-ray crystallography of the rabbit SERCA1a in 10 mM Ca^{2+} identified two binding sites in the transmembrane but none outside the membrane.

Figure 2 illustrates the structure of the Ca^{2+}-binding sites. The two Ca^{2+}-binding sites (I and II) are located side by side near the cytoplasmic surface of the lipid bilayer, with the site II ~3Å closer to the surface (Figure 1). Site I, the binding site for the first Ca^{2+},

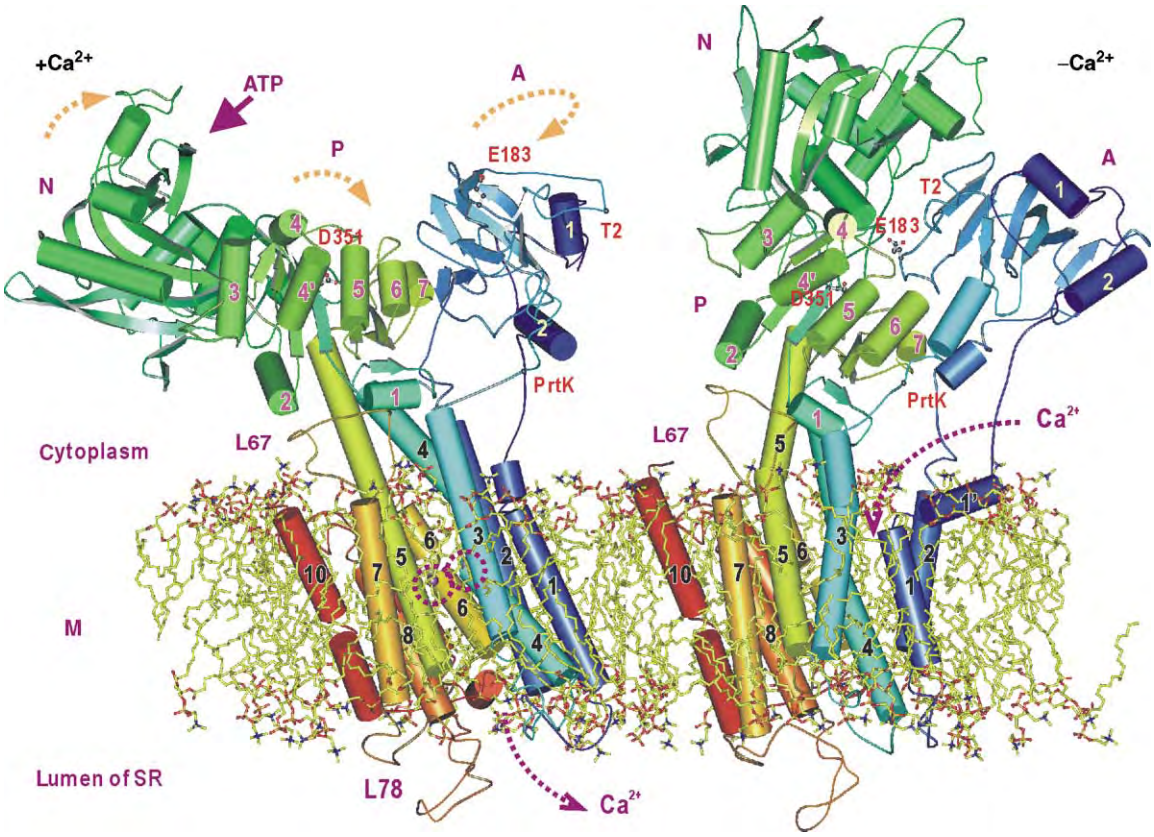

FIGURE 1 Ca^{2+}-bound and unbound forms of Ca^{2+}-ATPase in the lipid bilayer. The bilayer is generated by molecular dynamics simulation of dioleoylphosphatidylcholine. M3 and M5 helices in the unbound form are approximated with two and three cylinders, respectively. The color changes gradually from the N-terminus (blue) to the C-terminus (red). The arrows indicate the directions of movements accompanying the dissociation of Ca^{2+}. Two bound $Ca^{2+}$are shown as purple spheres (circled). T2 trypsin digestion site and a proteinase K digestion site (PrtK) are also marked.

is located at the center of the transmembrane domain in a space surrounded by M5, M6, and M8 helices. Ca^{2+} is coordinated by side chain oxygen of Glu771 (M5), Thr799, Asp 800 (M6), and Glu908 (M8) and two water molecules. M8 is located rather distally and the contribution of Glu908 is not essential in that Gln can substitute Glu908 to a large extent. Any substitutions to other residues totally abolish the binding of Ca^{2+}.

Site II is nearly "on" the M4 helix with the contribution of Asp800 (M6) and Asn768 (M5). The M4 helix is partly unwound (between Ile307 and Gly310). This part provides three main chain oxygen atoms to the coordination of Ca^{2+}. Glu309 provides two oxygen atoms and caps the bound Ca^{2+}. This arrangement of oxygen atoms is reminiscent of the EF-hand motif.

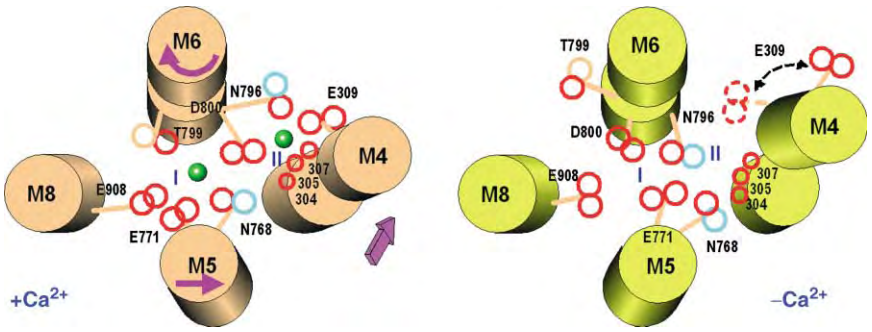

FIGURE 2 Schematic diagram of the Ca^{2+}-binding sites and the movements accompanying the dissociation of Ca^{2+}. The arrows indicate the movements of the helices in the transition from $E1Ca^{2+} \rightarrow E2(TG)$. Red circles, oxygen atoms (carbonyl oxygen atoms appear smaller); cyan circles, nitrogen; orange circles, carbon.

Thus, both site I and site II have seven coordination but have different characteristics. Asp800, on the unwound part of M6, is the only residue that contributes to both sites. Even double mutations of Glu309 and Asn768 leave 50% Ca^{2+} binding, indicating that site II is the binding site for the second Ca^{2+}.

Organization of the Cytoplasmic Domain

Structure of the P-Domain

The P-domain contains the residue of phosphorylation, Asp351. There are three critical aspartate (627, 703, 707) residues clustered around the phosphorylation site, in addition to an absolutely conserved Lys residue (Lys684). These key residues are very well conserved throughout the haloacid dehalogenase (HAD) superfamily, but also shared by bacterial two-component response regulator proteins, such as CheY and Fix J, which have folding patterns different from that of HAD. The P-domain has a Rossmann fold, commonly found in nucleotide-binding proteins, consisting of a parallel β-sheet (seven strands in Ca^{2+}-ATPase) and associated short α-helices. The catalytic residue (i.e., Asp351 in Ca^{2+}-ATPase) is always at the C-terminal end of the first β-strand, which is connected to a long insertion, the N-domain. Thus, the P-domain is formed by two regions far apart in the amino-acid sequence. This is why the P-type ATPase was thought to be an orphan in evolution for a long time. This system requires Mg^{2+} for phosphorylation. Mg^{2+} is coordinated by carboxyls of Asp351, Asp703, carbonyl of Thr353 and two water molecules. It is not known whether this Mg^{2+} is the same as that bound to ATP. Lys684 is particularly important for the binding of γ-phosphate of ATP.

Structure of the N-Domain

N-domain is the largest of the three cytoplasmic domains, containing residues Asn359–Asp601 (Figure 1), and connected to the P-domain with two strands. These strands bear a β-sheet like hydrogen-bonding pattern, presumably to allow large domain movements with a precise orientation. In particular, consecutive prolines (Pro602–603) appear to serve as a guide that determines the orientation of the movement. The N-domain contains the binding site for the adenosine moiety of ATP. Phe487 makes an aromatic–adenine ring interaction, which is a common feature in many ATP binding sites. Lys515, a critical residue, is located at one end of the binding cavity. This residue can be labeled specifically with FITC at alkaline pH and has been used for many spectroscopic studies. The binding of the adenine ring appears predominantly hydrophobic.

Structure of the A-Domain

A-domain is the smallest of the three cytoplasmic domains and consists of the N-terminal ~50 residues that form two short α-helices and ~110 residues between the M2 and M3 helices (Figure 1), which form a deformed jelly role structure. The A-domain contains a sequence motif ^{183}TGE, one of the signature sequences of the P-type ATPase. This sequence represents a loop that comes very close to the phosphorylation site Asp351, in the E2 and E2P states. Because this domain is directly connected to the M1–M3 helices and more indirectly to the M4–M6 helices, this domain is thought to act as the "actuator" of the gates that regulate the binding and release of Ca^{2+} ions.

Structural Changes Accompanying the Dissociation of Ca^{2+}

Rearrangement of the Transmembrane Helices

As illustrated in Figure 2, Ca^{2+}-ATPase undergoes large structural changes upon the dissociation of Ca^{2+}. Three cytoplasmic domains change their orientations and gather to form a compact headpiece. The P-domain inclines 30° with respect to the membrane and N-domain inclines 60° relative to the P-domain, whereas the A-domain rotates ~110° horizontally. The structure of each domain, however, is hardly altered. In contrast, some of the transmembrane helices are bent or curved (M1, M3, and M5) or partially unwound (M2); M1–M6 helices undergo drastic rearrangements that involve shifts normal to the membrane (M1–M4). Thus, the structural changes are very large and global; they are mechanically linked and coordinated by the P-domain.

M3–M5 helices are directly linked to the P-domain by hydrogen bonds (Figure 3). M3 is connected to the P1 helix at the bottom of the P-domain through a critical hydrogen bond involving Glu340. The top part of M5 is integrated as a part of the Rossmann fold (Figure 3) and moves together with the P-domain as a single entity. M4 and M5 are "clamped" by forming a short antiparallel β-sheet. M6 is also connected, though less directly, to the P-domain through L67 (Figure 1), which is, in turn, linked to M5 through a critical hydrogen bond. If the P-domain inclines, for instance, due to the bending of M5, all these helices (M3–M6) will incline and generate movements that have components normal

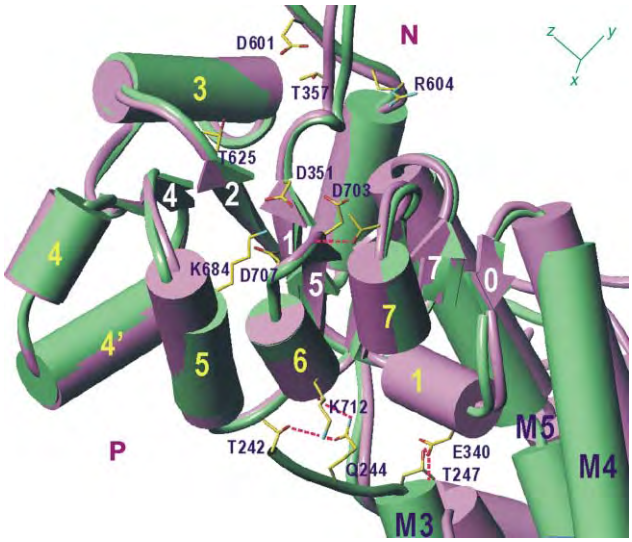

FIGURE 3 Organization of the P-domain and the linkage with the transmembrane helices. Superimposition of the E1Ca^{2+}(violet) and E2(TG) (light green) forms fitted with the P domain. The residues (in atom color) represent those in E2(TG).

to the membrane (Figure 4). Their amounts depend on the distances from the pivoting point, located around Gly770 at the middle of the membrane (double circle in Figure 4). The lower part below Gly770 hardly moves.

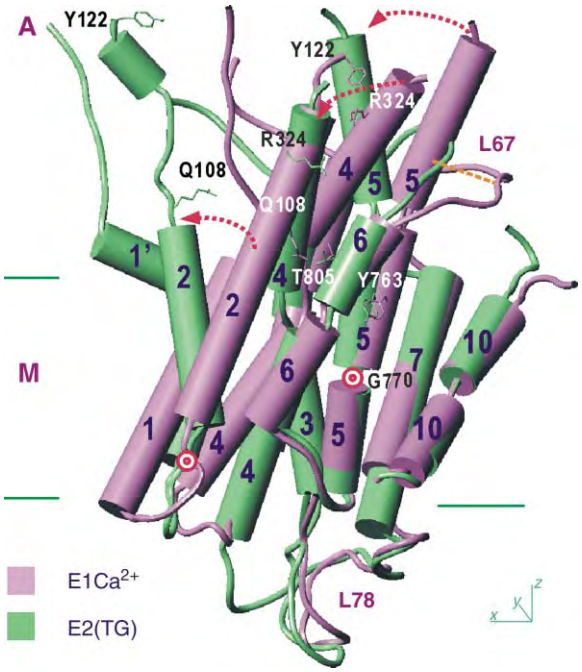

FIGURE 4 Rearrangement of transmembrane helices on the dissociation of Ca^{2+}. The models for E1Ca^{2+}(violet) and E2(TG) (light green) are superimposed. The M5 helix lies along the plane of the paper. M8 and M9 are removed. Double circles show pivot positions for M2 and M5. Arrows indicate the directions of movements during the change from E1Ca^{2+}to E2(TG). Orange broken line shows a critical hydrogen bond between the L67 loop and M5 helix.

The shift is therefore small for M6 and large for M3 and M4; whole M3 and M4 helices move downwards upon dissociation of Ca^{2+}, whereas M6 undergoes rather local changes around Asn796–Asp800.

Ca^{2+}-Binding Sites in the E2(TG) State

The most important movements of the transmembrane helices directly relevant to the dissociation of Ca^{2+} are: (1) a shift of M4 towards the lumenal (extracellular) side by one turn of an α-helix (5.5Å), (2) bending of the upper part of M5 (above Gly770) towards M4, and (3) nearly 90° rotation of the unwound part of M6. As a result, profound reorganization of the binding residues takes place and the number of coordinating oxygen atoms decreases (Figure 2). For site I, this is due to the movement of Asn768 toward M4 caused by the bending of M5; for site II, replacement of Asp800 by Asn796 (i.e., rotation of M6) is critical.

Role of the Large Conformational Movements

Homology modeling of the cation binding sites of Na$^+$K$^+$-ATPase suggests that a large downward movement of M4 (and M3) is needed for counter-transport. With the arrangements of residues observed with E2(TG) structure, it is straightforward to make two high-affinity K$^+$-binding sites, provided that Asn796 is replaced by Asp following Na$^+$K$^+$-ATPase sequence: the other coordinating residues are common to both ATPases. The key feature in the model is that the Asp (Asn796) is coordinated to both K$^+$, similar to Asp800 in coordination of 2Ca^{2+}. Because Asn796 is located one turn below where Asp800 is, M4 must move downwards to provide carbonyl groups for coordination of K$^+$. These rearrangements ensure that release of one type of cation coordinates with the binding of the other and allow the binding of ions of different radii with high affinity.

In summary, ion pumps use thermal movements of various domains very efficiently. Most of the movements described here can be related to the bending of the M5 helix. Because M5 participates in Ca^{2+} coordination and moves together with the P-domain, it is understandable that the phosphorylation (binding of phosphate and Mg^{2+}) at the phosphorylation site and the binding of Ca^{2+} to the transmembrane binding sites will alter the properties of the other. This appears to be the mechanism of long-distance (>50Å) intramolecular communication. Animations showing the conformation changes accompanying Ca^{2+}-dissociation are available (http://www.iam.u-tokyo.ac.jp/StrBiol/animations).

Exonucleases, Bacterial

Susan T. Lovett
Brandeis University, Waltham, Massachusetts, USA

Exonucleases are enzymes that catalyze hydrolysis of DNA or RNA from a free end. Exonucleolytic digestion of nucleic acids may be required for processing and for turnover of these macromolecules. In addition, RNA exonucleases contribute to the maturation of stable RNA molecules. The action of DNA exonucleases permits diverse processes such as mutation avoidance, repair, and genetic recombination.

Introduction

Nucleases are defined as enzymes that hydrolyze the phosphodiester bond of nucleic acids. Borrowing the system developed for proteases, nucleases have been classified whether they cleave internally in the DNA or RNA molecule (endonucleases) or from an end in a stepwise fashion producing mononucleotide products (exonucleases). This distinction is complicated by the fact that several enzymes require entry at a free DNA or RNA end but cleave internally (often referred to as endo/exonucleases). An example is the RecBCD recombination nuclease that unwinds DNA from an end and cleaves it as it travels, producing oligonucleotide products. Some exonuclease activities are found within proteins with other distinct catalytic activities, such as the 3′ DNA exonuclease activities associated with DNA polymerases.

The systematic purification and characterization of more than 20 exonuclease activities from *Escherichia coli* extracts have provided much of our knowledge about this group of enzymes (Tables I and II). Most *E. coli* exonucleases on DNA and RNA were identified and named arbitrarily (DNA exonucleases Exo I–X and RNase II) or by reference to their substrate specificity (RNase H, R, D, T oligoribonuclease, etc.). A few nucleases were identified first and named by their genetic function (such as RecJ exonuclease required for genetic recombination). The biological role of most *E. coli* exonucleases has now been confirmed by genetic experiments, although many exonucleases have redundant genetic function and genetic phenotypes are not manifested until multiple members are inactivated. Such overlapping functions are not surprising, given the great number of these enzymes in *E. coli* (at present count 15 DNA, 9 RNA exonucleases.) Orthologues of many of the *E. coli* exonucleases can be found in diverse bacterial genera and often in archaea and eukaryotes. *E. coli* appears to be especially rich in exonucleases, in contrast to other bacteria that have only a few exonucleases, as predicted by sequence similarity. However, since most exonuclease families were defined first by purification and characterization of representatives from *E. coli*, this may represent an ascertainment bias and there may be additional, presently unknown exonuclease families in other bacterial species but not in *E. coli*.

Biochemical Properties of Exonucleases

Mechanism

All DNA and RNA exonucleases, with the exception of DNase Exo VII, require a divalent-cation cofactor, commonly Mg^{2+} or Mn^{2+}, to accomplish hydrolysis of the phosphodiester bond. The crystal structures of many exonucleases have now been solved and reveal coordination of one or more divalent cations by aspartate, glutamate, or histidine residues. Such residues are found as evolutionarily conserved amino acid motifs within related exonucleases. A role for the metal ions was suggested by the structure published by Beese and Steitz for the 3′–5′ exonuclease of *E. coli* polymerase I, which contains two metal atoms, a single-strand DNA (ss DNA) substrate and deoxynucleoside monophosphate. They proposed that one metal activates a water molecule for the nucleophile in an SN2-type reaction; the other closely positioned metal is poised to stabilize the pentacovalent intermediate in the reaction and the leaving oxyanion. The universality of this two-metal-ion scheme is not clear: some exonuclease structures, such as that of the 5′ nuclease FEN-1, contain two more widely separated metal ions and other structures, such as DNA exonucleases Exo III and RecJ, reveal only one metal cation.

Two RNases, acting from a 3′ end, polynucleotide phosphorylase (PNPase) and RNase PH, are not, strictly

Polynucleotide phosphorylase (PNPase)	*pnp*	Unstructured RNAs	mRNA degradation, stable RNA maturation
RNase PH	*rph*	tRNA precursors	Stable RNA maturation
RNase BN	*rbn*	tRNA with aberrant 3′ ends, tRNA precursors	Stable RNA maturation defective tRNA degradation

[a] Although PNPase and RNase PH are phosphorylases not nucleases, they act to digest RNA in a polar fashion from a 3′ end.
[b] All *E. coli* exoribonucleases act 3′–5′.
[c] RNase T also possesses a potent exonuclease activity on single-strand DNA in a 3′–5′ fashion.
[d] May be identical to DNA exonuclease IV.

speaking, "nucleases," because they are not hydrolases but phosphorylases, using inorganic phosphate to attack the phosphodiester bond and releasing nucleoside diphosphate reaction products. These are, however, of related biological function and are included here and in many reviews of exoribonucleases.

Specificity

Many exonucleases have strict specificity for the sugar moiety in nucleic acids and therefore cleave only RNA or DNA. (RNase H is specific for RNA within a DNA hybrid.) Other nucleases, however, may cleave both RNA and DNA, e.g., RNase T of *E. coli*. It is difficult to tell from amino acid sequence information alone whether any given exonuclease will have a preference for DNA or RNA. Exonuclease superfamilies include both RNase and DNase members. Steric considerations may exclude RNA as a substrate for DNA-specific exonucleases; 2′-OH specific interactions may specify RNA as a preferred substrate.

Almost all exonucleases have a strict polarity of digestion, initiating attack from either the 3′- or 5′-end of a nucleic acid molecule. This polarity reflects the exonuclease's particular architecture of the amino acids and bound metal atoms that interact with the nucleic acid. Exceptions to strict polarity include those "exo/endonucleases" that cleave internally within DNA, producing oligonucleotide products, but require an end for entry, such as Exo VII, SbcCD, and RecBCD. The latter two DNA exonucleases are ATP dependent and may require ATP for associated helicase activity to move the enzyme along its DNA substrate. Some exonucleases are specific for the phosphorylation status of the end, indicating a specific interaction with the nucleic acid terminus. For example, many 3′–5′ exonucleases such as *E. coli* exonuclease I cannot attack a nucleic acid with 3′-phosphate; similarly, lambda bacteriophage exonuclease requires a 5′-phosphate in a double-strand DNA (dsDNA) end and will not initiate cleavage on a 5′-OH-containing DNA molecule. Many DNA exonucleases are specific for double-strand (Exo III, Exo VIII) or single-strand (RecJ, Exo I, Exo VII) DNA. Likewise, certain RNases may prefer unstructured RNA regions. The ssDNA-specific exonucleases accomplish their specificity sterically: they either possess a pore or have a deep cleft in which ssDNA but not dsDNA can reach the catalytic center of the enzyme. Oligoribonuclease has a size specificity and prefers short oligonucletide substrates less than five nucleotides in length but the molecular basis for this specificity is not understood.

Processivity

Exonucleases are classified "processive" if they catalyze multiple cleavage events upon a single binding to their nucleic acid substrates. In contrast, "distributive" must rebind substrate after each cleavage. The biochemical property of processivity has important biological consequence and allows exonucleases to rapidly digest appropriate substrates. Several processive nucleases (bacteriophage lambda exonuclease, *E. coli* Exo I) have toroidal or clamp-like structures that allow the enzyme to encircle its substrate, a simple way of

achieving processivity. Processivity can also be achieved by multiple binding interactions of the exonuclease to its substrate, as has been proposed for RNase II.

Structural Families

Comparison of exonuclease sequences from bacteria shows that the primary amino acid sequence of these proteins has diverged rather quickly. Nevertheless, conserved motifs emerge and several extensive sequence families can be recognized and are briefly discussed below. Members of these exonuclease families can often be found in all three domains of life: archaea, eubacteria and eukaryotes. In exonucleases for which there is structural information, these conserved motif residues coordinate metal cofactor or interact with substrate. These structural families can include members with diverse substrate specificities, including both exonucleases and endonucleases, and even phosphatases, RNases and DNases, processive and distributive enzymes, and a few are discussed briefly.

DEDD/DNAQ

An extensive group of 3′–5′ exonucleases is defined by three motifs carrying conserved aspartate and glutamate residues (Figure 1); hence, the alternate designation "DEDD" for this family of nucleases found in eukaryotes as well as prokaryotes. This family includes exonucleases with specificity for DNA (the proofreading exonucleases of DNA polymerases, *E. coli* exonucleases I and X), RNA (RNase D, oligoribonuclease), and those with dual specificity (RNase T). Both distributive and processive exonucleases are members of this family. *E. coli* possesses eight enzymes in this family (alignment shown in Figure 1). Structural information is available for several members of this superfamily including the proofreading exonuclease domain of DNA polymerases I and III of bacteria, and *E. coli* exonuclease I. The fold of these enzymes resembles RNase H1. Most structures include two metal atoms at the active site.

DHH/RecJ

The founding member of this family, RecJ, is a 5′–3′ ssDNA exonuclease involved in genetic recombination and DNA repair. The RecJ family encompasses a large family of proteins found in archaea and bacteria, very few of which have been characterized at the biochemical level. This family is defined by seven conserved motifs, primarily acidic residues, or histidines; the family is sometimes termed "DHH" after the amino acid sequence within one of these motifs. The RecJ family is particularly expanded in the archaea; for example, *Archaeoglobus fulgidus* possesses seven members of this family. There are eukaryotic members, but the yeast DHH protein is a phosphatase (polyphosphatase PPX1), not a nuclease. Therefore, the RecJ family is, more broadly, a phosphoesterase rather than a nuclease family.

XthA

E. coli exonuclease III is a 3′–5′ DNA exonuclease active on dsDNA; it also possesses 3′ phosphatase activity and endonuclease activity at abasic (apurinic/apyrimidinic) sites. Exo III is an important protein for base excision repair, as is its eukaryotic counterpart Ape1. Structurally, Exo III resembles eukaryotic DNase I, with a single metal at its active site and a large group of phosphatases, primarily involved in eukaryotic cell signaling processes.

FEN-1/5′ Nucleases

The founding member of this group is FEN-1 "flap-endonuclease" from eukaryotes and archaea; the eubacterial counterpart, both structurally and functionally, is the 5′ exonuclease domain of DNA polymerase I. Both proteins possess 5′–3′ exonuclease activity and endonuclease activity on ssDNA "flaps" adjacent to region of duplex DNA. These 5′-nucleases play an important role in processing of Okazaki fragments during lagging strand DNA synthesis. Structural information of archaeal FEN-1, DNA polymerase I, and the related RNase H activity from bacteriophage T4 shows two metals coordinated by glutamate and aspartate

Shown are aligned amino acid sequences of exonuclease I, exonuclease X, oligoribonuclease, RNase D, RNase T, and the 3′-exonucleases of DNA polymerases I, II, and III. Conserved acid residues are shown in bold and comprise metal coordination residues for those proteins with determined three-dimensional structure. Numbers refer to amino acid residues not shown.

residues. This family also includes eukaryotic Exo 1, a 5′-exonuclease implicated in eukaryotic mismatch repair, and *E. coli* exonuclease IX of unknown biological function.

Mre11/SbcD

Eukaryotic and archaeal Mre11 is the catalytic subunit of an ATP-dependent exonuclease with associated endonuclease activity. Mre11 shares sequence homology with bacterial SbcD protein. The nuclease activity specified by these subunits requires assembly of an active complex with one or two other additional proteins. One of these additional subunits possesses a coiled-coil structure: Rad50 in eukaryotes and archaea, SbcC in bacteria. Structural data are available for archaeal Mre11, showing two Mn^{2+} atoms, and Rad50. The Mre11 fold resembles metal-dependent phosphatases with the conserved phosphoesterase motifs (histidines, aspartates, and asparagines) making interactions with substrate or metal cofactors. Mre11 and SbcD exonucleases play a role in DNA repair and genomic surveillance.

Biological Roles of RNA Exonucleases

Turnover

mRNA half-lives in bacteria are short and degradation of mRNA is essential for viability. After initial endonucleolytic cleavage, degradation of mRNA in *E. coli* is accomplished by the combined action of RNase II and PNPase to produce short oligomers that are then digested by oligoribonuclease. These bacterial enzymes attack RNA in a 3′–5′ direction. Loss of either RNase II (a true exoribonuclease) or PNPase (a phosphorylase) can be tolerated by *E. coli*; however, inactivation of both enzymes or of oligoribonuclease is lethal to the cell. Aberrant or misfolded stable RNAs may also be subject to turnover by exoribonuclease action.

Processing

Proper maturation of stable RNAs requires the action of exoribonucleases. In *E. coli* several exoribonucleases act redundantly in processing of tRNA or rRNA. Maturation of stable RNAs seems to be most dependent on RNase T and RNase PH; the double mutant accumulates tRNA precursors and although viable, grows more slowly. Upon loss of five activities, RNase II, D, BN, T, and PH, *E. coli* becomes inviable; any single one of these enzymes can suffice to support viability, indicating significant functional overlap.

Biological Roles of DNA Exonucleases

Replication Fidelity

Exonucleases are integral to two major mechanisms that insure the fidelity of DNA replication: polymerase proofreading and mismatch repair. 3′–5′ exonuclease activity is a component of many bacterial DNA polymerases at a site or within a subunit distinct from the polymerase activity. Unpaired 3′-residues are more likely to be degraded by the exonuclease than to support polymer extension; this proofreading reaction contributes substantially to the accuracy of replication. Complete absence of 3′–5′ exonuclease activity of *E. coli* replicative polymerase, the DnaQ or ε-subunit of DNA polymerase III, causes cellular inviability due to the catastrophic accumulation of replication errors.

Misincorporations that escape polymerase proofreading can be recognized and excised by the mismatch repair pathway, which is initiated by the MutHLS proteins of *E. coli*. The excision tract, up to thousands of bases in length, can be directed either 3′ or 5′ to the mismatch and is catalyzed by the redundant action of four exonucleases, RecJ, Exo I, Exo VII, or Exo X, aided by the UvrD helicase of *E. coli*. Loss of mismatch repair elevates the frequency of spontaneous mutational events several orders of magnitude.

Scavenging of ssDNA by the 3′–5′ DNA exonucleases (*E. coli* Exo I, Exo VII, and Exo X) aborts a wide range of mutational events believed to be caused by nascent strand displacement and mispairing, including frameshifts, deletions, and quasipalindrome-associated mutational hotspots. These enzymes act redundantly in this process, which can be considered a type of "proofreading in trans."

Maturation of Okazaki fragments during DNA replication in *E. coli* is catalyzed by the 5′-exonuclease domain of polymerase I, functionally and structurally homologous to the FEN-1/Rad27 nuclease of eukaryotes and archaea. In addition to a nonspecific 5′-exonuclease activity, these enzymes specifically cleave the junction between ss and dsDNA, an activity often termed "flap" endonuclease activity. In some bacteria such as *Streptococcus pneumoniae*, loss of the 5′ nuclease domain of DNA polymerase I is lethal. *E. coli* mutants are viable and may, therefore, use a backup mechanism of Okazaki fragment maturation. The absence of the 5′-nuclease domain of polymerase I in *E. coli* elevates spontaneous mutation rates, as was first described for the related Rad27 of yeast; this elevated class of mutations consists largely of short sequence duplications. In a similar fashion, these 5′-nucleases also suppress expansion of tandem repeat arrays.

The SbcCD nuclease appears to play a role in genome surveillance and repair. Through its endonuclease activity, SbcCD breaks the chromosome at large inverted DNA repeats that form secondary structures, which can impede DNA replication. Such breakage and subsequent exonucleolytic processing may selectively remove such structures from the genome. The SbcCD nuclease may also mediate certain modes of double-strand break repair, independent of DNA secondary structures.

Recombination and DNA Repair

Exonucleases play an essential role in homologous recombination. Strand exchange is initiated by ssDNA, which binds the strand transfer protein RecA and initiates the homology-search process. Nicks or double-strand breaks in DNA are converted by exonucleases to recombinogenic ssDNA gaps or tails, respectively, by the degradation of one strand of the DNA duplex. During recombinational double-strand break repair in *E. coli*, the RecBCD nuclease provides this function by its combined ATP-dependent helicase and nuclease activities. RecBCD's nuclease activity is modulated by octameric "Chi" DNA sequences that act *in vivo* as hot spots of recombination by a molecular mechanism yet to be deciphered. In pathways of recombination independent of RecBCD, exonuclease function for recombination can be provided by the RecJ $5'-3'$ ssDNA exonuclease, acting in conjunction with a DNA helicase, such as RecQ. After recombinational joint molecules are formed by synapsis, degradation of one strand ("post-synaptic" DNA degradation) can extend and stabilize the heteroduplex intermediate by removing a competitor strand for pairing. It may be for this reason that in *E. coli* either RecJ ($5'-3'$) and Exo I ($3'-5'$) are required for efficient recombination, even when the presynaptic degradation is presumably occurring via the RecBCD nuclease. After exchange is complete, exonucleases may also participate in the trimming of unpaired ends to form mature recombinant molecules.

Conclusions

Exonucleases comprise a large set of structurally and biochemically characterized enzymes with diverse properties. Systematic characterization of exonucleases from the bacterium *E. coli* has provided much of our knowledge of this class of enzymes. Certain families of related exonucleases are found widely throughout bacteria, archaea, and eukaryotes, indicating the early evolution of nucleases and their important role in all cells. However, primary amino acid sequence cannot predict many elements of substrate specificity (such as DNase or RNase), other enzymatic properties such as processivity or biological function. A single *E. coli* cell contains more than 20 different exonuclease activities. Exonucleases often act redundantly in biological functions of RNA processing and degradation, mutation avoidance, and in DNA repair and recombination. Therefore, several biological functions of exonucleases probably remain unknown and are the focus of current work in the field.

Glossary

base excision repair A repair mechanism that removes damaged nucleotide bases from duplex DNA. The resulting abasic site is then incised by abasic endonucleases and repaired by exonucleases, polymerase and ligase.

genetic recombination A process by which homologous segments of DNA molecules are exchanged. Recombination serves as a relatively error-free mechanism for repair of chromosomal single-strand gaps or double-strand breaks.

heteroduplex A DNA duplex region formed by the pairing of two strands from different DNA molecules. Heteroduplex joint formation is the first step of homologous genetic recombination.

mismatch repair A conserved repair mechanism by which many replication errors ("mismatches") are detected and excised from duplex DNA.

okazaki fragments Short, discontinuous pieces of DNA, primed by RNA and synthesized during lagging strand DNA replication.

proofreading The $3'-5'$ exonucleolytic removal of polymerase incorporation errors in newly synthesized DNA.

Biography

Susan T. Lovett is a Professor in the Department of Biology and Rosenstiel Basic Medical Sciences Research Center at Brandeis University in Waltham, Massachusetts. Among her research interests are the DNA exonucleases that mediate genetic recombination, repair, and mutation avoidance. She and her colleagues discovered and characterized the RecJ exonuclease and Exonuclease X from *E. coli*. She received her Ph.D. in Molecular Biology from the University of California at Berkeley and trained as a postdoctoral fellow at Lawrence Berkeley Laboratory in Berkeley, California and the Harvard Medical School in Boston, Massachusetts.

F1–F0 ATP Synthase

Donata Branca
University of Padova, Padova, Italy

F1–F0 ATP synthases (also called F1–F0 or F-ATPases) are large protein complexes, weighing 550–650 kDa, located in the inner mitochondrial membrane, in the chloroplast thylakoid membrane and in the bacterial plasma membrane. They are the major ATP suppliers of most cells, synthesizing ATP in the terminal phase of oxidative phosphorylation or photophosphorylation. The synthesis of ATP from ADP and inorganic phosphate (Pi) is driven by protons (H^+) moving through the complex down the transmembrane H^+ gradient built by the respiratory or photosynthetic electron-transfer chains (or by light-driven H^+ pumps in some bacteria). The ATP synthases may also operate in the opposite direction, as H^+-pumping ATPases; this reversal, which may be accomplished by any ATP synthase *in vitro*, is physiologic in anaerobic bacteria, allowing them to build a transmembrane H^+ gradient (e.g., as required for the movement of flagella or for the uptake of nutrients). Thus, the ATP synthases reversibly convert the energy stored in the proton gradient into the chemical energy of ATP. The ATP synthases of all organisms are believed to have evolved from a common protobacterial ancestor. In fact they have a high degree of sequence homology within structurally and functionally important regions, display similar architectures, and operate with the same basic mechanism. Moreover, in eukaryotes, they are partially encoded by mitochondrial or chloroplast DNA.

Structure of the ATP Synthase Complex

ATP synthases are traditionally described as bipartite complexes, composed of two structurally and functionally distinct multisubunit portions (Figure 1A): a membrane-embedded F0, which translocates protons, and a membrane-peripheral F1 comprising a globular head, which synthesizes ATP, and a central stalk, which interacts with F0. A second, peripheral stalk, contributed by F1 and F0 subunits, also connects the outer regions of F1 and F0. F1 may be reversibly dissociated from F0 *in vitro*, with the isolated F1 still active, but only capable of hydrolyzing ATP (hence the ATPase designation), and the membrane-associated F0 retaining the ability to translocate protons down a concentration gradient. The isolated F1, and the F1-depleted membranes containing F0 are invaluable tools to investigate the structure and the enzymology of the synthases, even if lacking the coupling mechanism which allows the H^+-driven ATP synthesis by the intact complex. As to the operation of the complex, there is wide agreement that H^+ translocation through F0 triggers the rotation of the central stalk, which in turn promotes the synthesis of ATP by F1.

Structural, biochemical, and molecular biological studies have contributed to the knowledge of the architecture of the ATP synthases. The landmark achievement has been the high-resolution structure of the mitochondrial F1: the X-ray crystallographic studies on bovine heart F1 by Walker and co-workers (Figure 2A) have established the essential features of the mammalian complex. X-ray crystallographic work by Amzel, Pedersen and co-workers (Figure 2B) has contributed significant results on the rat liver F1 enzyme. Much less is known on F0, due to its membrane-intrinsic nature; the structural analysis of this portion of the synthase is so far limited to its isolated subunits or subcomplexes.

Subunit Composition

In the simplest ATP synthase, that of bacteria (Figures 1A and B), F1 contains five different subunits with a stoichiometry $\alpha_3,\beta_3,\gamma_1,\delta_1,\varepsilon$. F0 is composed of three kinds of subunits with a stoichiometry a_1,b_2,c_{10-14}. This core structure is substantially conserved in all ATPases, but for the presence of two homologous b and b′ subunits in chloroplast F0, of a single copy of the b subunit in mitochondrial F0 and of several additional subunits, whose roles are still poorly defined, in the stalk and in the membrane sector of the mitochondrial complex(Figure 1C). Finally, an inhibitor peptide (IF_1), unique to mitochondria, may reversibly associate to the synthase.

At present, the subunit nomenclature for the ATP synthases from different sources is confusing, partly due to historical reasons; as an example, the bacterial ε-subunit corresponds to the mitochondrial δ, and the bacterial δ-subunit to the mitochondrial oligomycin sensitivity conferring protein (OSCP), while the

mitochondrial ε-subunit has no bacterial counterpart (Figures 1B and C).

F1

The three α- and the three β-subunits of F1 are arranged alternately in an hexagonal ring of 90–100Å diameter, forming the bulk of the globular head of F1 (Figure 2A). The α- and β-subunits of F1 are homologous and share similar folds, comprising an N-terminal β-barrel domain, a central domain which includes the nucleotide-binding site, and a C-terminal bundle of α-helices. The γ-subunit has an elongated shape: a long C-terminal and a shorter N-terminal α-helix wrap in an antiparallel, asymmetric coiled-coil, and the central section of the chain folds in a globular domain. The terminal portion of the coiled coil inserts into the large central cavity of the $\alpha_3\beta_3$ hexamer (Figure 2A), making minimal contacts with its interior surface and reaching its top. The remainder of the γ-subunit protrudes to form a 47Å stalk, which contacts F0 at the membrane surface by means of a foot-shaped structure (Figures 1 and 2B), resulting from the interaction of its globular domain with the ε-subunit (or the δ- and ε-subunits in mitochondria). The bacterial δ-subunit (or the equivalent mitochondrial OSCP) is located externally on the upper half of the $\alpha_3\beta_3$ assembly, interacting with the N-terminal domains of at least one α-subunit (Figure 1).

F0

In F0 (Figure 1) the a subunit (the only main subunit still lacking a high resolution structure) is thought to be folded into five-transmembrane α-helices, the b-subunit comprises an α-helical hydrophilic and a potentially α-helical transmembrane domain, and the c-subunit folds in a hairpin-like structure, with two transmembrane α-helices linked by a short polar loop. Several c-subunits pack to form an oligomeric membrane-spanning ring, probably filled by membrane lipids. The number of monomers in the ring is generally thought to vary between species, and stoichiometries of 9–14 c-subunits have been proposed for the synthases of different sources. In bacteria, the packing of the c-subunits is suggested to vary even within a single species, as a result of modifications in the membrane lipid composition induced by different growing conditions. Irrespective of its stoichiometry, the c-ring spans the membrane, interacting with the foot of the F1 stalk by means of the polar loops of the c-subunits, while its external surface contacts the highly hydrophobic a subunit and the transmembrane domains of the b-subunit dimer (in bacteria and chloroplasts). The hydrophilic α-helices of the b-subunits project from

the membrane reaching the δ-subunit of F1. The b-subunit of mitochondrial F0, although monomeric, is thought to have an analogous organization and to contact the OSCP subunit of F1. The interaction between the F0 b and the F1 δ (or OSCP) subunits results in the second, peripheral stalk connecting the catalytic head to the membrane-intrinsic footpiece of the ATP synthase complex.

ATP Synthesis by F1

Catalytic Process

The catalytic cycle leading to the production of ATP involves three main steps: binding of Mg–ADP and P_i to the enzyme (both ADP and ATP are complexed with Mg^{2+}, as in all known reactions of these nucleotides), formation of the γ-phosphoanhydridic bond by removal of a water molecule, and release of Mg–ATP to the aqueous phase. Reversal of these steps leads to the hydrolysis of ATP, which is often studied as it requires simpler experimental systems (e.g., the isolated F1, or the complete F1–F0 complex in the absence of a proton gradient) than the synthesis. ATP is synthesized (or hydrolyzed) at three catalytic sites located on the β-subunits at the interface with an α-subunit (Figure 3). The α-subunits also contain nucleotide-binding sites which, although homologous to those of the β-subunits, are catalytically inactive (Figure 2A). Most of the amino acids involved in catalysis belong to the β-chain, but the adjacent α-chain also contributes essential residues, so that the enzyme functionally consists of three αβ catalytic pairs. As in many ATP-utilizing proteins, each nucleotide-binding site contains a P-loop, i.e., a conserved sequence motif – Gly-X-X-X-X-Gly-Lys-Thr/Ser – which participates in the binding of the phosphate groups. Other amino acids involved in the synthesis/hydrolysis of ATP have been identified by mutational and structural data; among them, the side chain of a glutamic acid, which has no equivalent in the inactive sites of the α-chains, appears essential for the formation/hydrolysis of the anhydridic bond of ATP.

Analysis of ATP synthesis has unexpectedly shown that the γ-phosphoanhydridic bond of ATP readily forms within the complex, owing to the much higher affinity of the catalytic sites for ATP than for ADP and Pi. However, the newly formed ATP remains tightly bound to the enzyme unless protons are flowing through F0 down a transmembrane gradient. This observation has provided evidence that the translocated protons are not directly involved in catalysis, suggesting instead that the H^+ flow is the exergonic process driving the major energy-requiring step of ATP synthesis, i.e., the decrease of the enzyme affinity for ATP.

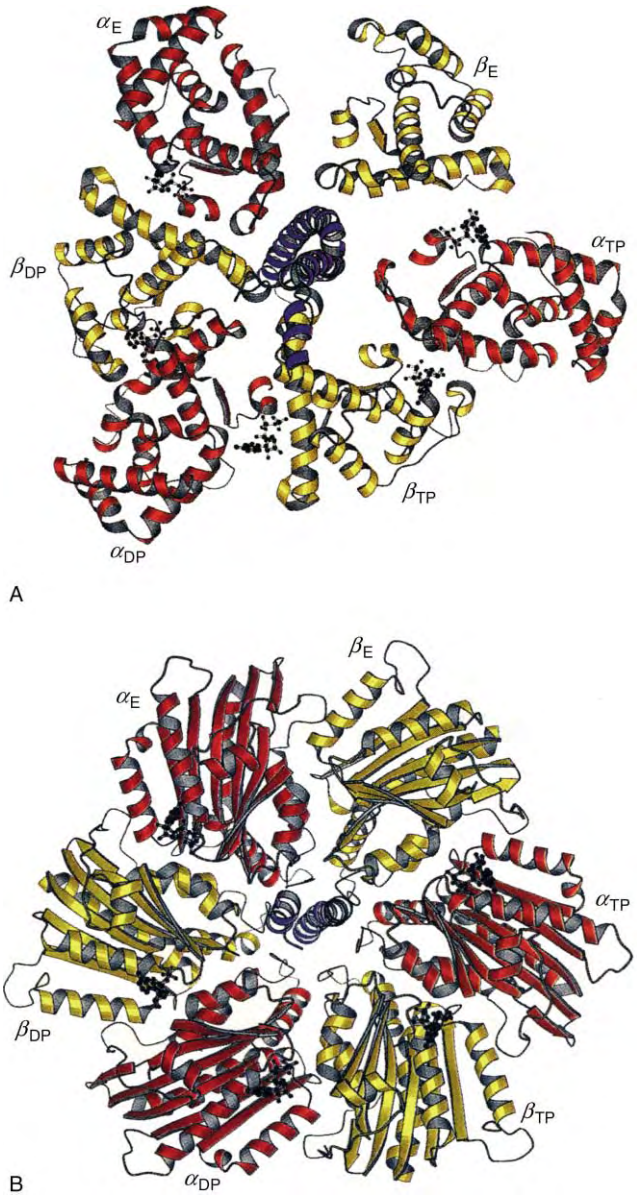

FIGURE 3 Asymmetric features of bovine F1. F1 was crystallized in the presence of AMP–PNP and ADP. The α-subunits are in red, the β-subunits are in yellow, and the γ-subunit (part of which is lacking, since it was disordered in the crystal) is in blue. All the α-subunits and the β_{TP}-subunit have AMP–PNP bound; β_{DP} has ADP and β_E has no nucleotide. (Reproduced from Abrahams, J. P., Leslie, A. G. W., Lutter, R., and Walker, J. E. (1994). (B) The γ-subunit coiled-coil and the nucleotide-binding domains of the α- and γ-subunits (viewed from the membrane side).

Binding Change Model

A further peculiar aspect of F1 revealed by the enzymological data is cooperative catalysis: the three β-subunit cannot operate independently, as revealed by the complete loss of enzymatic activity of the synthase

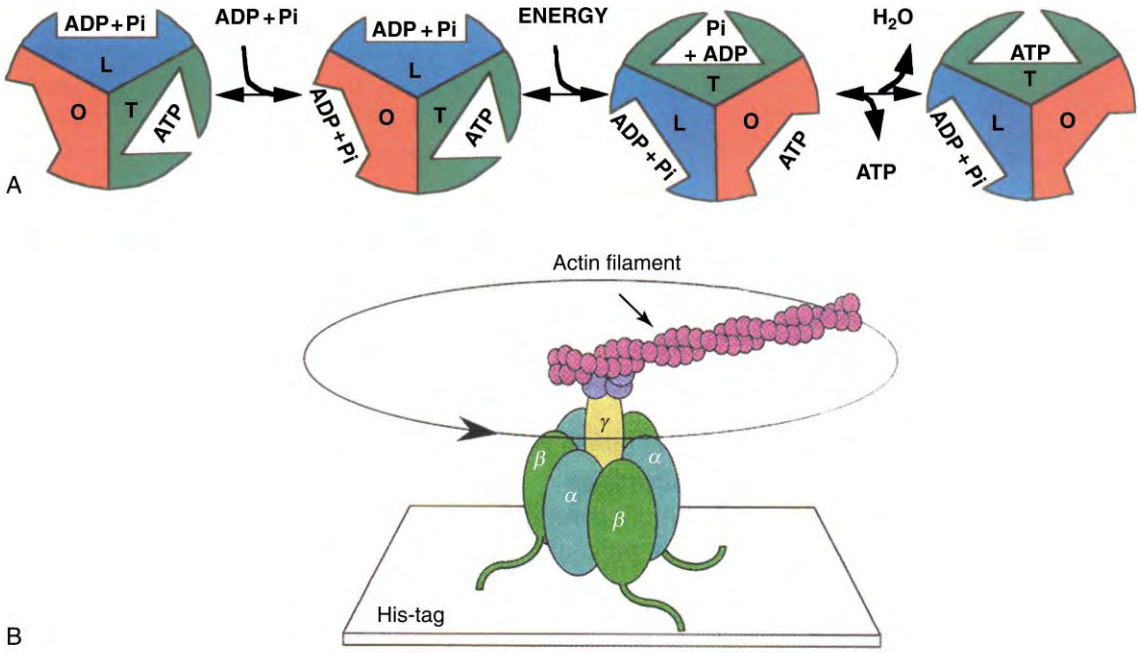

FIGURE 4 The binding change model of ATP synthesis and the rotation of the γ-subunit(A) Each circle represents a different conformation of $\alpha_3\beta_3$, the three sectors corresponding to the three $\alpha\beta$ pairs. Green sectors represent the "tight" (T) conformation, blue sectors represent the "loose" (L) conformation, and red sectors represent the "open" (O) conformation. Sci.* **22**, 420–423, with permission from Elsevier.)

upon inhibition of a single catalytic site of F1, implying that site-to-site interactions are essential to complete the catalytic cycle. According to the widely accepted binding change model (Figure 4A), proposed by Boyer in 1973 to explain the unusual catalytic features of the F1–F0 ATPase, as the synthesis of ATP proceeds each β-subunit sequentially adopts three conformations, corresponding to different binding affinities of the catalytic site for ATP, ADP, and Pi: the loose (L) conformation binds ADP and P_i with low affinity, the tight (T) conformation allows ATP to be synthesized by binding it with very high affinity, and the open (O) conformation releases the newly formed ATP to the medium. At any time the three β-subunits within F1 have different conformations and distinct steps of the enzymatic reaction take place at each catalytic site: when one β-subunit changes from the L to the T conformation, forming ATP from ADP and P_i, another β-subunit converts from the T to the O state, releasing ATP, and the third one shifts from the O to the L conformation, binding ADP and P_i. Thus, ATP is released by a catalytic site only upon binding of the substrates to another site, and the synthesis of ATP is the result of the concerted operation of the three $\alpha\beta$ pairs of F1.

The functional asymmetry predicted by the binding change mechanism has been substantiated by structural information. In fact, in the first F1 crystal described by Walker (Figure 3) the β-subunits have distinct tridimensional structures, arising principally from domain shifts, and the catalytic sites contain different nucleotides: one binds the ATP analogue AMP–PNP, one ADP, while the third one has no ligand. However, two main problems concerning the catalytic cycle are still debated: (1) the actual number of the catalytic sites of F1 involved in the synthesis of ATP and (2) the number of the distinct conformations cyclically adopted by each β-subunit.

Rotational Catalysis

The tridimensional structure of F1 has also revealed that the γ-subunit contributes to the asymmetry of F1 (Figure 3): its coiled-coil displays different interactions with each $\alpha\beta$-subunit pair, correlating with the conformational differences among the catalytic sites. These structural features support the rotary mechanism of ATP synthesis, as predicted by Boyer to account for the binding change model. According to this mechanism the asymmetric γ-subunit triggers the conformational transitions required to synthesize ATP by rotating relative to the $\alpha_3\beta_3$ ring, therefore interacting differently with each $\alpha\beta$ pair at any instant. The contact sites between the γ-subunit and each $\alpha\beta$ pair which are specifically

responsible for the conformational transitions envisaged by the binding change model remain controversial; however, an inventive experiment designed in 1997 by the groups of Yoshida and Kinosita has visually documented the rotation of the γ-subunit during ATP hydrolysis (Figure 4B). A single recombinant $\alpha_3\beta_3\gamma$ bacterial complex was anchored to a microscope slide, so that the γ-subunit projected upwards. An actin filament, much bigger than the enzyme and bearing a fluorescent tag, was linked to the γ-subunit, at a distance from the ring, to provide a long adjunct that could be observed under a fluorescent microscope. When Mg–ATP was added to this ATPase preparation, the actin filament began to rotate unidirectionally proving that the hydrolysis, and presumably the synthesis, of ATP entailed the physical rotation of the γ-subunit. At very low concentrations of ATP the rotary motion apparently splits into 120° steps, each evidently corresponding to the hydrolysis of one molecule of ATP. The efficiency of the conversion of the chemical energy from ATP hydrolysis into the mechanical energy of rotation was estimated to approximate 90%, consistent with the fully reversible operation of F1. The same biophysical approach has subsequently demonstrated that the whole central stalk assembly (i.e., the bacterial γ- and ε-subunits) revolves during the catalytic process.

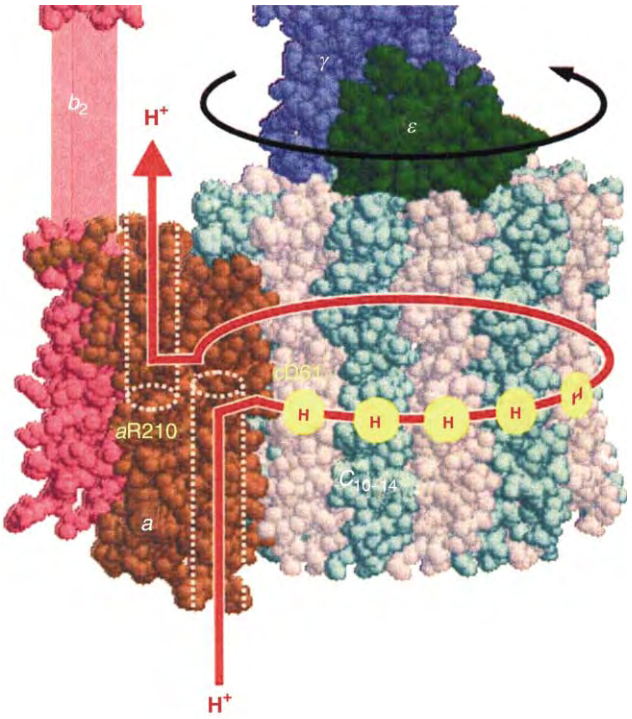

FIGURE 5 Structure of the ATP synthase showing a proposed proton transport path. aR210 and cD61 indicate the a-subunit arginine and the c-subunit aspartate required for the transmembrane movement of H^+; the dotted lines represent the putative half-channels for H^+. (Reproduced from Weber, J., and Senior, A. E. (2003). ATP synthesis driven by proton transport in F_1F_0-ATP synthase. *FEBS Lett.* **545**, 152–160 with permission of Federation of the European Biochemical Societies.)

Proton Translocation by F0

To mechanically connect the synthesis of ATP by F1 to the translocation of protons by F0, the rotation of the central stalk must be driven by protons moving through F0. However, the abovementioned lack of a high resolution structure of the intact F0 has so far hampered the efforts to define its fine molecular mechanism.

Amino acids essential for the transmembrane movement of protons have been identified both in the a-subunit and in the c-subunit, but not in the b-subunit, implying that the H^+ path is formed by a- and c-subunits. In particular, two interacting amino acids, predicted to be near the middle of the hydrophobic core of the membrane, are apparently crucial to H^+ transport: an aspartate (or glutamate) in the c-subunit, and an arginine in the a-subunit (Figure 5). The acidic residue reacts specifically with the synthase inhibitor dicyclohexylcarbodiimide (DCCD), and the translocation of protons through F0 is completely blocked by the binding of DCCD to just one of the several c-subunits, meaning that the c-subunits in the ring operate cooperatively.

In 1986, these experimental findings have led Cox and co-workers to propose that the c-ring rotates against the a-subunit so that, as each c-subunit moves past the a-subunit, a proton moves across F0. Recently, cross-linking studies have established that H^+ translocation does cause the c-ring to revolve, and that the central stalk is forced to rotate synchronously with the ring due to the connections between its foot-shaped portion and the c-subunits. In addition, extension of the procedure of Yoshida and Kinosita to the F1–F0 complex has confirmed the rotation of the c-ring.

The generally accepted model for the operation of F0 (Figure 5) envisages two disaligned half-channels (mainly located in the a-subunit) extending from the opposite surfaces of the membrane to the depth of the essential aspartate/arginine pair. To cross the membrane, a proton moves through one half-channel and binds to the negatively charged aspartate of one c-subunit, relieving the electrostatic interaction with the positively charged arginine. The uncharged c-subunit can thus come into contact with the hydrophobic core of the membrane, and the c-ring may rotate, therefore allowing the aspartate of the contiguous c-subunit to align to the half-channel and to bind another H^+. Protons are discharged to the opposite side of the membrane by means of the other half-channel following the rotation of the ring. Consistent with the actual operation of F0 and of the intact F1–F0 complex, the translocation of protons by this mechanism is passive and bidirectional,

unless a proton gradient across the membrane imposes a single direction of rotation.

Peripheral Stalk

The peripheral stalk is the least defined portion of the ATP synthase, consisting of b- and δ- (or OSCP) subunits, whose high resolution structures are still partially unknown. It is believed to act as a stator, i.e., to keep the catalytic head and the proton channel in the right relative orientation by preventing the a-subunit and the $\alpha_3\beta_3$ ring from rotating with the c-ring–γ–ε assembly (often referred to as the rotor of the complex).

Glossary

electron transfer chain A functional assembly of membrane-associated redox compounds which transfers electrons down a redox potential difference. It uses the energy thus made available to pump protons across the membrane, thereby generating a transmembrane proton gradient

F1–F0 Abbreviation of "coupling *f*actor *1*" and "*f*actor conferring sensitivity to *o*ligomycin": the proteins originally identified in mitochondria by E. Racker and co-workers as necessary for the synthesis of ATP, but not for the activity of the respiratory chain.

(ion) channel A transmembrane pathway that allows a passive flow of ions down a concentration or an electrical gradient. It may shift from an open to a closed state.

oligomycin An antibiotic that blocks both the synthesis and the hydrolysis of ATP in mitochondria. It does not block the hydrolysis of ATP by purified F1 preparations.

In the past, she has worked on the relationship between H^+ translocation and ATP synthesis in mitochondria. Her present interest is the role of calcium in intracellular proteolysis.

FAK Family

Steven K. Hanks
Vanderbilt University School of Medicine, Nashville, Tennessee, USA

The focal adhesion kinase (FAK) family is a small family of nonreceptor tyrosine kinases that function in adhesion-mediated signaling. The family contains just two vertebrate members: FAK and *p*roline-rich *t*yrosine *k*inase 2 (PYK2). Also included are homologues from invertebrate metazoans: DFak56 from *Drosophila* and KIN-31 from *C. elegans*. The FAK family is defined by the presence of three major conserved domains: central tyrosine kinase catalytic domain, amino-terminal FERM domain (related to domains found in the red blood cell band 4.1 protein, *e*zrin, *r*adixin, and *m*oesin), and carboxyl-terminal *f*ocal *a*dhesion *t*argeting (FAT) domain.

FAK

Focal adhesion kinase (FAK) (Figure 1) was the first member of the family to be described and has been most extensively studied, primarily in cultured fibroblasts. Its name derives from its prominent localization to cellular focal adhesions (Figure 2). Focal adhesions are sites where cell surface integrins cluster and make strong adhesive contact with components of the extracellular matrix (ECM) such as fibronectin, vitronectin, and collagen. Focal adhesion localization was the first indication that FAK could be involved in regulating aspects of cell behavior resulting from integrin-mediated adhesion. The FAT domain is necessary and sufficient for focal adhesion localization.

FAK Expression and Role in Development

FAK is widely expressed throughout embryogenesis and appears to function in many developmental processes. A role for FAK in gastrulation is suggested by observations, made in early embryos from *Xenopus* and chicken, of prominent FAK expression in the involuting mesoderm. FAK-deficient mouse embryos fail to develop past late stages of gastrulation, and exhibit dramatically retarded development of the antero-posterior axis, suggestive of defects in mesodermal migration. Studies using late-stage embryos from mouse, *Xenopus*, and zebrafish indicate high FAK expression associated with several developing systems including the central nervous system, somites, arterial walls, myotendinous junctions, and germ cells. FAK is ubiquitously expressed in adult tissues, with high levels found in brain, lung, and testis. In neuronal cells FAK is enriched in growth cones. Neuronal FAK is expressed from alternatively spliced transcripts resulting in short insertions in the region between the FERM and kinase domains.

FAK Activation and Signaling Mechanism

Like most tyrosine kinases, FAK is in its active signaling state when phosphorylated on tyrosine residues. FAK tyrosine phosphorylation results from integrin-mediated cell adhesion to the ECM and is maintained by Rho-mediated contraction of the actin cytoskeleton. The initial step in FAK activation is phosphorylation of Tyr-397, which occurs through intermolecular autophosphorylation. Neuronal-specific isoforms of FAK have a higher intrinsic capacity to autophosphorylate. A critical aspect of FAK signaling is the recruitment of Src-family kinases, which bind via their SH2 domains to the phosphorylated Tyr-397 site. This leads to Src-mediated phosphorylation of five other FAK tyrosine residues: 407, 576, 577, 861, and 925 (Figure 1). Tyrosines 576 and 577 reside in the kinase domain "activation loop," and evidence indicates that phosphorylation of these sites elevates catalytic activity. Phosphorylated Tyr-925 can bind the SH2 domain of the adaptor protein Grb2, suggesting a mechanism for integrin stimulation of "extracellular-signal regulated kinase" (ERK) via a FAK > Grb2/SOS > Ras pathway. The signaling functions of the Tyr-407 and Tyr-861 sites are unknown.

Src-family kinases recruited to the Tyr-397 site also phosphorylate two FAK-associated proteins: "Crk-associated substrate" (CAS) and paxillin. CAS, via its SH3 domain, interacts with either of two proline-rich motifs (PR1 and PR2) that reside in the region linking the kinase and FAT domain. Paxillin interacts with the FAT domain. For both CAS and paxillin, the major tyrosine phosphorylation sites are in Tyr-X-X-Pro (YxxP) motifs. Fifteen YxxP motifs constitute the major region of CAS tyrosine phosphorylation (known as the "substrate domain") while two YxxP motifs are

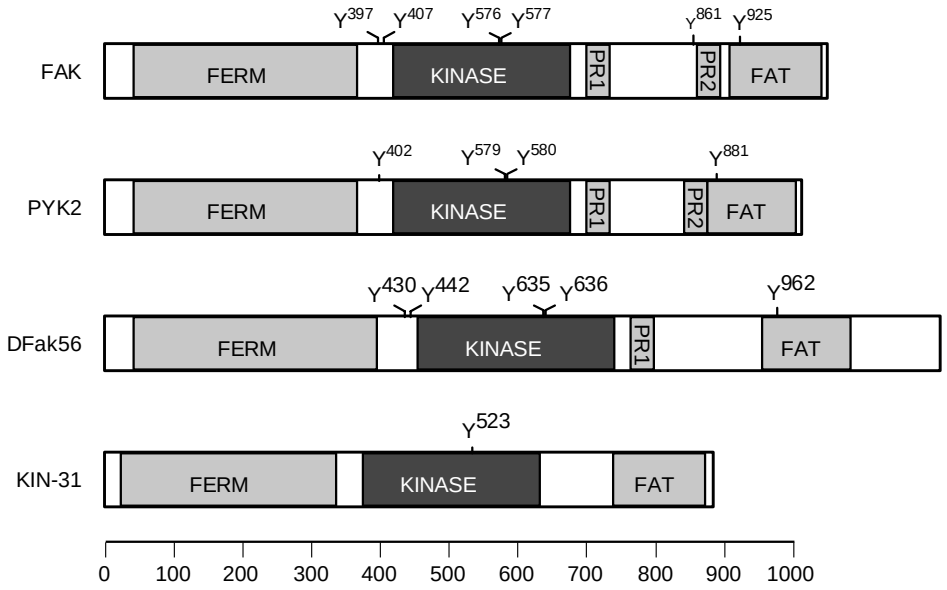

FIGURE 1 Members of the FAK family. FAK and PYK2 are vertebrate family members, DFak56 is from *Drosophila*, and KIN-31 is from *C. elegans*. Shown in the linear structures are major conserved domains, protein interaction motifs, and sites of tyrosine phosphorylation (see text for details). The scale bar represents number of amino acid residues.

the major paxillin sites. Phosphorylation of YxxP sites promotes downstream signaling events through recruitment of additional SH2-containing effector molecules. The c-Crk adaptor molecule binds to YxxP sites of both CAS and paxillin and appears to be a major downstream effector in signaling from the FAK/Src complex.

In addition to Src family kinases, the phosphorylated Tyr-397 site mediates interactions with SH2 domains of other signaling proteins including phosphatidylinositol 3-kinase (PI3K), the γ1 isoform of phospholipase C (PLC-γ1), Shc, Grb7, and Nck-2. Thus FAK likely promotes assembly of several distinct signaling complexes within a larger integrin-associated protein network.

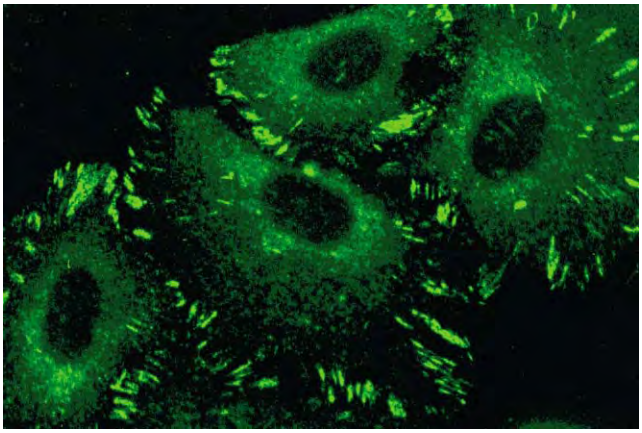

FIGURE 2 Localization of FAK in focal adhesions. Primary cultures of mouse keratinocytes were plated on fibronectin and stained using an antibody against FAK. The highly immunoreactive structures observed at the cell peripheries are focal adhesions.

Cellular Responses to FAK Signaling

Much evidence indicates that FAK functions to enhance the rate of cell motility. For example, fibroblasts derived from *FAK* −/− mouse embryos exhibit poor motility compared to cells from normal embryos, and the motility defect can be rescued by re-expressing wild-type FAK. Mutant FAK variants, either lacking the Tyr-397 site or deficient in catalytic activity, are unable to efficiently promote the motility response, indicating that FAK signaling is involved. A likely mechanism by which FAK promotes cell motility is by directing the extension of leading-edge lamellipodia. This occurs, in part, through activation of the small GTPase Rac, which can result from the recruitment of c-Crk to phosphorylated CAS and paxillin. One of the c-Crk SH3 domains interacts with the protein DOCK180 that promotes Rac GDP–GTP exchange. Interactions of the FAK Tyr-397 site with PI3K and Grb7 have also been implicated in the motility response.

In addition to regulating motility, FAK also functions as a positive regulator of cell growth by triggering both survival and proliferative signals. FAK-mediated signaling (requiring the Tyr-397 site) confers resistance to apoptosis resulting from various stimuli including loss of anchorage to the ECM (anoikis), oxidative stress, UV irradiation, and exposure to anti-cancer drugs. FAK survival signals can result from multiple downstream events including CAS/Crk complex formation and PI3K-mediated activation of Akt. FAK may also help

drive progression through G1 phase of the cell cycle through its ability to activate ERK kinases and promote transcriptional activation of the gene encoding cyclin D1.

PYK2

PYK2 is also known as CAK-β (cellular adhesion kinase β), RAFTK (related adhesion focal tyrosine kinase), and CADTK (calcium-dependent tyrosine kinase). The FAT and kinase domains of PYK2 each exhibit ~60% amino acid identity with the homologous domains of FAK, while the FERM domain is slightly less conserved (Table I). Both PR motifs in the kinase-FAT linking region are present in PYK2 (and capable of mediating interactions with CAS) but otherwise this region is poorly conserved, as is the short region amino-terminal to the FERM domain. Four tyrosine residues corresponding to sites of FAK phosphorylation are functionally conserved (Figure 1): phosphorylated Tyr-402 mediates interactions with Src-family kinases, phosphorylated activation loop tyrosines 579 and 580 stimulate PYK2 catalytic activity, and phosphorylated Tyr-881 binds Grb2.

PYK2 Expression and Roles in Development

PYK2 is expressed at high levels in the central nervous system and cells of hematopoietic origin, but is also detected in a variety of other cell types including fibroblasts, osteoclasts, epithelial cells, and smooth muscle cells. PYK2 levels increase dramatically in the forebrain around birth. A splice variant encoding a 42 amino acid insert between the two PR regions is predominantly expressed in neuronal cells. PYK2-deficient mice develop normally, but lack marginal zone B cells and have suppressed immunoglubulin production.

TABLE I

Conservation of FAK Family Domains[a]

	PYK2	DFak56	KIN-31
FERM	47	26	19
Kinase	58	63	47
PR linker	25	19	7
FAT	61	43	18

[a] Percent amino acid identities are shown compared to human FAK. Human PYK2 was used for the comparison. "PR linker" refers to the region containing proline-rich motifs that lies between the kinase and FAT domains.

PYK2 Activation and Signaling Mechanism

Like FAK, PYK2 activation can result from integrin stimulation. For example, PYK2 undergoes tyrosine phosphorylation following plating of megakaryocytes onto fibronectin and upon antibody stimulation of B cell integrins. In fibroblasts, PYK2 is detected in focal adhesions, consistent with the high conservation of the FAT domain. It is notable, however, that the FAT domain of PYK2 targets to focal adhesions inefficiently compared to that of FAK. PYK2 activation in response to integrin-mediated adhesion has been observed in *FAK −/−* fibroblasts. But re-expression of FAK in these cells effectively suppresses the PYK2 response, probably by displacing PYK2 from the adhesion sites. These observations suggest that PYK2 may not play as widespread a role in integrin signaling as does its sister molecule, FAK.

In contrast to FAK, PYK2 can be activated by extracellular signals that elevate levels of intracellular calcium and stimulate calcium-dependent isoforms of protein kinase C. These include agonists for G protein-coupled receptors, voltage-gated calcium channels, and the nicotinic acetylcholine receptor. Since protein kinase C is a protein-serine/threonine kinase it must stimulate PYK2 tyrosine phosphorylation through an indirect means, but the exact mechanism is unknown.

The downstream signaling events resulting from PYK2 activation are generally similar to those of FAK, involving autophosphorylation, recruitment of Src family kinases, and Src-mediated phosphorylation of other sites on PYK2 as well as PYK2-associated CAS and paxillin (Figure 3). The interaction of Grb2 with the PYK2 Tyr-881 site suggests a possible link between G protein-coupled receptors and ERK activation.

Cellular Responses to PYK2 Signaling

Unlike FAK, PYK2 overexpression does not efficiently promote fibroblast motility and results in apoptosis, rather than cell survival. Nevertheless, a critical role for PYK2 in the motility and migration of macrophages and B cells has been demonstrated using cells derived from PYK2-deficient mice. Defects in lymphocyte motility could explain the absence of marginal zone B cells in these animals. Through its ability to be activated by both integrin- and calcium/PKC-dependent mechanisms, PYK2 can function in numerous and diverse signaling pathways regulating a wide variety of cellular activities. In neuronal cells, for example, PYK2 has been implicated as a positive regulator of neurite outgrowth and NMDA channel activity. Other consequences of PYK2 signaling include inhibition of voltage-gated potassium channels leading to membrane depolarization of vascular smooth muscle cells, translocation of the

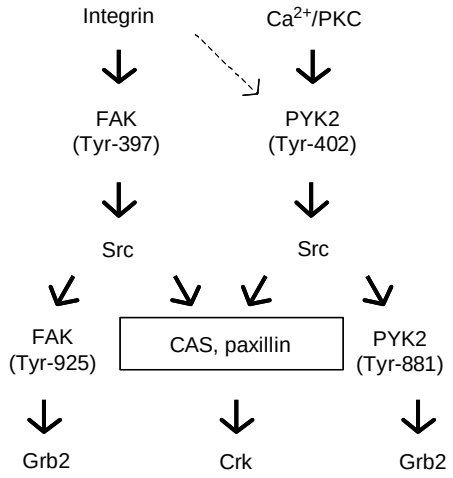

FIGURE 3 Signaling by FAK and PYK2. Both FAK and PYK2 can be activated by integrin-mediated adhesion, while PYK2 is uniquely activated through a calcium/PKC-dependent mechanism. A critical element of FAK and PYK2 signaling involves the recruitment of Src family kinases to sites of autophosphorylation. The associated Src family kinases then phosphorylate a conserved FAK/PYK2 tyrosine site to promote Grb2 binding, and also phosphorylate FAK/PYK2-associated proteins CAS and paxillin to promote binding of Crk. The adaptor molecules Grb2 and Crk interact with guanine-nucleotide exchange factors for small G proteins, including Ras and Rac, to promote downstream signals.

GLUT4 glucose transporter to the plasma membrane of adipocytes, stimulation of Na-HCO^{3-} cotransporter activity in renal epithelial cells, and angiogenesis of vascular endothelial cells.

Invertebrate Members of the FAK Family

Drosophila and *C. elegans* genomes each contain a single member of the FAK family: DFak56 in *Drosophila* and KIN-31 in *C. elegans*. FAK and PYK2 are more closely related to one another than they are to either DFak56 or KIN-31, indicating that the two vertebrate family members arose through a gene duplication event that occurred sometime after evolutionary separation from the invertebrates.

Drosophila DFak56 shows strong overall conservation with the two vertebrate family members, but is slightly more similar to FAK than to PYK2. The kinase domain of DFak56 is most highly conserved in comparison to FAK, followed in order by the FAT domain, the FERM domain, and the kinase-FAT linker region (Table I). Within the kinase-FAT linker, DFak56 contains a proline-rich motif corresponding to the PR1 site, but lacks the PR2 site. Of the six sites of FAK tyrosine phosphorylation, DFak56 lacks only the site corresponding to FAK Tyr-861. But DFak56 Tyr-962, which corresponds to the Grb2 binding sites in FAK and PYK2, lacks the asparagine residue at the +2 position necessary for Grb2 SH2 binding. A unique structural feature of DFak56 is an extended carboxyl-terminal region of unknown function. Like the vertebrate members of the FAK family, DFak56 exhibits autophosphorylation activity and undergoes tyrosine phosphorylation in response to integrin-mediated adhesion. DFak56 is broadly expressed during embyrogenesis, with strongest expression in the developing gut and central nervous system. The role of DFak56 in *Drosophila* development has yet to be defined through loss of function studies. However, overexpression of DFak56 in the wing imaginal disk leads to wing blistering, a phenotype associated with weakened integrin linkage to the actin cytoskeleton.

C. elegans KIN-31 is a predicted protein product of gene C30F8.4 that has yet to be characterized biochemically. Compared to other members of the FAK family, KIN-31 contains a well-conserved and apparently functional kinase domain, while both the FAT and FERM domains are rather poorly conserved (Table I). Interestingly, KIN-31 lacks key motifs associated with FAK family signaling including a tyrosine corresponding to the autophosphorylation site and proline-rich motifs in the kinase-FAT linker region. Thus the functional role of KIN-31 could be quite distinct from the other FAK family members. KIN-31 is expressed in all larval stages and is prominent in bodywall muscle cells. Surprisingly, there is no obvious phenotype associated with a deletion of the gene encoding KIN-31.

Biography

Steven K. Hanks is a Professor in the Department of Cell and Developmental Biology at Vanderbilt University School of Medicine. His principal research interest is the role of tyrosine phosphorylation in integrin signaling. He holds a Ph.D. from the University of Texas Health Science Center at Houston Graduate School of Biomedical Sciences and received postdoctoral training at the Salk Institute. He pioneered homology-based approaches to identify novel protein kinases, which led to the recognition of CDK4 and FAK. He developed an approach to classify eukaryotic protein kinases based on catalytic domain phylogeny.

Fat Mobilization: Perilipin and Hormone-Sensitive Lipase

Constantine Londos and Alan R. Kimmel
National Institutes of Health, Bethesda, Maryland, USA

Nature's solution for packaging energy reserves in organisms ranging from plants to mammals is to sequester energy-rich fatty acids, in the form of triacylglycerols (TAG) or cholesteryl esters, within intracellular neutral lipid storage droplets. The great survival value for this type of packaging is attributed to the high density of energy in fatty acids and the relatively low amount of water necessary for their storage. If man were to carry the energy equivalent of fat as carbohydrate, the additional required water would render man immobile. Typically, intracellular lipid droplets are coated with specific targeting classes of proteins, but enzymes involved in lipid metabolism may also be found in tight association.

Plant Lipid Droplets

The oleosins of plant seeds and tapeta were the first to be identified, and remain the most extensively studied, lipid droplet coat proteins. The oleosins are thought to protect the lipid depositions during dessication.

Animal Lipid Droplets

The first animal lipid droplet protein to be identified was perilipin of mammalian adipocytes. While perilipin has no obvious sequence relationship to the oleosins, it is related to several other animal proteins that also target lipid droplets. One of these, the adipose differentiation-related protein (ADRP), also termed adipophilin, was first identified as a gene that is highly expressed very early during adipocyte differentiation; subsequently, ADRP was found to be expressed ubiquitously and to coat the lipid droplets of all cells, excepting mature adipocytes. A third related protein, TIP47, was identified initially by a screen for proteins that interact with the mannose 6-phosphate/IGF2 receptor and was later also found to associate with lipid droplets. Based upon the sequence similarities among perilipin, ADRP, and TIP-47, the grouping has been described as the PAT protein family. S3-12 is an even more distantly related mammalian protein that is found on adipocyte plasma membranes and also on their intracellular lipid droplets. Several genes that encode PAT proteins in *Drosophila melanogaster* and *Dictyostelium discoideum* have also been identified. These genes are related to the mammalian counterparts not only in their protein-coding sequences, but also in their overall genomic structural organizations, indicating that they derive from a gene family of ancient origin. Further, the *Drosophila* and *Dictyostelium* PAT proteins localize to lipid droplets in fusion with green fluorescent protein (GFP) when expressed heterologously in the mammalian CHO fibroblasts. It is suggested that the PAT proteins share a specific and novel structural motif that determines their unique intracellular lipid droplet targeting ability. Moreover, each member of this protein family is likely to have an essential role in lipid metabolism.

Perilipin

The most extensively studied PAT protein is perilipin. There is a single gene for perilipin in mouse (and in human) that encodes multiple mRNA and protein species, resulting from differential splicing. The mRNAs encode identical amino termini but utilize distinct stop codons and display tissue-specific variants. Perilipin expression is highest in adipose tissue, with lesser amounts in steroidogenic tissue and only trace amounts elsewhere. Although cells contain a wide variety of lipid docking sites, the perilipins localize exclusively to the phospholipid monolayer that covers the underlying neutral lipid deposits of the droplet core (Figure 1). The perilipins are found on or within this phospholipid monolayer that forms the boundary between the aqueous cytosol and the hydrophobic lipid core of the droplet. Perilipin A (Peri A) is the largest and most abundant form. It has six consensus protein kinase A (PKA) sites that are phosphorylated upon elevation of cAMP during the lipolytic stimulation of adipocytes. Since lipolysis in

adipocytes is driven by a cAMP-mediated process, and given perilipin's subcellular localization and tissue specificity, it was predicted that it would play a central role in the regulation of adipocyte lipolysis. Functional analyses has confirmed this speculation.

Perilipin Function

Depending on its PKA-dependent phosphorylation state, Peri A exhibits two opposing functional properties. Nonphosphorylated Peri A serves to shield the triacylglycerols (TAG) within the droplets from lipases. By contrast, when phosphorylated by PKA, the protein facilitates TAG hydrolysis. The importance of the protective function of perilipin is best illustrated by the *peri*-null mouse that exhibits a ~70% decrease in adipose tissue weight without a change in gross animal weight or in caloric intake. This loss in adipose tissue is attributed to the constitutively high rate of basal lipolysis in the adipocytes lacking perilipin. Thus, perilipin is essential for animals to package and retain their energy reserve supply. These *peri*-null animals also revealed the critical role for perilipin in regulated lipolysis; in the absence of perilipin, adipocytes fail to respond maximally to lipolytic stimuli. Thus, in *peri*-null adipocytes as compared to wild type, quiescent cells have an elevated basal lipolytic rate, while PKA-activated cells have an attenuated lipolysis. These dual functions have been recreated and the mechanism confirmed by expressing wild type and mutant forms of Peri A in fibroblastic cells which lack endogenous perilipin protein. Perilipin, thus, protects lipids from hydrolysis in unstimulated cells, whereas PKA-phosphorylated perilipin is required for regulated lipid hydrolysis.

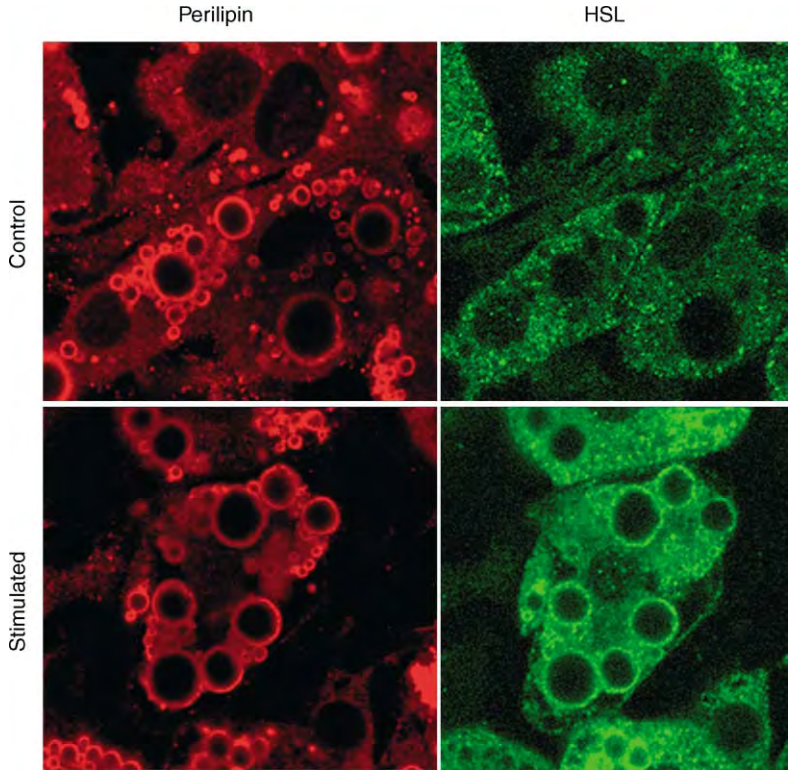

FIGURE 2 Migration of HSL from cytosol to lipid droplet surface upon stimulation. Red staining is perilipin at the lipid droplet surface. Green staining is HSL. Lower panels are resting adipocytes; upper panels show isoproterenol-stimulated cells. (Image courtesy of Dr. Carole Sztalryd, NIH.)

Adipocyte Lipolysis Catalyzed by Hormone-Sensitive Lipase

For many years, the prevailing model for adipocyte lipolysis was that hormone-sensitive lipase (HSL) was the rate-limiting enzyme and that the lipolytic rate *in vivo* was regulated exclusively by the PKA-dependent activation of HSL. This mechanism was questioned because phosphorylation of HSL *in vitro* elicits no more than a doubling of activity, whereas activation of cellular PKA increases lipolysis *in vivo* by 50- to 100-fold. The simple doubling of enzymatic activity was inadequate to explain the large increase in cellular lipolytic activity. Also, while HSL is easily identified in the cytosol of homogenates from quiescent adipocytes, the enzyme is absent from the aqueous fraction of homogenates from stimulated cells. HSL in stimulated cells was found subsequently to be associated with the cellular fraction containing the lipid storage. These data were confirmed by immunocytochemistry (Figure 2). It was not a great leap to conclude that PKA activation led to the translocation of HSL from the cytosol to the surface of the lipid storage droplet; subsequent experiments confirmed this hypothesis. An important breakthrough in understanding this mechanism came from studies with cells from the *peri*-null animals. Again, adipocytes from these animals exhibit elevated basal lipolysis, but are refractory to stimulation upon elevation of cAMP. The latter defect is downstream of the β-adrenergic receptor/G-protein/adenylyl cyclase complex that generates cAMP at the plasma membrane. Further exploration revealed that in the absence of perilipin, HSL cannot translocate from the cytosol to the lipid droplet surface in response to PKA activation. This finding established HSL translocation, and not activation per se, as the key reaction that elicits stimulated lipolysis in adipocytes and revealed the central role of perilipin in regulated lipid hydrolysis. Moreover, the HSL translocation reaction was reconstructed in nonadipocyte, CHO fibroblasts. HSL can be induced to translocate to the lipid droplet from the cytosol when coexpressed with wild-type perilipin. Translocation is not observed in the absence of perilipin or the presence of phosphorylation-defective variants of perilipin. Further, PKA-dependent phosphorylation of HSL itself was required to facilitate the translocation process.

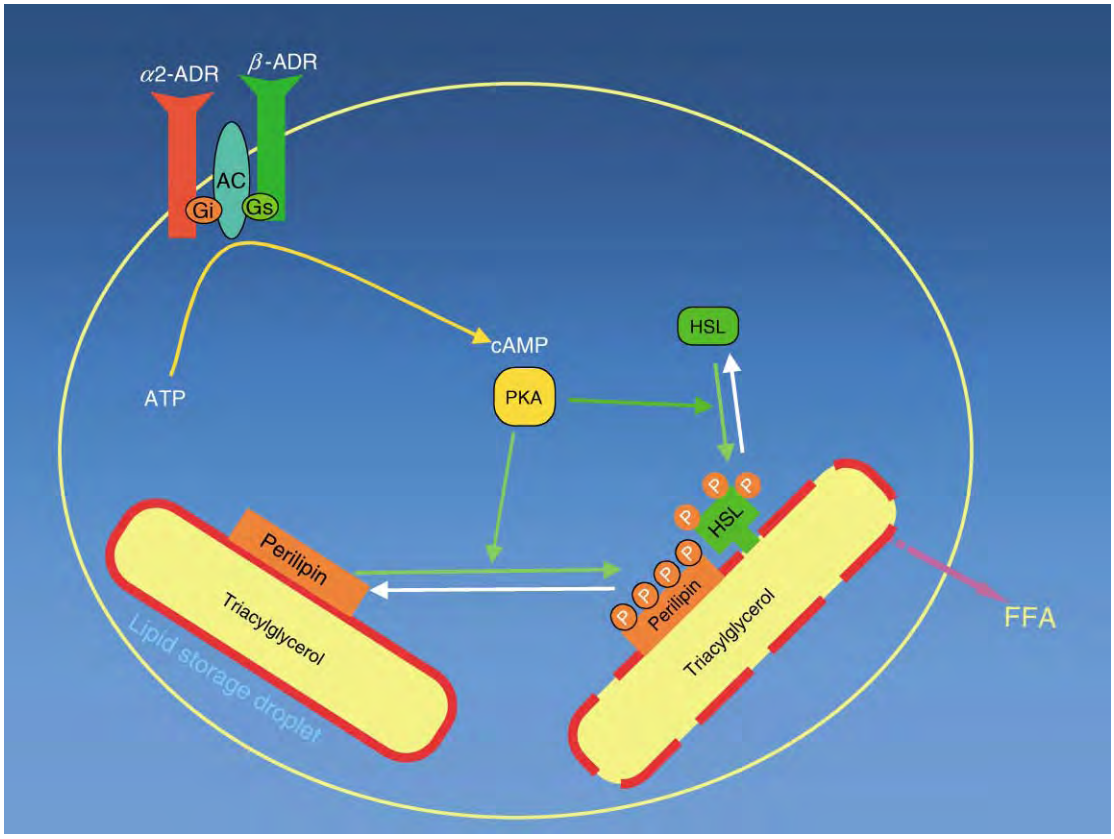

FIGURE 3 Model of the lipolytic reaction in adipocytes. Lipolytic stimulants activate adenylyl cyclase to increase cAMP which, in turn, activates protein kinase A which polyphosphorylates both hormone-sensitive lipase (HSL) and perilipin A. HSL then translocates from the cytosol to the lipid droplet surface. Phosphorylation of perilipin modifies the lipid droplet surface to accommodate the HSL.

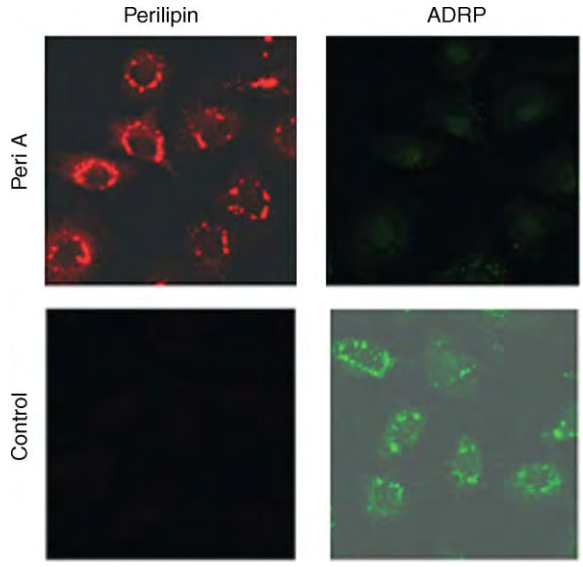

FIGURE 4 Displacement of ADRP by perilipin. Lipid droplets in lipid-loaded CHO fibroblasts stain for ADRP, but upon expression of perilipin A, the ADRP disappears and perilipin staining is seen around the lipid droplets.

Lipolysis Model

The current model for PKA-mediated lipolysis is depicted in Figure 3. In quiescent cells, cAMP levels are low, PKA is minimally active, and Peri A is unphosphorylated. Under these conditions, Peri A serves as a functional barrier for HSL access to the TAGs in the inner core of the intracellular neutral lipid droplets. Upon hormonal stimulation, cAMP levels rise, leading to the activation of PKA and the phosphorylation of both Peri A and HSL. Phosphorylation of Peri A at its three most N-terminal PKA sites readies the droplet surface to "accept" HSL. Phosphorylation of HSL at one of its two C-terminal PKA sites promotes the translocation of HSL from the cytosol to the lipid droplet surface. While it may be tempting to speculate that phospho-Peri A serves as the site for HSL docking at the droplet surface, it is difficult to believe this is the case. Potentially, unphosphorylated Peri A acts to sterically restrict access of all lipases to the surface of intracellular lipid droplets. It is, thus, not surprising that Peri A will inhibit lipolysis when expressed in cells that only possess PKA-insensitive lipases. However, phosphorylation of Peri A by PKA will stimulate lipolytic rates in these cells in excess of those observed in control cells that lack Peri A. Thus, it is suggested that Peri A phosphorylation alters the droplet surface to favor binding of all lipases, whether or not they are subject to PKA regulation. Perilipin may serve a space-making function. Phosphorylation of HSL separately facilitates binding to this "prepared" surface, effecting a synergism between Peri A and HSL during stimulation that raises the lipolytic rate 50- to 100-fold above basal levels and that is not observed with nonregulatable lipases.

It has been suggested that members of the PAT family of proteins play central roles in the regulation of lipid metabolism and energy homeostasis in organisms as diverged as *Dictyostelium* and mammals. This has been proven unequivocally for Perilipin and is strongly implied for ADRP. Recent data in *Drosophila* now extend these observations. *Drosophila* lacking one of their two PAT proteins exhibit a lean phenotype, while overexpression of the same protein leads to an increase in TAG stores, phenotypes that largely parallel those observed for perilipin (Figure 4).

Fatty Acid Oxidation

Horst Schulz
City College and Graduate School of the City University of New York, New York, USA

Fatty acid oxidation is the process by which fatty acids are degraded in living organisms. The initial event is the activation of fatty acids by esterification with coenzyme A (CoA). The degradation of the resultant fatty acyl coenzyme A (acyl-CoA) thioesters proceeds by a cyclic process named β-oxidation. Passage through one cycle of β-oxidation produces fatty acids that are shortened by two carbon atoms and yields acetate in the form of acetyl coenzyme A (acetyl-CoA). Repetitive cycling through β-oxidation results in the complete degradation of fatty acids.

Cellular Uptake and Activation of Fatty Acids

The uptake of fatty acids by animal cells seems to be a facilitated process even though fatty acids can diffuse unassisted across biological membranes. A number of proteins of the cellular membrane are thought to be involved in this process. However, their specific functions in fatty acid uptake have not been elucidated. Once fatty acids have crossed the cellular membrane, they either diffuse or are transported to mitochondria, peroxisomes, and the endoplasmic reticulum where they are activated by esterification with coenzyme A (CoA). The transfer of fatty acids from the cellular membrane to sites of their activation may be facilitated by fatty-acid-binding proteins (FABPs), a group of low-molecular-weight (14–15 kDa) proteins that are present in the cytosol of various animal tissues. The function of FABP as an intracellular carrier of fatty acids has not been proven nor other suggested roles of this protein in the uptake and storage of fatty acids have been established.

The cellular uptake of fatty acids is tightly coupled to their intracellular esterification with CoA. Acyl-CoA synthetases catalyze the ATP-dependent esterification of fatty acids and CoA to produce fatty acyl-CoA, AMP, and pyrophosphate. Long-chain specific acyl-CoA synthetases are associated with the outer mitochondrial membrane and the membranes of the endoplasmic reticulum and peroxisomes. Acyl-CoA synthetases with a preference for medium-chain fatty acids are mostly located in the matrix of mitochondria while short-chain specific acyl-CoA synthetases are found in the mitochondrial matrix and/or in the cytosol depending on the organ of the animal.

Fatty Acid Oxidation in Mitochondria

In animal cells, fatty acids are degraded both in mitochondria and peroxisomes, whereas in lower eukaryotes fatty acid oxidation is generally confined to peroxisomes. Acetyl-CoA formed by mitochondrial fatty acid oxidation is further oxidized to release energy that drives the formation of ATP by oxidative phosphorylation. In liver, acetyl-CoA is also utilized for the synthesis of ketone bodies.

Mitochondrial Uptake of Fatty Acids

Fatty acids are activated by their conversion to fatty acyl-CoA thioesters at the outer mitochondrial membrane while their degradation by β-oxidation takes place in the mitochondrial matrix. Because acyl-CoAs cannot efficiently cross the inner mitochondrial membrane, an uptake system exists that shuttles fatty acyl residues across the inner membrane. As illustrated in Figure 1, the acyl residue of fatty acyl-CoA is transferred from CoA to carnitine at the outer mitochondrial membrane catalyzed by carnitine palmitoyltransferase I (CPT I). The resultant fatty acylcarnitine can cross the inner mitochondrial membrane in exchange for carnitine. This exchange is catalyzed by carnitine:acylcarnitine translocase (T). Once fatty acylcarnitine is in the mitochondrial matrix, it is converted back to fatty acyl-CoA by carnitine palmitoyltransferase II (CPT II), which is associated with the inner mitochondrial membrane. Medium-chain and short-chain fatty acids are not activated in the cytosol but directly enter the mitochondrial matrix where they are converted to their acyl-CoAs by medium-chain and short-chain acyl-CoA synthetases, respectively.

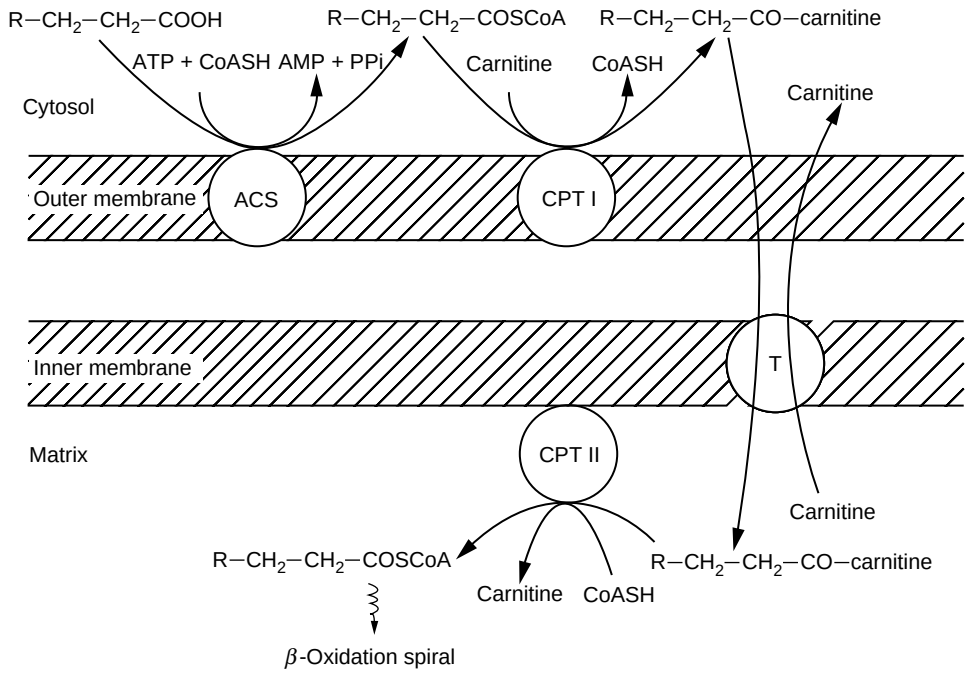

FIGURE 1 Carnitine-dependent transfer of fatty acyl groups across the inner mitochondrial membrane. ACS, acyl-CoA synthetase; CPT I and CPT II, carnitine palmitoyltransferase I and II, respectively; T, carnitine:acylcarnitine translocase.

β-Oxidation in Mitochondria

Fatty acyl-CoAs in the mitochondrial matrix are substrates of β-oxidation. This cyclic process consists of four reactions that shorten the acyl chain of fatty acyl-CoA by two carbon atoms at a time and produce acetyl-CoA. As shown in Figure 2, reaction 1a, β-oxidation begins with the removal of two hydrogens from carbon atoms 2 (α-carbon) and 3 (β-carbon) of acyl-CoA to form the corresponding 2-*trans*-enoyl-CoA. The hydrogens are initially accepted by the flavine adenine dinucleotide (FAD) cofactor of acyl-CoA dehydrogenase, the enzyme that catalyzes this reaction, then are transferred to the FAD of a soluble matrix enzyme named electron transferring flavoprotein and finally are fed into the mitochondrial electron transport chain, which supplies the energy for ATP formation by oxidative phosphorylation. In the second β-oxidation reaction, water is added across the double bond of 2-*trans*-enoyl-CoA by enoyl-CoA hydratase to yield L-3-hydroxyacyl-CoA (see Figure 2, reaction 2). The third reaction is the NAD^+-dependent dehydrogenation of L-3-hydroxyacyl-CoA catalyzed by L-3-hydroxyacyl-CoA dehydrogenase (see Figure 2, reaction 3). The product of this reaction, 3-ketoacyl-CoA, is the substrate of the fourth and last reaction of β-oxidation catalyzed by 3-ketoacyl-CoA thiolase, which cleaves the compound in the presence of CoA between carbons 2 and 3 to yield an acyl-CoA shortened by two carbon atoms and acetyl-CoA (see Figure 2, reaction 4). Repetitive cycles of β-oxidation result in the complete degradation of fatty acids to acetyl-CoA and also propionyl-CoA, if fatty acids with an odd-numbered number of carbon atoms are involved.

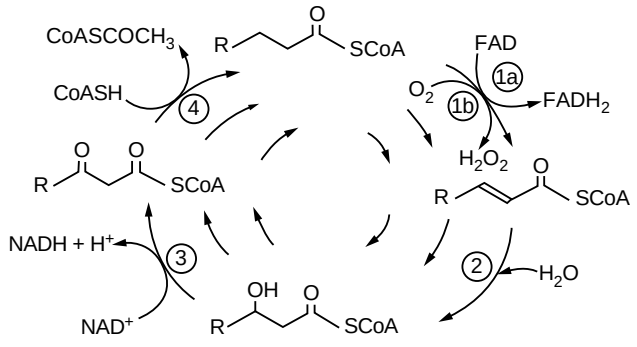

FIGURE 2 β-Oxidation of fatty acyl-CoA. Reactions 1a, 1b, 2, 3, and 4 are catalyzed by acyl-CoA dehydrogenase, acyl-CoA oxidase, enoyl-CoA hydratase, 3-hydroxyacyl-CoA dehydrogenase, and 3-ketoacyl-CoA thiolase, respectively. Abbreviations: FAD, oxidized form of flavine adenine dinucleotide; $FADH_2$, reduced form of flavine adenine dinucleotide.

Two or more enzymes with different acyl chain length specificities participate in each of the four reactions. Four acyl-CoA dehydrogenases are required for the β-oxidation of fatty acids. Their names, very long-chain acyl-CoA dehydrogenase, long-chain acyl-CoA dehydrogenase, medium-chain acyl-CoA dehydrogenase, and short-chain acyl-CoA dehydrogenase reflect their preferences for substrates of different acyl chain lengths.

Together they efficiently dehydrogenate all acyl-CoAs that are formed during the β-oxidation of most dietary fatty acids. Two enzymes, one with a preference for short-chain and medium-chain substrates and another most active with long-chain substrates, cooperate in each of the three other reactions to metabolize a range of β-oxidation intermediates of different acyl chain lengths.

β-Oxidation of Unsaturated Fatty Acids

Unsaturated and polyunsaturated fatty acids also are degraded by β-oxidation. However, additional reactions are required to metabolize pre-existing double bonds that would otherwise interfere with the complete β-oxidation of unsaturated fatty acids. All double bonds found in unsaturated fatty acids can be classified as either odd- or even-numbered double bonds. Both classes are present in linoleic acid, which contains an odd-numbered double bond at position 9 and an even-numbered double bond at position 12 (see Figure 3).

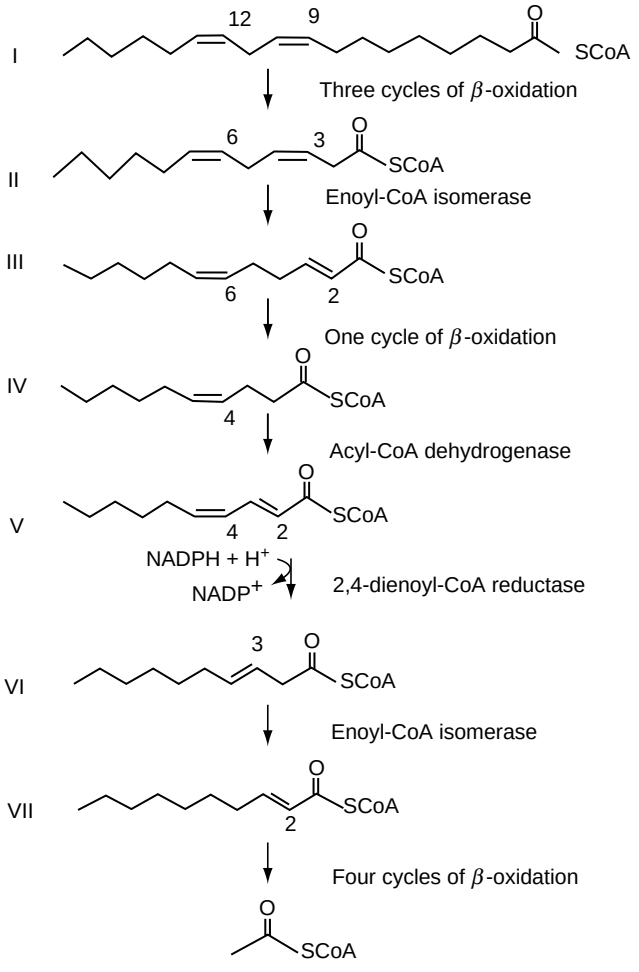

FIGURE 3 Pathway for the β-oxidation of linoleoyl-CoA.

The degradation of linoleic acid therefore illustrates the β-oxidation of all unsaturated fatty acids. As outlined in Figure 3, linoleoyl-CoA (I; all Roman numerals refer to compounds shown in Figure 3), after passing three times through the β-oxidation cycle, yields 3-*cis*,6-*cis*-dodecadienoyl-CoA (II). This metabolite cannot enter another cycle of β-oxidation due to interference by the double bond at position 3. However, an additional (auxiliary) enzyme, Δ^3,Δ^2-enoyl-CoA isomerase (enoyl-CoA isomerase), converts 3-*cis*,6-*cis*-dodecadienoyl-CoA (II) to 2-*trans*,6-*cis*-dodecadienoyl-CoA (III) that can complete its pass through one cycle of β-oxidation to yield 4-*cis*-decenoyl-CoA (IV). 4-*cis*-Decenoyl-CoA is dehydrogenated by acyl-CoA dehydrogenase to 2-*trans*,4-*cis*-decadienoyl-CoA (V), which is not a substrate of β-oxidation but which is reduced by NADPH in the presence of 2,4-dienoyl-CoA reductase, the second auxiliary enzyme, to 3-*trans*-decenoyl-CoA (VI). The latter compound is converted by enoyl-CoA isomerase to 2-*trans*-decenoyl-CoA (VII) that can be completely degraded by β-oxidation. A third auxiliary enzyme, $\Delta^{3,5}$,$\Delta^{2,4}$-dienoyl-CoA isomerase (dienoyl-CoA isomerase), catalyzes the isomerization of 3,5-dienoyl-CoA to 2,4-dienoyl-CoA. This reaction facilitates the complete β-oxidation of 3,5-dienoyl-CoAs that are minor metabolites of unsaturated fatty acids with odd-numbered double bonds.

Regulation of Mitochondrial Fatty Acid Oxidation

The rate of fatty acid oxidation changes in response to the nutritional and hormonal state of the animal. The rate of fatty acid oxidation is high during fasting but low in the fed animal. One cause for this change is the higher concentration of unesterified (free) fatty acids in the circulation of the fasting animal as compared to the concentration in the fed animal. An increased concentration of free fatty acids results in higher rates of cellular uptake and oxidation of fatty acids. In liver, which has high capacities for both synthesizing and oxidizing fatty acids, a reciprocal relationship exists between these two processes. After feeding, when carbohydrates are converted to triacylglycerols, the rate of fatty acid synthesis is high because acetyl-CoA carboxylase is active. This enzyme catalyzes the carboxylation of acetyl-CoA to malonyl-CoA, the first committed intermediate in fatty acid synthesis. Malonyl-CoA binds to and effectively inhibits CPT I that initiates the uptake of fatty acids by mitochondria. Thus, when fatty acids are rapidly synthesized, the cytosolic concentration of malonyl-CoA is high and the mitochondrial uptake and oxidation of fatty acids are inhibited. This situation is reversed during fasting when lower blood glucose levels cause the plasma

concentration of the hormone glucagon to increase and that of insulin to decrease. Glucagon promotes the phosphorylation and inactivation of acetyl-CoA carboxylase with the result that the cytosolic concentration of malonyl-CoA declines. The lower concentration of malonyl-CoA causes fatty acid synthesis to decrease and fatty acid oxidation to increase. The same regulatory mechanism may be effective in tissues like heart and skeletal muscle that oxidize fatty acids but do not synthesize them. Although malonyl-CoA is generated in these tissues by acetyl-CoA carboxylase, it seems to be metabolized by decarboxylation catalyzed by malonyl-CoA decarboxylase.

Fatty Acid Oxidation in Peroxisomes

Peroxisomes of animal cells contain a β-oxidation system that partially degrades fatty acids in contrast to mitochondria that break down fatty acids completely. The enzymes of peroxisomal and mitochondrial β-oxidation are not the same. Different genes encode most of the peroxisomal and mitochondrial enzymes. Substrates of peroxisomal β-oxidation are the CoA derivatives of fatty acids and carboxylic acids that are poorly or not at all taken up by mitochondria as, for example very long-chain fatty acids, methyl-branched carboxylic acids like pristanic acid, prostaglandins, dicarboxylic acids, xenobiotic compounds like phenyl fatty acids, and hydroxylated cholestanoic acids that are precursors of cholic acid. However, peroxisomes of lower eukaryotes catalyze the complete β-oxidation of fatty acids, whereas mitochondria in the same organisms generally are devoid of a functional β-oxidation system.

The uptake and activation of fatty acids by peroxisomes remain poorly understood. While some fatty acids like very long-chain fatty acids may be activated by conversion to CoA esters in the peroxisomal matrix after directly entering animal peroxisomes, other fatty acids or carboxylic acids seem to be activated outside of peroxisomes. The uptake of fatty acyl-CoAs by peroxisomes is suspected to take place but has not been demonstrated. Carnitine does not seem to be required for this uptake.

The four reactions of β-oxidation in peroxisomes are similar to the corresponding mitochondrial reactions (see Figure 2). An exception is the first reaction, in which fatty acyl-CoA is dehydrogenated to 2-*trans*-enoyl-CoA by acyl-CoA oxidase while oxygen is reduced to H_2O_2 (see Figure 2, reaction 1b). The latter product is converted to H_2O and O_2 by catalase that is present in peroxisomes. At least two acyl-CoA oxidases exist in animal peroxisomes; one named palmitoyl-CoA oxidase is active with long-chain and medium-chain, but not short-chain acyl-CoAs that have straight acyl chains while the second acyl-CoA oxidase also acts on branched-chain acyl-CoAs. Since the acyl-CoA oxidase activity of lower eukaryotes extends over the whole spectrum of acyl-CoAs of various chain lengths, peroxisomes in these organisms, in contrast to those in animals, can degrade fatty acids completely. The second and third reactions of peroxisomal β-oxidation are catalyzed by enoyl-CoA hydratase and 3-hydroxyacyl-CoA dehydrogenase, respectively, that are associated with a same polypeptide. Two such multifuntional enzymes, MFE 1 and MFE 2, are present in animal peroxisomes. They differ from each other in that the 3-hydroxyacyl-CoA intermediate formed and acted upon by MFE 1 has the L configuration, whereas the intermediate of MFE 2 is the D isomer. Peroxisomes of yeast and fungi only contain the type 2 multifunctional enzymes. Two types of 3-ketoacyl-CoA thiolases are present in rat peroxisomes. One of these thiolases, referred to as SCP_x-thiolase, is unusual because it is part of a bifunctional protein that additionally contains a lipid-binding segment named sterol carrier protein (SCP). Studies with β-oxidation mutants have led to the conclusion that the partial β-oxidation of straight-chain fatty acyl-CoAs, like very long-chain fatty acyl-CoAs, in animal peroxisomes requires palmitoyl-CoA oxidase, MFE 2, and 3-ketoacyl-CoA thiolase, whereas the partial degradation of branched-chain acyl-CoAs, like pristanoyl-CoA, involves branched-chain acyl-CoA oxidase, MFE 2, and SCP_x-thiolase. Unsaturated and polyunsaturated fatty acids also are partially degraded in peroxisomes. The necessary additional enzymes, enoyl-CoA isomerase, 2,4-dienoyl-CoA reductase, and even dienoyl-CoA isomerase, are present in this organelle. The products of peroxisomal β-oxidation are chain-shortened acyl-CoAs, NADH, and acetyl-CoA. Additionally propionyl-CoA is formed when methyl-branched-chain substrates are degraded. Acyl-CoAs may be converted to the corresponding acylcarnitines before they exit from peroxisomes. The necessary carnitine acyltransferases active with medium-chain and short-chain acyl-CoAs have been identified in peroxisomes. However, little is known about transporters that facilitate the efflux of products from peroxisomes.

α-Oxidation and ω-Oxidation

α-Oxidation is the process that results in the oxidative removal of the first carbon atom, the carboxyl group, of a fatty acid or carboxylic acid to yield CO_2 and a fatty acid or carboxylic acid shortened by one carbon atom. In animals, this process occurs in peroxisomes where, for example phytanic acid, which is derived from phytol of chlorophyll and which cannot be degraded by β-oxidation, is chain-shortened by one carbon atom to

pristanic acid that can be degraded by β-oxidation. ω-Oxidation is the process by which fatty acids are oxidized at their terminal (ω) or penultimate (ω-1) carbon atom to form dicarboxylic acids. This process occurs at the endoplasmic reticulum and requires molecular oxygen. When β-oxidation of fatty acids is impaired, more fatty acids are converted to dicarboxylic acids by ω-oxidation.

Biography

Horst Schulz is a Professor in the Department of Chemistry at City College of the City University of New York. His main research interest is the β-oxidation of saturated and unsaturated fatty acids with an emphasis on fatty acid oxidation in mitochondria. He received a Ph.D. from the Technische Universität Berlin in Germany and carried out research as a postdoctoral fellow at Cornell University Medical College and Duke University Medical Center.

Fatty Acid Receptors

Christer Owman and Björn Olde
Lund University, Lund, Sweden

Lipids provide energy to the organism and contribute to various cellular components, including organelles and plasma membranes. A particular class of lipids are unesterified and are usually known as free fatty acids. Although dietary fatty acids have a major role as nutrients in various types of metabolic functions, some of them also exert more specialized functions as signaling molecules when they act as messengers between cells and within tissues.

It became evident in the early 1990s that such functions were mediated via a family of transcription factors called peroxisomal proliferator-activated receptors (PPARs). This class of nuclear receptors plays a central role in regulating the storage and degradation of dietary lipids. However, not all biological effects of free fatty acids can be explained by nuclear receptor signaling, but rather show the characteristics of a cell surface receptor involvement. Indeed, a decade after the discovery of the PPARs, a group of free-fatty acid-activated receptors (FFARs), expressed on the cell surface, could be identified. They all belong to the superfamily of G protein-coupled receptors (GPCRs), which is the most widely distributed class of receptors on eukaryotic cells.

The two classes of fatty acid-activated receptors appear to have an overlapping, but not identical, function. It should now be possible to unfold many hitherto unexplained observations on the actions of free fatty acids in both normal and pathophysiological situations.

The PPAR Family of Receptors

The PPARs (Figure 1) constitute a family of three nuclear receptor isoforms named PPARα, PPARδ (sometimes called PPARβ), and PPARγ. They function as transcription factors in response to specific ligands and thereby control gene expression by binding to various response elements within gene promoters. The receptors always bind as heterodimers together with the so-called retinoid X receptor. Like the PPARs, the retinoid X receptor exists in three isoforms which are all activated by the naturally occurring 9-*cis* retinoic acid. After binding of the ligand to the receptor dimers, these interact with cofactors, resulting in increased rate of transcription initiation. All three receptor subtypes are localized in different chromosomes. The PPAR receptors have a physiological role as regulators in the metabolism of dietary lipids. Free fatty acids with long carbon chains, and particularly polyunsaturated fatty acids, constitute the major natural ligands for PPARs. The nuclear receptor family also includes receptors for steroid, thyroid, and retinoid hormones.

PPARα

The receptor PPARα is expressed in many metabolically active tissues, including heart, skeletal muscle, kidney, liver, as well as brown fat. In addition, it has a vascular localization, both in endothelium and smooth muscle cells, and is also present in monocytes (Figure 1). Accordingly, PPARα has been found to effectively improve cardiovascular risk factors, and it also enhances cardiovascular performance. It exerts a critical function in the regulation of the cellular uptake, activation, and β-oxidation of fatty acids; the receptor directly up-regulates enzymes in the peroxisomal β-oxidation pathway. PPARα was also suggested to be involved in immunmodulatory functions when it was found that leukotriene B_4 could specifically activate the receptor.

PPARδ

This receptor subtype (Figure 1) was first cloned as PPARβ in frog, but the generally agreed name for the receptor is now PPARδ. It has a ubiquitous localization in the body (often at lower expression levels than PPARα and γ), with a particularly high expression in brain, adipose tissue, and in skin. It is likely that PPARδ is involved in lipid homeostasis since, like the other two isoforms, it is activated by fatty acids and fatty acid metabolites. The ligand-binding profile is intermediate between PPARα and PPARγ. PPARδ has been suggested to be involved in the differentiation of cells within the central nervous system, and it may also have a role in myelinization and lipid metabolism in brain. The receptor has been reported to have importance for wound healing as well as in female fertility.

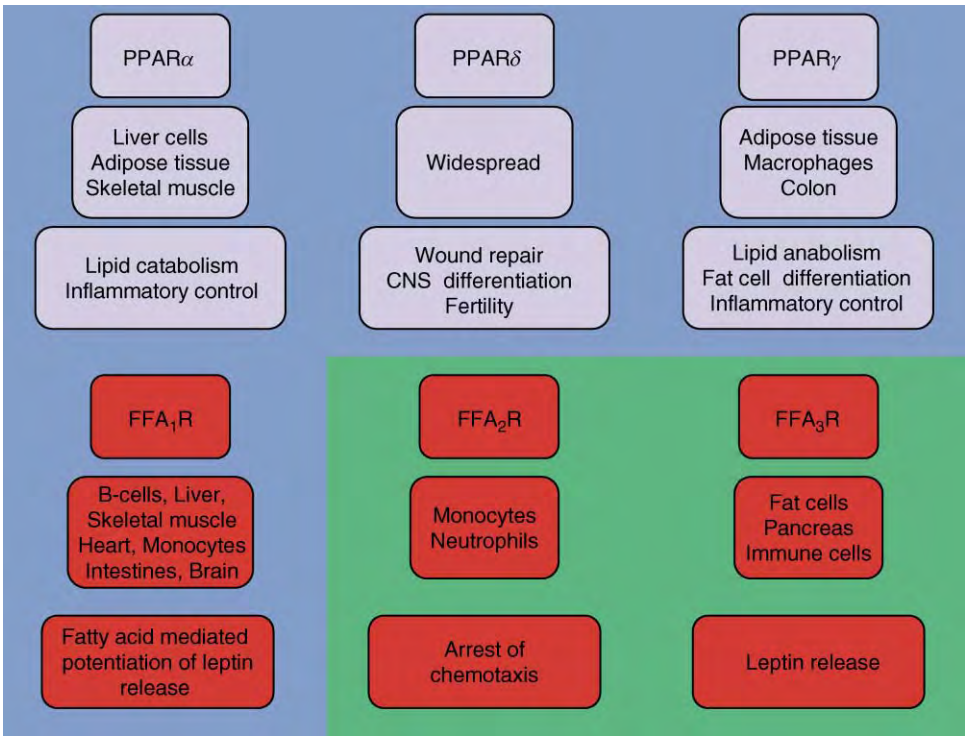

FIGURE 1 Panel summarizing the expression patterns (upper boxes) and the functional characteristics (lower boxes) of the two fatty acid receptor families, the PPARs and the FFARs. The blue background shading indicates the four receptors that are activated by medium- to long-chain free fatty acids, whereas the green background points out the two receptors that are activated by short-chain free fatty acids.

PPARγ

PPARγ is the most extensively studied of the three receptor subtypes. It shows, in contrast to the two other receptors, a considerable degree of conservation – some 95% identity at the protein level – among the various species from which is has been cloned. Three receptor isoforms, numbered 1–3, have been reported to arise from different promoter utilization. While PPARγ1 is expressed in a wide range of tissues, PPARγ2 is found predominantly in adipose tissue, whereas PPARγ3 is expressed only in adipose tissue, macrophages, and colon epithelium (Figure 1). PPARγ is a critical transcription factor in the regulation of adipocyte differentiation, and it also exerts an important function in insulin sensitization, atherosclerosis, and cancer. Activation of the receptor induces differentiation of cells into adipocytes, and it promotes the transcription of numerous important lipogenic proteins. It appears that PPARα and γ exert opposite but complementary functions in fat energy homeostasis; the former having a catabolic function whereas the latter is involved in lipid anabolism and energy storage.

It is evident from the above descriptions that the PPAR receptor family should play important roles in various types of life-style diseases. Actually, much of the focus on PPARγ is related to fatty acids being risk factors in type 2 diabetes, and to the fact that modern anti-diabetic substances of the thiazolidinedione class may use this receptor as a target, although other pathways for thiazolidinedione actions seem to exist. The compounds, also known as glitazones, exert their beneficial effect by enhancing the sensitivity of target tissues to insulin and by reducing the plasma levels of fatty acids, glucose, and insulin.

The FFAR Family of Receptors

In contrast to the nuclear PPAR receptors, the FFAR family consists of receptors that are localized to the plasma membrane of cells. Here, the receptor protein anchors as a serpentine with seven membrane-spanning helical segments, a typical feature of the superfamily of GPCRs. Based on this general structure they are also known as 7TM (for transmembrane) or heptahelix receptors. The three separate genes encoding the receptors of this family are present in a cluster on chromosome 19. As illustrated in Figure 1, the PPARs are activated only by free fatty acids having a carbon chain length above twelve, while the ligand spectrum for the FFARs include chain lengths down to one (formiate). The receptors are well conserved both in mammals and fish.

FFA_1R

This receptor was originally presented as an orphan receptor (i.e., without known ligand/function) with the provisional designation GPR40. Its identity and function was reported independently by three groups early in the year 2003. The encoded human receptor protein consists of 300 amino acid residues. FFA_1R is characteristically activated by medium-length (down to 10 carbons) to long-chain free fatty acids. Besides the effect of the natural ligands, a very intriguing observation was that also the anti-diabetic thiazolidinedione compound, rosiglitazone, activated the receptor.

According to the current understanding this novel receptor is primarily expressed in the insulin-producing pancreatic islets. It has also been reported to be present in liver, skeletal muscle, heart, intestines, monocytes, as well as in brain. FFA_1R has been tied to the so-called fatty acid potentiation of glucose-stimulated insulin secretion (GSIS) by pancreatic β-cells. In fact, fatty acids, like linoleic acid and γ-linoleic acid, have been shown to stimulate insulin release in mouse insulinoma cells through FFA_1R.

The identification of FFA_1R, having a ligand spectrum that is overlapping that of PPARγ (Figure 1), offers a new type of nutrient sensor in lipid homeostasis. It may provide a basis for understanding hitherto unexplained mechanisms involved in insulin release as well as in thiazolidinedione functions related to various therapeutic areas.

FFA_2R

The second FFAR, FFA_2R (previously known as GPR43), has the same general structure as FFA_1R and consists of 330 amino acid residues. In contrast to the latter, it is activated by short-chain (C1–C6) fatty acids, acetate (C2) being the most effective. It has a different expression pattern (Figure 1) in that it is found mainly in polymorphonuclear leukocytes, predominantly in monocytes and neutrophils.

Activation of FFA_2R expressed on immune cells causes pertussis toxin sensitive calcium mobilization and also leads to arrest of cellular chemotaxis. It is likely that this response is part of an immunmodulatory mechanism within the alimentary tract whereby short-chain fatty acids, known to be produced by the enteric bacteria, control the invasion of immune cells.

FFA_3R

The receptor, FFA_3R, was previously known as GPR41 and is structurally more closely related to FFA_2R than to FFA_1R. It forms a seven membrane-spanning protein comprising 346 amino acid residues. (A fourth annotated receptor, designated GPR42, has 98% deduced amino acid homology with GPR41; the corresponding gene is probably a pseudogene.) As depicted in Figure 1, the fatty acid ligand spectrum for FFA_3R is similar to that of FFA_2R, although butyrate (C4) and pentanoate (C5) are the most potent agonists for FFA_3R. The elicited response (as in the case of FFA_2R) is clearly pertussis toxin-sensitive. FFA_3R is predominantly expressed in adipose tissue, although expression has been reported also in pancreas and immune cells, as well as in placenta. FFA_3R has recently been shown to control leptin production in adipocytes.

Glossary

G protein Abbreviated term for "GTP (guanosine triphosphate)-binding regulatory protein," which, upon membrane receptor activation, serves as an intermediary protein between the receptor and a cell membrane-bound enzyme or ion channnel.

peroxisome Membrane-surrounded cell organelle where, e.g., hydrogen peroxide is generated and degraded.

promoter Specific DNA sequence containing the start site for RNA synthesis.

pseudogene Nonfunctional gene closely related to functional genes.

transcription factor Controls gene transcription and is one of several sequence-specific DNA-binding regulatory proteins.

Biography

Christer Owman is M.D. and Ph.D. (Lund University, Sweden) and Professor and Chair of the Division of Molecular Neurobiology, Department of Physiological Sciences, Wallenberg Neuroscience Center at the same University. He has published extensive work on autonomic neuro-receptor mechanisms. His present research interest is in molecular aspects of GPCRs, and he has discovered several previously unknown GPCRs. He is scientific founder of the small biotech company, HeptaHelix AB. He has served two terms as Dean of the Medical Faculty, Lund University.

Björn Olde is a Ph.D. from Lund University and is an associate professor there. He spent most of an extensive postdoctoral period with Dr. Craig Venter. His principal interest is in basic research and drug development focusing on GPCRs. He has developed uniquely sensitive cell-based reporter systems successfully applied to "deorphanize" several hitherto unknown GPCRs, followed by their further functional characterization.

Fatty Acid Synthesis and its Regulation

Steven D. Clarke
McNeil Nutritionals, New Brunswick, New Jersey, USA

Manabu T. Nakamura
University of Illinois at Urbana-Champaign, Illinois, USA

Fatty acid synthesis involves the *de novo* assembly of acetate into saturated fatty acids as well as the desaturation and elongation of the dietary essential fatty acids linoleic acid (C18:2$_{n-6}$) and α-linolenic acid (C18:3$_{n-3}$) to highly unsaturated 20- and 22-carbon fatty acids essential to reproduction, cell differentiation, inflammation, and cognition. Short-chain fatty acids are derived largely from bacterial fermentation such as that which occurs in the gut or rumen. Medium-chain fatty acids are characteristic of milk fat and are absorbed from the intestine directly into the portal blood, and subsequently metabolized largely by the liver. Fatty acids containing 14 or more carbons are absorbed from the intestine and transported to the periphery as chylomicrons. Very long chain fatty acids are largely found in neural tissue and used for myelin formation. Net fatty acid synthesis by humans is relatively small, but the *de novo* fatty acid biosynthetic pathway is essential for the production of malonyl-CoA, a metabolite inhibitor of carnitine palmitoyltransferase. Consequently, substrate flux through the *de novo* lipogenic pathway plays a key role in determining if a fatty acid is partitioned to fatty acid oxidation or triglyceride assimilation.

De novo Fatty Acid Biosynthesis of Saturated Fatty Acids

Saturated fatty acids are categorized as short (C2–C6), medium (C8–C12), long (C14–C18), and very long (C20–C24) fatty acids. Short-chain fatty acids are derived largely from bacterial fermentation such as that which occurs in the gut or rumen. Medium-chain fatty acids are characteristic of milk fat and are absorbed from the intestine directly into the portal blood, and subsequently metabolized largely by the liver. Fatty acids containing 14 or more carbons are absorbed from the intestine and transported to the periphery as chylomicrons. Very long chain fatty acids are largely found in neural tissue and used for myelin formation. The liver and adipose tissue of humans are the primary sites of conversion of excess carbohydrate to fatty acids, but fatty acid synthesis is more than just for conserving excess glucose as fat. Fatty acid synthesis is essential for cell membrane production, lung surfactant function, milk fat production, brain myelination, and fat storage. Consequently, nearly all tissues have the capacity to synthesize fatty acids.

De novo fatty acid biosynthesis in humans occurs in cytosol. Two enzymes, acetyl CoA carboxylase and fatty acid synthase, are required for this process. The first and rate-limiting step is the conversion of acetyl CoA to malonyl CoA by acetyl CoA carboxylase:

$$\begin{aligned} &CH_3CO-S-CoA + HCO_3^- + ATP \\ &\quad \rightarrow {}^-OOC-CH_2CO-S-CoA + H_2O + ADP + Pi \end{aligned}$$

Fatty acid synthase catalyzes all of the subsequent steps for the synthesis of long-chain saturated fatty acids. Fatty acid synthase is made of a single peptide chain that possesses seven distinct catalytic domains. Fatty acid synthase first adds two carbons to acetyl CoA using malonyl CoA. NADPH is used as a reducing power in this reaction:

$$\begin{aligned} &CH_3CO-S-CoA + {}^-OOC-CH_2CO-S-CoA \\ &\quad + Enzyme-SH + 2NADPH + 2H^+ \\ &\quad\quad \rightarrow CH_3CH_2CH_2CO-S-Enzyme + 2CoA-SH \\ &\quad\quad\quad + HCO_3^- + 2NADP^+ \end{aligned}$$

Fatty acid synthase repeats this acyl chain elongation two carbons at a time using malonyl CoA as a substrate:

$$\begin{aligned} &CH_3CH_2CH_2CO-S-Enzyme \\ &\quad + {}^-OOC-CH_2CO-S-CoA + 2NADPH + 2H^+ \\ &\quad\quad \rightarrow CH_3(CH_2)_3CH_2CO-S-Enzyme \\ &\quad\quad\quad + CoA-SH + HCO_3^- + 2NADP^+ \end{aligned}$$

When the carbon chain reaches 16, the thioesterase domain of fatty acid synthase releases free palmitate,

completing fatty acid biosynthesis.

$$CH_3(CH_2)_{14}CO-S-Enzyme + H_2O \rightarrow CH_3(CH_2)_{14}COO^- + H^+ + HS-Enzyme$$

Regulation of Pyruvate Entry into Mitochondria

Malonyl-CoA is the substrate used by fatty acid synthase to assemble the acetate units into fatty acids. Malonyl-CoA is produced from pyruvate through a series of reactions. The first step involves the mitochondrial formation of acetyl-CoA by pyruvate dehydrogenase's decarboxylation of pyruvate. This is followed by the intramitochondrial synthesis of citrate from acetyl-CoA and oxaloacetate. Citrate is transported from the mitochondria to the cytosol where it is cleaved by citrate lyase to cytosolic acetyl-CoA and oxaloacetate. The acetyl-CoA is available for carboxylation to malonyl-CoA by the biotin-containing enzyme acetyl-CoA carboxylase. The liver and adipose tissue of humans are the primary sites of conversion of excess carbohydrate to fatty acids. The source of hepatic or adipose pyruvate for fatty acid biosynthesis may be derived from the metabolism of glucose via the glycolytic pathway with the liver or adipocyte itself, or it may be provided to the liver and/or adipose tissues as lactate or alanine that is produced by glucose metabolism in peripheral tissues such as the small intestine and muscle. Entry of pyruvate into the tricarboxylic acid pathway of the mitochondria is determined by the activity of pyruvate dehydrogenase. The concentration of pyruvate dehydrogenase does not widely fluctuate, but its catalytic activity is suppressed by phosphorylation and enhanced by dephosphorylation of the enzyme. Insulin and glucose stimulate dephosphorylation, whereas glucagon and fatty acids enhance the phosphorylation. Thus, pyruvate entry into the mitochondria is highly dependent upon the macronutrient composition of the diet, and the ratio of insulin to glucagon.

Regulation of Malonyl-CoA Synthesis

The synthesis of malonyl-CoA is catalyzed by the biotin-containing enzyme acetyl-CoA carboxylase. Acetyl-CoA carboxylase exists as two isoforms: a liver or type I, and muscle or type II. Like pyruvate dehydrogenase, the catalytic activity, and hence the production of malonyl-CoA, of both acetyl-CoA carboxylase isoforms is regulated by phosphorylation and dephosphorylation of the protein. Acetyl-CoA carboxylase I and II are substrates for AMP kinase and cyclic AMP kinase. AMP kinase activity is enhanced by leptin and adiponectin, two hormones that stimulate fatty acid oxidation and inhibit fatty acid biosynthesis. The dephosphorylation of acetyl-CoA carboxylase is carried out by phosphatase 1 and 2, and phosphatase activity appears to be stimulated under conditions where glucose flux through glycolysis is high. Muscle acetyl-CoA carboxylase is not adaptive, but hepatic acetyl-CoA carboxylase, like other lipogenic enzymes, increases and decreases its concentration depending upon nutritional conditions, dietary composition, and hormonal milieu. For example, the hepatic abundance of acetyl-CoA carboxylase is low during fasting and diabetes, but is greatly induced by refeeding glucose or administering insulin.

Malonyl-CoA and Fatty Acid Metabolism

Malonyl-CoA is not only the substrate for fatty acid synthase, but it is a key determinant for the entry of fatty acids into the mitochondria, and appears to play a pivotal signaling role in appetite regulation. Malonyl-CoA is an inhibitor of carnitine palmitoyltransferase. Thus, high levels of malonyl-CoA suppress fatty acid entry into the mitochondria and this in turn leads to increased flux of fatty acids to triglycerides. On the other hand, conditions that lead to low cellular concentrations of malonyl-CoA favor fatty acid oxidation because the inhibition of carnitine palmitoyltransferase is released. Consequently, even though net fatty acid synthesis by humans may be relatively small, the fatty acid biosynthetic pathway plays an instrumental role in determining whether a fatty acid is stored as triglyceride or undergoes oxidation. Since excessive cellular triglyceride production and accumulation is causatively linked to the development of insulin resistance and type 2 diabetes, factors regulating the fatty acid biosynthetic pathway will exert a direct influence on the development of diabetes.

Nutritional Regulation of Lipogenic Gene Expression

Hepatic and adipose fatty acid biosynthesis is increased by the ingestion of a high-carbohydrate diet and decreased by the consumption of a high-fat diet. Dietary regulation of lipogenesis is not simply a product of nutritional manipulation of hormonal balance. Rather, nutrients exert a specific influence on the expression of glycolytic and lipogenic proteins. Nutrients exercise their influence by modulating gene transcription, mRNA processing, mRNA decay, and by stimulating posttranslational protein modifications.

Carbohydrate Induction of Lipogenic Gene Transcription

Since the early 1990s, a collection of transcription factors that are specifically targeted by glucose and fatty acids have been identified. Dietary carbohydrate induces lipogenic gene transcription in two ways. First, glucose increases the nuclear concentration of the potent lipogenic transcription factor, SREBP-1. SREBPs are a family of transcription factors that were first isolated as a result of their properties for binding to the sterol regulatory element of genes encoding proteins of sterol metabolism. SREBP-2 is a regulator of genes encoding proteins of cholesterol metabolism. SREBP-1 exists in two forms, 1a and 1c. SREBP-1a is the dominant form in cell lines and is a regulator of genes encoding proteins involved in fatty acid biosynthesis as well as cholesterolgenesis. SREBP-1c constitutes 90% of the SREBP-1 found *in vivo* and is a determinant of lipogenic gene transcription. SREBP-1 is synthesized as a 125 kDa precursor protein that is anchored in the endoplasmic reticulum membrane. Proteolytic release of the 68 kDa mature SREBP-1 occurs in the Golgi system, and movement of SREBP-1 from the endoplasmic reticulum to the Golgi requires the trafficking protein SREBP cleavage-activating protein. Once released, mature SREBP-1 translocates to the nucleus and binds to the classic sterol response element and/or to a palindrome CATG sequence. Glucose increases the abundance of precursor SREBP-1 by inducing SREBP-1 gene transcription. In addition, glucose elevates the nuclear concentration of SREBP-1 by stimulating the proteolytic release of mature SREBP-1 from its membrane-anchored precursor. A second effect of glucose is to stimulate the DNA binding activity of select transcription factors involved with the transcription of lipogenic genes, notably a unique carbohydrate response factor (CHORF). Glucose exerts its effect by elevating the cellular concentration of the pentose shunt metabolite xylulose-5-phosphate. Xylulose-5-phosphate is a positive metabolite effecter of phosphatase 2A, and increased phosphatase activity leads to the dephosphorylation of CHORF and a subsequent increase in its DNA binding to a specific carbohydrate response element (CHORE) in select glycolytic (e.g., pyruvate kinase) and lipogenic (e.g., fatty acid synthase) genes. The consequence is an increase in gene transcription followed by a rise in the abundance of glycolytic and lipogenic enzymes.

Suppression of Lipogenic Gene Expression by omega-6 and -3 Fatty Acids

Glucose stimulation of lipogenesis is a nice example of a feedforward regulatory mechanism that functions to enhance glucose storage as fatty acids. Interestingly the saturated fatty acid products of the *de novo* fatty acid synthetic pathway do not feedback and suppress glycolytic and lipogenic gene expression or activity. Only omega-6 and -3 fatty acids (e.g., linoleic ($C18:2_{n-6}$) and α-linolenic ($C18:3_{n-3}$)) interfere with glycolytic and lipogenic gene expression (Figure 1). Highly unsaturated 20- and 22-carbon omega-6 and -3 fatty acids (HUFAs) inhibit glycolytic and lipogenic gene transcription through two different types of DNA regulatory response regions (HUFA-RR). One type overlaps with the insulin response element (HUFA-RR/IRE), while the second region colocalizes with the carbohydrate response element (HUFA-RR/CHORE).

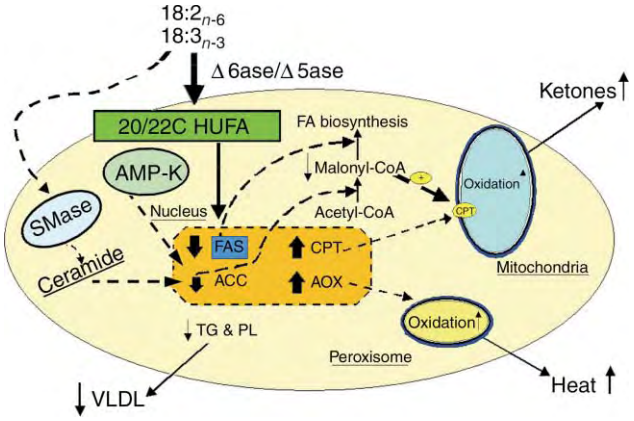

FIGURE 1 Regulation of hepatic gene expression and lipid metabolism by highly unsaturated fatty acids. Δ6ase, Δ-6 desaturase; Δ5ase, Δ-5 desaturase; HUFA, highly unsaturated fatty acids; AMP-K, AMP-kinase; SMase, sphingomyelinase; TG, triglyceride; PL, phospholipid; FA, fatty acids; FAS, fatty acid synthase; ACC, acetyl-CoA carboxylase; CPT, carnitine palmitoyltransferase; AOX, acyl-CoA oxidase; VLDL, very low density lipoproteins.

Colocalization of the HUFA-Response Region with the Insulin Response Element

The HUFA-RR/IRE contains recognition sequences for SREBP-1c, NF-Y, Sp1, and USF. HUFAs inhibit the activity of promoters containing the HUFA-RR/IRE by decreasing SREBP-1c and NF-Y interactions with their respective recognition sequences. HUFAs lower the concentration of SREBP-1 precursor protein as well as inhibit the proteolytic release and nuclear localization of mature SREBP-1. The HUFA-dependent inhibition of the proteolytic release of mature SREBP-1 and -2 may involve a stimulation of sphingomyelin hydrolysis and subsequent ceramide signaling. In addition to inhibiting the proteolytic release of SREBP-1, HUFAs reduce the cellular content of precursor SREBP-1 protein by reducing the cellular abundance of SREBP-1 mRNA. HUFAs decrease the hepatic abundance of SREBP-1 mRNA, and consequently the

hepatic content of precursor SREBP-1 protein, by accelerating SREBP-1 mRNA decay and by suppressing SREBP-1 gene transcription. The mechanisms by which HUFAs accelerate SREBP-1 mRNA decay remain unclear, but the mechanisms by which HUFAs suppress SREBP-1 gene transcription are beginning to emerge. The SREBP-1 gene contains two response elements for the lipogenic transcription factor LXR. Oxysterol ligand activation of LXR induces the transcription of SREBP-1. HUFAs reportedly displace oxysterol from LXR and in this way antagonize the transactivation activity of LXR. In addition, HUFAs may stimulate the "trapping" of LXR as a PPARα/LXR heterodimer. Thus, when the ratio of HUFA to oxysterol is low LXR/RXR heterodimers favor lipogenic gene expression, but when the ratio of HUFA to oxysterol is high, the PPARα/LXR and PPARα/RXR heterodimer mixtures are poised towards a gene profile that favors fatty acid oxidation over fatty acid synthesis. Although SREBP-1 metabolism is highly responsive to HUFA, it is only one of several transcription factors targeted by HUFA. In fact, $>50\%$ of the HUFA control of fatty acid synthase gene transcription can be attributed to the NF-Y site at $-99/-93$. NF-Y is an abundant heterotrimeric nuclear protein that interacts with histone acetyl transferases, and consequently plays a role in modifying histone structure. HUFAs do not reduce the nuclear abundance of NF-Y but rather suppress NF-Y transactivation activity by decreasing its DNA binding activity.

A Cho-Response Element within a Hufa-Response Region

The HUFA-RR of certain lipogenic genes, notably fatty acid synthase, contains DNA-binding sites for several transcription factors (e.g., carbohydrate response factor, HNF-4) whose DNA-binding activity is governed by the amount and type of fat in the diet. One factor that binds to this region and has received significant attention has been the carbohydrate response factor that uniquely interacts with the CHORE. The DNA binding activity of carbohydrate response factor is dependent upon its state of phosphorylation. Fatty acid activation of AMP-kinase leads to increased phosphorylation of the carbohydrate response factor and consequently decreased DNA binding and trans-activation activity. How HUFAs selectively activate AMP-kinase remains to be determined, but HUFA inhibition of lipogenesis and HUFA stimulation of fatty acid oxidation are consistent with the established role that AMP-kinase plays in the partitioning of fatty acids between triglyceride storage and fatty acid oxidation.

Unsaturated Fatty Acid Synthesis

Oleic and Palmitoleic Acid Synthesis

Palmitate (C16:0) and stearate (C18:0) are rapidly desaturated to mono-unsaturated palmitoleic (C16:1) and oleic (C18:1) acids by the stearoyl-CoA desaturase (also known as Δ-9 desaturase) system (Figure 2). Stearoyl-CoA desaturase exists in multiple isoforms that are derived from separate genes. The dominant form within a cell depends upon the origin of the cell. Stearoyl-CoA desaturase inserts a double bond between carbons 9 and 10. This desaturation reaction requires three different components: the desaturase itself, cytochrome b5, and cytochrome b5 reductase. Oleic acid synthesis is required for a variety of reasons. In particular it appears to be required for the hepatic secretion of very low-density lipoproteins.

Arachidonic and Docosahexenoic Acid Synthesis

While oleic acid clearly plays an important role in overall energy metabolism, it cannot fulfill the biological requirements for growth, reproduction, cell signaling, and cell differentiation. These requirements can only be fulfilled by long chain fatty acids from the omega-6 and omega-3 fatty acid family, i.e. linoleic ($C18:2_{n-6}$)

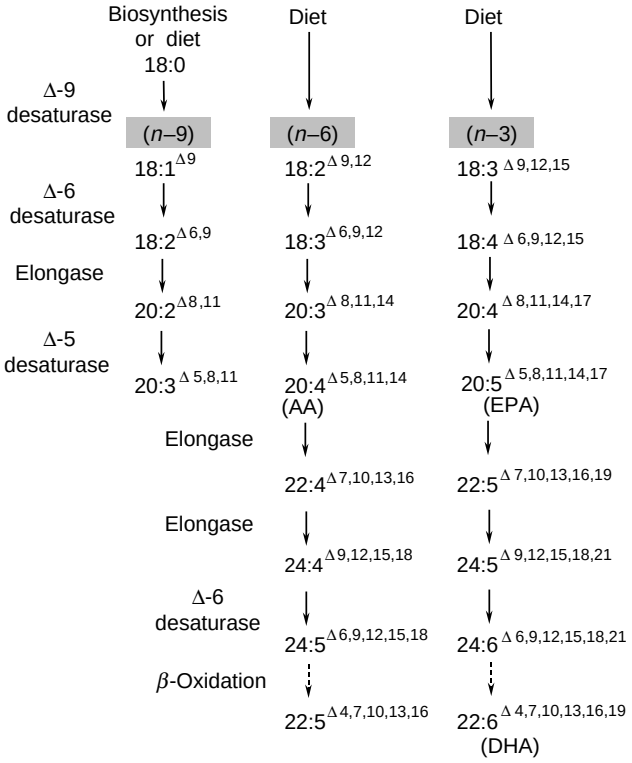

FIGURE 2 Synthesis of highly unsaturated fatty acids.

and α-linolenic (C18:3$_{n-3}$), respectively (Figure 2). Linoleate and α-linolenate undergo desaturation and elongation to 20- and 22-carbon highly unsaturated fatty acids. Prostaglandins and leukotrienes produced from arachidonic acid (C20:4$_{n-6}$) are required for blood clotting, cardiac function, reproduction, inflammatory response, and cell differentiation. Docosahexaenoic acid (C22:6$_{n-3}$) is required for cognition and brain development. Formation of bio-active 20- and 22-carbon highly unsaturated omega-6 and -3 fatty acids requires that the dietary essential fatty acids, linoleate and α-linolenate undergo two steps of desaturation that are catalyzed by the Δ-6 desaturase and Δ-5 desaturase. Both desaturases are expressed in all tissues. The human desaturase genes are members of a gene cluster on chromosome 11 that includes a third desaturase of unknown function, and a non-coding RNA gene that encodes an anti-sense transcript for Δ-5 desaturase. Nearly all human tissues express the products of the Δ-6 desaturase gene cluster. Unlike the stearoyl-CoA desaturase, the Δ-6 and Δ-5 desaturases contain a cytochrome b5 domain within the desaturase peptide. The rate of production of 20- and 22-carbon highly unsaturated fatty acids is dependent upon the tissue content of the two desaturases, and this in turn in determined by nutritional and hormonal factors that are similar to those that regulate the expression of lipogenic genes. The one notable difference between lipogenic and desaturase genes is that while HUFAs suppress both gene families, activators of peroxisome proliferator activator receptor-α induce desaturase genes but they suppress lipogenic genes. The increase in desaturase expression may be in response to a greater need for unsaturated fatty acids for the production of phospholipids, particularly in the liver for the secretion of very low density lipoproteins.

Biography

Steven D. Clarke is a Director of Science Research at McNeil Nutritionals. Dr. Clarke's research for over 25 years has addressed the nutrient control of the lipid metabolism with particular interest in nutrient–gene interactions. His research has resulted in over 100 publications, and he was among the first to recognize the unique role that polyunsaturated fatty acids play as nutrient sensors for the regulation of fatty acid synthesis and oxidation.

Manabu T. Nakamura received a Ph.D. from the University of California at Davis and is an Assistant Professor of Nutrition at the University of Illinois at Urbana-Champaign. Dr. Nakamura's research focuses on the mechanism by which animals adapt to a wide variety of diets. In particular, he has been working on the regulation of highly unsaturated fatty acid synthesis in mammals.

Ferredoxin

Giuliana Zanetti and Vittorio Pandini
Università degli Studi di Milano, Milan, Italy

Under the name ferredoxin (Fd) are comprised ubiquitous, small proteins containing one or two iron-sulfur clusters. These prosthetic groups contain iron and sulfur atoms, organized in three different types of centers: 2Fe–2S, 4Fe–4S, and 3Fe–4S. The presence of the cluster(s) confers to the protein the property of absorbing light in the visible region. Fd solutions are thus reddish brown in the oxidized state and fade upon reduction. Despite the type and number of clusters bound, Fds generally function in oxidoreduction reactions. Many Fds are involved as electron carrier of low redox potential in electron transport chains of fundamental metabolic processes like photosynthesis, nitrogen fixation, and assimilation of hydrogen, nitrogen, and sulfur. The first report of a nonheme iron protein in the bacterium *Clostridium pasteurianum* appeared in 1962, and was immediately followed by the discovery of a Fd in spinach chloroplast. By now, the family of Fds is greatly increased. Bacteria generally harbor many Fds, which differ in amino acid sequence, FeS cluster type, redox potential, and function. Eukaryotic organisms instead contain just one or two Fds of the 2Fe–2S type, except for plants in which several isoforms coexist. Here we will focus on this type of Fds with special emphasis on ferredoxin I of chloroplast.

2Fe Ferredoxins

The 2Fe ferredoxins (Fds) are hydrophilic, acidic proteins of 11–15 kDa which harbor a single 2Fe–2S cluster coordinated by four cysteine residues. They function as single-electron shuttle in fundamental metabolic processes. The family can be subdivided in two major classes, the mitochondrial-type and the plant-type Fds, based on the cysteine spacing in the iron–sulfur binding motif, the three-dimensional structure, and function. A third class of bacterial 2Fe–Fds has recently been recognized on the basis of sequence and spectroscopic properties.

Plant-Type 2Fe Fds

More than a hundred sequences of 2Fe Fds have been deposited in sequence databases. The polypeptide chain is 93–98 residues long, yielding a protein of molecular mass ~11 kDa. The archetype of this class is the chloroplast ferredoxin I (FdI), which in addition to its main role in the photosynthetic electron transfer to Fd–$NADP^+$ reductase (FNR), provides electrons to a large number of Fd-dependent enzymes involved in assimilatory and regulatory pathways (Figure 1).

Molecular Structure

The characteristic spacing of the cysteinyl residues in the iron-sulfur cluster binding motif for this class is $C–X_4–C–X_2–C$, which provides three of the four thiolate ligands to the two iron atoms, with the fourth ligand 29 residues downstream in the primary structure. Several Fds have been structurally characterized either by X-ray crystallography or NMR spectroscopy. They show a folding motif, dubbed β-grasp, which is similar to that of ubiquitin. It is constituted by a four-stranded antiparallel β-sheet and an α-helix lying perpendicularly to the sheet. A representation of the structure of recombinant spinach FdI is depicted in Figure 2 to show the secondary structure elements. The central core (β-grasp) holds the loop which harbors the Cys motif for binding the iron-sulfur cluster. In addition, two short β-strands, a second α-helix and a short C-terminal helical turn are present. The binuclear iron cluster is located near the surface of the protein with Fe1 atom more exposed to solvent. Upon protein reduction, Fe1 has been shown to become reduced. The surface of the Fd molecule shows an asymmetry in distribution of the many acidic residues, which cluster in two distinct areas around the FeS prosthetic group. This feature common to all plant-type Fds has been shown to be important for interaction with protein partners.

Physiological Function

The nuclear encoded FdI is imported in the chloroplast as an apoprotein, where it acquires the prosthetic group. FdI biosynthesis is under the control of light. As depicted in Figure 1, FdI forms transient electron transfer complexes with several different proteins. First it is reduced through electron transfer from the 4Fe–4S

(B) Detail of the iron–sulfur cluster showing the side chains of the cysteines (residues 39, 44, 47, and 77) and the two sulfide sulfur atoms which coordinate the two iron atoms. The figure was made with Molmol.

centers (F_A and F_B) of the subunit PsaC of photosystem I, by docking both to the PsaD and the PsaE subunits at the stromal side of the thylakoid membrane. Then, the reduced protein donates its electron to either one of the various enzymes known to be Fd dependent. NADPH production through FNR is the main role of FdI. Several studies employing a number of different techniques have attempted to define the binding region of FdI for its various redox partners. The three-dimensional structure of the Fd-FNR complexes both from *Anabaena* spp. and maize leaves have recently been obtained. Overall, the picture which comes out is that FdI acts a mobile electron shuttle between photosystem I and the enzyme partners, utilizing for the interaction the same acidic surface area surrounding the iron-sulfur cluster. The binding sites do not need to be exactly the same but may be just overlapping.

Fd isoforms are present in plastids of nongreen plant tissues and most recently, such type of Fd has been found in the organelle called apicoplast of protozoan parasites Apicomplexa (*Plasmodium* spp., *Toxoplasma gondii*, etc.). These Fds, which have a more positive redox potential than the photosynthetic ones are reduced by FNR isoforms at the expenses of NADPH and act as reductant of Fd-dependent pathways in these organelles.

Mitochondrial-Type 2Fe Fds

Mammalian adrenodoxin (Adx) is the prototype of this class, other well-known members are putidaredoxin of *Pseudomonas putida*, yeast Fd, and *Escherichia coli* Fd. The first two Fds have the role of providing electrons to cytochrome P450-catalyzed hydroxylation reactions, the latter two have been more recently implicated in iron-sulfur cluster biogenesis. They are 105–128 residues long, thus are up to 4 kDa larger than plant Fds. The typical Fe-S binding sequence is $C–X_5–C–X_2–C$, which provides three of the four thiolate ligands to the iron atoms, with the fourth ligand 35–37 residues downstream in the sequence. The three-dimensional structures of these Fds show high similarity to those of the plant Fds in the fold of the core involving

the N-terminal moiety (i.e., the β-grasp), but they have an additional C-terminal lobe, called interaction domain, which has been shown to be involved in binding both the redox partners, Adx reductase and cytochrome P450. As in the case of FdI, the binding sites may be separate but overlapping.

Thioredoxin-Type 2Fe Ferredoxins

Thioredoxin-like Fds were first identified in *Azotobacter vinelandii* and *C. pasteurianum*. They seem to be present only in bacteria. The polypeptide chain length is that usually reported for 2Fe Fds, i.e., 100–120 residues, but these Fds, being dimer, have a larger molecular mass. The cysteine motif for binding the iron-sulfur cluster is rather unique: $C-X_{10-12}-C-X_{29-34}-C-X_3-Cys$ and the crystal structure of *Aquifex aeolicus* Fd revealed a fold unusual for Fds and quite similar to that of thioredoxin. The function of these Fds is not yet known, although there are some indications for their involvement in nitrogen fixation.

Ferredoxins Containing 4Fe and 3Fe Iron–Sulfur Clusters

This class comprises 3Fe, 4Fe, 7Fe, and 8Fe Fds, which are small, bacterial proteins containing one or two FeS clusters of the cubane type. The iron and sulfide atoms alternate on the corners of a distorted cube. In the case of the 3Fe cluster, one corner is devoid of the fourth iron atom. The two types of clusters are in some cases interconvertible. The cysteine motif for the coordination of these iron–sulfur centers is $C-X_2-C-X_2-C$ with the middle cysteine replaced by aspartic acid or any residue in the case of 3Fe clusters, in a polypeptide chain of 60–100 residues. These Fds generally function as electron carrier in several metabolic pathways including pyruvate metabolism, nitrogen fixation, sulfate reduction, hydrogen production, and cytochrome P450 hydroxylations.

Ferredoxin-NADP$^+$ Reductase

Giuliana Zanetti and Alessandro Aliverti
Università degli Studi di Milano, Milan, Italy

The photosynthetic ferredoxin-NADP$^+$ reductase (FNR) is the prototype of a functional group of flavoenzymes that catalyze the exchange of reducing equivalents between NADP(H) and ferredoxins. In photosynthesis, FNR provides NADPH by pairing electrons supplied by photosystem I through ferredoxin. It is a monomeric protein comprising two domains, one for FAD binding and a Rossmann fold for NADP binding. Interactions with either substrates have been elucidated by biochemical studies and by solving the three-dimensional structures of their complexes with the enzyme. The other members of the group catalyze the reduction of ferredoxin at the expense of NADPH, and vary in physiological function, structure and localization.

Introduction

Ferredoxin-NADP$^+$ reductase (FNR) is the common name of members of a broad group of flavoenzymes (classified as EC 1.18.1.2) sharing the ability to catalyze the transfer of reducing equivalents between NADP(H) and ferredoxins (Fds). The best-known example is the photosynthetic FNR, the terminal component of the photosynthetic electron transport chain, both in eukaryotic and prokaryotic phototrophic organisms. In addition to this photosynthetic oxidoreductase, isoforms exist in non-photosynthetic cells. The subdivision between photosynthetic and non-photosynthetic FNRs is functional, and is based on the physiological direction of the catalyzed reaction, i.e., towards NADP$^+$ reduction in the case of photosynthetic FNR, and towards Fd reduction for heterotrophic FNRs (Figure 1). Besides such functional classification, a structural/phylogenetic one is possible, which distinguishes between plant-type and glutathione reductase-type FNRs. While all photosyntetic FNRs are plant-type, non-photosynthetic reductases are distributed between both structural classes.

Furthermore, the plant-type FNR is the prototype of a large superfamily of homologous enzymes, which display a great variety of catalytic functions. All members of this family possess the two-domain FNR unit and additional domains that modify and extend their functional properties.

Photosynthetic FNR

FNR was first discovered in 1956 by Avron and Jagendorf, who isolated it from pea chloroplasts as a NADPH-dependent diaphorase (i.e., a flavin-containing enzyme that catalyzes the transfer of reducing equivalents from NADPH to various electron acceptors). This chloroplast oxidoreductase was later shown by Shin and Arnon to mediate the transfer of electrons from ferredoxin to NADP$^+$.

Molecular Structure

Photosynthetic FNRs are monomeric proteins of about 35 kDa molecular mass, containing one molecule of non-covalently but tightly bound flavin adenine dinucleotide (FAD) as prosthetic group. FNRs from different eukaryotic sources show a high sequence similarity (~80% identity), which is spread over the entire polypeptide chain of ~300 amino acid residues. Cyanobacterial FNR possesses an additional N-terminal sequence of ~10 kDa involved in binding to phycobilisomes, light-harvesting structures of the thylakoid membrane of cyanobacteria. The three-dimensional (3D) structures of photosynthetic FNRs have been determined at high resolution (up to 1.7Å) by X-ray crystallography for the proteins from spinach, pea, paprika, and maize leaves, as well as from the cyanobacterium *Anabaena* spp. The enzyme molecule consists of two structural domains, each of ~150 residues (Figure 2). The N-terminal domain, comprising a six-stranded antiparallel β-barrel, a small β-sheet and an α-helix, provides most of the residues involved in FAD binding and is thus also known as the FAD-binding domain. The C-terminal domain, topologically similar to the supersecondary structure named Rossmann fold, binds NADP(H) and is thus indicated as the NADP-binding domain. However, both dinucleotides interact also with residues belonging to the other domain. Indeed, FAD- and NADP(H)-binding sites are located within a deep cavity at the interface of the two domains. The isoalloxazine ring of FAD, as in many flavoproteins, is sandwiched between the side-chains of two aromatic residues. In particular, the C-terminal tyrosine residue

PSI, photosystem I; FdI, photosynthetic isoform of Fd. (B) Scheme of the reaction catalyzed by non-photosynthetic FNR isoforms. Fd indicates any non-photosynthetic Fd isoform, including adrenodoxin. The dashed line indicates the electron transfer path.

makes an aromatic stacking interaction with the *re*-face of the isoalloxazine ring.

Subcellular Localization and Physiological Role

FNR is present in the chloroplasts of algae and higher plants. It is an extrinsic membrane protein localized on the side facing the stroma of the thylakoid membrane. FNR is the catalyst of the last step in the light-driven electron transport. FNR is thus directly responsible for producing the NADPH required in the Calvin cycle for carbohydrate biosynthesis. Reducing power is in turn provided to FNR by Fd, which acts as an electron shuttle by diffusing in the stroma between photosystem I and FNR and being reduced by the former and oxidized by the latter.

Catalytic Mechanism

FNR catalyzes the reversible transfer of reducing equivalents between the obligatory one-electron carrier ferredoxin (Fd) to the obligatory two-electron carrier NADP(H), according to the following balanced chemical equation:

$$2\mathrm{Fd}(\mathrm{Fe}^{2+}) + \mathrm{NADP}^{+} + \mathrm{H}^{+} \Leftrightarrow 2\mathrm{Fd}(\mathrm{Fe}^{3+}) + \mathrm{NADPH}. \quad (1)$$

The ability of FNR to pair single electrons in order to transfer them as a couple to a two-electron acceptor is a feature of the dehydrogenase-electron transferases class of flavoproteins to which FNR belongs, and is mediated by the FAD prosthetic group. FAD can exist in three redox states: oxidized, one-electron reduced (semiquinone form), and two-electron reduced (dihydroquinone form). During turnover, enzyme-bound FAD cycles among the three redox states described above, according to the reaction scheme shown in Figure 3. Two reduced Fd molecules sequentially transfer one electron at the time to FAD, before FNR can complete the catalytic cycle transferring a couple of electrons to $NADP^+$. Electron transfer is strictly coupled to proton (H^+) transfer, at least in steps 2 and 4. FAD protonation in step 2 is required to yield the neutral semiquinone form observed during turnover. In step 4, two electrons are transferred simultaneously with one H^+ in the form of a hydride ion (H^-). Catalysis proceeds according to a sequential ordered mechanism, through the formation of ternary complexes of FNR with both substrates. The redox potential of the FAD/$FADH^-$ couple in FNR is −360 mV, a value intermediate between that of FdI (−400 mV) and that of the $NADP^+$/NADPH couple (−320 mV).

Interaction with NADP(H)

FNR is a remarkably specific enzyme, showing a strong preference for $NADP^+$ over NAD^+. Substrate discrimination is due to a number of interactions that FNR establishes with the 2′-phosphate group of NADP(H). NADP(H) interactions with FNR have been described in terms of a bipartite binding mode, where the adenylate moiety of the dinucleotide binds independently of the nicotinamide one. Binding of the adenylate moiety occurs with high affinity and is the leading event in substrate recognition. In order to allow hydride transfer to occur between the reduced isoalloxazine ring and the nicotinamide, FNR has to undergo an induced-fit process where the nicotinamide ring of $NADP^+$ displaces the phenol ring of the C-terminal tyrosine residue from its stacking interaction with *re*-face of the isoalloxazine (Figure 2). A detailed picture of the enzyme–NADP(H) interaction has been obtained by producing an engineered FNR, where the C-terminal tyrosine was changed to a non-aromatic residue. This greatly stabilized the interaction between the flavin and the nicotinamide ring. Thus, X-ray crystallography of the NADP(H) complex with the mutant FNR revealed the hydride-transfer competent binding mode of the substrate (Figure 2).

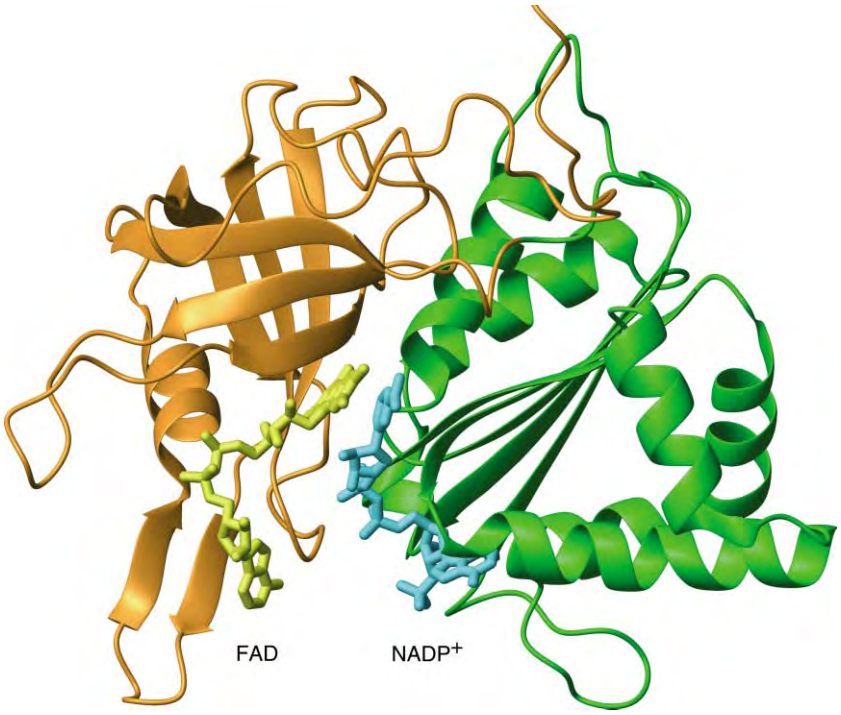

FIGURE 2 Ribbon model of the 3D structure of the pea photosynthetic FNR mutant with a serine replacing the C-terminal tyrosine residue. The FAD-binding and the NADP-binding domains are depicted in orange and green, respectively. The wireframes of bound FAD and NADP$^+$are shown in yellow and cyan, respectively. The figure was made with Molmol.

Interaction with Fd

Crystals of the complexes between FNR and Fd, both in the oxidized state, have been obtained for the eukaryotic (maize leaf) and the prokaryotic (*Anabaena* spp.) protein couples. X-ray structures are similar (Figure 4). Fd binds to a large concave region of FNR, which is contributed by both structural domains of the reductase, with the FAD-binding domain providing most of the interactions. Complex formation places the redox active prosthetic group at a distance (6.0–7.4Å) compatible with high-rate electron transfer. Protein–protein complex formation is thought to be initially driven by the mutual orientation of the dipole moments of the two molecules as they approach. After initial docking, minor adjustments are expected to occur to reach a conformation optimal for intermolecular electron-transfer, with the formation of a network of intermolecular weak bonds (salt bridges, hydrogen bonds, van der Waals, and hydrophobic interactions). Charge–charge interactions, which play a major role in the stabilization of the Fd–FNR complex, are formed between basic groups provided by FNR and acidic groups of Fd.

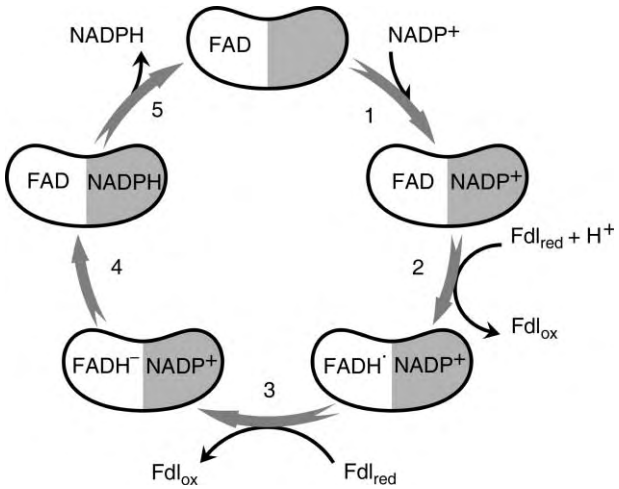

FIGURE 3 Simplified scheme of the mechanism of the reaction catalyzed by the photosynthetic FNR isoform. FdI indicates the photosynthetic Fd isoform present in chloroplasts. FdIox and FdIred indicate oxidized and reduced forms of FdI, respectively. FADH$^{\cdot}$ and FADH$^-$ indicate the neutral semiquinone and the hydroquinone anion of FAD, respectively.

Non-Photosynthetic Plant-Type FNRs

Root FNR

Non-photosynthetic plastids of higher plants contain an isoform of FNR, also known as root FNR. Root and leaf isoforms of FNR are clearly homologous, showing a sequence identity of ~48%, which corresponds to highly similar 3D structures. Isoform-specific

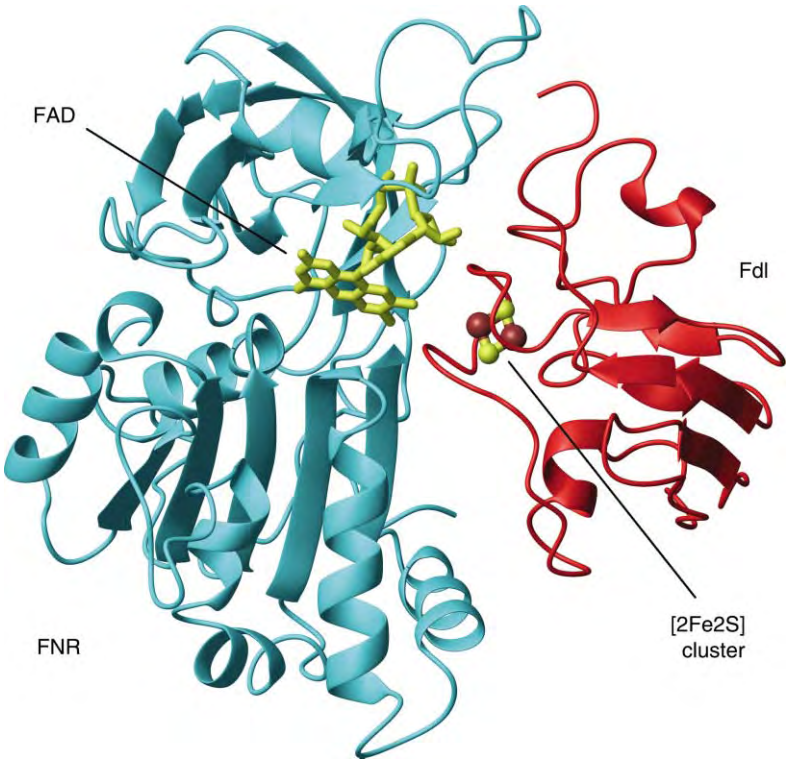

FIGURE 4 Ribbon model of the binary complex between maize photosynthetic FNR and FdI. FNR is depicted in cyan, while FdI is in red. The wireframe of FAD is shown in yellow. The iron–sulfur cluster is represented as a ball and stick model, with the iron atoms in brown and the sulfur atoms in yellow. The figure was made with Molmol.

differences are limited to the structure of surface loops of the molecules, the presence of a conserved disulfide bridge in the FAD-binding domain of the root isoform, a higher redox potential for the bound FAD of the root isoform, and different affinities for the Fd isoforms. Many of these structural and functional differences are instrumental for the diverse physiological role played by the two FNR isoforms. Indeed, the role of root FNR is opposite to that of the leaf isoform, i.e., transfer of reducing equivalents from NADPH to a root-specific Fd isoform to yield reduced Fd for several Fd-dependent pathways.

Bacterial and Apicomplexan FNR

FNRs belonging to the FNR structural family are present in some prokaryotic organisms such as *Escherichia coli* and *Azotobacter vinelandii*. A plant-type FNR has been recently identified in different species belonging to the *Apicomplexa*, a phylum of obligatory eukaryotic unicellular parasites, including the causative agents of malaria, toxoplasmosis, and coccidiosis. In the apicomplexan cell, the FNR is localized, together with a plant-type Fd, in a peculiar organelle, the apicoplast. Apicomplexan FNR is thus expected to play a metabolic function similar to that of root FNR, i.e., production of reduced Fd to be used in reductive biosynthetic pathways. Due to the increasing importance attributed to the apicoplast metabolism in parasite pathogenicity, apicomplexan FNR is an attractive target for novel antiparasitic drugs.

Heterotrophic Glutathione Reductase-Type FNRs

In addition to plant-type FNRs, various FNRs exist that – while being structurally and phylogenetically distinct from the former – show essentially the same catalytic activity, thus representing a noteworthy example of convergent evolution. Such FNRs show a significant sequence identity. The 3D structures of two of them (bovine adrenodoxin reductase and *Mycobacterium tuberculosis* FprA) have been determined and shown to be similar to that of glutathione reductase (GR). FNRs of the GR-like class thus have both domains based on the Rossmann fold motif for binding the nucleotides (FAD and NADPH). The prototype of such enzymes is adrenodoxin reductase (AdR), found in vertebrate mitochondria, where it transfers electrons from NADPH to an Fd known as adrenodoxin (Adx). AdR and Adx form an electron supply system for the cytochrome P450-catalyzed hydroxylation reactions to

produce steroid hormones, vitamin D metabolites, and bile acids. An AdR-homologous protein (Arh1) has been recently found in *Saccharomyces cerevisiae*. By now AdR and Adx have been shown to be ubiquitous in mitochondria of eukaryotes, where they play a role in the biogenesis of iron–sulfur clusters. More recently, an AdR-like enzyme (FprA) has been identified in *Mycobacterium tuberculosis*, showing that they are not restricted to eukaryotes. FprA is thought to have a critical role in the complex lipid metabolism of this pathogen as a source of reducing power for the unusually large numbers (~20) of cytochromes P450 present in this organism. This observation could eventually lead to novel pharmacological treatment for tuberculosis.

Fibroblast Growth Factor Receptors and Cancer-Associated Perturbations

Marko Kornmann
University of Ulm, Ulm, Germany

Murray Korc
Dartmouth Medical School, Lebanon, New Hampshire, USA

Fibroblast growth factors (FGFs) constitute a family of homologous heparin-binding polypeptides that presently consists of at least 23 members. FGFs play important roles in many biological functions, including development, pattern formation, cellular differentiation, metabolic regulation, tissue repair, angiogenesis, and mitogenesis. FGFs act by binding to a family of specific, high-affinity FGF receptors (FGFRs) that possess a discontinuous intracellular kinase domain. Perturbations in FGF–FGFR expression, localization, and signaling have been implicated in several pathological processes, including malignant transformation and tumor spread and metastasis.

Fibroblast Growth Factors

Genes

To date, 23 *Fgf* genes have been identified in vertebrates. Although human *Fgf15* and mouse *Fgf19* have not been described, human *Fgf19* is most closely related to mouse *Fgf15*, and both genes are closely linked to the *Fgf3* and *Fgf4* genes, raising the possibility that human *Fgf19* may be identical to mouse *Fgf15*. According to their evolutionary relationship, the 22 *Fgfs* in humans can be classified into several subgroups (Figure 1). Members of each subgroup may also share similar biochemical and developmental properties. For example, members of the *Fgf8* subgroup display similar receptor-binding properties and overlapping yet distinct expression patterns during development, underscoring both their commonality and uniqueness.

Proteins

Among vertebrates, fibroblast growth factors (FGFs) share 13–71% of their amino acid sequence homology. Most notably, there is an internal core region consisting of six identical and 28 highly conserved amino acids, which include the ten amino acid residues interacting with the high-affinity FGF receptors (FGFRs) within ~120 amino acid region. In FGF-1 and FGF-2 this areas consists of 12 antiparallel β-strands forming a structure exhibiting a threefold internal symmetry called a β-trefoil.

FGF4–8, 10, 17–19, 21, 23 possess classical N-terminal leader sequences that may allow for rapid and efficient secretion. This sequence is also present in FGF3 and 22. However, neither of these FGFs is efficiently secreted. By contrast, FGF-1, 2, 9, and 11–14, 16, and 20 lack a leader sequence for secretion. Nonetheless, FGF9, 16, and 20 have a hydrophobic region in the core domain allowing for secretion. Moreover, FGF1 and FGF2 may be released by an exocytotic mechanism, while FGF11–14 are thought to remain intracellularly. Posttranslational glycosylation, alternative splicing, and initiation of synthesis from N-terminal CUG sequences can result in several different molecular weight forms in the case of several FGFs.

Physiologic Actions

FGFs regulate diverse processes during development and exert a broad variety of functions in the adult organisms including growth, survival, apoptosis, motility, and differentiation.

Fibroblast Growth Factor Receptors

Genes

FGFRs are transmembrane proteins that are encoded by five distinct *Fgfr* genes. The extracellular portion of these receptors is usually composed of three immunoglobulin (Ig)-like domains (I–III), including a stretch of acidic residues (acidic box) between domain I and II, which is unique for the FGFRs. The hydrophobic

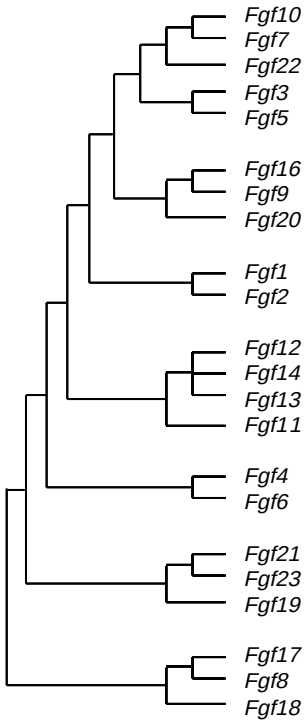

FIGURE 1 Evolutionary relationships within the human FGF family. (Adapted from Ornitz, D. M., and Itoh, N. (2001). Protein family review: Fibroblast growth factors. *Genome Biol.* **2**, 30051–300512, with permission.)

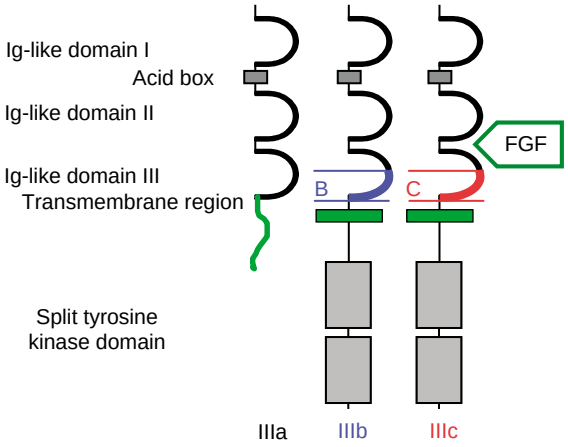

FIGURE 2 Schematic diagram of structural features of FGF receptors. FGFRs are usually composed of three extracellular immunoglobulin (Ig)-like domains (I–III) including a stretch of acidic residues (acidic box) unique for FGFRs, a hydrophobic transmembrane region followed by a juxtamembrane and a split tyrosine kinase catalytic domain. The IIIa isoform is devoid of any signaling capacity. In case of the IIIc isoform, the second half of the Ig-like domain III (solid) corresponds to the exon 7 sequence of the *FGFR1* gene and in case of IIIb, the second half of the Ig domain III (open) corresponds to the exon 6 sequence of the *Fgfr1* gene.

transmembrane region is followed by a juxtamembrane domain and a split tyrosine kinase catalytic domain (Figure 2). In contrast to FGFR1–4, FGFR5 contains a transmembrane domain, but no intracellular kinase domain. A special feature of the FGFR family is the existence of several receptor isoforms for FGFR1, 2, 3, and 4 that are generated by alternative mRNA splicing and result in different ligand-binding specificities.

Proteins

FGF signaling is generally mediated by a dual-receptor system, consisting of the high-affinity FGFRs and of low-affinity heparan sulfate proteoglycan receptors that are most often devoid of signaling capabilities but enhance ligand presentation to the receptors. The function of FGFR5, which is also devoid of intracellular signaling capacity, is presently unknown, but it may provide a binding site for FGFs. FGF binding results in receptor oligomerization, activation of the cytoplasmic tyrosine kinase domains and receptor autophosphorylation. Intracellular signaling is then mediated through the tyrosine phosphorylation of key substrates, and the activation of downstream pathways such as the mitogen-activated protein kinases (MAPK), extracellular signal regulated kinase-1 (ERK-1), and ERK-2. In general, activation of these pathways occurs following phosphorylation of FGF receptor substrate-2 (FRS-2) (Figure 3). However, the same signaling cascades can also be activated under certain circumstances through FRS-2 independent mechanisms (Figure 3).

The existence of at least 23 FGF ligands, 5 FGFRs, and multiple FGF isoforms and FGFR splice variants can potentially result in a large combinatorial set of interactions. This further increases the complexity, diversity, and functional specificity of FGFs. Most notably, alternative splicing of the second half of the Ig-like domain III results in three receptor variants, termed IIIa, IIIb, and IIIc (Figure 2). Due to the fact that FGF binding occurs between the Ig-like domains II and III, these splice variants are important for defining ligand binding. Thus, the IIIa splice variant yields a secreted receptor that is devoid of any signaling capacity. The expression of the IIIb variant is believed to be restricted to epithelial cell types, whereas the expression of the IIIc variant, especially in the case of FGFR2 and FGFR3, is believed to be restricted to mesenchymal cell types.

Physiologic Actions

The expression of FGFRs seems to be fundamental for many processes including limb, craniofacial, and lung development, hepatogenesis, osteogenesis, and inner ear formation. Mutations of *Fgfr1–3* genes have been linked to syndromes characterized by specific craniofacial and limb malformations. For example, mutations of *Fgfr2* were found in patients with Apert syndrome and mutations of *Fgfr3* in patients with achondroplasia.

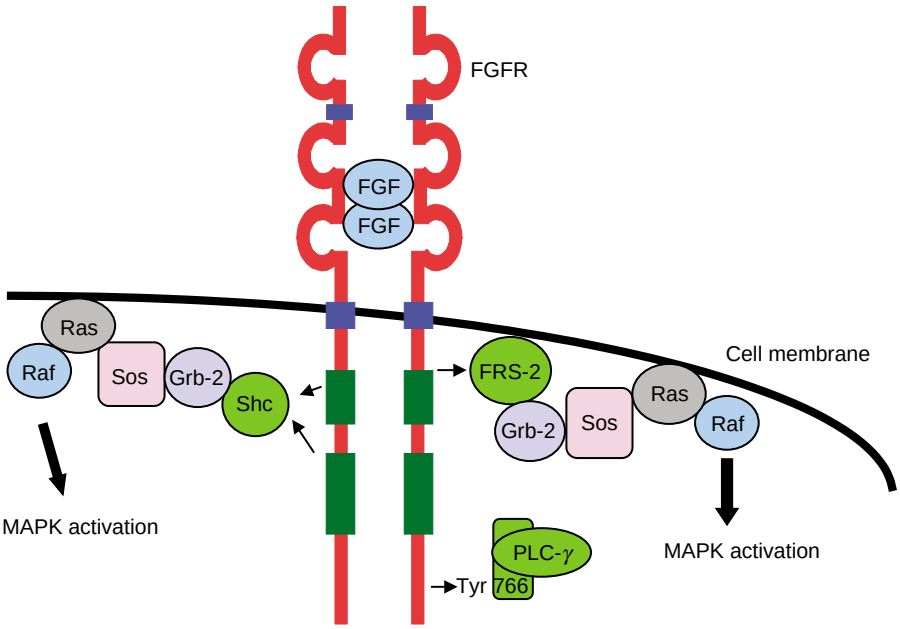

FIGURE 3 Schematic diagram of FGF signaling. FGF binding between Ig domain II and III results in receptor oligomerization, activation of the split cytoplasmic tyrosine kinase domains (rectangles) and receptor autophosphorylation. This is followed by binding, phosphorylation, and activation of fibroblast growth factor receptor substrate 2 (FRS2) or phospholipase C-γ (PLC-γ), which binds to tyrosine residue 766. Activation of the downstream mitogen-activated protein kinases (MAPK), extracellular signal regulated kinase-1 (ERK-1), and ERK-2 generally occurs via FRS2, but may also be mediated by an FRS2 independent pathway through the signaling molecules Shc, Grb-2, SOS, ras, and raf.

FGF Actions in Cancer

Many studies demonstrate that alterations of the expression of FGFs and FGFRs play an important role in the development and progression of various malignant diseases.

FGF2

FGF2 exerts mitogenic effects on various endothelial, mesothelial, and epithelial cell types. It is overexpressed in a great portion of human tumor cell lines and various human malignancies. High levels of FGF2 in the serum of patients or in tumor specimens have been correlated with advanced tumor stage and poor prognosis in several gastrointestinal and other cancers, including thyroid, lung, and renal cell cancer. However, FGF2 expression may be associated with favorable prognosis in ovarian and breast cancer.

FGF1

FGF1 is also a potent mitogenic factor for many normal and malignant cells and is also expressed in a variety of cultured cell lines and tissues. Although FGF1 is present in many malignancies and can display similar biological activities as FGF2, FGF1 expression has not been clearly demonstrated to correlate with clinico-pathological parameters in human cancers.

FGF3

The *Fgf3* gene was initially identified as murine mammary tumor virus integration site oncogene homologue (*int2*) implicated in mouse mammary tumors. *Fgf3* is localized on chromosome 11q13, a locus frequently amplified in malignant diseases. Amplification of *Fgf3* was associated with poor prognosis in breast cancer and biological aggressiveness in ovarian and esophageal cancer. The overexpression of FGF3 in normal mouse mammary cells resulted in the development of orthotopically implanted tumors in nude mice, underscoring the important role of FGF3 in mammary tumorigenesis.

FGF-4

Fgf4, also called "human stomach cancer transforming factor-1" (*hst-1*), was discovered when DNA from stomach tissues was shown to induce the malignant transformation of fibroblasts. The same oncogene was isolated by transfection of Kaposi sarcoma DNA and is therefore also called "kaposi sarcoma *Fgf*" (*kFgf*). *Fgf4* is also located on chromosome 11q13 together with *Fgf3*. Amplification of *Fgf4* correlates with increased risk of systemic recurrence after resection of esophageal

cancer and with nodal involvement in head and neck cancers. Moreover, FGF4 overexpression increases the metastasic potential of breast cancer cells in association with altered expression of matrix metallo-proteinases.

FGF5

Fgf5 was also initially identified as a transforming proto-oncogene. In addition to being expressed in fibroblasts, FGF5 is expressed in breast cancer and several cancers of the gastrointestinal and urinary tract. Exogenous FGF5 exerts proliferative effects on cultured pancreatic cancer cells which express FGFR1 IIIc suggesting that FGF5 may act as paracrine and autocrine factor in pancreatic cancer.

FGF6

FGF6 or human stomach transforming factor-2 also displays transforming potential and was found in prostate cancer in conjunction with FGFR4. Exogenous FGF6 enhances the proliferation of primary prostatic epithelial and stromal cells and prostate cancer cell lines suggesting that FGF6 may act as paracrine and autocrine factor in prostate cancer.

FGF7

FGF7 is an important mitogen for a variety of epithelial and cancer cells, including liver, pancreas, gastrointestinal tract, lung, and breast. Inhibition of FGF7 signaling results in reduced mobility and invasion of breast and gastric cancer cells. FGF7 is overexpressed in many cancers, but is expressed at lower levels in squamous cell carcinomas of the head and neck and endometrial cancers by comparison with the corresponding normal tissue. In many cases, FGF7 is not expressed in the cancer cells, but in the adjoining cellular elements within these pathological tissues. Moreover, serum FGF7 levels are lower in patients with prostate cancer in comparison to patients with benign prostatic hyperplasia. Together, these observations suggest that FGF7 may differentially modulate tumor growth depending on its site of expression and on the expression and localization of the FGF receptors in these tissues.

FGF8

FGF8 or androgen-induced growth factor was isolated from SC-3 androgen-stimulated mouse mammary carcinoma cells and found to be overexpressed in breast cancer. *Fgf8* has been proposed to enhance murine mammary tumorigenesis in cooperation with the *Wnt-1* proto-oncogene. It was found that the four known human FGF8 isoforms (a, b, e, and f) display different proliferating and transforming potencies, the FGF8b isoform being the most potent. Constitutive expression of FGF8b resulted in enhanced invasion, angiogenic capacity, and tumor growth of breast cancer cells, underscoring its potential role in this malignancy.

FGF9-23

Expression of FGF9 or glia-activating factor, FGF10, and FGF19 was detected in various cancer tissues and these FGFs are also able to act as mitogens. FGF19 transgenic mice that overexpress FGF19 in skeletal muscle, exhibits elevated hepatic α-fetoprotein levels at 2 months of age and develop hepatocellular carcinomas by 10 months of age.

FGFR Actions in Cancer

In order to exert their activities, FGFs are dependent on the presence of high-affinity FGFRs. Changes in isoform expression of various FGFRs appear to be important for the enhancement of tumorigenesis and transformation.

FGFR1

FGFR1 is expressed in a wide variety of cell types and tissues including many malignancies. Amplification of the *Fgfr1* locus on chromosome 8p12 was associated with nodal involvement in breast cancer and poor prognosis of patients with bladder cancer. An atypical stem-cell myeloproliferative disorder evolving toward acute myelogenous leukemia is characterized by a 8p12–11 breakpoint and at (8;13) translocation, resulting in an aberrant formation of a tyrosine kinase with the catalytic domain of FGFR1 and constitutive kinase activity. This translocation was also found in breast cancer. Expression of *Fgfr1* in transgenic mice suggests that FGFR1 plays an important role in mammary gland tumorigenesis. Deletions of 8p12 have been reported for choriocarcinoma and frequent disturbances including amplification or deletions have been reported in prostate cancer. FGFR1 expression can also be induced by overexpression of cyclin D1 in fibroblasts via the pRb/E2F pathway. Cyclin D1 is known to be overexpressed in many malignancies and correlates with poor prognosis in several malignancies. Recent evidence also suggests that N-cadherin expression can enhance tumorigenesis via FGFR1. FGFR1 ligand-induced internalization was reduced by N-cadherin mediated by the first two Ig-like domains and resulted in increased FGFR1 stability and sustained activation of mitogen-activated protein kinase.

A potent ligand of FGFR1, FGF2, has been shown to be an important prognostic factor for many malignancies. Nevertheless, high FGFR1 expression was only associated with poor differentiation in prostate cancer,

advanced stage in head and neck squamous cell carcinoma, and nonsmall-cell lung cancer. In addition, recent evidence suggests that alterations in the expression of certain splice variants may be responsible for malignant transformation. Thus, expression of FGFR1 IIIc in normal ductal pancreatic epithelial cells resulted in the establishment of an autocrine loop and cellular transformation with increased proliferation and *in vivo* tumor formation. Expression of FGFR1 IIIc in the cancer cells, which are of epithelial origin, has been linked to the pathogenesis of pancreatic and prostate cancers. Additionally, altered expression of FGFR1 splice variants have been reported in breast cancer. Specifically, the 2-Ig like isoform (also called FGFR1β) is up-regulated in pancreatic, prostate, and breast cancers, and in astrocytomas and glioblastomas in comparison to the 3-Ig form (FGFR1α).

Inhibition of FGFR1 signaling using dominant-negative or soluble forms of the receptor resulted in significant growth inhibition in pancreatic, breast, prostate, and several other cancer cell lines. Using vaccination with *Xenopus* FGFR1 in a murine tumor model resulted in the production of FGFR1-specific autoantibodies and effective antitumor activity and suppression of angiogenesis.

FGFR2

FGFR2 is also found in a wide variety of cell types and tissues and was first identified as an amplified gene from a human gastric cancer cell line. Amplification of *Fgfr2* on chromosome 10q26 was also observed in breast and oral squamous cell carcinomas. One important isoform, keratinocyte growth factor (KGFR), is devoid of the Ig-like domain I and the acidic box and contains sequences encoding the IIIb variant. Overexpression of KGFR occurs in gastric and pancreatic cancers, and is associated with poor differentiation in prostate cancer, whereas KGFR expression is lower in endometrial cancer in comparison to the normal endometrium.

An essential feature of *Fgfr2* is its proposed strictly tissue-specific expression using exon IIIb in epithelial cells and IIIc in mesenchymal cells. Exon switching from IIIb to IIIc in conjunction with the presence of stromal cell-derived FGF7 was accompanied with malignant progression in a prostate cancer model, down-regulation of IIIb with malignant progression of the prostate, and dedifferentiation of normal oral keratinocytes into a malignant phenotype. This exon switch from FGFR2 IIIb to FGFR2 IIIc can be induced by the presence of FGF1 and 2 in keratinocytes, fibroblasts, and bladder carcinoma cells. Re-expression of KGFR by transfection in human salivary gland adenocarcinoma cells which lost KGFR expression in the process of malignant transformation, resulted in growth inhibition, induction of differentiation, and apoptosis. *Fgfr2* mutations linked to craniosynostosis syndromes and resulting in constitutive receptor activation with transforming potential were also detected in gastric cancers, suggesting that gain-of-function mutations of *Fgfr2* can also play a role in tumorigenesis.

FGFR3

Mutations of *Fgfr3* were identified in a great portion of bladder carcinomas and at low frequency in cervical, urothelial cell, and colorectal carcinomas. Many of these mutations occurred at highly conserved sequences in the Ig-like domain III, highlighting the functional importance of this domain. Mutations were not detected in stomach, rectum, prostate, ovarian, breast, brain, or renal tumors or cell lines. Interestingly, the presence of FGFR3 mutations in bladder and urothelial cell carcinoma was associated with better clinical outcome.

Nuclear accumulation of FGFR3 has been reported in breast cancer samples. This is probably related to a splice variant in which exons 7 and 8 are deleted resulting in the translation of a soluble intracellular FGFR3 missing the transmembrane domain, but with an intact kinase domain. Using other splice variants that are devoid of the acidic box, it could be shown that inhibitory functions of FGFR3 can be abolished. Other variants with altered ligand-binding specificities were described in osteosarcoma and squamous carcinoma cell lines. Thus, depending on the mutations and the receptor splice variant expressed, FGFR3 can display transforming potential, supporting the possible role of FGFR3 in the pathogenesis of some malignancies.

FGFR4

G to A conversions resulting in a substitution of glycine by arginine at position 388 in the transmembrane domain of the *Fgfr4* gene have been described. Expression of this receptor in mammary tumor cells increased cell mobility and the presence of this allele was associated with lymph node metastases and more advanced disease in colon cancer and reduced disease-free survival in breast cancer. Amplification of *Fgfr4* on 5q35.1-qter has been reported in some breast and ovarian cancers, leukemias, and lymphomas. FGFR4 overexpression was also reported in endocrine tumors of the digestive system, several gastrointestinal and urinary tract cancers as well as breast and lung cancers. FGFR4 expression has also been correlated with a lower differentiation state and tends to be associated with shorter patient survival in astrocytomas. Furthermore, a truncated form of FGFR4 lacking the first two Ig-like domains was identified in human pituitary tumors. Because the N terminus of this truncated receptor lacks a signal peptide, it is not inserted into

the plasma membrane and resides in the cytoplasm. The truncated receptor is constitutively phosphorylated and exhibits transforming potential in fibroblasts. Its expression in transgenic mice results in formation of pituitary tumors suggesting that this isoform may play a role in the development of pituitary tumors.

Experiments using dominant-negative FGFR4 also suggest that FGFR4 may be involved in matrix adhesion and therefore tumor dissemination. Expression of FGFR4 induced membrane ruffling, a sign of transformation of breast cells, in the presence of FGF1 or 2. Furthermore, the differentiation of teratocarcinoma cells was associated with loss of FGFR4 expression.

Nothing is presently known about involvement of FGFR5 in any malignancies.

Summary

In addition to their role in many biological processes during development and in the adult, FGFs and FGFRs are involved in the pathobiology of many malignancies. One important reason for this seems to be the altered expression of FGFs and FGFRs and their isoforms resulting in the aberrant activation of autocrine and paracrine signaling loops that eventually promote tumorigenesis. Other changes include the expression of abnormal FGFs or FGFRs with constitutive activation of FGFR tyrosine kinase signaling. Thus, the functional analysis of the role of FGF–FGFR alterations in specific cancer entities may lead to novel and highly specific treatment strategies.

Biography

Marko Kornmann is an Assistant Professor of Surgery in the Department of Visceral and Transplantation Surgery at the University of Ulm in Germany. His principal research interests are in molecular and biological alterations of growth factor pathways in gastrointestinal malignancies. He holds an M.D. and Ph.D. from the University of Ulm and received his postdoctoral training at the University of California, Irvine.

Murray Korc is the Joseph M. Huber Professor and Chairman in the Department of Medicine at Dartmouth-Hitchcock Medical Center and Professor of Pharmacology and Toxicology at Dartmouth Medical School in Hanover, New Hampshire. His principal research interests are in the elucidation of the molecular alterations that occur in pancreatic cancer.

Flavins

Barrie Entsch and David P. Ballou
University of Michigan, Ann Arbor, Michigan, USA

The word flavin in biochemistry comes from the Latin word meaning yellow. The root word flavin was used in the early twentieth century to refer to yellow compounds extracted from tissue samples. Richard Kuhn is credited with the preparation of pure riboflavin (which he called lactoflavin – from milk) and its structural determination. Kuhn received the Nobel prize for this and other work in 1938. Today, the term flavin is reserved for a group of compounds that contain the fused three-ring structure called isoalloxazine which is responsible for the yellow color.

The most important flavins in nature are riboflavin, flavin mononucleotide (FMN), and flavin adenine dinucleotide (FAD) as shown in Figure 1. Riboflavin is often known as vitamin B2 (one of the soluble vitamins), which is an essential requirement in the diet of mammals and many other organisms. Riboflavin is manufactured by most microorganisms and plants. There is now a great deal of information on the process of biosynthesis. Organisms that require riboflavin as a vitamin use specific enzymes and ATP to convert the compound into both FMN and FAD. These nucleotides are used as cofactors (or prosthetic groups) in the structure and function of many proteins. The relationship with proteins is so important that we normally think of flavins in the context of protein structures. Thus, we refer constantly to flavoproteins as proteins with a flavin cofactor. This article describes the fundamentally important functions of these compounds in a wide variety of chemical processes in nature.

Chemistry

The chemistry of flavins has been studied extensively. Riboflavin is a stable compound with a variety of interesting properties. FMN and FAD are much more important in cells, but are less stable in solution because of the presence of phosphate ester and anhydride bonds. Riboflavin is responsible for the important biological chemistry of all flavins. Only the reactions most relevant to life are mentioned below. One reason that flavoproteins have been so extensively analyzed is that they can be studied by examining the properties of their cofactor that is nearly always involved in the core function of each protein. Another reason is the variety of chemical properties that have been exploited for important biological functions of considerable diversity.

Redox Properties

Oxidized flavins (called flavoquinones) can be reduced by two electrons and protons, and the redox potential for reduction is ~ -0.2 V at pH 7 (Figure 2). Reduced flavins (flavohydroquinones) are thus moderate reducing agents and can occur as either a neutral or an anionic form. Part of the versatility of flavins comes from their ability to be reduced in one-electron steps because flavins are capable of forming stable free radicals (flavosemiquinones in Figure 2). A neutral and an anioic free radical can be formed by flavins and both occur in nature. Proteins modify these redox properties by the interactions formed with the flavin cofactor to establish a wide variety of biological processes. Flavins can pass electrons to transition metal ions. Many proteins make use of this property to link stable reducing compounds (e.g., NADH) to reactive metal ions and one-electron processes in electron transport chains. Flavins are almost always involved as the transforming molecule.

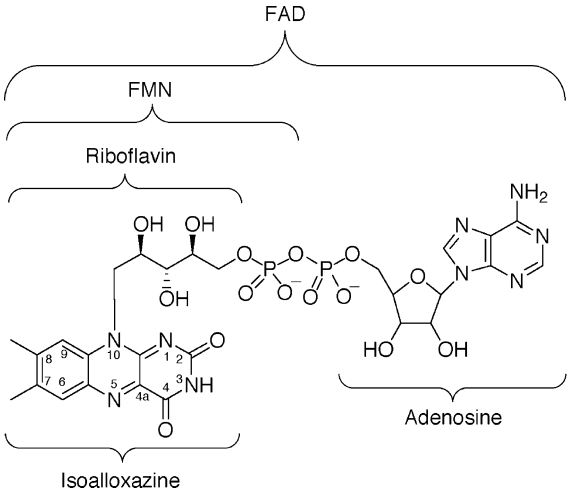

FIGURE 1 The structures of flavins discussed in this article. The numbering system shown for the isoalloxazine ring is used in the text.

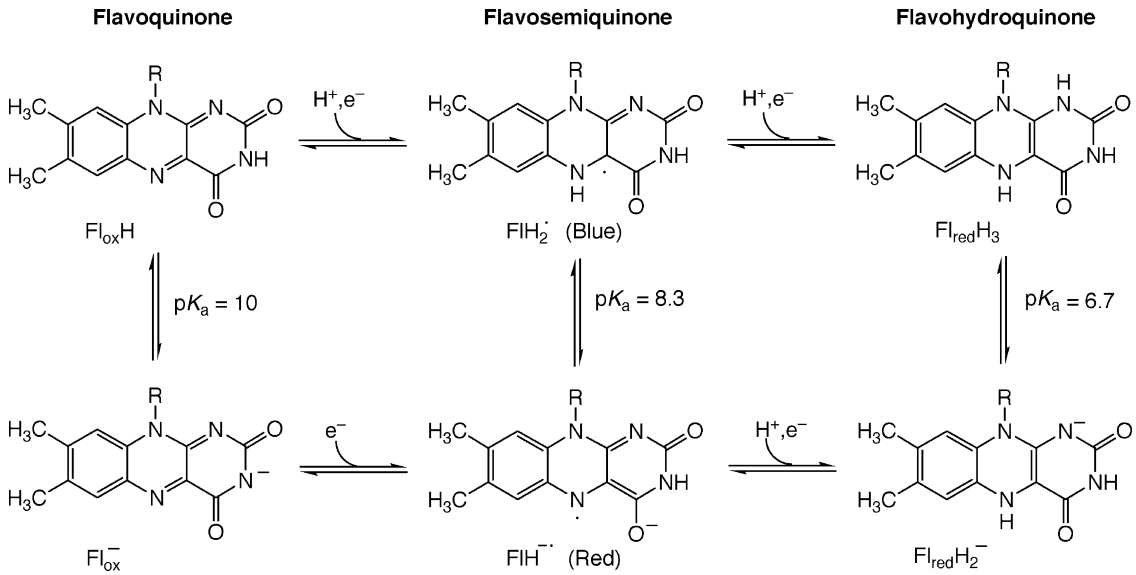

FIGURE 2 The redox states of the isoalloxazine ring that are observed in natural systems.

Oxygen and Other Derivatives

Flavins, unlike most organic molecules, react with oxygen. This reactivity is a product of the redox properties mentioned above. Oxygen is unreactive without the formation of free-radical intermediates. Reduced flavins provide the capacity for one-electron reductions and have the additional ability of forming reactive covalent adducts with oxygen and other molecules. Bruice and colleagues have shown that the reactions between reduced flavins and oxygen involve covalent adducts and free-radical intermediates. Many proteins take advantage of the oxygen adducts (Figure 3) to help carry out chemical reactions. A wide variety of biological processes depend upon the specific interactions between particular proteins and these flavin adducts. A small number of proteins form stable covalent bonds to the flavin through the 8-position (Figure 1).

Spectroscopic Properties

Oxidized flavins (the stable form) are normally yellow due to a major electronic transition observed at ~450 nm (Figure 4). Full reduction of flavins (two equivalents) gives a structure that has a low absorbance beyond 400 nm, and thus looks almost colorless (pale yellow) by comparison to oxidized flavins. Free-radical flavins (flavosemiquinones) have complex spectra with spectacular colors – either red or blue (Figure 4), depending on the state of protonation. Flavins also form charge-transfer complexes with a variety of other compounds. These complexes have a range of different visible spectra with a corresponding variety of colors. Various proteins can stabilize one or more of these chemical species, so that flavoproteins can

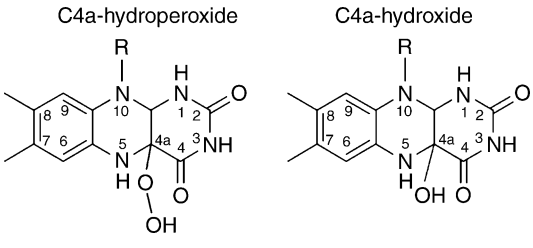

FIGURE 3 The structure of transient oxygen derivatives of the isoalloxazine ring that are important in protein function. Note that thiol groups can form a similar structure to the C4a-hydroxide. The biological function of the sulfur derivative is discussed in this article.

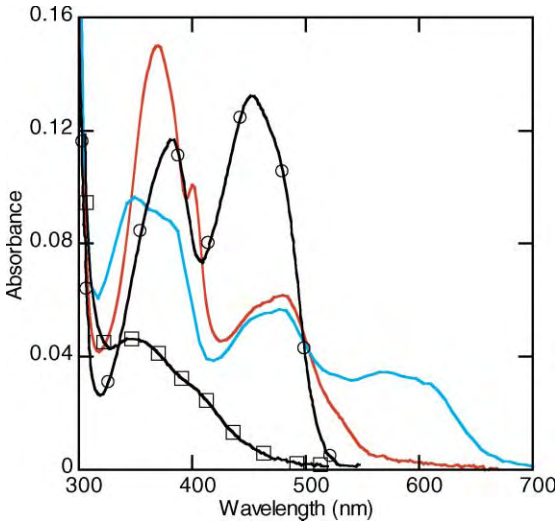

FIGURE 4 Absorption spectra of the redox states of FAD in glucose oxidase. A solution of 9.5 μM oxidized enzyme (solid line/open circles) was photoreduced in anaerobic conditions at pH 9.2 to form the red, anionic semiquinone. The solution was shifted to pH 5.0 with citric acid to form the blue semiquinone, and then reduced with glucose to form the hydroquinone (solid line/open squares).

have many colors, as well as change color during catalytic function.

Flavins have important luminescent spectral properties. Many flavins are fluorescent, and the fluorescence properties are strongly influenced by association with proteins and by the oxidation state or formation of derivatives. These properties can be studied in biological systems because the flavin can be excited by light (between 350 and 480 nm) and the emitted light is a broad band with a peak near 530 nm. This property provides a sensitive assay of flavins down to $\sim 10^{-9}$ M. The fluorescent properties of flavoproteins often provide information not available from absorbance properties. Flavins can even be trapped in excited states and this has been exploited in living systems. Nature has also utilized the enhanced reactivity of the excited states of flavins that last long enough to be chemically useful.

Types of Flavoproteins

To try to display the diversity and utility of flavin function in living systems, we adapt below the classification system for flavoproteins developed by Massey.

Pyridine Nucleotide Oxidoreductases

There is a diverse group of proteins that connects the stable reducing currency of cells (NADH/NADPH) with other redox processes required for cellular function. For example, glutathione reductase is one of a group of related disulfide reductases that contain both FAD and a pair of reactive cysteine residues in the active site. The function of this enzyme is to help maintain a reducing environment within cells by keeping glutathione reduced. Glutathione then carries out many important functions such as reducing disulfides in proteins and removing hydrogen peroxide from cells (catalyzed by glutathione peroxidase). Through the flavin buried in the protein, the enzyme can use the reducing power of NADPH to reduce the disulfide of glutathione, because the flavin reacts rapidly with thiols by the formation of a transient covalent adduct (Figure 3). Another example is ferredoxin reductase, the enzyme principally associated with photosynthesis that enables reactive, strongly reducing proteins such as ferredoxin to provide stable reducing equivalents in the cell as NADPH. Through the FAD in the active site, the enzyme can accept single reducing electrons from ferredoxin (electrons collected from the reactive free-radical photochemical process) that can then be safely stored as NADPH.

Dehydrogenase/Electron Transferase

There are a limited number of enzymes that use flavins to link oxidation of a stable metabolite to electron transport chains for energy conservation in cells. For example, succinate dehydrogenase is a component of the "citric acid cycle" in mitochondria and it links directly into the respiratory complexes through an iron/sulfur cluster complex. The FAD in this enzyme is covalently linked to the protein where it accepts a pair of electrons from the oxidation of succinate and then transfers single reducing electrons into the respiratory complex II. The acyl-CoA dehydrogenases in animals have a similar fundamental role in obtaining energy from the oxidation of fats. These enzymes contain FAD and the latter accepts electrons from a fatty acyl-CoA to initiate oxidation of a fatty acid. In this case, the electrons are transferred to the respiratory chain in mitochondria through another soluble flavoprotein called the electron transferring flavoprotein. In plants, the process of fatty acyl-CoA oxidation occurs in glyoxisomes (rather than mitochondria) by the use of similar enzymes that are oxidases. That is, after being reduced by the fatty acyl-CoA, the enzyme flavin reacts with oxygen to dispose of the reducing electrons. The difference between these enzymes in animals and plants is a subtle change in the protein interactions with the FAD that changes the course of the reaction.

Electron Transfer Proteins

There is a small group of proteins that act to provide single reactive reducing electrons for a variety of biological reactions. Most of these proteins contain iron/sulfur complexes, but a few are flavoproteins that use the ability of flavins to form stable free radicals. For example, flavodoxins are widespread in microorganisms and have been extensively studied. The protein in flavodoxins makes a specific interaction with the isoalloxazine ring that stabilizes the blue neutral radical (Figures 2 and 4), and makes further reduction difficult. Thus, when reduced, flavodoxins are strong one-electron reducing agents. Electron transferring flavoprotein referred to earlier is a different member of this family of proteins.

Oxygenases

Flavins are widely employed in cells to unlock the reactivity of the oxygen molecule. Oxygenases not only react with oxygen, but they also incorporate oxygen into metabolites. There are many types of flavoprotein oxygenases that tame oxygen for useful purposes. For example, *p*-hydroxbenzoate hydroxylase adds one atom of oxygen to an aromatic ring so that it

can eventually be used for carbon and energy supply for a microorganism. Oxygenated aromatic rings are then converted to aliphatic compounds by subsequent metabolic steps. *p*-hydroxybenzoate hydroxylase contains FAD in the structure and has been studied extensively to understand this type of reaction. In catalysis, the reduction of FAD by NADPH is tightly controlled in a remarkable process. The enzyme senses the presence of the substrate *p*-hydroxybenzoate in the active site and responds by swinging the isoalloxazine ring to the surface of the protein where it contacts the NADPH. This process makes use of the flexibility of the ribityl side chain of FAD. Then, after reduction, the isoalloxazine swings back into the interior of the protein where it not only reduces oxygen, but also forms a transient covalent adduct (Figure 3, hydroperoxide) in the controlled environment of the enzyme. The peroxide provides the reactive oxygen to oxygenate the substrate. Cyclohexanone monooxygenase provides a different example where the FAD, after reduction by NADPH, reacts with oxygen to form a peroxide anion that reacts rapidly with the carbonyl group of cyclohexanone. Another variation is found in lactate monooxygenase. Here, the enzyme flavin (FMN) is reduced by the substrate lactate to form pyruvate that is held by the enzyme and oxygenated by the peroxide formed from the reaction between reduced FMN and oxygen.

Oxidases

Flavoproteins can also use oxygen as a sink for removing unwanted reducing electrons. This process was briefly referred to above in relation to fatty acyl-CoA oxidase in plants. Another important example is glycolate oxidase in plants. During photosynthesis, glycolate is formed as an unwanted byproduct and must be removed. Glycolate oxidase uses FMN to oxidize glycolate to glyoxalate, which is then aminated to glycine, a normal metabolite. This process occurs in peroxisomes where oxygen is used to react with reduced FMN to remove the reducing electrons from glycolate, rather than through an electron transport chain. The oxygen is reduced to hydrogen peroxide (similar to the oxygenases), but the peroxide is released from the enzyme and must be removed from the cell by other enzymes such as catalase to prevent dangerous side reactions. Other examples of this use of oxygen by flavoproteins are D-aminoacid oxidase in kidneys and glucose oxidase in fungi. It is the absence of a flavoprotein oxidase function (gulonolactone oxidase) that explains why humans require vitamin C in their diets, when most animals can make this molecule. In humans, the gene for this enzyme has mutated and no longer codes for a functional protein.

Photochemistry

Flavoproteins show some really novel functions when the properties of their excited states are utilized in cells. A classic example is bacterial luciferase, which is an enzyme that produces lime-green light from chemical energy. The light-producing process is an outgrowth of the reactions of the oxygenases. NADH is used to reduce FMN by one enzyme and then the reduced FMN binds to luciferase where it reacts with oxygen to form the flavin C-4a-hydroperoxide (Figure 3). The novel reaction occurs when the hydroperoxide oxidizes a fatty aldehyde to form the corresponding fatty acid. In this reaction the protein traps the FMN in an excited state of the flavin C-4a-hydroxide (Figure 3), which can decay with the release of a photon. Many marine animals in the deep oceans form symbiotic relationships with the bacteria that make luciferase. The animal can then form light-emitting organs essential for communication, hunting, or defense.

Just as remarkable as luciferase is DNA photolyase, which is found in all cells. An essential part of cellular survival is the maintenance of the integrity of genetic information in the face of damage by environmental factors. One source of damage is UV light, which can cause cross-linking of bases in the DNA helix. It is the task of DNA photolyase to repair the damage often by using the same source of light that caused the damage. This enzyme contains both an FAD and an accessory pigment. The flavin functions in the protein in the reduced state, where it is converted to a powerful reducing agent when excited by energy from light. The excited reduced state is powerful enough to break down the unwanted covalent bonds in damaged DNA and thus repair the integrity of the genetic information. Electrons used for this purpose are then recovered to reform the reduced FAD.

Another developing story about flavoprotein photochemistry involves flavins as blue-light photoreceptors. For example, phototropins are photoreceptors for some plant responses to light. These proteins contain FMN that forms a transient and reversible covalent bond to an active site cysteine upon illumination. This complex is thought to form through a free-radical mechanism of excited state flavin chemistry.

Medical Significance

It is extremely rare for riboflavin deficiency to occur in humans because of its widespread occurrence in food. However, some flavoproteins are important in medical practice. A few examples are mentioned below.

A common medication for gout (caused by excess uric acid) is allopurinol. This drug inhibits xanthine oxidase, a complex flavoprotein involved in formation of the uric

acid that causes gout. Uric acid is the end product of the natural breakdown of purines in the body.

Another complex flavoprotein, monoamine oxidase is a target for modulation by drug therapy, particularly for depression, because this enzyme degrades some of the potent natural neurotransmitters involved in mental disorders.

The flavoprotein, methylenetetrahydrofolate reductase is involved in the formation of the amino acid methionine. About 12% of the human population has a form of the enzyme that leads to elevated homocysteine in the blood, a major risk factor in cardiovascular disease.

Some medications for stomach ulcers work because they are substrates for the bacterial flavoprotein, nitroreductase produced by the ulcer-causing *Helicobacter pylori*. The reduced products formed from the drug by the enzyme kill the bacterial cells.

Biography

Dr. Barrie Entsch retired from the position of Associate Professor of Biochemistry at the University of New England, Australia in 2002. He now works as a Research Fellow in Biological Chemistry at the University of Michigan, Ann Arbor. He has collaborated on mechanistic studies of flavoproteins with David Ballou and Vincent Massey for more than 30 years. He was awarded several Australian Research Council Grants for research with flavoproteins, particularly oxygenases.

David Ballou has been a Professor on the faculty of the Department of Biological Chemistry at the University of Michigan since 1972. His work has mainly been mechanistic and structural studies on a wide variety of redox enzymes. These include flavoproteins, cytochrome P450, cobalamin-containing enzymes, non-heme iron oxygenases, and copper enzymes. He has specialized in the development of rapid kinetic and spectroscopic methods for studying these systems.

Flippases

Charles J. Waechter
University of Kentucky College of Medicine, Lexington, Kentucky, USA

Membrane proteins referred to as flippases play a vital role in membrane biology by overcoming the biophysical barrier imposed by the greasy, hydrophobic core of the bilayer common to biological membranes, and facilitating the transbilayer movement of the hydrophilic headgroups of phospholipids and glycolipids. This article summarizes the transbilayer events involved in biosynthetic processes and establishing phospholipid asymmetry and speculates on the mechanism(s) that could overcome the thermodynamically unfavorable spontaneous flip-flopping of the various polar lipids. More detailed reviews of some aspects of the flip-flopping of phospholipids and dolichol-linked saccharide intermediates can be found in the references cited at the end of this article.

Introduction

During the bioassembly of N-linked oligosaccharides, C- and O-linked mannosyl units in proteins, glycosylphosphatidylinositol (GPI) anchors, glycosphingolipids, and newly formed phospholipid bilayers in eukaryotic cells, charged hydrophilic headgroups must diffuse transversely through the hydrophobic core of the endoplasmic reticulum (ER) and an early Golgi compartment. Similarly, in prokaryotes phospholipids and undecaprenyl pyrophosphate-linked glycosyl building blocks must be translocated from the inner leaflet to the outer monolayer during the expansion of the cytoplasmic membrane and the biosynthesis of cell-wall components. Biochemical and biophysical model systems indicate that the unassisted transbilayer movement of polar lipids with charged headgroups is highly unfavorable thermodynamically and much too slow to allow cells to synthesize the essential glycoconjugates in a physiologically requisite time frame. Thus, it has been proposed that the "flip-flopping" of the amphipathic precursors/intermediates is mediated by a class of membrane proteins referred to as flippases. The term "flippase" was originally suggested by Mark Bretscher during the 1970s.

The transbilayer movement of lipids with the generalized structure of a polar lipid (A) and of mannosylphosphoryldolichol (Man-P-Dol) (B) mediated by a flippase is illustrated in Figure 1. Table I summarizes several examples of polar lipids whose transverse diffusion is believed to be facilitated by flippases in prokaryotic and eukaryotic cells. Despite the critical function of flippases in membrane biology, there are still very large gaps in the information about their structures, the genes encoding this vital class of proteins and the mechanism(s) by which they shield and permit the passage of the polar moieties through the hydrophobic core of the ER and other cellular membranes.

Expansion of the ER Bilayer during Membrane Biogenesis

It is well established that the major site of phospholipid biosynthesis *de novo* in eukaryotes is on the cytoplasmic leaflet of the ER membrane. Clearly, to have uniform expansion of the bilayer during active membrane biogenesis, ~50% of the newly formed phospholipids must be translocated to the lumenal monolayer. The landmark study of Kornberg and McConnell proved that the unassisted movement of spin-labeled phosphatidylcholine (PC) molecules between the two leaflets of pure lipid vesicles did not occur fast enough to maintain bilayer expansion at physiological rates. Further emphasizing the essential role of flippases, the classic experiments of James Rothman and Eugene Kennedy demonstrated that movement of phosphatidylethanolamine molecules, newly synthesized on the cytoplasmic leaflet of a *B. megaterium* cell, to the extracellular monolayer was remarkably faster than the rate of spontaneous diffusion in artificial lipid bilayers. Primarily due to severe technical difficulties inherent in studying the phospholipid flippase(s), there is still very little known about the structure and mechanism of this eminently important class of membrane proteins. Bishop and Bell proposed the novel idea of following the transport of a water-soluble analogue (diC_4PC) of PC by sealed microsomal vesicles to implicate one or more ER proteins in the transbilayer movement of the major membrane phospholipid. The PC flippase is

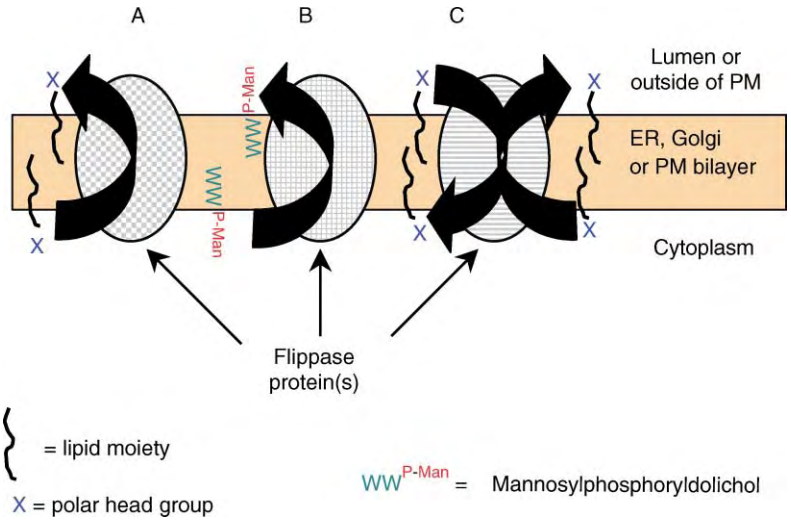

FIGURE 1 Illustration of the flippase-mediated transbilayer movement of a membrane lipid with the generalized structure of a polar lipid (A) or mannosylphosphoryldolichol (B) from the cytoplasmic leaflet to the lumenal monolayer in the ER or Golgi. The ATP-dependent flip-flopping of a phospholipid from the outer surface of the PM (C, left) or the bidirectional, ATP-independent movement of a polar lipid mediated by scramblases is depicted in model (C). Although the translocation in examples in A and B are illustrated as being unidirectional, these processes appear to be bidirectional.

depicted in Figure 1A. The basic principle of this experimental approach is to design a water-soluble form of the polar lipid in which the hydrophobic groups are reduced in size to increase their solubility in aqueous solutions while retaining the essential structural features recognized by the proteins mediating their translocation. Although this experimental approach and alternate methods have been utilized by other researchers more recently to make progress toward these goals, the PC and other phospholipid flippases in biogenic membranes remain to be identified, isolated, and cloned. Presumably, neutral lipids such as cholesterol, coenzyme Q, and neutral glycerides diffuse transversely in cellular membranes by a protein-unassisted process since they lack charged, hydrophilic groups.

Aminophospholipid Flippases/ Translocases, Floppases, Scramblases, and Phospholipid Asymmetry

In most, if not all, cellular membranes phospholipids are distributed asymmetrically between the two leaflets, a property that is critical to membrane function. Thus, in addition to the flippases crucial to uniform expansion of the bilayer in the ER during membrane biogenesis, another set of flippases is required to maintain the proper distribution of phospholipids between the two leaflets of membranes in the various cellular compartments. The combined action of aminophospholipid flippases, two types of outwardly driven floppases (multidrug resistance, MDR, P-glycoprotein, other

TABLE I

Summary of Specific Flip-Flopping Events in Prokaryotic and Eukaryotic Cells

Polar lipid	Membrane site	Transbilayer movement from
Aminophospholipids (PS/PE)	Plasma membrane	Outer leaflet to inner monolayer
PC and other glycerophospholipids, GlcN-Pl, Man-P-Dol, Glc-P-Dol and $Man_5GlcNAc_2$-P-P-Dol	ER	Cytoplasmic to lumenal leaflet
Glucosylceramide	Early Golgi	Cytoplasmic to lumenal leaflet
Glycerophospholipids, and undecaprenyl-P(P)-linked cell-wall intermediates	Bacterial cytoplasmic membrane	Cytoplasmic leaflet to exterior monolayer (or outer membrane)

members of the MDR family and members of the multidrug resistance-associated protein, MRP, subfamily) and possibly the ATP-independent, bidirectional scramblases (Figure 1C) are believed to play a role in the asymmetric distribution of PC and other membrane phospholipids between the two leaflets of the plasma membrane (PM) and other cellular membranes. The best characterized of the candidate flippases is the ATP/Mg^{2+}-dependent aminophospholipid flippase. The properties of this type of flippase have been studied extensively, and progress has been made in purifying the protein component(s). It has been found in the PM of erythrocytes and other mammalian cells, synaptosomes, chromaffin granules, and secretory vesicles. This flippase appears to play a direct role in maintaining the enrichment of PS and PE in the inner leaflet of the PM by moving the two aminophospholipids from the outer to the inner leaflet of the plasma membrane against a concentration gradient at the expense of ATP. In Figure 1C (left) the lipid moiety would be diacylglycerol and the polar headgroup (X) would be either phosphorylserine or phosphorylethanolamine. The loss of this activity due to diminishing ATP pools or the loss of the protein(s) allows PE/PS to diffuse back to the outer monolayer where the surface alteration is recognized by the immune system as an early signal in apoptosis.

However, inhibition of the flippase or loss of ATP is insufficient to cause a rapid loss of plasma membrane PS asymmetry. Rapid PS externalization requires the additional activation of a (Ca^{2+}-dependent) scramblase. The bidirectional, ATP-independent scramblase (Figure 1C) plays an important role in platelet activation, blood clotting, and apoptosis.

There is good evidence that floppases (Figure 1A) mediate the ATP-dependent translocation of cholesterol, PC, and sphingolipids from the cytoplasmic to the external leaflet of the plasma membrane. More details of the latter two classes of "flippases" can be found in the excellent review by Dr. D. Daleke cited at the end of this article.

Protein N-Glycosylation

N-linked oligosaccharide chains are initially synthesized as the dolichyl pyrophosphate (Dol-P-P) linked precursor oligosaccharide by a two-stage process in the ER. In the first stage, three lipid intermediates, mannosylphosphoryldolichol (Man-P-Dol), glucosylphosphoryldolichol (Glc-P-Dol), and a heptasaccharide intermediate ($Man_5GlcNAc_2$-P-P-Dol) are synthesized in the ER by enzymes with active sites facing the cytoplasm. In the next stage these three glycolipid intermediates diffuse transversely to the lumenal monolayer where four more mannosyl units are added to $Man_5GlcNAc_2$-P-P-Dol with Man-P-Dol (Figure 1B) functioning as the mannosyl donor. Finally, three glucosyl units are donated by Glc-P-Dol, completing the synthesis of the oligosaccharyl donor, $Glc_3Man_9GlcNAc_2$-P-P-Dol. Based on evidence obtained from biophysical and enzymological topological studies, it is very likely that the transverse diffusion of the three intermediates requires ER proteins functioning as flippases to maintain lipid intermediate biosynthesis and protein N-glycosylation at physiologically relevant rates. Evidence has been obtained for the presence of ER proteins that mediate the transbilayer movement of short-chain, water-soluble analogues of Man-P-Dol and Glc-P-Dol by sealed vesicles from rat liver and brain by a variation of the experimental approach pioneered by Bishop and Bell. Preliminary studies using this transport technique indicate that the flippases are bidirectional and ATP independent. It is plausible that this class of flippase acts by facilitated diffusion, and the transbilayer movement of the lipid intermediates is driven by mass action as they are consumed during $Glc_3Man_9GlcNAc_2$-P-P-Dol synthesis on the lumenal surface. Hopefully, the *in vitro* assays will provide a means to isolating the ER proteins involved in this flip-flopping process. More recently, genetic and biochemical studies have implicated the *Rft1* protein in the transbilayer movement of $Man_5GlcNAc_2$-P-P-Dol in the yeast, *S. cerevisiae*. The structure of the yeast protein may provide clues to the identity of the gene encoding the corresponding protein in mammalian cells. The identification of the flippase proteins involved in the "dolichol pathway" and the corresponding genes should ultimately be relevant to the diagnosis of related genetic defects in patients with as yet uncharacterized forms of congenital disorders of glycosylation.

Relationship of a Man-P-Dol Flippase to the Biosynthesis of Other Mannose-Containing Glycoconjugates

Protein O- and C-Mannosylation

In yeast and mammalian cells, many proteins are modified by the addition of mannosyl units from Man-P-Dol to either serine/threonine in O-mannosidic linkage or to the indole ring of tryptophan residues in a C-mannosidic linkage. Since Man-P-Dol is believed to be formed only on the cytosolic face of the ER (Figure 1B), and these modifications appear to occur on the lumenal side of the ER, a Man-P-Dol flippase is essential for O- and C-mannosylation of proteins, as well as completing the synthesis of $Glc_3Man_9GlcNAc_2$-P-P-Dol and to maintain normal rates of protein N-glycosylation.

GPI Anchors

One class of proteins that is associated with membranes, despite not having any transmembrane domains, is attached by an amide linkage to GPI anchors. The biosynthesis of the GPI anchors theoretically requires at least two ER flippases. The best current evidence indicates that the early intermediate, GlcN-PI, is formed on the cytoplasmic face of the ER, and is subsequently translocated to the lumenal monolayer where the GPI anchor is completed and the appropriate polypeptides are covalently attached to the ethanolamine moiety by a transpeptidation reaction. The completion of the anchor on the lumenal surface also requires Man-P-Dol as a mannosyl donor, and the transverse diffusion of the mannolipid intermediate requires a flippase that is discussed above.

Glucosylceramide

The enzyme that synthesizes glucosylceramide (Glc-Cer) from UDP-glucose and ceramide in an early Golgi compartment has an active site that is oriented toward the cytoplasm. Since more complex cerebrosides and gangliosides are elaborated on the interior of the Golgi compartments, it is necessary for the Glc-Cer formed on the cytosolic side to be translocated to the lumenal leaflet where the glucosyl unit can be elongated by lumenally oriented glycosyltransferases. Thus, in this flippase-mediated event the lipid moiety would be ceramide and the polar headgroup would be a β-linked glucosyl group as illustrated in Figure 1A. The biosynthesis of the complex glycosphingolipids also requires a set of Golgi proteins to mediate the transbilayer movement of the sugar nucleotides required for ganglioside synthesis. Since there is experimental evidence that some fraction of the Glc-Cer formed on the cytoplasmic leaflet of an early Golgi compartment can be translocated directly to the inner surface of the PM, there may also be a PM flippase that mediates the movement of Glc-Cer to the outer leaflet.

Bacterial Cell Walls

In gram-positive and gram-negative bacteria, some of the building blocks for the assembly of peptidoglycan, lipopolysaccharide, and several other cell-wall complex glycoconjugates are synthesized on the inner face of the cytoplasmic membrane while attached to undecaprenyl pyrophosphate (Und-P-P). There is solid genetic evidence for the presence of membrane proteins that mediate the transbilayer movement of the bacterial lipid intermediates so the assembly of the cell-wall components can be completed on the exterior face of the cytoplasmic membrane, or in the case of gram-negative bacteria, on the outer membrane. The *Wzx* family has been proposed to encode proteins involved in the translocation of Undec-P-P linked intermediates in bacteria. There is recent evidence that the *wzxE* gene encodes a protein involved in the transbilayer movement of a trisaccharide lipid intermediate in the biosynthesis of the enterobacterial common antigen in *E. coli*. Although there is very limited information about their structures at this time, it is quite possible that the prokaryotic flippases resemble their eukaryotic counterparts. The intriguing question of why the polyisoprenoid glycosyl carrier lipids became longer (C55 for prokaryotes to C75–95 for eukaryotes) and acquired the saturated α-isoprene unit in dolichols during evolution remains to be explained.

Glossary

dolichyl monophosphate An eukaryotic glycosyl carrier lipid containing 15–20 isoprene units in which the α-isoprene unit is saturated.

flippase A general term for a class of membrane proteins proposed to facilitate the transbilayer movement of the polar headgroup of a phospholipid, glycosphingolipid, or a polyisoprenyl-P(-P) linked glycosyl intermediate.

scramblase Bidirectional, ATP-independent transporters that randomly redistribute polar lipids formed *de novo* in the endoplasmic reticulum. This class also facilitates the nonspecific, bidirectional movement of phospholipids in the plasma membrane.

transverse diffusion The "flip-flopping" or transbilayer movement of a polar membrane lipid from one leaflet to the opposite monolayer of a cellular membrane.

undecaprenyl phosphate A fully unsaturated bacterial glycosyl carrier lipid containing eleven isoprene units.

Biography

Charles Waechter received a Ph.D. in biochemistry in 1971 studying the regulation of membrane phospholipid biosynthesis in *S. cerevisiae* with Robert L. Lester (University of Kentucky College of Medicine). His major research interest, in the biosynthesis and function of lipid intermediates in protein N-glycosylation in mammalian cells, began as a postdoctoral fellow with Dr. William Lennarz (The Johns Hopkins University School of Medicine) during 1971–74. He is currently professor of Molecular and Cellular Biochemistry at the University of Kentucky College of Medicine, and has served on the editorial board of *The Journal of Biological Chemistry and Glycobiology*, in the Neurological Sciences Study Section at NIH, and in the Tumor Biochemistry Study Section of the ACS.

Focal Adhesions

Eli Zamir and Benjamin Geiger
The Weizmann Institute of Science, Rehovot, Israel

Focal adhesions (also known as focal contacts) are integrin-dependent adhesions in which the cell membrane is attached at its external surface to the extracellular matrix (ECM) and at its internal aspect to the actin cytoskeleton. These transmembrane interactions are mediated via a complex network of cytoplasmic proteins, forming a submembrane plaque. Additional ECM–integrin–actin-mediated adhesion sites, termed focal complexes, fibrillar adhesions, 3D-matrix adhesions, and podosomes, are related to focal adhesions, although the details of their molecular structures and functions differ. In addition to playing central roles in cell migration and morphogenesis, focal adhesions and related structures convey adhesion-triggered signals across the cell membrane, regulating cell proliferation, differentiation, and death.

Cell Adhesion

In multicellular organisms, cells adhere to their neighbors either directly or via a complex meshwork of fibers, known as the extracellular matrix (ECM). This adhesion is not a passive attachment but rather a complex process mediating specific, and dynamically regulated, cell interactions as well as crucial signaling cross-talks between the cell and its environment. Indeed, cell adhesion plays a fundamental role in embryogenesis and organogenesis as well as in cellular processes such as cytoskeletal organization, cell motility, and regulation of cell cycle and differentiation.

Moreover, cell adhesion is not a single molecularly uniform event but rather a highly diversified process at the cellular, molecular, and functional levels. For example, cell-to-cell adhesion occurs at tight junctions, gap junctions, chemical synapses, adherens junctions, desmosomes, and various carbohydrate-mediated contacts. Cell–ECM adhesions can involve a large variety of ECM proteins and glycosaminoglycans and their respective receptors, and they occur at specialized cellular sites such as intermediate-filament-associated hemidesmosomes and the widely occurring actin-associated contacts of the focal-adhesion type, which is addressed here.

Focal Adhesions—A Historical Perspective

Specialized adhesions between cultured fibroblasts and the underlying substrate were revealed over 30 years ago by interference–reflection microscopy and electron microscopy. These studies showed that the attached cells contain many specialized and defined regions (commonly measuring 0.25–2 by 2–10 μm) along the ventral plasma membrane, which are in a very tight contact (10- to 15-nm gap) with the substrate. Moreover, these sites, which were termed focal contacts or focal adhesions, appeared to be associated with the termini of actin microfilaments. These early studies revealed that focal adhesions are responsible for tight ECM contacts in which the extracellular substrate and the actin cytoskeleton are physically linked.

Following the early structural studies, the molecular composition of focal adhesions was addressed by immunofluorescence and immunoelectron microscopy, yielding a long list of diverse proteins, starting with α-actinin and vinculin. Biochemical examination of these proteins suggested that they are capable of establishing a complex network of protein–protein interactions with both cytoskeletal and signaling partners and implicated focal adhesions in both mechanical and signaling processes. Studies carried out with different cell types, in culture and *in vivo*, exposed to a variety of conditions established that focal adhesions are not the only sites mediating ECM–integrin–actin binding, and added to this group focal complexes, fibrillar adhesions, 3D-matrix adhesions, and podosomes (Figure 1).

The Molecular Organization of Focal Adhesions

Focal-adhesion components were identified, primarily by immunofluorescence, in studies conducted in many laboratories for the last two decades. More than 50 distinct proteins were reported to localize, stably or transiently, in focal adhesions and related cell–matrix

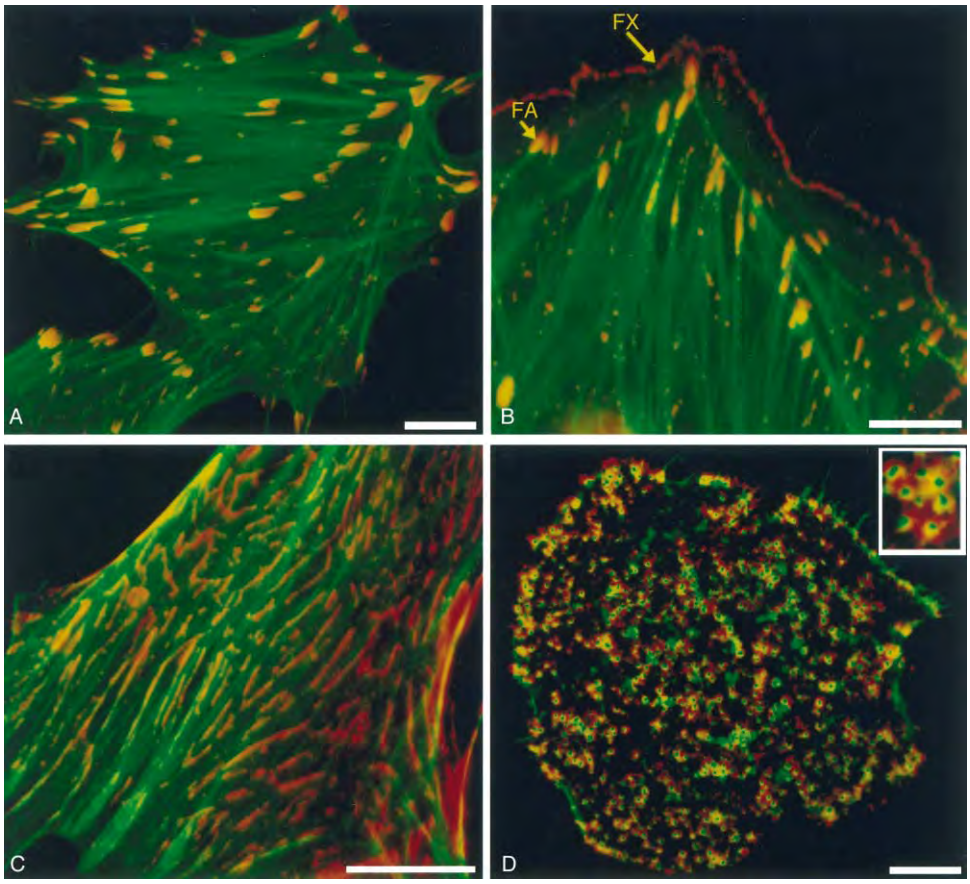

FIGURE 1 Focal adhesions and related adhesion sites. (A) Stationary human fibroblasts, stained for actin (green) and vinculin (red), having typical ovular focal adhesions located at the ends of actin stress fibers. (B) Migrating endothelial cells (porcine aortic endothelial cells, PAEC) stained for actin (green) and phosphotyrosine (red), displaying both focal adhesions (FA) and focal complexes (FX). Focal complexes have a circular morphology and are located at the edge of the lamellipodium where actin is organized as a dense network of highly branched fibers. (C) Human fibroblasts stained for actin (green) and for the fibronectin receptor $\alpha_5\beta_1$ integrin (red), which is enriched in fibrillar adhesions. (D) A mouse osteoclast, stained for actin (green) and paxillin (red), showing typical podosomes—doughnut-shaped adhesions with an actin core. The insert shows a cluster of podosomes at a higher magnification. Scale = 10 μm.

contacts. These molecules are largely segregated into three major structural domains, including the transmembrane domain, the cytoskeleton domain, and the interconnecting submembrane plaque (Figure 2).

The Receptors and their ECM Ligands

The membrane domains of ECM adhesions contain-specific integrins, which are heterodimers of α- and β-subunits that bind the ECM via a large extracellular domain. Integrins span the membrane and contain a cytoplasmic region through which they interact with plaque proteins. The most common integrins found in focal adhesions and related ECM adhesions are the fibronectin receptor, $\alpha_5\beta_1$, and the vitronectin receptor, $\alpha_V\beta_3$.

Additional, somewhat less characterized, membrane-bound components of focal adhesions include potentially adhesive molecules such as syndecan-4 and the hyaluronan-binding protein layilin, as well as the tyrosine phosphatase LAR and the glycoprotein SHPS-1, a substrate of the tyrosine phosphatase SHP-2 (Figure 2). The role of these membrane molecules is still not known.

The Cytoskeletal Domain

Focal adhesions are associated with the termini of actin bundles termed stress fibers. The polarity of the attached actin filaments is apparently uniform, with their barbed ends pointing to the membrane. That area of the actin cable is particularly enriched with actin-associated proteins such as the actin-bundling protein α-actinin. Actin is also associated with the other forms of integrin-mediated adhesion, although not in a form of stress fibers (Figure 1).

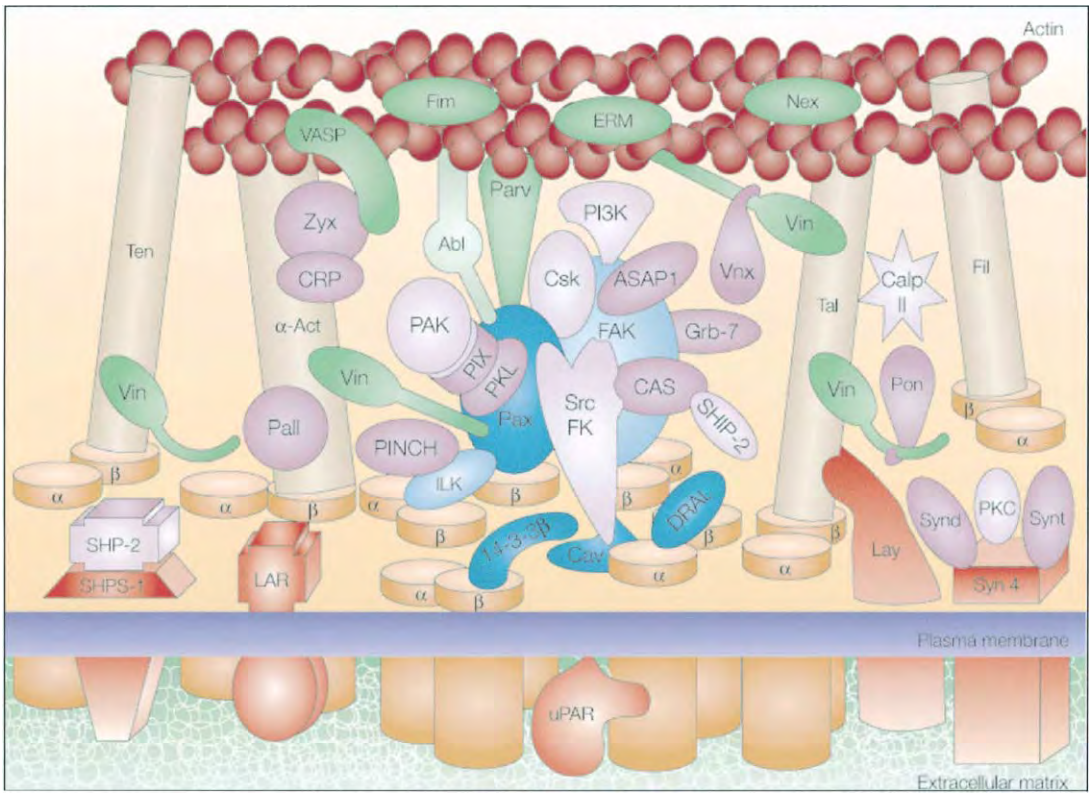

FIGURE 2 A scheme depicting the complexity of the main molecular domains of cell–matrix adhesions. The main adhesion receptors are heterodimeric (α and β) integrins. Additional membrane-associated molecules enriched with these adhesions include syndecan-4 (Syn4); layilin (Lay); the phosphatase LAR; SHPS-1, the substrate of the cytoplasmic phosphatase SHP-2; and the urokinase receptor (uPAR). Proteins that interact with both integrin and actin, and that function as the structural scaffolds of focal adhesions, include α-actinin (α-Act), talin (Tal), tensin (Ten), and filamin (Fil). Integrin-associated molecules include focal adhesion kinase (FAK), paxillin (Pax), integrin-linked kinase (ILK), DRAL, 14-3-3β, and caveolin (Cav). Actin-associated proteins include VASP, fimbrin (Fim), ezrin-radixin-moesin proteins (ERM), Abl kinase, nexillin (Nex), parvin/actopaxin (Parv), and vinculin (Vin). Other proteins, many of which may serve as adapter proteins, include zyxin (Zyx), CRP, palladin (Pall), PINCH, PKL, PIX, vinexin (Vnx), ponsin (Pon), Grb-7, ASAP1, syntenin (Synt), and syndesmos (Synd). Among these are several enzymes, such as SHP-2, SHIP-2, PAK, PI-3 kinase (PI3K), Src-family kinases (Src FK), Csk, the protease calpain II (Calp II), and PKC. Reprinted by permission from Geiger, B., Bershalsky, A., Pankov, R., and Yamada, K. M. (2001). Extracellular matrix-cytoskeleton crosstalk. *Nat. Rev. Mol. Cell Biol.* **2**, 793-805. Copyright 2001, Macmillan Magazines, Ltd.

The Submembrane Plaque

The submembrane plaque is a multiprotein complex that interconnects actin to the membrane in focal adhesions and related adhesions. Some of the plaque components contain binding domains for both actin and integrin, including talin, α-actinin, tensin, and filamin, and may function as direct integrin-actin linkers (Figure 2). Additional integrin-associated molecules do not bind directly to actin and may link the cytoskeleton to the membrane indirectly, via other plaque components. Some of them, such as focal adhesion kinase (FAK), the LIM-domain protein DRAL, integrin-linked kinase (ILK), and 14-3-3β, are signaling molecules (Figure 2).

Yet another group of focal-adhesion-associated proteins includes actin-binding proteins that were not shown to interact directly with integrins, including vinculin, VASP/Ena, and ezrin–radixin–moesin (ERM) proteins (Figure 2). Vinculin plays a pivotal role as a central linker interacting with many plaque proteins (e.g., talin, α-actinin, VASP/Ena, ponsin, and vinexin), acidic phospholipids, and actin. Finally, a very large group of proteins consists of adapter proteins, which apparently interact with actin-bound and integrin-bound components and link them to one another.

The components of cell–matrix adhesions have an unusual wide range of intrinsic activities. Beyond their protein–protein binding specificities, many of these proteins are enzymes, such as tyrosine kinases (e.g., members of the Src family and FAK), serine/threonine kinases (e.g., ILK, PKC, and PAK), tyrosine phosphatases (e.g., SHP-2 and LAR-PTP), inositol 5′-phosphatase (SHIP-2), modulators and adapters of small GTPases (e.g., ASAP1, DOCK180, PIX and GRAF),

and other enzymes such as PI 3-kinase and the protease calpain II (Figure 2). It should be pointed out that the true molecular complexity of focal adhesions is probably greater than depicted in Figure 2 because many of these components represent products of multigene families and may undergo posttranslational modification and proteolytic cleavage.

A striking characteristic of many focal-adhesion components is that they are multidomain proteins that can interact with several distinct partner molecules. For example, vinculin, FAK, Src family kinases, and paxillin can each bind to more than 10 different partners. Thus, the theoretical number of different combinations of molecular interactions that might be involved in linking integrins to actin is enormous.

Diversity of Cell–Matrix Adhesion Sites

Adhesions with the ECM are formed by essentially all adherent cells, in culture and *in vivo*. Yet their morphology, size, molecular composition, and subcellular distribution can be quite heterogeneous. These adhesions share, however, two common features: they are mediated by integrins and they interact with the actin cytoskeleton. Focal adhesions, the best-characterized form, are flat elongated structures, several square microns in area and are usually located near the periphery of cells, associated with bundles of actin microfilaments (Figures 1A and 3). The development

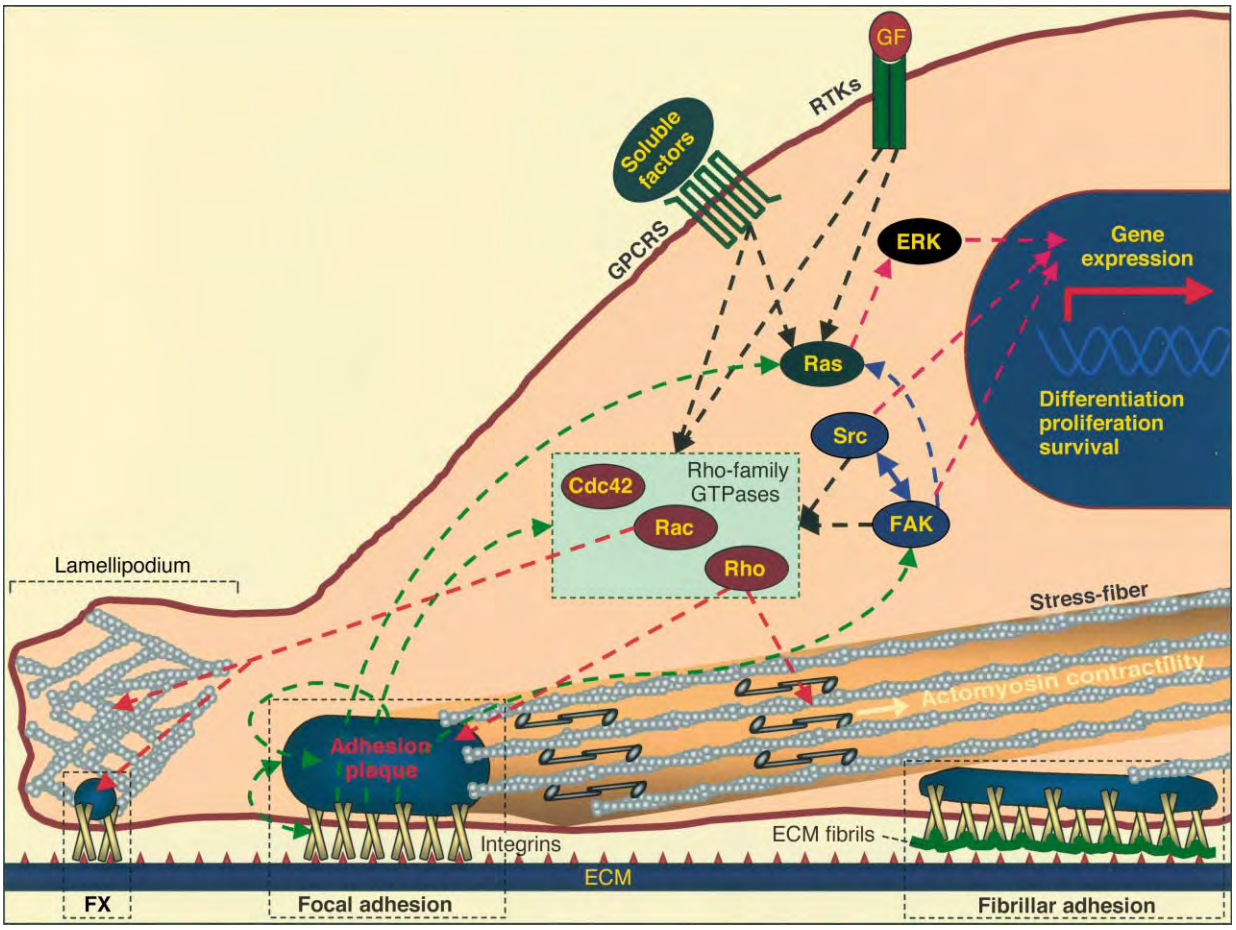

FIGURE 3 A simplified scheme highlighting the major pathways of focal adhesion mediated signaling. Rho family GTPases, including Rho, Rac and Cdc42, are regulated by integrins, growth factors (GFs), receptor tyrosine kinases (RTKs) and G protein coupled receptors (GPCRs). Cdc42 induces the formation of filopodia (not shown) and activates Rac. Rac induces the formation of a meshed network of branched actin filaments, extension of lamellipodia, and formation of focal complexes (FX). Rho induces actomyosin contractility and organizes actin in contractile bundles called stress fibers. Rho activation drives the development of focal adhesions from focal complexes. Rho-induced contractility is also essential for the development of fibrillar adhesions and their translocation toward the cell center. In adhesion sites, integrins activate locally the tyrosine kinases FAK and Src, which then regulate the enzymatic activities and interactions of many other focal-adhesion components. Integrins also affect gene expression, mainly through the activation of the Ras-ERK pathway, and thereby regulate differentiation, proliferation, and survival.

of focal adhesions is stimulated by the small GTPase Rho and requires actomyosin contractility. Characteristic focal-adhesion plaque proteins include vinculin, talin, paxillin, and tyrosine-phosphorylated proteins. Focal adhesions are particularly prominent in cultured cells growing on solid surfaces, yet structures with similar molecular properties are also found *in vivo*.

Another group of matrix adhesions is the focal complexes, which are small, dot-like adhesions present mainly close to the edges of the lamellipodium (Figures 1B and 3). These sites can be associated with cell migration or serve as precursors of focal adhesions. Their formation is induced by the Rho family GTPase Rac.

In the more central locations of many cell types, there are the fibrillar adhesions (also referred to as ECM contacts), which are elongated or dot-like structures associated with ECM fibrils (Figures 1C and 3). The typical components of fibrillar adhesions are extracellular fibronectin fibrils, the fibronectin receptor $\alpha_5\beta_1$ integrin, and the cytoplasmic protein tensin. Fibrillar adhesions emerge from focal adhesions in an actomyosin-dependent fashion.

Another form of ECM adhesions is the podosomes, which are small ($\sim 0.5\ \mu m$ diameter) cylindrical structures containing typical focal-adhesion proteins such as vinculin and paxillin (Figure 1D). Podosomes are found in a variety of malignant cells and in some normal cells such as macrophages and osteoclasts. Characteristic and indispensable proteins of podosomes are gelsolin and dynamin, which localize to tubular invaginations of the plasma membrane typical for these structures. Finally, another type of adhesion is the 3D-matrix adhesions, formed with three-dimensional ECM, which differ from focal adhesions in their overall morphology, fine molecular composition, and function.

Signaling

Focal adhesions and related structures are involved in adhesion-mediated signaling processes affecting various cellular processes such as proliferation, differentiation, anchorage-dependent survival, spreading, and migration. The main signaling paths include the stimulation of local tyrosine phosphorylation driven by FAK and Src, activation of small GTPases of the Rho and Ras family, and the extracellular signal-regulated kinase (ERK) pathway (Figure 3). It is proposed that tethering of FAK to clustered integrins leads to its autophosphorylation, recruitment of Src, and phosphorylation of their downstream targets. The presence of a variety of kinases and their substrates in the submembrane plaque suggests that additional signaling processes are activated by matrix adhesion, yet definitive information about these signaling processes is still scarce.

Focal adhesions themselves are regulated by several signaling systems. In addition to Rho and Rac, excessive Src-mediated phosphorylation and stimulation of appropriate cells by growth factors (e.g., EGF or neuregulin), phosphatases, and proteases have a profound effect on the organization of cell–matrix adhesions.

Focal Adhesions and Mechanosensitivity

Mechanical forces play a key role in the development and fate of focal adhesions and focal complexes. The transition from focal complex to focal adhesion and the growth of focal adhesions require local tension and are dramatically suppressed following treatment with inhibitors of Rho kinase or myosin light-chain kinase (Figure 4). Focal complexes do not appear to depend on actomyosin contractility and even become abundant upon inhibition of cellular contractility. Similarly, the

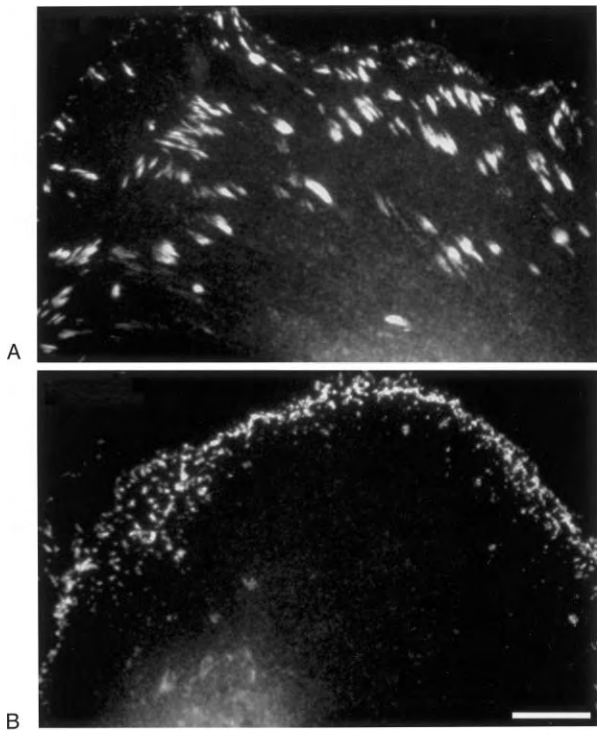

FIGURE 4 The key role of actomyosin contractility in the organization of adhesion site. Rat embryonic fibroblasts (REF52), stably expressing β_3-integrin-GFP, were either (A) untreated (control) or (B) treated with the Rho-kinase inhibitor Y-27632 prior to fixation. Inhibition of actomyosin contractility by Y-27632 causes disassembly of focal adhesions and accumulations of focal complexes. Scale = 10 μm.

maintenance of fibrillar adhesions is not affected by the inhibition of contractility, yet their emergence from peripheral focal adhesions requires actomyosin-driven tension.

Glossary

fibrillar adhesions Elongated or dot-like adhesions that are associated with fibronectin fibrils, mostly along the central areas of the cell.

focal adhesions Flat elongated adhesions associated with prominent actin bundles (stress fibers); also known as focal contacts. They are usually located near the periphery of the cell.

focal complexes Small dot-like adhesions located mainly at the edge of lamellipodium. They are induced by Rac, are associated with cell migration, and can develop into focal adhesions.

podosomes Small cylindrical adhesions found in osteoclasts, macrophages, and various malignant cells.

Rac A Rho family GTPase that stimulates the extension of the lamellipodium and formation of focal complexes.

Rho A Rho family GTPase that stimulates stress-fiber and focal-adhesion formation.

Biography

Benjamin Geiger is the Head of the Department of Molecular Cell Biology, The Weizmann Institute of Science, Israel, and the incumbent of the E. Neter Chair in Cell and Tumor Biology. His research interests are the molecular basis for cell adhesion. He received a B.Sc. from Tel Aviv University, an M.Sc. from Hebrew University, Israel and a Ph.D. and Professorship from The Weizmann Institute of Science, Israel.

Eli Zamir is a Postdoctoral Fellow in the Department of Molecular Cell Biology, The Weizmann Institute of Science, Israel. His research interests are in the structural and functional diversity of cell–matrix adhesions, and in resolving the structure and function of multi-component interaction networks in cells. He received a B.Sc. from Tel Aviv University, Israel and an M.Sc. and a Ph.D. from The Weizmann Institute of Science, Israel.

Free Radicals, Sources and Targets of: Mitochondria

Alberto Boveris
University of Buenos Aires, Buenos Aires, Argentina

Enrique Cadenas
University of Southern California, Los Angeles, California, USA

Mitochondria constitute an active source of free radicals, continuously producing $O_2^{\cdot-}$ (superoxide radical) and $^{\cdot}NO$ (nitric oxide), by auto-oxidation of ubisemiquinone ($UQH^{\cdot}$) and by the enzymatic action of mitochondrial nitric oxide synthase (mtNOS), respectively. These two primary products generate a series of derived and reactive oxidizing species, as H_2O_2 and alkyl and peroxyl radicals. $^{\cdot}NO$ inhibits cytochrome oxidase, competitively with O_2, and ubiquinol–cytochrome c reductase activities. Peroxynitrite ($ONOO^-$), the product of the reaction of $^{\cdot}NO$ with $O_2^{\cdot-}$, inhibits NADH-dehydrogenase. The $[O_2]/[^{\cdot}NO]$ ratio in the tissues is consistent with a respiratory inhibition of 16–26%. The intramitochondrial production of free radicals is involved in a series of oxidative stress situations, in the syndrome of mitochondrial dysfunction, in mitochondrion-dependent apoptosis, in aging and in neurodegenerative diseases. At the same time, $^{\cdot}NO$ and H_2O_2 seem to constitute a pleitrophic signal indicating high mitochondrial energy charge.

Introduction

More than two centuries after Lavoisier's description of animal respiration as a biological oxidation, there is still a fresh and active interest in the mechanisms and the regulation of the processes that link the oxidation of food components to energy production in mammals and in the recognition that the modulation of energy production and expenditure underlies the whole process of life and death of a cell. At the foundation of biochemistry, in the 1920s, there was a controversy on how the hydrogen atoms of organic molecules would end in the H_2O molecule: there were two views – hydrogen activation and oxygen activation, championed by Wieland and Warburg, respectively. The first view involved H_2O_2 as an important intermediate and the second one supported the idea of H_2O as the direct product of O_2 reduction. The monumental contribution of Warburg, identifying cytochrome oxidase as the enzyme catalyzing the overwhelming part of O_2 uptake in biological systems, eclipsed the dispute. However, the concept of the partial reduction of O_2 in biological systems emerged again in 1946 with Michaelis' ideas of univalent electron transfer between biological molecules when he described hydroperoxyl radical ($HO_2^{\cdot}$, the protonated base of superoxide free radical: $O_2^{\cdot-}$), hydrogen peroxide (H_2O_2), hydroxyl radical ($HO^{\cdot}$), and water (H_2O) as the four steps of the univalent reduction of the O_2 molecule. These concepts were strengthened when Gerschman postulated in 1954 that oxygen-free radicals were the common biochemical mechanisms of oxygen and radiation toxicity. At that time, $HO^{\cdot}$ and $HO_2^{\cdot}$ were known as toxic species in radiation chemistry and biology, but by no means it was admitted that these highly reactive free radicals could be produced in physiological conditions. Gerschman exposed small mammals to hyperbaric O_2 to increase the tissue levels of oxygen-free radicals and found synergism between radiation and hyperbaric O_2 in decreasing the survival time of exposed mice.

The transcendental and landmark discovery of superoxide dismutase (SOD) by McCord and Fridovich in 1969 introduced a new dynamism to the understanding of free radical reactions in biological systems. The existence of the enzyme, first described in erythrocytes and later in bacteria and in mammalian organs, implied that its substrate, $O_2^{\cdot-}$, was a normal biological metabolite. In a few years, a dogma advanced by Fridovich evolved: $O_2^{\cdot-}$ and H_2O_2 interact in biological systems and produce the highly toxic $HO^{\cdot}$, which is the chemical species responsible for biological damage. The elegant classification of bacteria as aerobes (protected by superoxide dismutase and catalase), aerotolerant anaerobes (protected by superoxide dismutase but not by catalase), and anaerobes (without protection by superoxide dismutase and catalase) paved the way to the extension of the concept to mammalian biology, oxygen toxicity, and human pathology.

In parallel, mitochondria were recognized by Boveris and Chance in 1972–73 as an active source of H_2O_2 that diffuses to the cytosol. The concept collided with the idea of H_2O_2 produced and utilized in the intraperoxisomal space and avoided as a cellular metabolite. Shortly after, Boveris and Cadenas described $O_2^{\cdot-}$ as the stoichiometric precursor of mitochondrial H_2O_2 and suggested ubisemiquinone ($UQH^{\cdot}$) as the main source of $O_2^{\cdot-}$ upon auto-oxidation. Mitochondria were recognized as the more generalized and quantitatively main source of $O_2^{\cdot-}$ in mammalian organs by 1980. Other sources of $O_2^{\cdot-}$, such as polymorphonuclear leukocytes, xanthine oxidase, and liver endoplasmic reticulum, were also identified as active $O_2^{\cdot-}$ sources that proved to be decisive in specific conditions.

The existence of the family of superoxide dismutases with one of them, Mn-SOD, specific for the mitochondrial matrix, and the mitochondrial production of $O_2^{\cdot-}$ in all aerobic cells were the two ideas that gave the strongest support for the participation of oxygen-free radicals in mammalian and human physiology, pathology, and aging.

The mechanistic concept that was currently accepted for the deleterious action of oxygen-free radicals in biological systems, called the Fenton/Haber–Weiss pathway, involved a primeval and dual role for $O_2^{\cdot-}$, as precursor of H_2O_2 and as reductant of cellular Fe^{3+}, and a second reaction between H_2O_2 and Fe^{2+}, involving the homolytic scission of the peroxide bond and the generation of the highly toxic $HO^{\cdot}$.

The discovery of the generation of nitric oxide ($^{\cdot}NO$) in mammals as a signaling molecule, with roles as intercellular messenger in the cardiovascular system, as neurotransmitter, and as component of the signaling and cytotoxic mechanisms of the immunological system along with the identification of $^{\cdot}NO$ as a free radical, produced a revolution in the concepts of free radical metabolism and signaling in mammalian organs. The linear Fenton/Haber–Weiss pathway evolved to a Y-shaped scheme of the pathways of free radical reactions in mammalian organs (Figure 1).

The redox transitions of ubiquinone, oxygen, and nitric oxide are shown in green, red, and blue, respectively. $O_2^{\cdot-}$, superoxide anion, H_2O_2, hydrogen peroxide; $HO^{\cdot}$, hydroxyl radical; $^{\cdot}NO$, nitric oxide; $ONOO^-$, peroxynitrite; UQH_2, ubiquinol; $UQH^{\cdot}$, ubisemiquinone; UQ, ubiquinone.

The Mitochondrial Production of $O_2^{\cdot-}$ and H_2O_2

Mitochondria were recognized as subcellular organelles by application of supravital stainings by the end of 19th century, and as the powerhouses of cells, sites of the biochemical process of oxidative phosphorylation in the 1950s, after the availability of electron microscopy and the modern methods of cell fractionation. Mitochondrial isolation permitted the identification of the inner mitochondrial membrane as the site in which the mitochondrial complexes I–V were constitutive proteins and as the coupling membrane for the transduction of the redox chemical energy of NADH oxidation into ATP high-energy phosphate bond. By 1955, Chance and Williams produced a complete description of the redox states of the components of the mitochondrial respiratory chain, and defined the operational concepts of mitochondrial metabolic states and respiratory control. The latter concept elegantly describes the state 4 to state 3 transition in which ADP regulates the rate of mitochondrial electron transfer and respiration. State 4, with availability of respiratory substrate but not of ADP, was described as "controlled or resting respiration," whereas state 3, with ample respiratory substrate and ADP availability, was defined as the "active respiration," i.e., the maximal physiological rate of ATP production and O_2 consumption. By determination of the rates of mitochondrial O_2 uptake in both state 4 and state 3, and of the O_2 uptake of tissue slices and perfused organs, it was estimated that mammalian tissue mitochondria under physiological conditions are mostly (60–70%) in state 4, whereas the rest (30–40%) are in state 3, thus meaning that in a physiological setting there is a 30–40% utilization of the ATP-producing capacity.

Isolated mitochondria were identified as sources of H_2O_2, in a process modulated by the mitochondrial state 4/state 3 transition; the rate of H_2O_2 generation in state 4 is about 4–6 times higher than that in state 3.

This fact indicates that a component of the respiratory chain, markedly changing its redox steady state level in the state 4/state 3 transition is the H_2O_2 generator. The rates of H_2O_2 production of mitochondria isolated from mammalian organs are in the range of 0.3–0.8 nmol $H_2O_2 min^{-1} mg^{-1}$ protein for state 4 and 0.05–0.15 nmol $H_2O_2 min^{-1} mg^{-1}$ protein for state 3. In the case of rat heart and liver, mitochondrial H_2O_2 production accounts for ~0.5% of the physiological O_2 uptake.

The mechanistic option for O_2 reduction, between either one 2-electrons step to yield H_2O_2 or two 1-electron steps to yield $O_2^{\cdot-}$ as intermediate, was solved by the fact that submitochondrial particles show a 2 to 1 ratio of $O_2^{\cdot-}$ and H_2O_2 productions, thus establishing $O_2^{\cdot-}$ as the stoichiometric precursor of mitochondrial H_2O_2. The main part of mitochondrial $O_2^{\cdot-}$, ~70%, is vectorially released to the mitochondrial matrix, where it encounters specific intramitochondrial Mn-SOD. Steady state concentrations of 0.08–0.2 nM $O_2^{\cdot-}$ and 5–50 nM H_2O_2 are estimated for the mitochondrial matrix, with a content of 3–10 μM Mn-SOD. The release of $O_2^{\cdot-}$ to the mitochondrial intermembrane space, accounting for ~30% of the mitochondrial $O_2^{\cdot-}$ production, was recognized, being probably in functional relationship to the Cu,Zn-SOD of this compartment. $O_2^{\cdot-}$, from the intermembrane space is released into the cytosol through a voltage-dependent anion channel. Hence, mitochondria may be considered as effective sources of cytosolic $O_2^{\cdot-}$ and this species may contribute to the redox regulation of cell signaling.

Two main $O_2^{\cdot-}$ generating reactions have been described for the mitochondrial respiratory chain. In both cases the intermediate semiquinone form of redox pairs components of the respiratory chain, ubiquinol/ubiquinone, and the $FMNH_2$/FMN component of NADH dehydrogenase, i.e., $UQH^{\cdot}$ and $FMNH^{\cdot}$, respectively, are collisionally and nonenzymatically auto-oxidized by molecular O_2 to yield $O_2^{\cdot-}$. In the case of $UQH^{\cdot}$ auto-oxidation, the chemical process is called the Boveris–Cadenas reaction (reaction [1]) with a second-order reaction constant of $8 \times 10^3\ M^{-1}\ s^{-1}$; it is considered the main mitochondrial $O_2^{\cdot-}$-producing reaction and a biological pacemaker of the aging process.

$$UQH^{\cdot} + O_2 \rightarrow UQ + H^+ + O_2^{\cdot-} \qquad [1]$$

Figure 2 illustrates the mitochondrial reactions that produce $O_2^{\cdot-}$ as well as their vectorial release to the cytosol and to the intermembrane space. Auto-oxidation of other components of the mitochondrial respiratory chain is thermodynamically feasible, but these reactions are not kinetically important on quantitative basis.

The spontaneous surface chemiluminescence of *in situ* organs supported the idea of mitochondria as the main physiological source of oxidizing free radicals. The assay is based in the production of the chemiluminescent species singlet oxygen ($^1O_2$), a downstream by-product of the free radical recombination reactions in biological systems (Figure 1). Liver and brain chemiluminescence increased under hyperbaric O_2 and in ischemia reperfusion following a dependence on mitochondrial $O_2^{\cdot-}$ generation in these conditions.

The Mitochondrial Production of $^{\cdot}NO$

At the beginning of the 1990s, the extraordinary research activity on biological $^{\cdot}NO$ production,

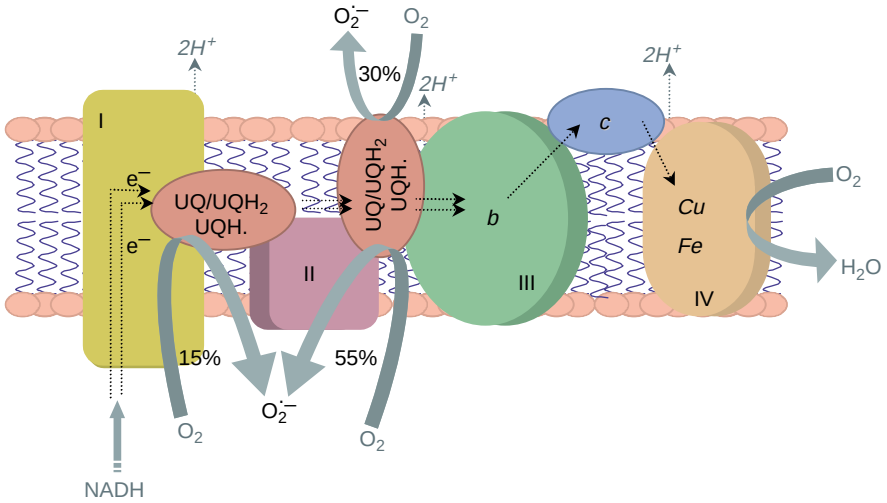

FIGURE 2 Sites of superoxide anion production in the mitochondrial respiratory chain. UQH_2: ubiquinol; UQ: ubiquinone; and $UQH^{\cdot}$: ubisemiquinone. The percentages close to superoxide anion ($O_2^{\cdot-}$) indicate the relative contribution of each reaction to the total mitochondrial $O_2^{\cdot-}$ production.

identified three different nitric oxide synthases (NOS): neuronal NOS (nNOS or NOS-I), inducible or macrophage NOS (iNOS or NOS-II), and endothelial NOS (eNOS or NOS-III). Immunocytochemical assays with antibodies against eNOS gave evidence of a nitric oxide synthase (NOS) located in mitochondria, which was named mtNOS and advanced as a regulator of mitochondrial and cellular respiration. The determination of mtNOS enzymatic activity was elusive for a few years, until two independent groups located in Zurich and Los Angeles/Buenos Aires, succeeded in showing $^{\cdot}NO$ production by rat liver mitochondria and mitochondrial fragments. The original observations in liver mitochondria were later extended to mitochondria from brain, heart, thymus, kidney, and diaphragm, thus dissipating the skepticism on mtNOS activity stemming from a contamination produced during cell fractionation. Mitochondrial $^{\cdot}NO$ production is carried out by mtNOS, a classic NOS, that requires NADPH (K_M = 12–20 μM), arginine (K_M = 5–50 μM), O_2 (K_M = 35–70 μM), and Ca^{2+} for enzyme activity. Calmodulin, tetrahydrobiopterine, and thiols increase the enzymatic activity. The intramitochondrial concentrations of NADPH, arginine, O_2, and Ca^{2+} are in excess or in the range needed for enzymatic activity. The methodology currently used to measure mtNOS activity determines NO production rates of 0.30–1.20 nmol $^{\cdot}NO\ min^{-1}\ mg^{-1}$ protein in mitochondria and submitochondrial preparations.

Recently, in a pivotal contribution, Giulivi and coworkers sequenced the 1429 amino acids of rat liver mtNOS and found it identical to nNOS splice variant αmirystoylated and phosphorylated in posttranslational processes. Transcripts corresponding to nNOSα were found in liver, brain, heart, kidney, skeletal muscle, lung, testis, and spleen. Hence, it is clear that mtNOS is a constitutive protein of the inner mitochondrial membrane with its substrates present in the mitochondrial matrix. Interestingly, a whole series of physiological situations were reported to regulate the level and activity of mtNOS that were up-regulated during brain development, by cold exposure, and by acute hypoxia, and down-regulated by thyroxin and angiotensin II. Treatments with enalapril, the converting-enzyme inhibitor, increased mtNOS activity. Pharmacological administration of haloperidol and chlorpromazine decreased brain mtNOS activity.

Intramitochondrial steady-state concentrations of $^{\cdot}NO$ are calculated as 20·50 nM and a release of 29 nM $^{\cdot}NO$ was electrochemicaly measured after supplementation of a single mitochondrion with Ca^{2+}. In the tissues under physiological conditions with a steady-state oxygenation of 20 μM O_2, the $[O_2]/[^{\cdot}NO]$ ratio is 500–1000, which competitively inhibit cytochrome oxidase by 16–26%. $^{\cdot}NO$ and $O_2^{\cdot-}$ metabolism in the mitochondrial matrix are linked by the very fast reaction between $^{\cdot}NO$ and $O_2^{\cdot-}$ to produce $ONOO^-$. This oxidative utilization of $^{\cdot}NO$ is the main (60–70%) pathway of $^{\cdot}NO$ metabolism, but at the same time it is only a minor part (15%) of intramitochondrial $O_2^{\cdot-}$ utilization. The reductive utilization of $^{\cdot}NO$ by ubiquinol and cytochrome oxidase provides a minor (20%) pathway of $^{\cdot}NO$ catabolism. The cellular conditions in which $^{\cdot}NO$ diffuses from mitochondria to cytosol, as well as the conditions in which $^{\cdot}NO$ diffuses from cytosol to mitochondria are unsolved questions for the complex process of intracellular signaling. Figure 3 shows a view of the integrated metabolism of $O_2^{\cdot-}$ and $^{\cdot}NO$ in mitochondria.

The effects of $^{\cdot}NO$ on mitochondrial electron transfer were reported in 1994 by two British research groups as the inhibition of brain and muscle cytochrome oxidase (complex IV) activity by low $^{\cdot}NO$ concentrations within a reversible and O_2-competitive biochemical process. The observation was rapidly confirmed by other groups using $^{\cdot}NO$ donors and pure $^{\cdot}NO$ in liver, heart, and brown fat mitochondria. $^{\cdot}NO$ levels of 0.1–0.3 μM decreased cytochrome oxidase activity and mitochondrial respiration to one half. The inhibition is reversible by dilution, hemoglobin supplementation, or exposure to $O_2^{\cdot-}$. The O_2-competitive inhibition of cytochrome oxidase renders the inhibition more important at low O_2 concentrations; ratios of $^{\cdot}NO/O_2$ affinities of 150–500 were reported for enzymatically active cytochrome oxidase. A second sensitive point in the mitochondrial respiratory chain is at the ubiquinol–cytochrome *c* reductase segment (complex III); half inhibition of electron transfer between cytochromes *b* and *c* occurs at 0.2–0.4 μM $^{\cdot}NO$, enhancing the production of $O_2^{\cdot-}$ and H_2O_2 in submitochondrial particles and in mitochondria. A third sensitive point is located at NADH-dehydrogenase (complex I), in this case, $ONOO^-$ appears as the effective inhibitory agent.

Figure 4 illustrates the direct and indirect effects of $^{\cdot}NO$, in the latter case through $ONOO^-$ formation, on the mitochondrial respiratory chain. The reversible effects of $^{\cdot}NO$ on cytochrome oxidase and ubiquinol-cytochrome *c* reductase are two sides of the regulation of mitochondrial respiration by $^{\cdot}NO$. On the one hand, the inhibition of cytochrome oxidase and, on the other, the supply of $O_2^{\cdot-}$ to remove the respiratory inhibition, as it may become a physiological need with high steady-state concentrations of $^{\cdot}NO$, as it is the case in ischemiareperfusion and in inflammation. The irreversible effects of $ONOO^-$ on complexes I and III are related to situations in which sustained high levels of $ONOO^-$ lead to mitochondrial dysfunction and apoptosis.

Concerning the important question of whether or not mtNOS enzymatic activity regulates mitochondrial functions under physiological conditions, several reports described the modulation of mitochondrial O_2 uptake and H_2O_2 production by the activity of mtNOS in

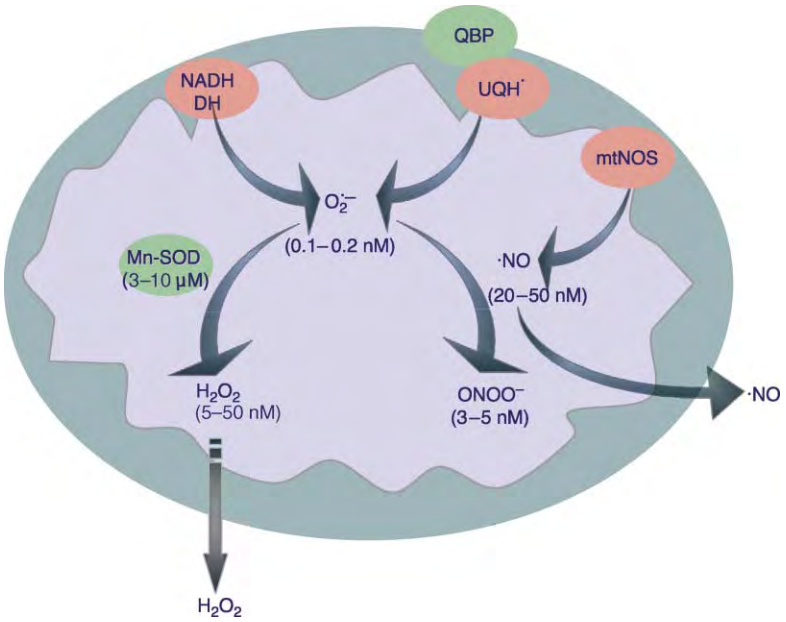

FIGURE 3 Metabolism of superoxide radicals and nitric oxide in the mitochondrial matrix. The numbers below the symbols indicate physiological steady-state concentrations for mammalian organs. The arrows reaching outside the mitochondrion indicate diffusion of H_2O_2 and ·NO to the cytosol. QBP: ubiquinone binding protein; NADH DH, NADH dehydrogenase; mtNOS, mitochondrial nitric oxide synthase; Mn-SOD, Mn-superoxide dismutase.

isolated mitochondria. The current view is that mtNOS does regulate mitochondrial respiration; hence, mtNOS, cytochrome oxidase, and F_1-ATPase are the three regulatory proteins of cellular O_2 uptake and energy production. The biochemical activity of mtNOS (expressed as nmol ·NO min^{-1} mg^{-1} protein) is usually measured as the difference in ·NO production between the assay performed in the presence of arginine and in the presence of a competitive inhibitor of NOS, such as NMMA or NNA. The *regulatory activity* of mtNOS is best expressed by the difference in the rates of O_2 uptake or H_2O_2 production between the system supplemented with arginine, the highest mtNOS activity, and the system in the presence of the NOS inhibitor, the lowest

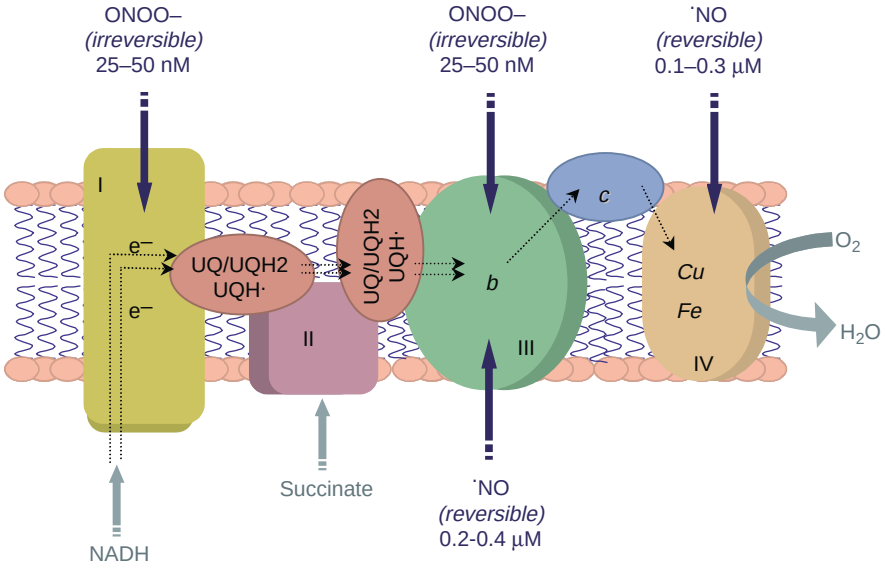

FIGURE 4 Sites of action of nitric oxide and peroxynitrite in the mitochondrial respiratory chain. Reversible and irreversible indicate the type of inhibition and are understood as regulatory or toxic processes, respectively. The indicated steady-state concentrations were determined or estimated to reduce enzymatic activity to one half, at a concentration of 100–150 μM O_2.

mtNOS activity. The *regulatory capacity* of ·NO, estimated as the ratio of the rates of *regulated* O_2 *uptake*/·NO production or of *regulated* H_2O_2 *production*/·NO production is ~70 for O_2 uptake and ~0.4 in H_2O_2 production. The activity of mtNOS in isolated mitochondria markedly increased the $[O_2]_{0.5}$ of mitochondrial O_2 uptake from 1.1 μM O_2 in the case of inactive mtNOS, to 2.2 μM O_2 in the case of an active mtNOS. However, it is not clear to what extent these effects, observed with isolated mitochondria, occur under physiological conditions in myoglobin-containing tissues and in blood-perfused organs, due to the high affinity of the two mentioned hemoproteins for ·NO.

The Physiological Role of the Mitochondrial Production of $O_2^{\cdot-}$, H_2O_2, and ·NO

The early recognition that $O_2^{\cdot-}$ and H_2O_2 are both able to initiate reactions harmful to cell and tissues is now complemented by the concept that both $O_2^{\cdot-}$ and H_2O_2 are carefully regulated metabolites capable of signaling the regulatory devices of the biochemical and genetic systems of the cell. ·NO was initially recognized as an intercellular messenger and later as an intracellular regulator. At present, the three chemical species are considered to participate in integrated processes of intracellular regulation and in intercellular signaling, communication, and cytotoxicity. The redox regulation of gene expression and intercellular communication is just starting to be understood as a vital mechanism in health and disease.

The fine regulation by H_2O_2 of cell function was advanced by Antunes and Cadenas in 2001 when they showed that in Jurkat T-cells, steady-state concentrations below 0.7 μM H_2O_2 place cells in a proliferative state, whereas at 1.0–3.0 μM, H_2O_2 cells develop programmed cell death, and at levels higher than 3.0 μM H_2O_2 cells undergo necrosis. H_2O_2 and ·NO share the chemical properties of being uncharged and the biological property of being highly diffusible through biological membranes, at variance with $O_2^{\cdot-}$ and $ONOO^-$ that are charged and non-diffusible molcules. Consequently, the first two species are suitable for cellular and intercellular signaling, and the two latter for signaling and cytotoxicity in confined spaces.

There is evidence that H_2O_2 and ·NO are able to modulate mitogen-activated protein kinases (MAPKs), the widespread integral components of intracellular phosphorylation and dephosphorylation signaling cascades involved in cell survival, proliferation, differentiation, and death. The interactions are complex and seem to involve intracellular glutathione and $ONOO^-$. Both, H_2O_2 and ·NO diffusing from mitochondria to the cytosol are considered to constitute a pleiotropic signal involved in the regulation of a series of cellular processes, among them JNK signaling…NO diffusing from mitochondria may also modulate (inactivate) JNK1 via S-nitrosylation. The concept of narrow ranges of intracellular messenger molecules for different or opposite biological actions, as observed for H_2O_2 levels in the proliferation/apoptosis transition, is now applied to effector systems with two regulators, H_2O_2 and ·NO, with the consequence of four different responses for the combination of the two binary conditions of low and high level of the two signals (Figure 5).

It has been understood for the last 30 years that excess generation of $O_2^{\cdot-}$ and H_2O_2 leads to oxidative stress and harmful biological situations. ·NO has been added to these two species in the last decade. The classical concept of oxidative stress, as brought forward by Sies implies an imbalance between oxidants and antioxidants, in favor of the former. The situation is understood as reversible, especially by supplementation with antioxidants, and also as leading, sooner or later, to biological dysfunction. The concept is applicable to subcellular organelles, cells, organs, systems, or whole organisms. From a biochemical perspective, oxidative stress is determined by an increased steady-state level of at least one of the oxidant species ($O_2^{\cdot-}$, H_2O_2, ·NO, $ONOO^-$, $HO^{\cdot}$, $ROO^{\cdot}$, and $^1O_2$) that leads to increased levels of the other oxidizing species downstream of the

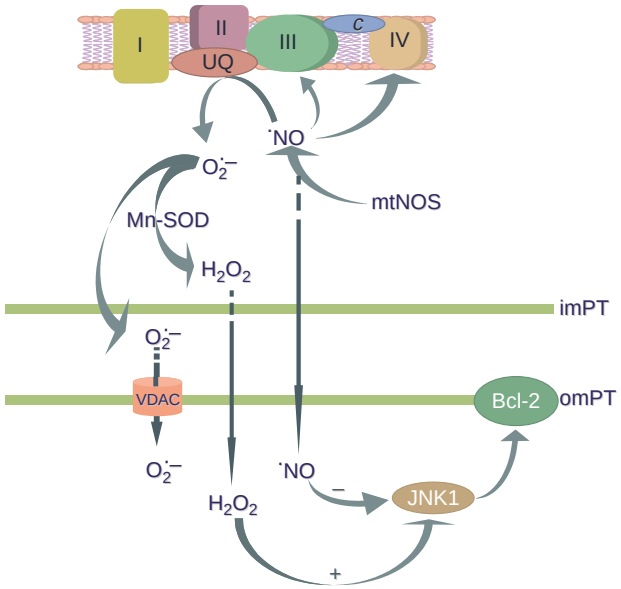

FIGURE 5 Mitochondrial production of oxygen- and nitrogen-centered radicals and cell signaling. The scheme shows the sites of action of nitric oxide (·NO) on the respiratory chain, the ensuing production of $O_2^{\cdot-}$ and H_2O_2, the release of these reactive species from the mitochondrion (controlled by VDAC in the case of $O_2^{\cdot-}$), and their effect on JNK signaling.

free radical pathways (Figure 1) and to biochemical damage.

Oxidative Stress and Dysfunctional Mitochondria: Mitochondria as Targets of Free Radicals

In the last few years, the concept of dysfunctional mitochondria was associated with mitochondrial features under oxidative stress, biological damage, and pathological conditions. Mitochondria are considered dysfunctional by comparison of their functions and properties with normal control mitochondria. The classic mitochondrial properties, that reflect their energy-producing physiological function, i.e., the state 3 rate of O_2 uptake, the respiratory control, the membrane potential, and the ADP:O ratio, are the parameters that, when decreased, support the contention of dysfunctional mitochondria. In addition, dysfunctional mitochondria frequently show increased rates of $O_2^{\cdot-}$ and H_2O_2 production.

Mitochondrial dysfunction is a mitochondrial syndrome that has been observed in ischemia/reperfusion, endotoxic and septic shock, a series of pathological situations, and aging. The syndrome is characterized by decreases in the rates of state 3 respiration and ATP synthesis, in mitochondrial membrane potential, and in respiratory control ratio, and by increases in the rate of state 4 respiration, and mitochondrial size and fragility. The reported decreases in the rates of state 3 respiration and of mitochondrial electron transfer are in the range of 30–40%; it seems that more damaged mitochondria are not compatible with living cells. There are three main chemical species involved in the molecular mechanism of this syndrome; the triad is constituted by $O_2^{\cdot-}$, $^{\cdot}NO$, and peroxynitrite ($ONOO^-$). The first chemical species is the free radical $O_2^{\cdot-}$, that is continuously produced in the auto-oxidation of $UQH^{\cdot}$ and $FMNH^{\cdot}$, intermediates of the respiratory chain function, and mainly dismutates to H_2O_2. The second free radical is $^{\cdot}NO$, that is continuously produced by mtNOS as regulator of respiration and mainly converted to $ONOO^-$. The latter, the third member of the triad, is produced by collision of $O_2^{\cdot-}$ and $^{\cdot}NO$ in the fastest reaction known in biological systems ($k = 1.9 \times 10^{10}\ M^{-1}\ s^{-1}$), except for the neutralization reaction of H^+ and HO^- ($k = 14 \times 10^{10}\ M^{-1}\ s^{-1}$). Peroxynitrite is a powerful oxidant, that when produced in excess, as in ischemia/reperfusion and inflammation, produces tyrosine nitration of intramitochondrial proteins. Intramitochondrial levels of 3–5 nM $ONOO^-$ have been estimated for physiological conditions, and levels above 20−30 nM are considered cytotoxic. The whole syndrome of dysfunctional mitochondria appears mainly driven by excess $^{\cdot}NO$ and $ONOO^-$.

Selective inhibition of NADH-dehydrogenase (complex I) activity in submitochondrial particles by $ONOO^-$ has been reported. Complex I dysfunction was also reported in animal models and in human neurodegenerative diseases. This selective mitochondrial defect is understood as secondary to a sustained oxidative stress and was reported in aged humans and in patients with neurodegenerative disorders, among them Parkinson's and Alzheimer's diseases. The near-target generation of $O_2^{\cdot-}$ by NADH-dehydrogenase and of $ONOO^-$ after molecular collision of $O_2^{\cdot-}$ with matrical $^{\cdot}NO$, is considered determinant in the selective impairment of complex I in neurodegenerative diseases.

The continuous mitochondrial production of free radicals and oxidizing species makes mitochondria the quantitatively most important source of these harmful species in the cell, and, at the same time, the sensitivity of mitochondrial functions to increased levels of the oxidizing free radicals and related chemical species renders mitochondria the most sensitive cellular target for the deleterious action of free radicals. The rapid mitochondrial turnover ($t_{1/2}$ of about 7 and 28 days in liver and brain, respectively) seems to reflect this double role of mitochondria as source and target of biologically harmful free radicals.

Mitochondrion-Dependent Apoptosis

The role of mitochondria in apoptosis is now well-established; a specific mitochondrion-dependent pathway of cell death is differentiated from the death-receptor-mediated apoptosis. Mitochondrion-dependent apoptosis entails oxidative stress and is modulated by MAPK signaling through JNK activation associated with Bcl-2 down-regulation, cytochrome *c* release, and the downstream activation of caspases. A very early activation of mtNOS has been reported in thymocyte-induced apoptosis. Thapsigargin supplementation of isolated thymocytes sequentially increases cytosolic Ca^{2+} and the activities of mtNOS and of the NOS of endoplasmic reticulum. A crosstalk between mitochondria and endoplasmic reticulum, in which Ca^{2+} and $^{\cdot}NO$ are the signals, is established in the initial phase of thymocyte apoptosis followed by the well-established mitochondrial changes that are characteristic of mitochondrion-mediated apoptosis: fall in mitochondrial membrane potential, mitochondrial dysfunction, opening of the membrane transition pores (MTP), and cytochrome *c* release.

The central role of mitochondria in the cell death program is exerted during the first and reversible phase of early apoptosis through the release of H_2O_2 and $^{\cdot}NO$ to either activate or inhibit cytosolic JNK, respectively, which attached to mitochondria catalyzes phosphorylation of Bcl-2 and Bcl-x_L and other not yet identified mitochondrial proteins. JNK-mediated phosphorylations initiate the steps to the second and irreversible phase of apoptosis by opening the inner membrane transition pore and by releasing $Ca^{2+}$and $O_2^{\cdot -}$ to the intermembrane space, followed by the opening of the outer membrane transition pore and release of cytochrome *c* to the cytosol. The next steps in the execution of the cell death program, such as apoptosome assembly and caspase activation, are independent of mitochondrial intervention.

The Mitochondrial Hypothesis of Aging

In the last few years, a strong current of opinion has linked the processes of mitochondrial oxyradical production, continuous oxygen toxicity, aging, and lifespan, in "the mitochondrial hypothesis of aging" following the idea of mitochondria as the biological clock. The free radical theory of aging was proposed by Harman in 1956 and considered that aging was caused by the cumulative and random effects of free radicals; an increased median lifespan in rats and mice supplemented in their food with organic antioxidants was observed. The continuous mitochondrial production of $O_2^{\cdot -}$ and $^{\cdot}NO$ as primary free radicals, with a whole series of derived reactive species, such as H_2O_2, $ONOO^-$, $HO^{\cdot}$, $ROO^{\cdot}$, and $^1O_2$, supports the notion of mitochondria as pacemakers of organ aging. As mentioned above, increased intramitochondrial steady-state concentrations of reactive oxygen and nitrogen species have been associated to the appearance of dysfunctional mitochondria in situations of acute oxidative stress, such as ischemia/reperfusion, and endotoxic or septic shocks. The persistence of a chronic oxidative stress situation is considered an effective aging factor. It is worth noting that increased levels of oxidative stress markers, such as 8-hydroxydeoxyguanosine, protein carbonyls, hydroperoxides, and TBARS, have been reported upon aging. Dysfunctional mitochondria, with decreases in the state 3 respiration, membrane potential, and respiratory control, and with increased size have been reported upon aging. Interestingly, some of the altered parameters were partially or totally normalized by treatment with antioxidants.

It is noteworthy that some mitochondrial macromolecules appear selectively damaged upon aging. In this way, mitochondria are the pacemaker of aging, both as the main continuous source and as the main target of oxidizing free radicals. Ames and co-workers pioneered the field with the observation of increased mtDNA damage, expressed as the level of 8-hydroxy-deoxyguanosine in tissues and in urine and in old animals as compared with young ones. Other mitochondrial macromolecules, such as mtRNA and the regulatory factor Bcl-2, have been reported damaged upon aging. Some mitochondrial enzymatic activities as NADH-dehydrogenase, cytochrome oxidase, adenine nucleotide translocase, and carnitine-acyl transferase are selectively decreased upon aging. There is a hypothesis linking these observations that considers that damaged mtDNA and mtRNA will produce, through mitochondrial protein synthesis, faulty polypeptides that would contribute along with protein carbonyls, hydroperoxides, and TBARS, to sub-optimal enzyme function and the appearance of dysfunctional mitochondria. The latter would signal for lysosomal digestion and for apoptosis. The decrease in energy availability and in tissue-active cells, as consequence of the decreased amount of mitochondria and of the enhanced apoptosis, would lead to the reduction in tissue function that is characteristic of tissue aging.

Glossary

apoptosis The active process by which cells execute a series of processes leading to cell death in a way that is not harmful for the tissue and the organism. It is opposite to inflammation and necrosis, a process in which toxic products reach the neighbor cells.

free radicals Molecules, better understood as chemical species, having an unpaired electron in their external orbitals. The feature makes the chemical species unstable and highly reactive with low specificity. However, some biologically produced free radicals, such as superoxide radicals ($O_2^{\cdot -}$) and nitric oxide ($^{\cdot}NO$), are relatively stable and quite selective in their reactions. Other biologically produced radicals, such as hydroxyl, alkyl and peroxyl ($HO^{\cdot}$, $R^{\cdot}$, $ROO^{\cdot}$) radicals, are highly reactive and unspecific. The point near the chemical symbols indicates the unpaired electron.

hydrogen peroxide The product of the bivalent reduction of the oxygen molecule (HOOH; H_2O_2); it is not a free radical, but originates $HO^{\cdot}$ radical upon interaction with Fe^{2+}.

mitochondrial electron transfer chain A series of biological and organic molecules embedded in the inner mitochondrial membrane that have chemical groups able to undergo reversible cycles of reduction/oxidation. The function of the mitochondrial respiratory chain channels the reducing equivalents from food components to the oxygen molecules and constitute the biochemical basis of respiration.

Biography

Alberto Boveris is a Professor of Physical Biochemistry at the University of Buenos Aires (Argentina). He has B.S. degrees in pharmacy and biochemistry and a Ph.D. from the same university. During 1975–79, Boveris and Cadenas described the mitochondrial production of superoxide radical and hydrogen peroxide. His current research interests are aging mechanisms, organ chemiluminescence, and mitochondrial nitric oxide synthase.

Enrique Cadenas is a Full Professor and Chairman of Molecular Pharmacology and Toxicology at the School of Pharmacy of the University of Southern California. He holds an M.D. and a Ph.D. from the University of Buenos Aires (Argentina) and an honorary Ph.D. from the University of Linköping (Sweden). His fields of investigation include quinone redox reactions and mitochondrial metabolism and signaling.

Friedreich's Ataxia

Paul E. Hart and Anthony H. V. Schapira
University College London, London, UK

Friedreich's ataxia (FRDA) is an autosomal-recessive disorder that causes ataxia, sensory loss, cardiomyopathy, skeletal abnormalities, and in a proportion of patients diabetes and optic atrophy. It is the commonest inherited ataxia with an estimated prevalence of 1:29 000. Carrier prevalence is between 1:60 and 1:90. The responsible gene and its gene product, frataxin, have both been identified. Ongoing investigations into the function of frataxin, and the pathophysiology of FRDA are opening up new avenues for therapeutic intervention in this devastating neurodegenerative disorder.

Historical Perspective

In a series of five papers published between 1863 and 1877, Nicholaus Friedreich reported nine members of three families who had onset in puberty of ataxia, dysarthria, sensory loss, muscle weakness, scoliosis, foot deformity, and cardiac symptoms. Areflexia was only described in the final two reports, but was later adopted as one of the clinical diagnostic criteria. Over a century later the elucidation of the molecular mechanism of Friedreich's ataxia (FRDA), and the availability of genetic testing for diagnosis, allowed greater clarity regarding the phenotypic spectrum of this disorder.

Clinical Features

Disease onset ranges from 1.5 to 51 years in reported series. Loss of ambulation has been reported to occur at a mean of 15.5 $\pm$ 7.4 years after disease onset but ranges between 3 and 44 years. Death is most commonly as a consequence of cardiomyopathy and is at a mean age of 37.5 $\pm$ 14.4 years. Retrospective analysis of disease progression has reported a mean time to wheelchair confinement of 11 years. Atypical presentations include onset over the age of 25 years (late-onset Friedreich's ataxia (LOFA)), the preservation of lower limb reflexes (Friedreich's ataxia with retained reflexes (FARR)), and presentation as a pure spastic paraparesis, spastic ataxia (Acadian FRDA), pure sensory ataxia, or chorea.

Pathology

Pathological studies of FRDA report changes maximal in dorsal root ganglia, dorsal columns, corticospinal tracts, and heart. Macroscopically the spinal cord is atrophic with the posterior and lateral columns particularly affected. Changes within the nervous system are thought to be the consequence of a dying back process from the periphery affecting the longest and largest myelinated fibres that show changes of an axonopathy. Demyelination is seen in the dorsal columns. The cerebellar cortex shows only mild neuronal loss, but the dentate nucleus, and Clarke's column in the cord show marked changes. The cerebellar and occipital cortex, show reduced phospholipid levels in the absence of neuronal loss.

Genetics

In 1988 the FRDA gene was mapped to chromosome 9. The gene was linked to 9q13-21.1 in 1990 and cloned in 1996. Ninety-eight percent of cases are now known to be the result of a homozygous GAA triplet repeat expansions in intron 1 of the FRDA gene. This is a unique trinucleotide repeat (TNR) disorder in that its inheritance is autosomal recessive, its location is intronic, and it involves a GAA trinucleotide as opposed to CAG repeat as found in the majority of TNR disorders. The repeat length in normal individuals is 6-34, but is expanded in patients and carriers to between 67 and 1700. Repeat lengths are unstable. Paternal transmission is associated with a reduction in repeat length, an effect that increases with increasing paternal age. Maternal transmission can cause an increase or decrease in repeat length, and expansions are greater with increasing maternal age. The remaining 2% of patients are compound heterozygotes harboring an expanded repeat on one allele and a point mutation on the other. Twenty-three different point mutations are described to date and include missense, frameshift, splice site, initiation codon, and nonsense mutations. The former are found only in the C-terminal suggesting that functional domains reside in this part of the protein.

The location of these mutations in highly or poorly conserved amino acids correlates with the severity of the phenotype and the presence of atypical features. No cases resulting from homozygous point mutations have been described, although the population incidence of such individuals has been calculated to be $1{:}100 \times 10^6$. Clinically typical FRDA may occur in individuals in the absence of linkage to chromosome 9 suggesting that a second locus may exist.

Phenotype–Genotype Correlations

Clinical parameters correlate with the repeat length size. The size of GAA1 (the larger repeat allele) accounts for between 33% and 73% of the variation in the age of onset in various studies. GAA2 (the smaller allele) accounts for less than 20% of this variability. Indeed, GAA1 correlated better than GAA2 for several disease parameters and disease complications, including cardiomyopathy, in all studies except one. By contrast, the development of diabetes mellitus in FRDA correlated in only one study.

Further variation may result from other factors. The GAA repeat length may vary in a tissue-specific pattern due to mitotic instability, and peripheral blood samples may be a poor indicator of repeat lengths in pathologically affected tissues. GAA1 has been shown to differ in different brain regions and in various tissues. *Cis*-acting factors may also influence the phenotype. Potential mechanisms would include effects upon the stability of the trihelix structure by sequence alterations within or flanking the GAA expansion. Other genetic or environmental factors may also exert an influence on the phenotype. This is illustrated by the finding that the age of onset in sibs correlates strongly regardless of the degree of difference between their repeat lengths.

Gene and Gene Product

The FRDA gene contains seven exons within 80 kb of nuclear DNA. Transcription most commonly generates a 1.3 kb product translated into a 210 amino acid protein named frataxin. Alternative splicing generates a 171 amino acid protein of uncertain significance. Frataxin and mRNA levels are maximal in tissues of high mitochondrial content (heart, pancreas, liver, and skeletal muscle), although not all of these exhibit obvious clinical involvement in FRDA. Within the CNS, mRNA levels are highest in the cord, low in the cerebellum, and very low in the cerebral cortex. Frataxin appears to play a role in development; its homozygous knockout is lethal at an early embryological stage. Frataxin mRNA levels are high in fetal spinal cord, dorsal root ganglion, heart, liver, skeletal muscle, and skin. Lymphocytes from patients with homozygous expansions contain low levels of frataxin and these levels, and that of the mRNA, are inversely related to the size of the smaller repeat. The block is thought to occur at the level of transcript elongation, and the mechanism for this is believed to be through the formation of unusual DNA structures, such as DNA triplexes, by the GAA/TTC repeats. Several point mutations appear to alter the secondary structure of the protein and thus influence mitochondrial uptake or cleavage.

The function of frataxin is incompletely understood. The amino acid sequence shows no strong homology to any proteins of known function. It has, however, been shown to contain an N-terminal mitochondrial targeting sequence in its first 55 amino acids. The predicted mitochondrial location was confirmed when tagged expressed frataxin was shown to colocalize with mitochondrial markers in HeLa and COS cells. An inner membrane and a matrix location within the mitochondrion have both been proposed. X-ray crystallography studies reveal similarities to ferritin, a site for protein–protein interaction, and the ability to bind one molecule of iron. Point mutations in the protein core cause more severe phenotypes than those within the ferritin-like anionic patch, or flat external protein interaction surface.

A number of animal and cell models of FRDA, including transgenic mice, have provided insights into the pathogenesis of FRDA. Increased susceptibility to oxidative stress, increase in cellular and mitochondrial iron content, defects of the iron–sulfur center containing complexes of the mitochondrial respiratory chain, and reduced mitochondrial DNA levels have all been reported. Some of these changes have also been reported in human tissue. A role for frataxin in mitochondrial iron–sulfur (Fe–S) center synthesis has been proposed. The exact relationship between these biochemical perturbations remains incompletely understood.

Therapeutic Intervention

Based on the improved understanding of the pathogenesis of FRDA, a number of novel therapeutic strategies have been evaluated. Iron chelation restores mitochondrial iron levels and prevents MRC dysfunction in yeast models, but their *in vivo* use has been problematic. Antioxidants, including idebenone, coenzyme Q_{10}, vitamin E, N-acetyl cysteine, and selenium, have also been used. In some studies idebenone has resulted in a decrease in cardiac hypertrophy and decreases in surrogate markers of oxidative damage to DNA. Other studies have failed to show a benefit. Combined therapy with coenzyme Q_{10} and vitamin E has shown improvement in magnetic resonance spectroscopy and echocardiographic parameters.

Future therapeutic trials in FRDA may make use of antioxidants or other agents coupled to the triphenylphsphonium cation, which facilitates mitochondrial targeting of the agent. Potentials for gene therapy are also being explored, and may utilize drugs that interfere with the "sticky DNA" structures that are thought to be the cause of the transcription blockade that occurs in FRDA.

Biography

Paul Hart is a Wellcome Research Training Fellow and Neurologist at the Department of Clinical Neurosciences, Royal Free Campus, University College London. His Ph.D. and primary research interests are on the interactions between nuclear and mitochondrial DNA, and the role of mitochondrial dysfunction in neurodegeneration.

A. H. V Schapira is Chairman, University Department of Clinical Neurosciences at the Royal Free and University College Medical School, and Professor of Neurology at the Institute of Neurology, Queen Square, London. His primary research interests are into the aetiology and pathogenesis of neurodegenerative diseases including Parkinson's disease, Huntington's disease, and Friedreich's Ataxia.

G Protein Signaling Regulators

John H. Exton
Vanderbilt University, Nashville, Tennessee, USA

Regulators of G protein signaling are important controllers of the system by which many agonists (hormones and neurotransmitters) transmit their signals across the cell membrane to influence intracellular processes. This system involves heterotrimeric G proteins, which are activated when the agonists bind to their specific receptors, and effectors (enzymes and ion channels), which are the targets of the G proteins. Activation of the G proteins by the receptors involves the release of GDP from their α-subunits and the subsequent binding of GTP, and the dissociation of the $\beta\gamma$-subunits from the G proteins. The GTP-bound α-subunits and the free $\beta\gamma$-subunits then act on their target effectors. Turning off the system requires the hydrolysis of GTP to GDP by the intrinsic GTPase of the α-subunits and this is a relatively slow process. Regulators of G protein signaling accelerate the GTPase activity thereby terminating the stimulation of effectors and allowing the G protein to revert to its GPD-liganded heterotrimeric state where it can activate again by agonist binding to receptor.

Discovery of Regulators of G Protein Signaling

Regulators of G protein signaling (RGSs) were discovered as negative regulators of G protein signaling in *S. cerevisiae* and *C. elegans*. In *S. cerevisiae*, a mutation termed *sst2* caused the yeast to become supersensitive to mating pheromone. However, at the time the *SST2* gene was identified, knowledge of signaling pathways was rudimentary and the connection to G proteins could not be made. Later it became clear that signaling in yeast was similar to that in mammals, i.e., the topology of pheromone receptors was similar to that of G protein-coupled receptors and the yeast G_α subunit shared considerable identity with mammalian $G_{i\alpha}$. Later, genetic evidence indicated a direct interaction between SST2 and G_α, and studies of mutations in G_α and SST2 led to the conclusion that SST2 acted as a GTPase-activating protein (GAP) for G_α.

Genetic analysis of *C. elegans* revealed a gene (*egl-10*) that encoded a protein that was similar in its C-terminal region to SST2. Similar to what was found in *S. cerevisiae*, the function of EGL-10 (to increase the frequency of egg laying via serotonergic motor neurons) depended on the presence of a G_α protein (GOA-1) that was homologous to mammalian $G_{o\alpha}$.

Multiple homologues of SST2 and EGL-10 have been identified in higher eukaryotes, utilizing yeast two-hybrid screens, database searches for related sequences, polymerase chain reaction, and rescue of the SST2-deficient phenotype in yeast. A large family of RGS proteins (more than 30 members) that show activity to different G proteins has now been identified in mammals (Table I). They differ significantly in size, but all have a diagnostic RGS core domain and exhibit GAP activity towards heterotrimeric G proteins.

Structure of RGS Proteins

RGS proteins have a conserved RGS domain of ~130 amino acids (Figure 1). This domain is capable of binding G_α subunits and stimulating GTP hydrolysis. In addition, certain RGSs have other domains in their N- and C-terminal regions. These may be PDZ, PTB, GGL, PH, DH, PX, and DEP domains, transmembrane spans, cysteine strings, and domains that bind the adenomatous polyposis coli protein (APC), GSK3, β-catenin, PKA, GRK, and G$\beta\gamma$ (Figure 1, see legend for definitions). The presence of these domains illustrates that RGSs have more functions than GAP activity and are targeted to membranes by multiple mechanisms.

The RGS domain has been defined by X-ray crystallography as a complex between RGS4 and $G_{\alpha i}1$, and by NMR analysis of a fragment of GAIP. The domain is globular and mostly helical in structure, based on a four-helix bundle and a second domain composed of the N- and C-terminal helices. Many of the most conserved residues face into the helical bundles, and others are involved in G_α binding. Three interhelix loops make contact with the three switch regions of G_α (those regions that show the greatest conformational changes when GDP is replaced by GTP), but there is no contact with bound GTP.

Mechanisms of RGS Proteins

RGS proteins interact with active (GTP-bound) G_α-subunits and accelerate the hydrolysis of GTP. In the absence of RGSs and certain effectors, the rate of hydrolysis of GTP by G_α-subunits is very slow and inappropriate for rapid on/off signaling. RGSs can increase the rate of GTP hydrolysis by up to 2000-fold. RGSs act by altering the conformation of the G_α–GTP complex thus causing G_α to be a more efficient GTPase. The transition state intermediate involved in the hydrolysis of GTP can be mimicked by the complex G_α–GDP–$A1F_4$, and this has helped elucidate the mechanism of action of RGSs through crystallographic and other studies. As noted above, RGS proteins have a broad interface with G_α-subunits that includes the three switch regions. In the case of RGS4, the major change exerted on $G_{\alpha i}1$ is decreased mobility of switch II, and it has been suggested that switch II is stabilized in a catalytically active conformation. Because of the conservation of key residues in the contact site of the RGS domain, this mechanism is probably general. Other residues that have been shown by mutation to affect the GAP activity of the RGSs are probably involved in stabilizing the catalytic conformation of the G_α-subunit or altering the affinity of RGS for G_α. Although the usual mode of action of RGSs is to interact with G_α-subunits, some of them can also interact directly with effectors. For example, RGS2 can inhibit type V adenylyl cyclase.

From their structure, RGS proteins are predicted to be soluble. However, their mechanism requires that they act at the plasma membrane. The generation of GTP-liganded G_α-subunits in response to receptor activation would be expected to recruit RGSs to the membrane. However, transmembrane segments, lipid modifications, e.g., palmitoylation, and domains that interact with membrane lipids may also be involved, and there is evidence that some RGSs can be recruited selectively to the plasma membrane by receptors.

Selectivity of RGS Action

In view of the large number of RGSs, some selectivity in their interactions with G_α-subunits would be expected (Table I). Since certain receptors can couple to more than one G protein, the selective modulation of one G_α by an RGS protein can change the output from such receptors. However, selectivity has been hard to define *in vitro* and may involve restrictive patterns of cellular expression of the RGS and G_α proteins. *In vitro* analysis of RGS selectivity has involved single-turnover GAP assays, studies of competition with substrate and coimmunoprecipitation and coadsorption assays. For example, GAIP displays activity towards G_i and G_q class α-subunits, but the closely related RGSZ1 and RGSZ2 are selective for $G_{\alpha z}$ and display low activity towards $G_{\alpha q}$. RGS6 and RGS11 are selective for $G_{\alpha o}$ compared with other $G_{\alpha i}$ class subunits, and RGS2 prefers $G_{\alpha q}$. Surprisingly, only one RGS (sorting nexin 13) has been reported to act on $G_{\alpha s}$.

In a cellular setting, the selectivity of RGSs for certain G_α-subunits is less readily defined than *in vitro* since the readouts are quite distal from the interactions. RGS2 displays selectivity for $G_{\alpha q}$, in accordance with *in vitro* studies. RGS16 inhibits the activation of p38 MAP kinase by PAF more effectively than the activation of ERK2, whereas RGS1 has the opposite effects. In dorsal root ganglion cells, α_2-adrenergic activation of $G_{\alpha i}$ and $G_{\alpha o}$ was enhanced by antibodies against RGS4 and GAIP, whereas antibodies to other RGSs had no effect. Microinjection of the RGS proteins confirmed these results.

Concerning the receptor selectivity of RGS proteins, there have been few studies. In pancreatic acinar cells,

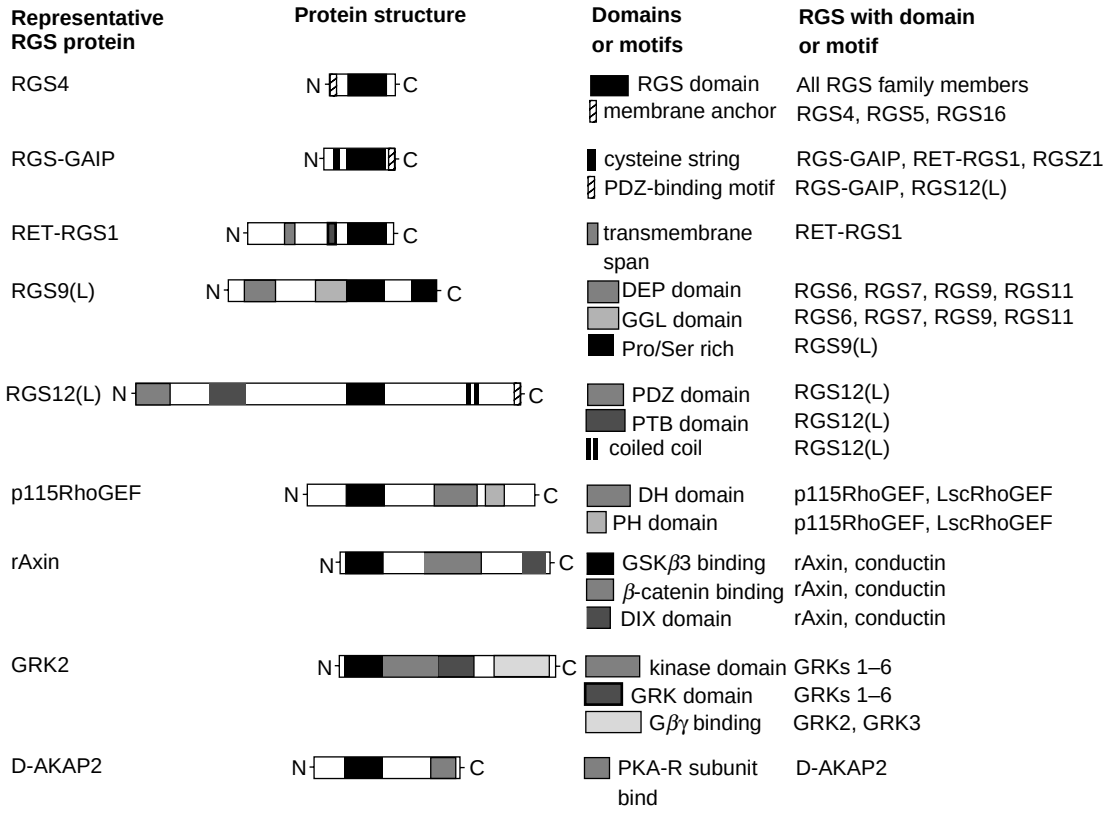

FIGURE 1 Structural organization and motifs in RGS proteins. (Modified from Hepler, J. R. (1999) Emerging roles for RGS proteins in cell signalling. *Trends Physiol. Sci.* **20**, 376–382.) PDZ (PSD-95, disk-large and zo-1), DEP (disheveled, egl-10 and pleckstrin), GGL (Gγ subunit-like), PTB (phosphotyrosine binding), DH (Dbl homology), PH (pleckstrin homology), GSKβ3 (glycogen synthase kinase β3-binding), DIX (disheveled homology), GRK (G protein-coupled receptor kinase), PKA-R (regulatory subunit of cAMP-dependent protein kinase).

RGS4 blocked G_q-mediated PLC activation initiated by M_3 muscarinic, cholecystokinin, and bombesin receptors. However, it was more potent against the muscarinic receptors. RGS1 and RGS16 were also more selective against M_3 muscarinic receptors. Surprisingly RGS2, which has activity towards $G_{\alpha q}$, did not show the same selectivity. The molecular basis for this receptor selectivity is presently unknown.

Significance of RGS Action

The primary action of RGSs is to induce rapid signal termination upon removal or inactivation of agonists in G protein-coupled receptor systems. The "knockout" of RSG9 prolongs photon responses because $G_{\alpha t}$ remains active. In addition this approach has been used to show that RGS3 and RGS5 selectively suppress MAP kinase activation by M_3 muscarinic and AT_{1A}-angiotensin receptors, respectively, in vascular smooth muscle. On the other hand, transgenic mice overexpressing RGS4 in ventricular tissue develop less ventricular hypertrophy in response to pressure overload, apparently because of reduced $G_{\alpha q}$ action. It should also be noted that RGSs can inhibit effectors by mechanisms not involving their GAP activity. This may be because the RGSs compete with the effectors for binding the G_α-subunits or because the RGSs inhibit the effectors directly.

Although signal termination is an important component of RGS action, this is not the whole story. There are interesting kinetic aspects to RGS action which arise from the cycle of activation/deactivation that G protein-coupled receptor systems undergo. For example, the activating receptors can only interact with the GDP-liganded form of G_α. Thus RGS activity can promote the association of G_α with the receptor through the generation of G_α–GDP, and permit G protein activation to continue.

Through their actions, RGS proteins modulate a variety of hormone- and neurotransmitter-stimulated responses in cells. These include the activity of adenylyl cyclase, the mitogen-activated protein kinase (MAP kinase) family, phospholipase C (with attendant changes in inositol trisphosphate and Ca^{2+} ions), G protein-gated inward rectifying K^+ (GIRK) channels, and cGMP phosphodiesterase in the retina (with altered phototransduction). Studies of the GIRK channels have revealed that RGS proteins can alter the timing,

amplitude and duration of the K^+ currents. An interesting group of RGSs is the RhoGEFs. These are guanine-nucleotide-exchange factors for the small G protein Rho. The first of these was discovered in *Drosophila*, where genetic analysis indicated that a RhoGEF (DRhoGEF2) acted downstream of the concertina gene, which is the *Drosophila* homologue of $G_{\alpha 12}$. Several laboratories then showed that $G_{\alpha 12}$ acted directly on three mammalian homologues of DRhoGEF2 (p115 RhoGEF, PDZ-RhoGEF, and LARG). In particular, the N-terminal region of p115 was observed to be similar to the conserved region of RGSs, and p115 was found to associate with $G_{\alpha 12}$ and $G_{\alpha 13}$ through its RGS domain. Even more interesting were the findings that $G_{\alpha 13}$ could stimulate the GEF activity of p115 towards Rho, and that the RGS domain of p115 displayed GAP activity towards $G_{\alpha 12}$ and $G_{\alpha 13}$. There is now much evidence that p115 and related RhoGEFs mediate the activation of Rho induced by agonists whose receptors are coupled to G_{13}. RGS16 inhibits $G_{\alpha 13}$-mediated activation of Rho by binding directly to $G_{\alpha 13}$ and disrupting its interaction with p115. The binding does not involve the RGS domain of RGS16.

Although they do not contain the RGS domain, many effectors of G proteins act as GAPs towards G_α-subunits. Examples are phospholipase C, which acts on $G_{\alpha q}$, and the γ-subunit of cGMP phosphodiesterase, which acts on transducin. In the case of transducin, RGS proteins and the phosphodiesterase act synergistically to inactivate the G protein.

Regulation of RGS Proteins

RGS proteins can be regulated by various mechanisms. One is by transcriptional regulation of their cellular levels. Other mechanisms include covalent modification, cellular relocalization, and interaction with regulatory proteins and lipids. The yeast RGS SST2 can be regulated at the transcriptional level by mating factor. Almost all RGSs are expressed in brain, although they are restricted to certain regions. They can be regulated by neurotransmitters through changes in their mRNA levels. In other tissues, there is transcriptional regulation involving growth factors and other peptides.

Regulation of RGSs also occurs at the post-transcriptional level. For example, phosphorylation can alter their degradation through ubiquitin-dependent proteolysis or by affecting a PEST sequence(s). For example, TNFα can protect RGS7 from proteolysis through phosphorylation of a Ser/Thr sequence near the GGL and RGS domains. RGS activity can also be modified by phosphorylation of its G_α targets. Phosphorylation of $G_{\alpha z}$ by protein kinase C inhibits the GAP activity of RGS5. Another modification is reversible palmitoylation of either the RGS or its substrate G_α. The effects on the RGS may be positive or negative, depending on the assay used, but palmitoylation of G_α-subunits usually results in inhibition of the GAP activity of the RGS.

RGS proteins can bind to a variety of cellular proteins (Figure 1). As noted in the section on structure, they contain many different protein-binding motifs. They can also bind lipids, e.g., PIP_3, Ca^{2+}-calmodulin, and the APC protein. RGS12 is the only RGS that contains a PDZ domain and thus can interact with proteins that contain a PDZ-binding motif, e.g., IL-8. AKAP2 binds the regulatory subunit of cAMP-dependent protein kinase (PKA). RGS6, RGS7, RGS9, and RGS11 contain a DEP domain and this is involved in membrane localization. Axin and conductin, which are scaffolding proteins, block signaling by Wnt proteins, which are involved in development. The RGS domains of these proteins bind the APC protein, whereas other domains bind β-catenin and GSK3.

Important interacting partners of the RGSs are the $\beta\gamma$-subunits of G proteins ($G_{\beta\gamma}$). These bind to G_α cooperatively with respect to GDP and suppress receptor-independent activation of G proteins. They also anchor G_α to the plasma membrane and regulate many effector proteins, e.g., adenylyl cyclase, phospholipase C, ion channels, and lipid kinases. With respect to RGS proteins, $G_{\beta\gamma}$ inhibits the GAP activity of many of these proteins. It appears that $G_{\beta\gamma}$ interacts with both the RGS and its target G_α-subunits. Several RGSs contain a GGL domain that is similar in sequence to $G_{\beta\gamma}$. It has also been shown that RGS11 binds Gβ5, and that the binding involves the GGL domain. Binding of $G_{\beta 5}$ to other RGSs has been demonstrated *in vivo*. In addition, RGSs can inhibit the effects of $G_{\beta\gamma}$-subunits on effectors by virtue of the generation of G_α·GDP which recombines with $G_{\beta\gamma}$ to reform inactive heterotrimeric G proteins. In the case of RGS3, there is another mechanism, namely its binding to $G_{\beta 1\gamma 2}$-subunits to inhibit signaling to effectors. This effect involves two regions of RGS3 separate from the RGS domain.

RGS Proteins as Drug Targets

Because the importance of G protein-coupled receptors in regulating a large variety of physiological processes, the RGSs represent very attractive targets for therapeutic intervention. Alterations in their expression indicate that they regulate cardiac function, immune responses, neuronal function, behavior, vision, and embryonic development. There is also evidence that they may be involved in the diseases of retinitis pigmentosa, schizophrenia, Parkinson's disease, chronic heart failure, drug addiction, and prostate cancer. Drugs could be targeted to RGSs in several ways, and could act as agonists or inhibitors. The first approach is to target the RGS/G_α

interface, which involves certain amino acids that are essential for the contact. The second is through modulation of the proteins and lipids that act as allosteric modifiers of RGS action. This also includes covalent modifications. The third is modification of the membrane attachment of the RGSs since it is essential for them to be recruited to the plasma membrane in order to exert their effects. In all cases, determination of the amino acid residues involved in RGS selectivity and in their interactions with allosteric regulators will be essential for the development of drugs of sufficient specificity to be therapeutically useful.

Glossary

GAP A GTPase-activating protein that acts on monomeric and heterotrimeric G proteins to inactivate them. GAPs for heterotrimeric G proteins are RGSs and certain effectors.

G protein A signal-transducing protein that binds GTP (active form) or GDP (inactive form). Occurs in monomeric and heterotrimeric forms. Heterotrimeric G proteins are comprised of α-, β-, and γ-subunits. The α-subunit binds the guanine nucleotides and interacts with effector enzymes or ion channels. Heterotrimeric G proteins are activated by receptors with seven-transmembrane-spanning domains termed G protein-coupled receptors.

phosphorylation The modification of proteins by protein kinases and lipids by lipid kinases involving the addition of phosphate groups. This results in changes in the activity of the proteins or in the generation of new lipids with different functions.

receptor A membrane protein that binds and is activated by hormones, neurotransmitters, growth hormones, and cytokines.

Biography

John Exton is a Professor of Molecular Physiology and Biophysics, Professor of Pharmacology and Investigator of the Howard Hughes Medical Institute at Vanderbilt University. His principal research interests relate to signal transduction involving G proteins and phospholipases. He received an M.D. and Ph.D. from the University of Otago, New Zealand, and was a postdoctoral fellow under Charles R. Park and Earl W. Sutherland at Vanderbilt. He is a member of the National Academy of Sciences.

G Protein-Coupled Receptor Kinases and Arrestins

Jeffrey L. Benovic
Thomas Jefferson University, Philadelphia, Pennsylvania, USA

Many transmembrane signaling systems consist of specific G protein-coupled receptors (GPCRs), which transduce the binding of a diverse array of extracellular stimuli into intracellular signaling events. GPCRs function to regulate many biological processes including neurotransmission, sensory perception, cardiovascular function, chemotaxis, embryogenesis, cell growth and development, differentiation, and apoptosis. To ensure that extracellular signals are translated into intracellular signals of appropriate magnitude and specificity, most signaling cascades are tightly regulated. GPCRs are subject to three principal modes of regulation: (1) desensitization, in which a receptor becomes refractory to continued stimuli; (2) endocytosis, whereby receptors are removed from the cell surface; and (3) down-regulation, where total cellular receptor levels are decreased. GPCR desensitization is primarily mediated by second-messenger-dependent kinases, such as protein kinase A (PKA) and protein kinase C (PKC), and by G protein-coupled receptor kinases (GRKs). GRKs specifically phosphorylate activated GPCRs and initiate the recruitment of arrestins, which mediate receptor desensitization, endocytosis, and down-regulation.

The GRK Family of Proteins

GRKs are found in metazoans and, in mammals, the seven GRKs can be divided into three subfamilies based on overall structural organization and homology: GRK1 (also termed rhodopsin kinase) and GRK7; GRK2 (βARK1), and GRK3 (βARK2); and GRK4, GRK5, and GRK6. GRKs are serine/threonine kinases with a tripartite modular structure. A central ~330 amino acid catalytic domain, most related to those of other AGC kinases such as protein kinase A, protein kinase C, and PDK1, is flanked by an ~180 residue N-terminal region that contains a regulator of G protein signaling homology (RH) domain, and an ~80–180 amino acid C-terminal lipid-binding domain that varies in structure (Figure 1) .

Specificity of GRK Interaction with GPCRs

GRKs specifically phosphorylate agonist-occupied GPCRs. While no clear consensus sequence for GRK-mediated phosphorylation has been identified, specific sites for GRK-mediated phosphorylation have been mapped to either the carboxyl terminal tail or the third intracellular loop of a number of GPCRs. Experiments with synthetic peptide substrates have revealed a preference of GRK1 and GRK2 family members for serines/threonines flanked by acidic residues, whereas GRK4 family members appear to prefer serines/threonines flanked by basic residues. Overall, the specificity of receptor phosphorylation by GRKs appears to be determined by a combination of binding determinants between the receptor and GRK.

Important insight has also been provided by manipulation of GRK expression in intact cell systems. Co-expression studies have revealed that a wide variety of GPCRs can serve as GRK substrates. Several strategies that reduce endogenous GRK levels/function in cells, including inhibitory antibodies, antisense DNA and dominant negative GRKs have also been used to assess specificity. For example, incubation of inhibitory GRK-specific monoclonal antibodies with various permeabilized cell types suggests the preferential regulation of both β_2- and α_2-adrenergic receptors (β_2AR and α_2AR) by the GRK2 subfamily. Similarly, the use of GRK-specific antisense constructs in various cell types reveals subtype-specific regulation of H2 histamine receptors (by GRK2), PACAP type 1 and CRF1 receptors (by GRK3), D1 dopamine and metabotropic glutamate type 1 receptors (by GRK4), thyrotropin receptors (by GRK5), and CGRP receptors (by GRK6).

Insight into GRK specificity/function has also been gained from *in vivo* strategies. Transgenic mice with cardiac-specific overexpression of GRK2 or a carboxyl-terminal GRK2 mini-gene, which serves as a GRK2 inhibitor, demonstrate *in vivo* effects on cardiac function.

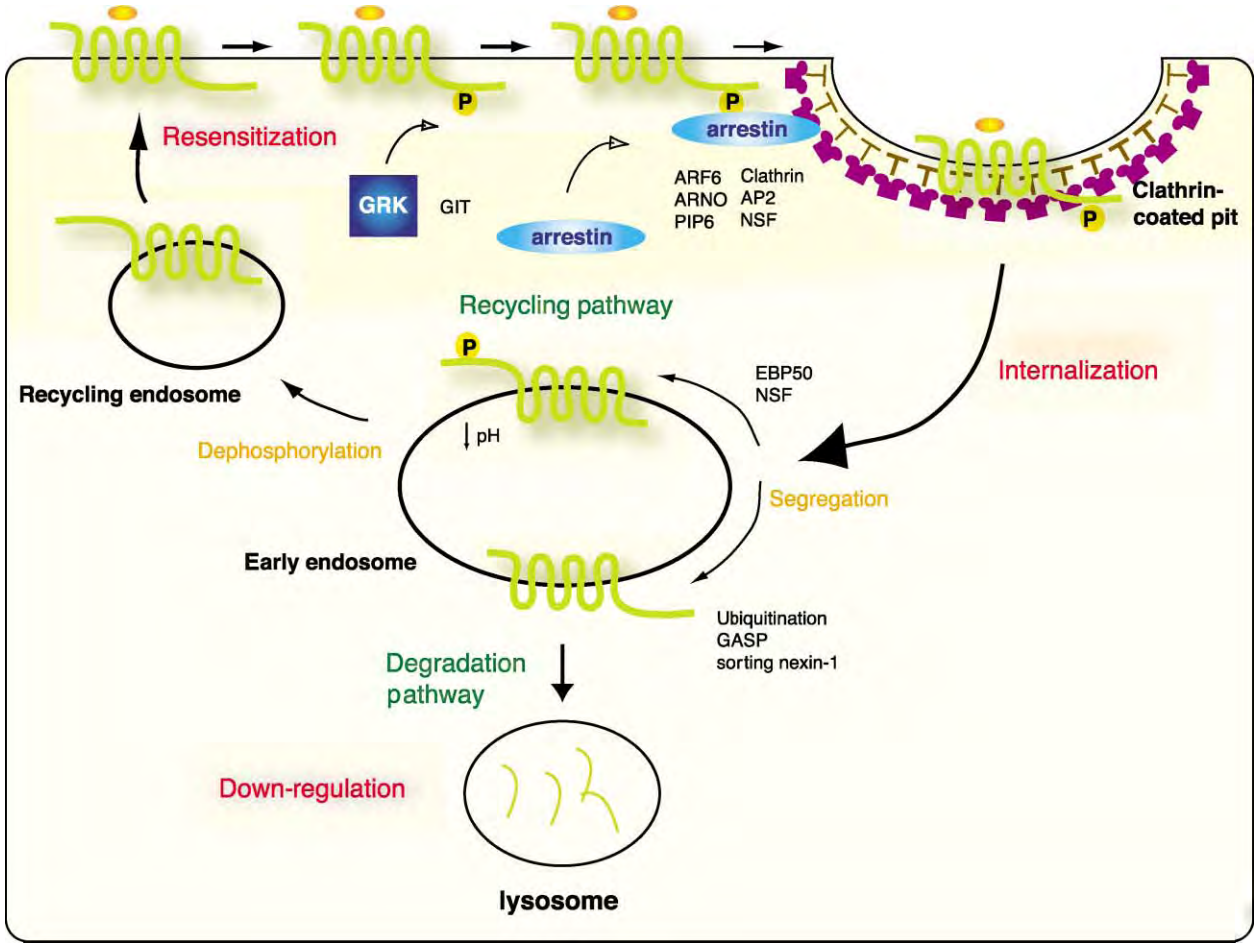

FIGURE 1 Schematic representation of G protein-coupled receptor (GPCR) trafficking. Agonist-activated receptors are phosphorylated by a GRK leading to the recruitment of arrestins. Arrestins serve as adaptor proteins by virtue of their ability to link receptors to components of the transport machinery such as clathrin, AP-2, and phosphoinositides leading to internalization. Additional interactions with GRKs and arrestins appear to play a role in this process. Once in endosomes, recycling receptors (recycling pathway) are readily segregated from receptors destined for lysosomes (degradation pathway). Although poorly understood, the sorting decision may be regulated by specific and distinct protein interactions or modification by ubiquitin. Receptors that enter the recycling pathway enter recycling endosomes and traffic back to the cell surface resulting in resensitization. Receptors that enter the degradation pathway traffic to lysosomes where they are proteolyzed, leading to a loss in the total cellular complement of the receptor, a process known as down-regulation.

Specifically, while GRK2 overexpression leads to increased uncoupling of the βAR from adenylyl cyclase and an associated decrease in left ventricular contractility, mice overexpressing the GRK2 inhibitor demonstrate increased left ventricular contractility even in the absence of β-agonist. Cardiac-specific overexpression of GRK5 in transgenic mice has a similar effect on βAR-mediated signaling and contractility, while the angiotensin II-mediated contractile response is attenuated only in the GRK2-overexpressing mice. Further demonstration of specificity is suggested in transgenic mice with myocardial overexpression of GRK3, where no effect on βAR response is observed. Moreover, studies involving cardiac overexpression of individual GRKs in mice revealed that GRK3 > GRK5 > GRK2 at desensitizing α_{1B}-adrenergic receptor signaling in the heart.

Functional knockouts of GRKs have provided unique insight into potential physiological roles of these proteins. Disruption of the GRK2 gene in mice by homologous recombination results in embryonic lethality as a consequence of hypoplasia of the ventricular myocardium, suggesting a role for GRK2 in cardiac development. In contrast, disruption of the mouse GRK3 gene results in normal development and physiology, although specific defects in desensitization of odorant-induced cAMP responses in olfactory epithelium and cholinergic response of airway smooth muscle are observed. A GRK5 knockout results in muscarinic supersensitivity and impaired receptor desensitization, while disruption of the GRK6 gene results in altered SDF-promoted chemotaxis of lymphocytes, supersensitivity to the locomoter-stimulating

effects of cocaine and amfetamine, and enhanced coupling of postsynaptic D2-like dopamine receptors. These findings suggest that GRKs are involved not only in regulating signaling, but may also have critical roles in regulating growth and development.

Regulation of GRK Function

A critical component in generating specificity is the molecular mechanism responsible for regulating the activity and cellular localization of GRKs. Recent studies have provided increased detail for known regulatory mechanisms as well as revealing previously unrecognized forms of regulation. For example, phosphorylation appears to play an important role in regulating GRK activity. GRK2 phosphorylation by ERK1/2 inhibits GRK2 activity while phosphorylation by PKA, Src, and PKC results in increased activity. In contrast, GRK5 activity is attenuated by PKC phosphorylation, but stimulated by autophosphorylation. GRK function is also regulated by interaction with a large number of additional proteins including G protein α- and $\beta\gamma$-subunits, clathrin, the GRK-interacting protein GIT1, caveolin-1, phosphoinositide 3-kinase-α and γ, cytoskeletal proteins such as tubulin and actin, and various calcium-binding proteins.

Phospholipids also play an important role in regulating GRK function since G$\beta\gamma$-mediated activation of GRK2 is dependent on negatively charged phospholipids including PIP_2. Interestingly, while GRK4 subfamily members do not bind G$\beta\gamma$-subunits, these kinases share an N-terminal PIP_2-binding domain that may facilitate receptor phosphorylation. These kinases also have the ability to associate with phospholipids via a C-terminal domain that is either palmitoylated (GRK4 and 6) or can directly bind phospholipids (GRK5). Thus, the immediate phospholipid environment may have a general and critical role in modulating GRK function. Taken together, multiple mechanisms including GPCR, G protein, and phospholipid binding play an important role in regulating GRK activity and function.

Structural Basis of GRK Function

The X-ray crystal structure of GRK2 complexed with G$\beta\gamma$ provides significant insight into GRK function. GRK2 is composed of three primary domains, an N-terminal RH domain, a central kinase catalytic domain, and a C-terminal PH domain. Interestingly, the crystal structure reveals that the RH, kinase, and PH domains form an equilateral triangle that is $\sim$80Å on a side. The RH domain consists of two discontinuous regions and contacts both the kinase and PH domains. The kinase domain is most similar to that of PKA and PDK1 and appears to be in an inactive conformation in the crystal structure. Interestingly, the structure of the RH and kinase domain core appears to have similarities to the inactive structure of Src with one region of the RH domain (the α10 helix) potentially functioning to regulate GRK activation. The C-terminal PH domain of GRK2 mediates phospholipid and G$\beta\gamma$ binding. Docking analysis of the GRK2/G$\beta\gamma$ complex with a GPCR and Gαq suggests that all three proteins should be able to bind to GRK2 simultaneously. This would represent an effective way of turning off signaling by phosphorylating receptor and sequestering Gαq and G$\beta\gamma$, thereby preventing interaction with effector molecules.

Role of GRKs in Disease

While various *in vitro* and *in vivo* manipulations of GRKs have provided significant insight into their function, various experimental approaches have led to a growing appreciation of the physiological and pathophysiological roles of GRKs in human disease. Several studies have demonstrated increased expression of GRKs associated with congestive heart failure (CHF), hypertension, and myocardial ischemia. In experimentally induced models of CHF, both GRK2 and GRK5 expression and activity was enhanced 2–3 fold in the left ventricular myocardium early in CHF progression. While it is not clear whether this increase in GRK levels is causal or a byproduct of elevated hormones secondary to disease, it is interesting that myocardial ischemia, which is associated with a large local release of noradrenaline, also produces a rapid increase in GRK2 mRNA levels. Since cardiac-specific overexpression of either GRK2 or GRK5 in transgenic mice produces decreases in cardiac function, the myocardial GRK overexpression that occurs during CHF could potentially contribute to pathology through increased βAR desensitization.

Several studies have also shown that GRK expression is selectively regulated as a function of the hypertensive state. In a comparison of normotensive and mildly hypertensive subjects, GRK2 protein expression in lymphocytes was positively correlated with blood pressure and negatively correlated with β_2AR-mediated adenylyl cyclase activity. These results suggest that GRK2 expression may underlie reduced β_2AR responsiveness characteristic of the hypertensive state. Another form of hypertension (human essential hypertension) involves impairment in dopamine-promoted urinary sodium excretion. Defective D1 dopamine receptor/G protein coupling in the kidney proximal tubule is the cause of the impaired renal dopaminergic action in this form of hypertension. Recent studies suggest that single nucleotide polymorphisms of GRK4 increase GRK activity and cause D1 receptor/G protein uncoupling in the renal proximal tubule. Moreover, expression of polymorphic GRK4 in transgenic mice produces

hypertension. Taken together, these findings suggest that GRKs play a role in vascular and renal control and may represent novel therapeutic targets for the treatment of human hypertension.

The visual transduction system provides another example of the critical role of GRKs in pathophysiology. Various methods of genetic analysis have revealed inherited mutations in GRK1 associated with a visual degenerative disease known as stationary night blindness or Oguchi's disease. Genetic analysis of several Oguchi patients demonstrated a lack of functional *grk1* alleles. A more detailed analysis of this disruption uncovered a profound abnormality in recovery of rod photoreceptors after light activation. These discoveries clearly demonstrate the sensitivity of phototransduction to GRK1 dysfunction and suggest potential future targets for gene therapy.

The Arrestin Family of Proteins

Arrestin (also termed S-antigen, visual arrestin, or arrestin-1) was initially identified in the visual system as a 48-kDa protein that redistributed from the cytoplasm to the disk membrane following light activation of bovine rod cell outer segments. Arrestin-1 is a 404 amino acid protein and binds to the light-receptor rhodopsin in a light- and phosphorylation-dependent manner resulting in suppression of G protein signaling. Gene targeting has demonstrated a clear physiological role for arrestin-1 in quenching phototransduction in mice. In addition, mutations in human arrestin-1 have been identified in Oguchi's disease.

Evidence for the involvement of arrestins in the regulation of additional GPCRs was initially suggested by the finding that purified arrestin-1 could impair β_2AR/G protein coupling in a phosphorylation-dependent manner. Subsequent studies identified a 418 amino acid arrestin-1 homologue (termed β-arrestin-1 or arrestin-2) that could effectively uncouple phosphorylated β_2AR from G protein. Arrestin-2 is widely expressed and has been broadly implicated in regulating GPCR desensitization. Subsequent studies identified two additional members of the arrestin family, arrestin-3 (also termed β-arrestin-2) and arrestin-4 (also termed cone arrestin). The four mammalian arrestins are divided into two major classes, visual and nonvisual, based on their localization and function. The nonvisual arrestins, arrestin-2 and arrestin-3, are broadly distributed and function in multiple processes including GPCR desensitization, endocytosis, recycling, down-regulation, and signaling. The visual arrestins, arrestin-1 in rod cells and arrestin-4 in cone cells are highly localized and play a primary role in quenching phototransduction.

Molecular Nature of Arrestin Interaction with GPCRs

An important feature of arrestin interaction with GPCRs is the ability of arrestins to recognize both the activation- and phosphorylation-state of the receptor. The observation that arrestins discriminate between agonist-activated and nonactivated GPCRs suggests that arrestins contain domains that specifically contact regions of the receptor exposed following receptor activation. Initial localization of such domains was provided by the observation that truncated arrestin-1 partially retained the ability to bind with light-activated rhodopsin. It was further demonstrated that at least three regions within the N-terminal half of arrestin-1 were involved in recognizing light-activated rhodopsin.

The importance of receptor phosphorylation in arrestin binding has also been explored in significant detail. The phosphorylation-recognition domain within arrestin-1 (residues 163–179) has been extensively characterized. These studies revealed two relatively independent changes that occur in arrestin on receptor binding: (1) increased binding affinity of the phosphorylation-recognition region of arrestin for the phosphorylated C terminus of rhodopsin, and (2) mobilization of additional receptor binding sites. These experiments also revealed that charge inversion of Arg-175 generates an "activated" form of arrestin that demonstrates phosphorylation-independent receptor binding. These studies and others provide the basis for a model of GPCR/arrestin interaction that is initiated by the activation- and phosphorylation-dependent binding of arrestin to receptor, culminating in a conformational change in arrestin that promotes additional interactions with the receptor.

Role of Arrestins in GPCR Endocytosis

Radioligand binding and immunocytochemical techniques have demonstrated that many GPCRs undergo endocytosis and multiple studies have implicated an important role for GRKs and arrestins in this process. Initial efforts revealed that GRK2 and nonvisual arrestins could enhance agonist-dependent endocytosis of the β_2AR. Additional analysis revealed that arrestins promoted endocytosis of agonist-activated GPCRs via an ability to interact with clathrin, the major protein component of the clathrin-based endocytic machinery. Predictably, arrestin mutants impaired in clathrin binding are largely defective in promoting β_2AR endocytosis. Consistent with these findings, minigenes expressing the C-terminal clathrin-binding domains of arrestin-2 or -3 are constitutively localized to clathrin-coated pits and function as dominant negative inhibitors of GPCR endocytosis. Additional studies have implicated a role

for nonvisual arrestin interaction with the β-subunit of the adaptor protein AP-2 in GPCR endocytosis and there also appears to be a critical role for arrestin interaction with PIP_2 in this process. In fact, a mutant arrestin-3 that is defective in phosphoinositide binding can still interact with the agonist-activated receptor but does not localize to clathrin-coated pits. Thus, nonvisual arrestin interaction with clathrin, AP-2, and PIP_2 contribute to arrestin-promoted endocytosis of GPCRs.

Role of Arrestins as Scaffolds in Cell Signaling

Several studies suggest that arrestins also have roles beyond regulating GPCR desensitization and trafficking. The finding that arrestin-2 binds directly to c-Src provided initial insight into this possibility. This interaction appears to be mediated via a proline-rich region in arrestin-2 interacting with the SH3 domain in Src, although the catalytic domain of Src may also contribute to binding. Since arrestin-2–Src interaction may be regulated by arrestin phosphorylation, the current model proposes that arrestin-2 binding to receptor promotes arrestin dephosphorylation enabling c-Src to bind and be recruited to clathrin-coated pits as part of a receptor–arrestin–Src complex. This localization may regulate Src-mediated phosphorylation of components (e.g., dynamin) that may, in turn, contribute to the regulation of GPCR trafficking and/or signaling.

Additional studies have suggested a role for arrestins as MAP kinase scaffolds. Several studies have focused on the potential involvement of arrestin-2 in GPCR-mediated activation of ERK1/2 and have demonstrated formation of complexes that contain receptor, arrestin-2, ERK1/2, and either raf-1 or Src. Studies have also demonstrated that arrestin-3 can directly bind to JNK3 and ASK1, a JNK kinase kinase, suggesting a role for arrestin-3 as a MAP kinase scaffold. Interestingly, stimulation of the AT_{1A} angiotensin receptor resulted in JNK3 activation and triggered the colocalization of arrestin-3 and active JNK3 to intracellular vesicles. Thus, arrestins may serve as scaffolds to mediate GPCR activation of various MAP kinase complexes.

The Structural Basis for Arrestin Function

Initial structural insight on arrestins was provided by the X-ray crystal structure of arrestin-1 while more recently the crystal structure of arrestin-2 has been solved. In general, arrestins have an elongated shape and are almost exclusively made up of β-sheets and connecting loops with the exception of one short α-helix. Each arrestin molecule is composed of two major domains termed the N domain and C domain that are held together by a set of buried salt bridges termed the polar core. The N and C domains are connected by a short hinge and are thought to move relative to each other in the process of arrestin's transition into an active conformation. The arrestin polar core is comprised of charged residues from the N-terminus, N domain, C domain, and C-terminus, thus bringing different parts of the molecule together to maintain a basal conformation. The residues involved in formation of the polar core are highly conserved, suggesting that this structural element is conserved in all arrestins and critical for function. Because the buried side chains of the polar core achieve neutrality by an elaborate network of electrostatic interactions, it has been suggested that disturbance of the polar core by introduction of a phosphate group from the receptor promotes structural changes that result in an active conformation of the protein. Disruption of polar core interactions can be simulated by charge inversion of an arginine (Arg-175, 169, and 170 in arrestin-1, -2, and -3, respectively) that lies in the center of the polar core. Mutation of this arginine results in an arrestin that binds equally well to phosphorylated and non-phosphorylated GPCRs suggesting that this residue plays a key role in recognition of phosphorylated receptor and in maintaining the basal conformation of arrestin. Taken together, these studies suggest that activation of arrestin results in significant structural changes that play an important role in mediating the various protein interactions and cellular functions of arrestin.

Glossary

desensitization A loss in responsiveness of a signaling system often due to an agonist-promoted decrease in coupling between receptor and G protein.

down-regulation A decrease in the total cellular level of a receptor typically due to prolonged incubation with agonist.

endocytosis The process of cellular uptake of a protein that often occurs through clathrin-coated pits for G protein-coupled receptors (GPCRs).

phosphorylation The transfer of phosphate from ATP to a serine, threonine, or tyrosine on a protein.

Biography

Jeffrey L. Benovic is Professor and Vice Chair in the Department of Microbiology and Immunology at Thomas Jefferson University in Philadelphia. His principal research interests are on the regulation of GPCR signaling with particular emphasis on the role of GRKs and arrestins in this process. He holds a Ph.D. in biochemistry from Duke University, where he also received his postdoctoral training. He has authored over 200 articles on GPCR signaling and regulation.

G_{12}/G_{13} Family

Stefan Offermanns
University of Heidelberg, Heidelberg, Germany

The ubiquitously expressed mammalian G proteins, G_{12} and G_{13}, constitute one of the four families of heterotrimeric G proteins (G_s, $G_{i/o}$, $G_{q/11}$, and $G_{12/13}$). Heterotrimeric G proteins, which consist of α-, β-, and γ-subunits, are defined by their α-subunit and act as molecular switches, which transmit signals from heptahelical G-protein-coupled receptors (GPCRs) at the plasma membrane to intracellular effectors. Orthologues of the mammalian G_{12} and G_{13} α-subunits, $G\alpha_{12}$ and $G\alpha_{13}$, have also been found in other multicellular organisms like *Drosophila melanogaster* and *Caenorhabditis elegans*. G_{12}/G_{13} regulate cytoskeletal rearrangements and cell growth in part via the small GTPase Rho.

General Properties and Modifications

The α-subunits of G_{12} and G_{13}, $G\alpha_{12}$ and $G\alpha_{13}$, have been identified by Mel Simon's group using a PCR cloning approach. $G\alpha_{12}$ and $G\alpha_{13}$ share 67% sequence identity and have a length of 377–380 amino acids. Biochemical analysis of purified $G\alpha_{12}$ and $G\alpha_{13}$ has revealed a relatively low rate of GTP hydrolysis, as well as a relatively slow guanine nucleotide exchange rate. Their expression levels in most cells appear to be lower than those of other G protein α-subunits. Both, $G\alpha_{12}$ and $G\alpha_{13}$, undergo palmitoylation, a reversible post-translational modification, which occurs at cysteine residues close to their N termini. Palmitoylation localizes G_{12} and G_{13} to the inner side of the plasma membrane and is required for proper signaling via G_{12}/G_{13}. *In vitro* experiments have shown that purified $G\alpha_{12}$ is a substrate for protein kinase C, whereas $G\alpha_{13}$ can be phosphorylated by protein kinase A. The physiological significance of these phosphorylations is unclear.

Receptor-Mediated Activation of G_{12} and G_{13}

It has been difficult to provide direct evidence for the coupling of a defined receptor to G_{12}/G_{13}. However, for a variety of GPCRs coupling to G_{12}/G_{13} could be demonstrated using different methods including the immunoprecipitation of receptor-activated G proteins, as well as genetic approaches. These studies revealed that some lipid mediators such as lysophospholipids or thromboxane A_2, various peptides such as endothelin, angotensin II, or substance P as well as the protease thrombin act on receptors, which are able to couple to G_{12}/G_{13} (Table I). G_{12} and G_{13} appear to be activated by GPCRs, which also couple to G_q/G_{11} and in some cases to G_i/G_o. However, not all G_q/G_{11}-coupled receptors are also able to activate G_{12}/G_{13}.

Cellular Functions of G_{12}/G_{13}

Most information on the cellular functions regulated via G_{12}/G_{13} came from indirect experiments employing constitutively active mutants of $G\alpha_{12}/G\alpha_{13}$ which lack the intrinsic GTPase activity due to an exchange of a glutamine residue (Q231 and Q226 in human $G\alpha_{12}$ and $G\alpha_{13}$, respectively) to a leucine residue. Several laboratories could show that transfection of these mutants into different cell types leads to cellular transformation. Interestingly, human $G\alpha_{12}$ was first cloned in a screen for transforming oncogenes from a Ewing Sarcoma cDNA library. However, it is still unknown whether $G\alpha_{12}$ or $G\alpha_{13}$ are involved in the pathogenesis of any neoplastic disease. In subsequent studies, the expression of constitutively active mutants of $G\alpha_{12}/G\alpha_{13}$ was shown to induce a variety of signaling pathways leading to the activation of various downstream effectors including phospholipase A_2, Na^+/H^+ exchanger or c-Jun N-terminal kinase.

Another important cellular function of G_{12}/G_{13} is their ability to regulate the formation of actomyosin-based structures and to modulate their contractility by increasing the activity of the small GTPase RhoA. The RhoA-mediated formation of actin stress fibers in fibroblasts activated by various G-protein-coupled receptor agonists is one of the best described cellular paradigms for G_{12}/G_{13}-mediated Rho activation and subsequent rearrangement of the actin cytoskeleton. This phenomenon involves a Rho-induced bundling of

TABLE I

GPCRs Shown to Couple to G_{12}/G_{13}

Receptor	Endogenous ligand(s)	G-protein subclass(es)
AT_1	Angiotensin II	$G_{12/13}$, $G_{q/11}$, $G_{i/o}$
B_2	Bradykinin	$G_{12/13}$, $G_{q/11}$
ET_A	Endothelin-1, -2	$G_{q/11}$, $G_{12/13}$, G_s
ET_B	Endothelin-1, -2, -3	$G_{12/13???}$
GAL2	GALP, Galanin	$G_{i/o}$, $G_{q/11}$, $G_{12/13}$
5-HT_{2C}	Serotonin	$G_{12/13}$, $G_{q/11}$
LPA_1 (Edg2) LPA_2 (Edg4)	Lysophosphatidic acid	G_i, $G_{q/11}$, $G_{12/13}$
LPC_1 (G2A)	Lysophosphatidylcholine	$G_{12/13}$, $G_{q/11}$,
NK_1	Substance P	$G_{12/13}$, $G_{q/11}$
PAR-1 PAR-3/4	Thrombin and others	$G_{12/13}$, $G_{q/11}$, G_i
$S1P_2$ (Edg5) $S1P_3$ (Edg3)	Spingosine-1-phosphate	$G_{12/13}$, G_i, $G_{q/11}$ $G_{12/13}$, G_i, $G_{q/11}$
TP	Thromboxane A_2	$G_{q/11}$, $G_{12/13}$
TSH	Thyrotropin	$G_{12/13}$, G_s, $G_{q/11}$, G_i
V_{1A}	Vasopressin	$G_{12/13}$, $G_{q/11}$

Summarized are findings from various laboratories which are based on the immunoprecipitation of receptor activated $G\alpha_{12}/G\alpha_{13}$ using photoaffinity labeling or a GDP/[^{35}S]GTPγS exchange assay as well as on genetic evidence from $G\alpha_{12}/G\alpha_{13}$ deficient cells. Please note that this list is far from being complete.

actin filaments into stress fibers and the clustering of integrins and associated proteins into focal adhesion complexes. The ability of $G\alpha_{12}/G\alpha_{13}$ to induce actin stress fiber formation in fibroblasts was first described by the group of Gary Johnson. Regulation of actin-based structures via a G_{12}/G_{13}-mediated and Rho-dependent pathway has also been shown to occur in many other eukaryotic cells. For instance, in neuronal cells, activation of Rho through lysophosphatitic acid or thrombin receptors leads to the formation of contractile actomyosin filaments eventually leading to the induction of neurite retraction, cell rounding, or axonal growth cone collapse. In vascular smooth muscle cells, the G_{12}/G_{13}-Rho-mediated pathway has been shown to contribute to the vasoconstrictor-induced actomyosin-based cell contraction, and the same pathway appears to be involved in the platelet shape change response.

Proteins Directly Interacting with $G\alpha_{12}/G\alpha_{13}$

Until recently, it was not clear how G_{12} and G_{13} regulate the function of RhoA. In general, the activation of Rho by exchange of GDP for GTP is catalyzed by guanine nucleotide exchange factors (GEFs), which in turn are regulated by various, mostly ill-defined mechanisms in the cell. First indications that a RhoGEF protein is regulated by G_{12}/G_{13} came from studies on early gastrulation events in *Drosophila*. Genetic analysis indicated that DRhoGEF2, a *Drosophila* RhoGEF protein, functions downstream of the *Drosophila* $G\alpha_{12}/G\alpha_{13}$ orthologue, the *concertina* gene product. Subsequently, three mammalian RhoGEF proteins (p115RhoGEF, PDZ-RhoGEF, and LARG) were described which are able to interact with activated $G\alpha_{12}/G\alpha_{13}$. This family of RhoGEF proteins is characterized by the presence of a "regulator of G protein signaling" (RGS)-domain, which mediates the interaction with the α-subunits of G_{12}/G_{13}. While the RhoGEF activity of PDZ-RhoGEF and LARG appears to be activated by both, $G\alpha_{12}$ and $G\alpha_{13}$, p115 RhoGEF activity is stimulated only by $G\alpha_{13}$. In addition, the RGS domains of these RhoGEF proteins accelerate the intrinsic GTP hydrolysis activity of $G\alpha_{12}/G\alpha_{13}$ *in vitro* and, thus, function as "GTPase-activating proteins" (GAPs). While it is now well established that RhoGEF proteins which contain an RGS-domain interact with $G\alpha_{12}/G\alpha_{13}$, the precise mode of this interaction is still not completely clear. In addition, several groups have found evidence for an involvement of tyrosine kinases in the regulation of Rho via G_{12}/G_{13}. In any case, regulation of RhoGEF proteins by $G\alpha_{12}/G\alpha_{13}$ provided the missing link between G_{12}/G_{13} and their ability to activate the small GTPase RhoA, which then mediates the effects of G_{12}/G_{13} on the cytoskeleton and may also be involved in the transforming activity of these G proteins (Figure 1).

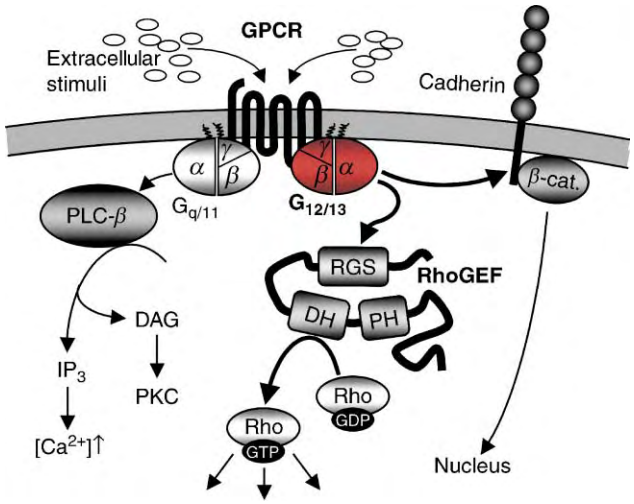

FIGURE 1 Some of the signaling processes mediated by G_{12}/G_{13}. G-protein-coupled receptors (GPCRs) which couple to G_{12}/G_{13} also activate G_q/G_{11}. RhoGEF, guanine nucleotide exchange factor for Rho proteins; PLC-β, phospholipase C β; β-cat., β-catenin; DAG, diacylglycerol; IP_3, inositol-1,4,5-trisphosphate; PKC, protein kinase C; RGS, "regulator-of-G-protein-signaling" domain; DH, "dbl-homology" domain; PH, "pleckstrin-homology" domain; see text for details.

Recently, an interesting link between G_{12}/G_{13} and cadherin-mediated signaling was described by the group of Pat Casey. Active $G\alpha_{12}$ and $G\alpha_{13}$ interact with the cytoplasmic domain of some type I and type II class cadherins, such as E-cadherin, N-cadherin, or cadherin-14, causing the release of β-catenin from cadherins (Figure 1). This down-regulates cadherin-mediated cell activation, and the release of β-catenin from cadherins may be a mechanism, by which $G\alpha_{12}/G\alpha_{13}$ induces cellular transformation.

Various other proteins including Bruton's tyrosine kinase, the Ras GTPase-activating protein Gap1m, radixin, heat shock protein 90, or protein phosphatase type 5 have been shown to interact with $G\alpha_{12}$ and/or $G\alpha_{13}$. However, the biological significance of these interactions are not yet clear.

In vivo Functions of G_{12}/G_{13}

The fact that G_{12}/G_{13} appear to be the major mediators of the activation of RhoA via GPCRs suggests that they are involved in multiple biological processes including morphogenetic processes, regulation of cell shape, or regulation of cell movements. Strong evidence for *in vivo* functions of G_{12}/G_{13} came so far mainly from the analysis of phenotypical changes of null-mutants of these G protein α-subunits in mice, flies, and worms. Experiments in *Drosophila* have provided genetic evidence for a physiological role of the G_{12}/G_{13}/RhoGEF-mediated pathway leading to Rho activation. By gene inactivation and epistasis experiments it could be shown that a signaling pathway, consisting of the G_{12}/G_{13} orthologue *concertina*, the *Drosophila* RhoGEF protein DRhoGEF2, as well as of Rho is involved in the actin/myosin-mediated cellular shape change, which results in the ventral furrow formation of the *Drosophila* embryo. Interestingly, loss of DRhoGEF2 results in a more severe phenotype than observed in *concertina* mutant embryos, suggesting that the *concertina* gene product conveys only part of the upstream regulation of DRhoGEF2.

While mice lacking the $G\alpha_{12}$ gene (*gna12*) are phenotypically normal, deletion of the $G\alpha_{13}$ gene (*gna13*) results in embryonic lethality at embryonic day 9.5 due to a defect in angiogenesis. Chemokinetic effects of thrombin were completely abrogated in fibroblasts lacking $G\alpha_{13}$, indicating that $G\alpha_{13}$ is required for full migratory responses of cells to certain stimuli. The defects observed in $G\alpha_{13}$-deficient embryos and cells occurred in the presence of $G\alpha_{12}$, and loss of $G\alpha_{12}$ did not result in any obvious defects. However, $G\alpha_{12}$-deficient mice, which carry only one intact $G\alpha_{13}$ allele also die *in utero*, and $G\alpha_{12}/G\alpha_{13}$ double deficient mice die even earlier than $G\alpha_{13}$ single deficient animals. This genetic evidence indicates that $G\alpha_{13}$ and its closest relative, $G\alpha_{12}$, fulfill at least partially nonoverlapping cellular and biological functions, which are required for proper mammalian development. Mouse lines carrying conditional mutants of the $G\alpha_{12}/G\alpha_{13}$ genes might allow one to analyze some of the functions of these proteins in the adult mammalian organism.

Glossary

actin stress fiber Bundles of actin microfilaments which are found on the ventral side of cells cultured on artificial surfaces. They contain myosin and α-actinin as well as a variety of other structural and regulatory proteins which allow them to contract and to exert tension. The ends of stress fibers terminate at specific sites at the plasma membrane (focal adhesions) which are involved in cell adhesion. Activation of RhoA has been shown to induce actin stress fiber formation.

angiogenesis Growth of new blood vessels by sprouting from existing ones.

cadherins Calcium-dependent adhesion proteins, characterized by the presence of cadherin repeats, which are present in the extracellular part of the protein. Cadherins mediate Ca^{2+}-dependent homophilic adhesion. Cadherins are divided into two subfamilies, the classic cadherins and the protocadherins. Classic cadherins are subdivided into four subfamilies, the type I classic

cadherins, the type II classic cadherins, the desmosomal cadherins, and the so-called "other classic cadherins."

guanine nucleotide exchange factor (GEF) Guanine nucleotide exchange factors (GEFs) are proteins which catalyze the release of nucleotide bound to small GTPases like RhoA. In most cases, GEFs bind to the GDP bound GTPase, causing dissociation of the GDP. GTP, which is present at higher concentrations in the cell than GDP, then binds to the GTPase, and the GEF is released.

RhoA Small GTP-binding protein (small GTPase). Being one of the best studied members of the Rho-family of small GTPases, it has been shown to play an important role in the regulation of the actin cytoskeleton.

$GABA_A$ Receptor

Richard W. Olsen
University of California, Los Angeles, California, USA

Gregory W. Sawyer
Oklahoma State University, Tulsa, Oklahoma, USA

γ-Aminobutyric acid (GABA) is the neurotransmitter at most inhibitory synapses in the central nervous system. This amino acid is synthesized in one step from L-glutamate by the enzyme glutamic acid decarboxylase (GAD). GAD is present only in GABAergic neurons, comprising up to 30% of those in the nervous system of all organisms, and is a marker for GABA synapses. Dysfunction of GABA, including GAD, is implicated in a variety of neuropsychiatric disorders, including epilepsy, anxiety, depression, and drug dependence.

Fast inhibitory synaptic transmission is mediated primarily by the GABA-type A receptor ($GABA_A$ receptor (GABAR)), a ligand-gated chloride ion channel. Some slow inhibition is mediated by GABA at the GABA-type B ($GABA_B$) receptor, a G protein-coupled receptor. GABAR are members of a neurotransmitter receptor superfamily that includes the nicotinic acetylcholine receptors, glycine receptors, and serotonin $5HT_3$ receptors. The nicotinic acetylcholine receptors and the GABAR are families of heteropentameric isoforms, or receptor subtypes. These have different age-dependent and brain regional localization, circuit participation, and, thus, involvement in different functions and behaviors. Despite the lack of X-ray crystallographic data on the structure of GABAR, considerable information about functional domains within the protein is evolving. GABAR are the targets of important drugs, including general anesthetics and agents, such as the benzodiazepines used to treat epileptic seizures, anxiety, and sleep disorders. Benzodiazepines are synthetic compounds with important clinical utility (neuroactive drugs). The benzodiazepine "receptor," or site that mediates their pharmacological effects, is a portion of the GABAR protein itself; indeed, the binding site appears to be a modified version of the binding site for GABA.

Molecular Structure

Heteropentamers

The members of the superfamily share a pseudo-symmetric, pentameric membrane-spanning structure, with all subunits contributing equally to the ion channel (Figure 1). Each member of the superfamily is made from a family of homologous subunits of 45–67 kDa, with a conserved topology. These subunits each possess a long extracellular N terminus, which in some cases carries the neurotransmitter-binding site, four membrane-spanning domains, including the ion channel wall in M2, and a large variable sequence intracellular loop between M3 and M4. Although the structure of these complicated oligomeric receptor-channel membrane proteins has so far not been solved by crystallographic methods, some structural information has been obtained for other kinds of membrane receptors, ion channels, and, particularly, the extracellular domain of the nicotinic acetylcholine receptor, found to be exactly homologous to a snail acetylcholine-binding protein.

A Family of Isoforms

The heteropentameric GABAR protein is most often made from α, β, and γ subunits. The most common combination contains two copies of one α-subunit, two copies of one β-subunit, and one copy of $\gamma 2$, arranged as in Figure 2. The isoform most abundantly expressed in the CNS contains $\alpha 1\beta 2\gamma 2$. Those containing $\alpha 2$ or $\alpha 3$ are less abundant, and $\alpha 4$, $\alpha 5$, and $\alpha 6$-containing GABAR are even less abundant, with very restricted regional expression. Each α has a preferential β-partner ($\beta 1$, $\beta 2$, $\beta 3$, or θ, similar to avian $\beta 4$), although some α can combine with different β-subunits in different regions. Some GABAR isoforms appear to contain two different α-subunits, but these are relatively nonabundant. Additional rare isoforms have subunits substituted for $\gamma 2$. For example, the $\alpha 4$ and $\alpha 6$ subunits can combine with $\gamma 2$ or with δ in cerebellar and dentate gyrus granule cells and thalamic relay cells. Rarely, $\gamma 1$, $\gamma 2$, or ε (related to avian $\gamma 4$) can substitute for $\gamma 2$ in pentamers containing certain $\alpha\beta$ combinations.

Anatomical Localization and Functional Heterogeneity

Each GABAR subunit shows a specific anatomic and cellular localization as determined by assay of mRNA

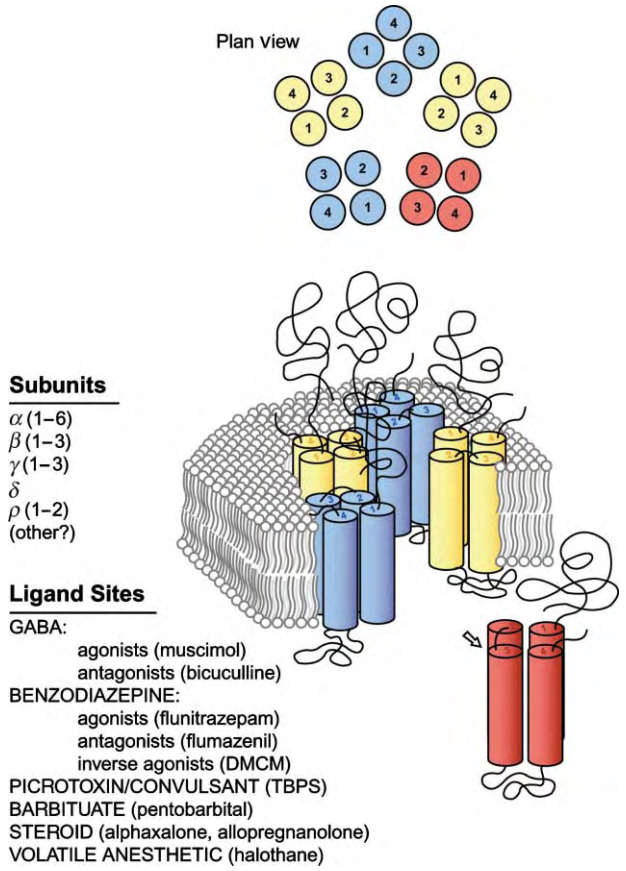

FIGURE 1 Schematic of GABA$_A$ Receptors. The protein is shown as a pseudo-symmetric membrane-spanning ion channel protein made of five homologous subunits, each of which has four membrane-spanning regions as shown in the pull-out subunit. The view from outside the cell (plan view) shows the arrangement around the central core, the chloride ion channel. Also indicated are the subunit families that can be utilized in composing each receptor, and the ligand-binding sites present on the receptor.

and polypeptides, indicating tissue-specific gene expression. Subunit–subunit associations and heteropentamer localization have been revealed by colocalization, copurification, or coimmunoprecipitation studies. Furthermore, there is specific localization to subcellular sites on the plasma membrane, such as synaptic versus nonsynaptic regions, cell bodies versus axons and dendrites, including positioning at postsynaptic locations apposed to specific cellular inputs. For example, the abundant isoform $\alpha1\beta2\gamma2$ is found primarily on inhibitory interneurons, thus inhibiting inhibition and producing a net excitatory circuit. Alternatively, many isoforms containing $\beta3$ are partnered with $\alpha2$, $\alpha3$, and $\alpha5$ subunits and localized on cells that use neurotransmitters other than GABA. These include principal excitatory cells, in which case GABAR inhibit a local circuit. The $\alpha1$ subunit appears to occur at any and all subcellular locations within a given cell, while the $\alpha2$ is limited to axo-axonal synapses in some cells. Thus the nature of the α-subunit, or perhaps specific partnering, may play a role in localization. In addition, heterogeneity has been demonstrated in the developmental profile of individual subunits in brain regions and cells.

The heterogeneity in subunit composition for the GABAR isoforms provides an explanation for pharmacological subtypes based primarily on ligand affinities, and secondarily on other factors such as sensitivity to regulatory systems. GABAR in certain brain regions, with certain subunit compositions, vary in their sensitivity to modulatory drugs like general anesthetics, including barbiturates, and benzodiazepines, as well as the biologically endogenous modulators, the neurosteroids. The neurosteroids are hormone metabolites that have rapid and direct effects on neurons, such as modulation of GABAR. Metabolites of the female sex hormone progesterone (allopregnanolone), corticosteroids (tetrahydrocorticosterone), and possibly androgens, enhance GABAR currents and appear to reach effective concentrations during certain physiological and pathological conditions. This field of research is just in its infancy.

Insights Gained from Transgenic Mice

Interestingly, the specific anatomical location and circuitry of GABAR subtypes dictates the specificity of functions and involvement in specific behaviors. Thus, transgenic and gene-targeted mice have demonstrated a role for certain subunits in particular functions and abnormalities, as well as pharmacology. For example, a mouse knockout for the $\gamma2$ subunit reveals a role for this subunit in proper synaptic localization and clustering of GABAR, and a role in anxiety, stress, and fear conditioning. Knockout of the $\beta3$ subunit produces a severe phenotype with epilepsy, motor incoordination, hyperactivity, and cognitive defects. These observations suggest that decreased levels of $\beta3$ subunit expression may contribute to Angelman syndrome, a human genetic disease with similar phenotype. Knockout of the common $\alpha1$ and $\beta2$ subunits have surprisingly little phenotype, perhaps due to compensatory increases in other subunits. Knockout of the $\alpha6$ subunit reveals its obligatory partnership with the δ subunit in the cerebellum, since no δ peptide is expressed in surface receptors. Knockout or knockdown of the $\alpha5$ subunit yields an animal with improved spatial memory acquisition, implicating $\alpha5$-containing GABAR in the CA1 region in mechanisms that are inhibitory for learning. Genetic knockins of point mutations for drug-binding sites have revealed subunit and subtype functions such as the differential importance of the $\alpha1$-subunit and its sites of expression in sedative/hypnotic functions, the $\alpha2$-subunit in anxiety, and the $\beta3$-subunit but not $\beta2$-subunit in the action of the intravenous anesthetic etomidate. Aberrant plasticity of GABAR in
