Personal Note From The Editor

Many years ago I taught African history at a secondary school in Central Africa. A few years before, some of the teachers in the country had designed a syllabus that included pre-European history, since the curriculum, left over from colonial days, did not include any mention of Africa before the Portuguese. After a year of teaching from this revised version, I asked my students what they thought was the most significant moment in African history, and virtually all of them said it was the arrival of David Livingstone.

It may well be that that was the most important moment for Africa, but it shocked me at the time that no one considered any African achievements worth mentioning. Over these years I have come to see that the dominance of the West means not only that Westerners disparage the rest of the world but also that the rest of the world sees itself as inferior to the West. This book is meant to take one step towards rectifying that, by describing the scientific achievements of those who have been overlooked or undervalued by scholars in both the West and the East.

The book is more than just a compilation of disparate articles; it is a glimpse into how people describe and perceive and order the world. I hope the reader will do some exploring. In addition to reading about Maya astronomy, one can read about Mesoamerican mathematics and medicine, as well as a general article on magic and science, because all the fields are interrelated and entwined. It might be useful to read about astronomy in Africa and in Australia, to see how similar and different these cultures are. One can travel across disciplines, following the achievements of one culture, and across cultures, comparing the same discipline. And then it would be useful to read an essay on Transmission of Knowledge, or Rationality and Method, to put the articles and their contents in a broader philosophical and social context.

My hope, and that of the advisors and contributors to the project, is that the *Encyclopaedia* will expand the horizons of scholars, teachers, and students by illustrating how extensive the accomplishments of non-Western scientists are. May our future students never believe that science is limited to a fraction of the world.

—·—·—

A note about the authors' names, especially Asian ones: I made many embarrassing errors confusing peoples' surnames and given names, but I was reluctant to change authors' names to conform to the Western style, as it went against the spirit of the *Encyclopaedia*. Therefore, I have left the names as the authors wrote them.

There is no cure for curiosity.

Tim Davis, *My Life in Politics*, 2006

Dedicated with affection and admiration to Dr. Robert Friedlander, Sarajune Dagen, and the nurses in the brain surgery unit at Brigham and Women's Hospital, Boston. You saved my life.

Acknowledgements

My greatest thanks go to the scholars who participated in the project. They very generously gave me their work, their advice, their suggestions, and their time.

I thank my editor, Maja de Keijzer, for taking on such an enormous project with enthusiasm and affection. She is always gracious and kind and careful with my many requests. Sometimes I forget that I am not the only person she has to deal with. Andrew Spencer has walked me and the project along rough technological roads, paving the way and making it easy. I have abundant admiration for his technical skill, calming manner and excellent judgment.

At Hampshire College, I thank Gai Carpenter, the Director of the Library, and Aaron Berman, the Dean of Faculty. They have been completely supportive of this project that often takes my mind away from where it probably should be. Thanks also to Josiah Erikson, computer genius and very good guy. I had two excellent students who also helped me. Thank you Kathy Lindroos and Warren Leonard.

Bob, Tim, Lisa, Lisa: you're the best.

Introduction to the Second Edition

"Some people now incorporate bits and pieces of information about other cultures' science into their courses; we hope that in ten years, minds and curricula will have expanded to include much more of this material." That line is a quotation from the Introduction to the first edition of the *Encyclopaedia of the History of Science, Technology, and Medicine in Non-Western Cultures*. Ten years has passed. What has changed?

The most dramatic change has been technological. When I began working on the first edition, in 1992, only a handful of people had email access, and that was especially true for people outside of Europe and North America. Just getting in touch with people was a major obstacle. Months, sometimes years, passed between the time an invitation was extended and accepted, and an article was sent, edited and sent back, and approved. Electronic books did not exist. Images and bibliographies were necessarily limited, as we did not want to make the encyclopaedia too large. Now we have an encyclopaedia that goes far beyond the limits imposed by print. We are in the midst of a new kind of scholarly communication.

The second change becomes apparent by looking over the scholarly literature in the field. In some disciplines, twice as many new books and articles were published in the last decade than had been published in the 10 years before the first edition. With the increase in scholarship, we find that we no longer have to defend our field of study. One of the weaknesses of the first edition was that we did not always eliminate the anti-Eurocentric language and occasionally allowed a polemical tone to come through. In the new edition, we move from advocacy to analysis.

Another advantage of the increase in relevant scholarship is that we have been able to find materials that we were unable to find before. This new edition includes sections on ceramics, architecture, water management, brewing, fishing, cosmology, and many more entries on ethnobotany, metallurgy, and on city and town planning.

What is perhaps even more interesting is that it is not just scholarly interest that has increased over this period. A lead article in the *New York Times Magazine* on February 23, 2003 discussed the field of ethnomathematics, which is a major focus of the encyclopaedia. In this area, the mathematical activities of many cultures, such as Indian geometry or mapmaking in the Marshall Islands, are recognized as mathematics, where before they were relegated to the field of anthropology and dismissed as not having any mathematical value. It is particularly relevant that educators have picked up this notion and are trying to study and teach science through the lens of culture. What a perfect time to expand the encyclopaedia and take advantage of this new interest.

The Electronic Version

The web makes a cross-cultural, cross-disciplinary comparison especially easy. A reader can search "lunar mansions" and be taken to all the mentions of lunar mansions, not just in the articles specifically devoted to that topic, but in any of the rest of the encyclopaedia, as in the chapter on Ibn Majid, an Arab navigator of the fifteenth century. It also makes it possible to connect the philosophical essays with the more empirical ones, making it easier to broaden users' views to include philosophical, social, historical, geographical, and scientific aspects. This is a conscious instrument drawn to promote cross-cultural interaction. The electronic edition has hyperlinks to other articles in the encyclopaedia, and to sites suggested by the authors. We have greatly increased the number of images. We hope to be able to continue to add to this over the years. We plan to keep the encyclopaedia updated. This means not just updating and adding to the research there, but being able to introduce new topics as they become available.

I think our prediction of 1997 has partially come true, and I hope the new edition will reach farther, dig deeper, and touch many more minds and hearts. As Tim Davis says in *My Life in Politics* (Aperture, 2006), "There is no cure for curiosity."

Abacus

Sr. Barbara E. Reynolds

In contemporary usage, the word *abacus* refers to a computational device with beads sliding on fixed rods, often associated with the Japanese or Chinese. However, the word *abacus* has Latin roots, suggesting a rich history in Western as well as Eastern cultures.

The present-day abacus, called *suan-pan* in China, *soroban* in Japan, and *schoty* in Russia is still in use by shopkeepers throughout Asia and in Chinatowns around the world. It works on a place-value or positional system of numeric notation, similar to that of our familiar Hindu-Arabic numerals. The number of beads on each rod represents the value of the digit in that place, with higher place values to the left (or, on the *schoty,* above) and lower place values to the right (or below). Numeric values are read from left-to-right (or top-to-bottom) similarly to the written numerals. For example, the numeral 341 is represented by 3 beads on the *hundreds* rod, 4 beads on the *tens* rod, and 1 bead on the *units* rod.

On Chinese and Japanese models the rods are vertical, and the beads on these rods are divided into two groups by a horizontal bar, which separates the beads into a set of one or two beads above the bar and another set of four or five beads below the bar. The beads above this horizontal bar are valued at five times the beads below the bar. Thus, for example, the number 756 is represented by 1 five-bead and 2 one-beads on the *hundreds* rod, 1 five-bead and no one-beads on the *tens* rod, and 1 five-bead and 1 one-bead on the *units* rod. To operate the abacus, first clear it by pushing all the beads away from the horizontal bar, the beads in the lower section are pushed down while those in the upper section are pushed up. This can be done quickly by tilting the abacus slightly so that all the beads slide down, then laying the abacus on a flat horizontal surface and running the index finger between the bar and beads in the upper section, pushing them away from the bar. The abacus is operated using the thumb and the index finger to push beads toward or away from the bar as values are added or subtracted. To add 341 + 756, first push the beads in place to represent 341, then push additional beads in place to represent 756. On the *hundreds* rod there will be 3 one-beads plus 1 five-bead and 2 additional one-beads; on the *tens* rod there will be 4 one-beads and 1 five-bead, and on the *units* rod there will be 1 one-bead, 1-five bead and 1 additional one-bead. The result can be read as 10 *hundreds*, 9 *tens*, and 7 *ones*. In practice this is quickly simplified by regrouping the beads to 1 *thousand,* 0 *hundreds,* 9 *tens,* and 7 *ones,* or simply 1097. That is, whenever 5 one-beads are accumulated below the bar they are exchanged for 1 five-bead above the bar, and whenever 2 five-beads are accumulated above the bar, they are exchanged for 1 one-bead in the next column to the left.

The Chinese *suan-pan*, which is first mentioned in the literature in the twelfth century, traditionally has two five-beads and five one-beads on each rod. So it is possible to accumulate a value of 15 (2 five-beads plus 5 one-beads) on each rod during the computation, and this must be simplified as described above before the result can be read out. The Japanese *soroban*, developed in the early 1930s, has shorter rods with one five-bead and four one-beads on each rod. With the *soraban* the value on any rod cannot go above 9 (1 five-bead plus 4 one-beads) so that simplifications must be carried out continuously throughout the computation. Since each bead is moved through a shorter distance, an experienced, skillful user can perform computations more quickly on the *soroban* than on the *suan-pan*.

The Russian *shoty*, developed in the 17th century, has horizontal rods, with ten beads on each rod. Numeric values are read from top down, with each rod valued at 10 times the value of the rod immediately below it. That is, the *hundreds* rod is above the *tens* rod, which is above the *units* rod. Calculating with the *shoty* resembles finger counting, each bead representing one finger, or one unit in its respective place value. If you hold your hands out in front of you with the palms away from you, your two thumbs will be side-by-side, flanked by the four fingers of each hand. Similarly, the two middle beads on each rod of the *shoty* representing the thumbs are in a contrasting color to the two sets of four beads each on either side. This makes it easier to see the values without consciously counting the beads. To clear the value on the *shoty* the beads are all pushed to the right. Beads are pushed to the left or right as numbers are added or subtracted.

Archeological evidence in the form of bead-frame calculators as well as piles of small smooth rounded stones, which could have been used as counters for reckoning, suggests that in ancient times (300 BCE to 500 AD), computations in the marketplace throughout the Roman empire were commonly worked out by casting stones (*calculi*) in the sand or on a specially marked counting table (*abax*). Lines in the sand or on the table top would mark off space for *ones*, *tens*, *hundred*s, and so on. To make the values easier to read, stones placed on the line between two spaces would denote values halfway between the lower-valued unit on the right and the higher-valued unit on the left. For example, a stone on the line between the *ones* and the *tens* would be valued as *five*, and a stone on the line between the *tens* and the *hundreds* would be valued as *fifty*.

Roman numerals could have been used to easily record the results of computations done on a sand-reckoner or counting table. The Roman numerals I, X, C, and M represent stones in the units, tens, hundreds, and thousands spaces, respectively, while V, L, and D represent values on the lines, 5, 50 and 500. On some surviving counting tables, the Roman numerals I, X, C, and M have been scratched onto the table top in the appropriate spaces, making it a simple matter to record the final result of the computation. The Roman numeral CCVIII (represented by 208 in Hindu-Arabic numerals) would be cast on the counter-top using two stones in the *hundreds* space, one stone on the line between the *tens* and the *units* spaces, and three stones in the *units* space. Similarly, the Roman numeral DCXXVIIII (or 629) would be cast using one stone on the line between the *thousands* and the *hundreds* spaces, one stone in the *hundreds* space, two stones in the *tens* space, one stone on the line between the *tens* and the *units* spaces, and four stones in *units* space. The use of a quasi-positional subtractive principle in Roman numerals – so that IIII is represented as IV and VIIII as IX – is a later development used only sparingly in ancient and medieval times.

To add CCVIII + DCXXVIIII, the person doing the calculating (probably a merchant), would first cast stones representing CCVIII, and then the additional stones representing DCXXVIIII. These would be regrouped by rearranging the stones in full view of the customer first as D CC C XX VV III IIII, and then simplified as D CCC XXX V II (or simply as 837 in our more familiar numerals).

In the early fourteenth century, bankers and merchants were still required by law to use Roman numerals to record business transactions. Since the Gutenberg printing press was not invented until about 100 years later, the majority of the population was illiterate (i.e., not taught to read the printed word). Recording the result of the previous example, DCCCXXXVII, in Roman numerals requires ten symbols, one symbol on the paper for each stone on the counting table. Recording the same result using Hindu-Arabic numerals would require only three symbols. Zero was a difficult concept, one that was not easily adopted. The Hindu-Arabic numeral 500 requires three digits, but would be represented by a single stone on the abacus, and by the single letter D using Roman numerals. Although the idea of zero as a placeholder was sometimes understood in medieval times, it simply was not needed in doing computations using an abacus. If results were recorded using Roman numerals, the clear correspondence between the stones on the counting table and the symbols on the paper was readily apparent. Thus, using Roman numerals, the customer would be assured that the merchant or banker was accurately recording the result of the transaction.

The Roman bead-frame calculators found at some archeological sites are small enough to be held in one hand and have a design similar to the Chinese *suan-pan*. This evidence suggests that the abacus was taken from Western Europe to the East by Christian migrations. In the late fourth century, Arabs brought the concept of a numeral for zero to the West from the Hindus in India.

Abortion

Malcolm Potts

Abortion, along with circumcision, is amongst the oldest operations known to human kind. While abortion meets an extraordinarily important need of the individual, society commonly treats it differently from other aspects of medical science. Usually, there is little honor to be gained by improving abortion technologies.

The explanations and beliefs different cultures develop concerning the origin and maturation of pregnancy help determine attitudes to abortion. The *Quʾrān*, for example, describes pregnancy as a process of increasing complexity progressing from, "a drop of seed, in a safe lodging, firmly affixed" to a "lump" with "bones, clothed with flesh", and some Islamic theologians permit abortion early in pregnancy. Most abortions are performed because the woman feels she cannot support the child if born, although unmarried women, especially in non-Western traditional societies, may abort for fear of punishment. In the ancient Ugandan royal household, abortion was carried out on princesses so as not to divide the kingdom.

Abortion is known in practically all cultures from preliterate societies to the most industrialized. Abortionists are often also traditional birth attendants or medicine men. A spectrum of techniques is used which differ in their complexity and in their consequences, and which are greatly influenced by the stage of pregnancy when the procedure is carried out. In non-Western societies most techniques fall into one of three categories: herbal remedies, abdominal massage, and the insertion of foreign bodies into the uterine cavity.

In many contemporary non-Western cultures a variety of brews and potions are concocted to bring on a late menstrual period. Such methods were also widely sold in Western cultures until the reform of the abortion law. The open sale of emmenogogues (medicines to bring on a late period) in Manila, Lima, or Dacca today finds a close parallel in Boston in the nineteenth century United States, or Birmingham, England in the middle of this century. The *Jamu* remedies sold every day in Indonesia include a number of emmenogoges. The use of a tea brewed with the spiny nettle (*Urtica magellanica*) by the Aymara Indians of Bolivia living near Lake Titicaca and the juice of hibiscus leaves (*Abelomschus diversifolius*) in the Pacific islands are two examples from among many herbal remedies in preliterate societies.

The use for abortifacient medications is usually limited to the first six or eight weeks after the last menstrual period. Many do not work, but rely on the fact that spontaneous abortion is common and will often be ascribed to a traditional remedy when one has been used. Others are physiologically active, either on uterine muscle or the embryo, although they often need to be used in doses that may be toxic to the woman. In the 1970s and 1980s the Human Reproduction Program of the World Health Organization tested a number of such abortifacients from around the world, and at least one, from Mexico, underwent preliminary screening by a pharmaceutical company. The time of collection, the method of preparation, and details of use may all be critically important in determining the outcome. An alternative technique for studying traditional abortifacients was developed by Moira Gallen in the Philippines, who worked with vendors of traditional abortifacients and then followed up the women who used them. The data suggest some herbal remedies do indeed bring on a late period.

An amalgamation of Western and non-Western cultures has taken place in Brazil where the Western drug Cytotec, an oral form of prostaglandin, is sold illicitly to women with an unintended pregnancy. It is estimated there are one to four million illegally induced abortions in Brazil each year, and each woman has one to three abortions in a lifetime. Cytotec produces bleeding from the uterus which, although it does not always lead to abortion, is usually sufficient to take the woman to the hospital, where the abortion is invariably completed in the operating theater. It is relatively safe but can be very painful. Until restrictions were placed on sales in 1991, 50,000 packets a month were being sold.

The second set of abortion technologies, with a history stretching back to preliterate societies, involves physical trauma to the woman's body. Many cultures associate falls and physical violence with abortion, as did the ancient Hebrews (*Bible:* Exodus 21: 22). The oldest visual representation of an abortion anywhere in the world is on a bas relief in the great temples of Ankor Wat built by King Suryavarman II (AD 1130–1150). Massage abortion remains common from Burma, through

Thailand and Malaysia to the Philippines and Indonesia. Traditional birth attendants use their hands, elbows, bare feet, or a wooden mallet (as portrayed on the Ankor reliefs) to pound the uterus and terminate an unwanted pregnancy. Operators begin by asking the woman to empty her bladder and then try to draw the uterus from beneath the pubic bone so they can apply pressure to the abdominal wall. Sometimes these procedures lead to vaginal bleeding and abortion with relative ease; on other occasions the pain may be so severe that the operator has to stop and return some other time. A study in Thailand estimated that 250,000 such massage abortions take place in the villages of Thailand each year. Gynecologists in Malaysia have described how women are sometimes admitted to hospital for what appear to be the symptoms of appendicitis, with fever and rigidity of their abdominal muscles; when the abdomen is open, the uterus is found to be so bruised and damaged that it may be necessary to do a hysterectomy.

This specialized technique, which has to be learnt from generation to generation, is largely limited to Southeast Asia, although the American Indian Crows and Assiniboines used a board, on which two women jumped, placed across the abdomen of a recumbent pregnant woman, and Queensland native Australians used a thick twine wound around the abdomen combined with "punching" the abdominal wall.

The third types of abortion techniques are the most common and are found in all continents. They involve passing a foreign body through the uterine cervix in order to dislodge the placenta and cause an abortion. In traditional societies a twig or root may be used and it may take a day or more for the procedure to work. The major risks are infection and hemorrhage. The Smith Sound Inuit used the thinned down rib of a seal with the point cased in a protective cover of tanned seal skin, which could be withdrawn by a thread when the instrument had been inserted into the uterus. The Fijians fashioned a similar instrument from *losilosi* wood, but without the protective cover for insertion, and the Hawaiians used a wooden dagger-shaped object up to 22 cm long which was perceived as an idol Kapo. In contemporary Latin America and much of urban Africa, the commonest method of inducing abortion is to pass soft urinary catheters, or *sonda*, such as those used by doctors when men have enlarged prostates. Such catheters are readily available, although traditional abortions do not always use adequate sterile techniques and, even under the best of conditions, leaving such a catheter in place can be associated with infection.

Epidemiological studies show beyond all doubt that the safest way of inducing first trimester abortion is through the use of vacuum aspiration, and most legal abortions in the Western world are done using this technique. A small tube, varying in diameter from something slightly larger than a drinking straw to about 1 cm, is passed through the cervix, and attached to a vacuum pump. In the first three months of pregnancy such a procedure generally takes about 5 min and is commonly done as an out patient procedure under local anesthesia.

Vacuum aspiration abortion was described in nineteenth century Scotland, but the technique used today was invented in China sometime in the 1950s by Wu and Wu. The method spread across certain parts of the Soviet Union and into Czechoslovakia and some other areas of Eastern Europe. In the 1960s a nonmedically qualified practitioner from California called Harvey Karman invented a piece of handheld vacuum aspiration equipment. Karman got the idea from descriptions of procedure performed in China, Russia, and Eastern Europe, and the flow of ideas has gone full circle with the syringe equipment now being widely used in many non-Western countries, such as Bangladesh, Vietnam, and Sri Lanka.

In the Ankor reliefs the women having abortions are surrounded by the flames of hell. Although abortion was disapproved of in the East, it was still considered a crime against the family, not against the state as it is commonly perceived in the West. Abortion before the felt fetal movements was legal in Britain and all states of the United States in 1800 and illegal in those same places by 1900. With the expansion of colonialism, Western abortion laws were imposed upon all colonized nations of the Third World. The nations of the then British Empire either adopted a form of the 1861 Offenses Against the Person Act of Queen Victoria's England or a version of the Indian penal code. French colonies enacted the code of Napoleon and even countries that were not colonized, such as Thailand and Japan, adopted some form of restrictive abortion legislation in the nineteenth century derived from Western statutes.

The second half of the twentieth century has seen a reversal of many restrictive laws. The majority of the world's population now lives in countries which have access to safe abortion on request. The technologies used all over the world owe a great deal to non-Western philosophies and inventiveness.

Abraham Bar Ḥiyya (Savasorda)

Tony Levy

Abraham bar Ḥiyya, also called Savasorda (latinized from the Arabic *ṣāḥib al-shurṭa* = Chief of the guard), flourished in Barcelona, in Christian Spain, but was probably educated in the kingdom (*tā'ifa*) of Saragossa, during the period in which it was ruled by the Arabic dynasty of the Banū Hūd. Thus his scientific education could be related to the well known scientific talents of some of the Banū Hūd kings.

Having mastered the Arabic language and culture, he was a pioneer in the use of the Hebrew language in various fields. He wrote on philosophy, ethics, astronomy, astrology, mathematics, and calendrial calculations. He clearly indicated that his Hebrew compositions were written for Jews living in southern France, who were unacquainted with Arabic culture and unable to read Arabic texts.

Two mathematical compositions by Abraham Bar Ḥiyya, and four astronomical ones are known.

Yesodey ha-tevuna u-migdal ha-emuna (The Foundations of Science and the Tower of the Faith) was supposed to be a scientific encyclopedia, of which only the mathematical sections survived. Presumably an adaptation from some unknown Arabic composition, it dealt with basic definitions and knowledge in arithmetic, geometry, and optics.

Ḥibbur ha-meshiḥa we ha-īshboret (The Composition on Geometrical Measures) dealt with practical geometry. This book enjoyed a very large diffusion in medieval Europe in its Latin version, the *Liber embadorum*, translated by Plato of Tivoli (1145), who was assisted by the author himself. The importance of this text for the development of practical geometry in Europe has been noted by ancient and modern scholars.

Seferṣsurat ha-areṣ we-tavnit kaddurey ha-raqi 'a (Book on the Form of the Earth and the Figure of Celestial Spheres), together with *Ḥeshbon mahalakhot ha-kokhavim* (Calculations of the Courses of the Stars) and The *Luḥot* (The Astronomical Tables), offered a basic astronomical knowledge founded on Arabic sources such as the works of al-Farghānī and al-Battānī.

Sefer ha-'Ibbur (The Book of Intercalation) dealt with calendrial calculations and aimed "to enable the Jews to observe the Holy Days on the correct dates."

Bar Ḥiyya can rightly be considered the founder of Hebrew scientific culture and language.

Abraham Ibn Ezra

Samuel S. Kottek

Abraham Ibn Ezra was born in Toledo, Spain in 1089. In his youth, he studied all the branches of knowledge that Arabic and Jewish gifted (and well to do) youngsters could master, and was mainly known as a poet. Around 1140, he left Spain and wandered through Italy, southern France, and England. Also, legend says that in his old age he traveled to the Holy Land. During his itinerant life, Ibn Ezra met scores of scholars and wrote a number of works, of which his commentary on the Pentateuch and the Prophets in the most widely known.

He was a real polymath, who wrote on Hebrew philology (*Moznei Leshon ha-Kodesh*), translated several works on grammar from Arabic into Hebrew, and wrote on the calendar, mathematics (*Sefer ha-Mispar*, Book of the Number), and philosophy and ethics (*Yesod Mora* on the meaning of the commandments). He is considered one of the Jewish Neoplatonists, in particular regarding his description of the soul.

In his view, intellectual perfection is the only way to enjoy a relationship with the divine Providence. As a scientist, Ibn Ezra (also known by the name of Avenezra, sometimes misspelled Avenaris) is mainly known for his works on astronomy (*Sefer ha-ʿIbbur*: *Ta'amei ha-Luḥot*, Book on Intercalation) and for his treatise on mathematics mentioned above. He also composed a number of brief astrological works, most of them still unpublished. It is not known whether Ibn Ezra ever practiced medicine. He certainly showed in his biblical commentary a fair degree of knowledge in medicine and biology.

It has been said that Ibn Ezra wrote over 100 works, which seems rather exaggerated; certainly many fewer have survived. Ibn Ezra was the Paracelsian type of scholar, learning from each new experience, from each encounter with other scholars, living a simple life and despising wealth. It is particularly striking that he wrote only in Hebrew, contrary to nearly all his contemporaries in Spain who wrote in Arabic. This is mainly due to the fact that he wandered throughout Europe and North Africa, using the language that was common to all his coreligionists. He may be considered an ambassador of Spanish scholarship to the Jewish Diaspora at large. He died in 1164.

Abū Jaʿfar al-Khāzin

JAN P. HOGENDIJK

Abū Jaʿfar Muḥammad ibn al-Ḥusay al-Khāzin was a mathematician and astronomer who lived in the early tenth century AD in Khorasān. Until recently, it was believed that there were two different mathematicians in the same period, namely Abū Jaʿfar al-Khāzin and Abū Jaʿfar Muḥammad ibn al-Ḥusayn, but in 1978 Anbouba and Sezgin showed that they are the same person.

In mathematics, Abū Jaʿfar al-Khāzin is mainly known because he was the first to realize that a cubic equation could be solved geometrically by means of conic sections. Al-Māhānī (ca. AD 850) had shown that an auxiliary problem in Archimedes' *On the Sphere and Cylinder* II: 4, which Archimedes had left unsolved, could be reduced to a cubic equation of the form $x^3 + c = ax^2$. Abū Jaʿfar knew the commentary to Archimedes' work by Eutocius of Ascalon (fifth century AD), in which Eutocius discusses a solution of the same auxiliary problem by means of conic sections. Abū Jaʿfar drew the conclusion that the equation $x^3 + c = ax^2$ could also be solved by means of conic sections. Abū Jaʿfar also studied a number of other mathematical problems. He stated that the equation $x^3 + y^3 = z^3$ did not have a solution in positive integers, but he was unable to give a correct proof. He also worked on the isoperimetric problem, and he wrote a commentary to Book X of Euclid's *Elements*.

In astronomy, Abū Jaʿfar's main work was the *Zīj alṣafāʾiḥ* (the Astronomical Handbook of Plates). A manuscript of this work has recently been discovered in

Srinagar. The work deals with a strange variant of the astrolabe. One such instrument, made in the twelfth century, was still extant in the beginning of this century in Germany, but it has since disappeared. Photographs of this instrument have been published by David King. Abū Jaᶜfar developed a homocentric solar model, in which the sun moves in a circle with the earth as its center, in such a way that its motion is uniform with respect to a point which does not coincide with the center of the earth.

Abū Kāmil

Jacques Sesiano

Abū Kāmil, Shujāᶜ ibn Aslam (ca. 850–ca. 930), also known as "the Egyptian Reckoner" (*al-ḥāsib al-miṣrī*) was, according to the encyclopedist Ibn Khaldūn's report on algebra in his *Muqaddima*, chronologically the second greatest algebraist after al-Khwārizmī. He was certainly one of the most influential. The peak of his activity seems to have been at the end of the ninth century.

Although at the beginning of his *Kitāb fī'l-jabr wa'l-muqābala* (Algebra) he refers to al-Khwārizmī's similar work, Abū Kāmil's purpose is radically different, for he is addressing an audience of mathematicians presumed to have a thorough knowledge of Euclid's *Elements*. His *Algebra* consists of four main parts.

a. Like his predecessor, Abū Kāmil begins by explaining how to solve the six standard equations and to deal with algebraic expressions involving an unknown and square roots. The next section (Book II) contains, as in his predecessor's work, six examples of problems and the resolutions of various questions, but the whole is notably more elaborate and geometrical illustrations or proofs are systematically appended. With Book III comes a difference, already hinted at in the introduction to the treatise: the problems now contain quadratic irrationalities, both as solutions and coefficients, and require notable proficiency in computing. Quadratic irrationalities may thus be said to enter definitely the domain of mathematics and no longer be confined to their Euclidean representation as line segments.
b. These extensions found in Book III are put to immediate use in the resolutions of problems involving polygons in which the link between their sides and the radii of a circumscribed circle is reducible to a quadratic equation – since they are all constructible by ruler and compass.
c. The subsequent set of quadratic indeterminate equations and systems is most interesting. The methods presented are similar to those of Diophantus's *Arithmetica*, but there are new cases and the problems are presented in a less particular form. Abū Kāmil surely relied on some Greek material unknown to us.
d. A set of problems which are, broadly speaking, applications of algebra to daily life are directly appended to the former. Some of these, which correspond to highly unrealistic situations, belong more to recreational mathematics. The inclusion of such problems in an algebraic textbook was to become a medieval custom, with both mathematical and didactical motives. The *Algebra* ends with the classical problem of summing the successive powers of 2, which, from the ninth century on, became attached to the 64 cells of the chessboard.

Abū Kāmil's Arabic text is preserved by a single, but excellent, manuscript. The *Algebra* was commented upon several times, in particular in Spain, and the first large mathematical book of Christendom, Johannes Hispalensis's *Liber mahameleth*, is basically a development and improvement of parts *a* and *d*. Despite the *Algebra*'s importance in Spain, no Latin translation was undertaken until the fourteenth century, when Guillelmus (presumably: de Lunis) translated half of it (up to the beginning of part *c*). This translation is better than Mordekhai Finzi's fifteenth century Hebrew one, which, however, covers the whole work. Since these translations were late, Abū Kāmil had no direct influence in the Christian West. Similar material, however, may be found in writings of Leonardo (Fibonacci) of Pisa (fl. 1220).

Abū Kāmil also wrote *Kitāb al-ṭair* (Book of the Birds), a small treatise consisting of an introduction and six problems all dealing with the purchase of different kinds of birds, of which one knows the price per unit, the total number bought and the amount spent (both taken to be 100). Since there are more unknown kinds (3–5) than equations, these linear problems are all indeterminate. Abū Kāmil undertook to determine their number of (positive integral) solutions, which he found to be, respectively, 1, 6, 96 (correct: 98), 304, 0, 2676 (correct: 2,678). Although such problems are frequently met in the medieval world, Abū Kāmil remained seemingly unparalleled in his search for all solutions in various cases.

Kitāb al-misāḥa wa’l-handasa, or *Kitāb misāḥat al-araḍīn* (On Measurement and Geometry) is an elementary treatise on calculating surfaces and volumes of common geometrical figures. Since it is meant for beginners, demonstrations and algebra are left out. Why Abū Kāmil found it necessary to write such an elementary book becomes clear when he describes some of the formulas then in use by official land surveyors in Egypt.

Finally, *Kitāb al-waṣāyābi’l-juḏūr* or *Kitāb al-waṣāyābi’l-jabr wa’l-muqābala* (Estate Sharing Using Unknowns, or Using Algebra) applies mathematics to inheritance problems. Abū Kāmil begins by explaining the requirements of the Muslim laws of inheritance and discussing the opinions of known jurists.

Bibliographic sources inform us that Abū Kāmil also wrote another treatise on algebra, and a further one on the rule of false position.

Note that two of the subjects included by al-Khwārizmī in his *Algebra* were treated by Abū Kāmil in separate works. From that time onward, algebra textbooks adopted the same form as his.

Abū ’l-Barakāt

Y. Tzvi Langermann

Abū al-Barakāt al-Baghdādī (d. 1164 or 1165) was one of the most original thinkers of the medieval period. Born a Jew in about 1080, but converted late in life to Islam, Abū ’l-Barakāt was a prominent physician and natural philosopher who achieved considerable fame during his own lifetime, as his appellation *awḥad al-zamān* (Unique of His Age) attests. His numerous insights into physics and metaphysics have been elucidated by the late Shlomo Pines in a number of brilliant studies, on which this résumé depends in large measure.

Abū ’l-Barakāt’s contributions are all contained in his *chef d’œuvre*, *al-Muʿtabar* (That Which has been Attained by Reflection). Although there may be some doctrinal discrepancies between various passages in the book, which may be due to the fact that the work is actually a collection of notes compiled over a considerable period of time, each section by itself displays a very clear and systematic exposition, surveying earlier opinions on the subject, objections to these, and possible answers to the objections (including the occasional concession that the objection is valid and necessitates a revision of the original idea), followed by Abū ’l-Barakāt’s own opinion. Abū ’l-Barakāt exhibits a remarkable ability to disentangle issues that had become densely intertwined through centuries of debate, for example the three notions of time, space, and the infinite. Particularly significant are the occasions when the author gives great, occasionally decisive, weight to “common opinion,” on the grounds that the issues at hand – the notions of time and space are the most important to fall into this group – involve a priori concepts which must be elucidated by examining how people actually perceive, rather than a posteriori academic analysis.

Some of the ideas which Abū ’l-Barakāt advances in the course of his discussions prefigure much later notions which proved to be correct: for example, the idea that a constant velocity applied to a moving body causes it to accelerate. Others, by contrast, showed themselves to be wrong: for instance, the idea that every type of body has a characteristic velocity which reaches its maximum when the resistance is zero. (In this way, Abu ’l-Barakāt answers the objection that bodies moving in a vacuum would have an infinite velocity.) All in all, the work of Abū ’l-Barakāt and its continuation by his student Fakhr al-Dīn al-Rāzī constituted a most serious challenge to the formulations of Ibn Sīnā, which then dominated physical and metaphysical thought in Near East.

All that we possess in the way of medical writings by Abū'l-Barakāt are a few prescriptions for remedies. These remain in manuscript and are as yet unstudied.

Abū'l-Fidāʾ

Emilia Calvo

Abū'l-Fidāʾ Īsmāʿīl ibn ʿalī ibn Maḥmūd ibn Muḥammad ibn ʿUmar ibn Shahanshāh ibn Ayyūb ʿImād al-Dīn al-Ayyūbī was a prince, historian, and geographer belonging to the Ayyūbid family. He was born in Damascus, Syria in AD 1273 and soon began his military career against the Crusaders and the Mongols. In AD 1299 he entered the service of the Sultan al-Malik al-Nāṣir and, after 12 years, he was installed as governor of Ḥamā. Two years later he received the title of al-Malik al-Ṣāliḥ. In AD 1320 he accompanied the Sultan Muḥammad on the pilgrimage to Mecca and was given the title of al-Malik al-Muʾayyad. He died at Ḥamā, Syria in AD 1331.

Abū'l-Fidāʾ is the author of some poetic productions, such as the version in verse of al-Māwardī's juridical work *al-Hāwī*. However, his celebrity is based on two works which can be considered basically compilations of earlier works which he elaborated and completed. One of them is the *Mukhtaṣar Taʾrīkh al-bashar* (A Summary on the History of Humanity) written in AD 1315 as a continuation of the *Kāmil fī-l-taʾrīkh* of Ibn al-Athīr. It was divided into two parts: the first was devoted to pre-Islamic Arabia and the second to the history of Islam until AD 1329. It was kept up to date until AD 1403 by other Arabic historians. It was translated into Western languages and became the basis for several historical syntheses by eighteenth-century Orientalists.

Abū'l-Fidāʾ's most important scientific work is *Taqwīm al-buldān* (A Sketch of the Countries) written between AD 1316 and 1321. It consists of a general geography in 28 chapters.

This book includes the problems and results of mathematical and physical geography without touching upon human geography or geographical lexicography. There is a table of the longitudes and latitudes of a number of cities, including the differing results found in the sources, setting up a comparative table for geographical coordinates. Among the sources of the book are geographers such as Ibn Hawqal and Ibn Saʿīd al-Maghribī.

This work was translated into German, Latin, and French between the sixteenth and the nineteenth centuries, making a significant contribution to the development of geography.

Abū'l-Ṣalt

Julio Samsó

Abū'l-Ṣalt is known as Abū'l-Ṣalt al-Dānī. He was an Andalusian polymath born in Denia in 1067. In about 1096 he went to Egypt where he lived for sixteen years. An unsuccessful attempt to rescue a boat loaded with copper which had sunk in the harbor of Alexandria cost him 3 years in prison, after which he migrated to Mahdiyya (Tunis) where he died in 1134.

He wrote about pharmacology (a treatise on simple drugs, *Kitāb al-adwiya al-mufrada*, translated into Latin by Arnold of Vilanova), music, geometry, Aristotelian physics, and astronomy, and he seems to have been interested in a physical astronomy, different from the Ptolemaic mathematical astronomy which predominated in al-Andalus. His treatise on the use of the astrolabe, *Risāla fī-l-ʿamal bi-l-asṭurlāb*, written while he was in prison, probably introduced into Eastern Islam the characteristic Andalusian and Maghribi device, present in the back of Western instruments, which establishes the relation between the date of the Julian year and the solar longitude. He is also the author of a short treatise on the construction and use of the equatorium, *Ṣifat ʿamal ṣafīḥa-jāmiʿa* *tuqawwim bi-hā-jamiʿ al-kawākib al-sabʿa* (Description of the Way to Use a General Plate With Which to Calculate the Positions of the Seven Planets) which follows the techniques developed in al-Andalus by Ibn al-Samḥ (d. 1035) and Ibn al-Zarqāllu (d. 1100), although it also presents original details which show his ingenuity. He probably reintroduced this instrument in the Islamic East where it had appeared in the tenth century but was later forgotten until it was recovered by al-Kāshī (d. 1429).

Abū'l-Wafā'

Yvonne Dold-Samplonius

Abū'l-Wafā' al-Būzjānī, Muḥammad ibn Muḥammad ibn Yaḥyā ibn Ismāʿīl ibn al-'Abbās, was born in Būzjān (now in Iran) on 10 June 940. After he moved to Baghdad in 959, he wrote important works on arithmetic, trigonometry, and astronomy.

Abū'l-Wafā' provided new solutions to many problems in spherical trigonometry and computed trigonometric tables with an accuracy that had not been achieved until his time. He made astronomical observations and assisted at observations in the garden of the palace of Sharaf al-Dawla. Finally, he wrote two astronomical handbooks, the *Wāḍiḥ Zīj* and *al-Majisṭī* (*Almagest*). More information about Abū'l-Wafā''s tables must be obtained from *zījes* that have incorporated material from his works, such as the *Baghdādī Zīj*, compiled shortly before the year 1285 by Jamāl al-Dīn al-Baghdādī. A solar equation table attributed to Abū'l-Wafā' occurs in it.

Several later *zījes* incorporate Abū'l-Wafā''s mean motion parameters. Various sine and cotangent values which he gave in the extant part of *al-Majisṭī* are equal to the values found in al-Baghdādī's sine and cotangent tables. Furthermore, al-Baghdādī's table for the equation of daylight was computed by means of inverse linear interpolation in a sine table with accurate values to four sexagesimal places for every 15° of the argument, and Abū'l-Wafā' is known to have computed an accurate sine table with just that format.

In *Risāla fī iqāmat al-burhān ʻalā 'l-dā'ir min al-falak min qaws al-nahār waʻrtifā' nisf al-nahār waʻrtifā' al-waqt* (On Establishing the Proof of the [rule for finding the] Arc of Revolution from the Day Arc, the Noon Altitude, and the Altitude at the Time), Abū'l-Wafā' deals with a fundamental problem of ancient astronomy that of finding the time in terms of solar altitude. He mentions in the introduction that the formula stated by Ḥabash al-Hāsib (fl. 850) is only approximate. Abū'l-Wafā' gives three proofs of the formula. The procedure of the first two proofs deals entirely with rectilinear configurations inside the sphere, in spite of the fact that the relation being investigated concerns arcs on the surface of the sphere. This technique was characteristic of Hindu spherical astronomy, as well as that of the Greeks prior to the application of Menelaus' Theorem. The method used in the third proof consists essentially of two applications of the Transversal Theorem. Contrary to Hindu trigonometry and most Islamic astronomers, Abū'l-Wafā' was one of the few who defined the trigonometric functions with respect to the unit circle, as is the case nowadays. In *Fī ḥirāfat al-abʿād bain al-masākin* (On the Determination of the Distances Between Localities) Abū'l-Wafā' gives two rules for calculating the great circle distance between a pair of points on the earth's surface. He applies both to a worked example: given the terrestrial coordinates of Baghdad and Mecca he calculates the distance between them, a matter of some interest to Iraqi Muslims undertaking the pilgrimage. The first method employs standard medieval spherical trigonometry and can be regarded as a byproduct of a common procedure for calculating the *qibla*, the direction of Muslim prayer. It is called by al-Bīrūnī "the method of the *zījes*." The second method is less ordinary and its validity is not obvious. In addition to the tangent function, it employs the versed sine, a term Abū'l-Wafā' does not use in the treatise studied above, but which appears frequently in the literature. The origin of this second rule might stem from the so-called *analemma method*, a common and useful ancient technique for solving spherical astronomical problems. The general idea was to project or rotate elements of the given solid configuration down into a single plane, where the desired magnitude appeared in its true size. The resulting plane configuration was then solved by constructions to scale or by plane trigonometry. Aside from the trigonometry, the text is of interest as an intact example of medieval computational mathematics. Numbers are represented in Arabic alphabetical sexagesimals throughout. The results of the multiplications suggest that all operations were carried out in sexagesimal arithmetic, with none of the very common intermediate transformations into decimal integers. Trigonometric functions and their inverses are carried out to four sexagesimal places. Al-Ḥubūbī challenged Abū'l-Wafā᾿ to produce and prove a rule for calculating the area of a triangle in terms of its sides. In his *Jawāb Abī al-Wafā᾿Muḥ ibn Muḥal-Būzjānī ᶜammā sa'alahu al-Faqīh Abū ᶜAlī al-Ḥasan ibn Ḥārith al-Ḥub ūbī fī misāḥat al-muthallathāt* (Answer of Abū'l-Wafā᾿ to the Question Put to Him by the Jurist Abū ʻAlī al-Ḥasan al-Hubūbī on Measuring the Triangle), Abū'l-Wafā᾿ gives three such rules. None of these is identical with "Heron's Rule," but all are equivalent to it. The earliest work on finger reckoning that has survived is Abū'l-Wafā᾿'s *Fīmāyahtāju ilaihi l-kuttāb wa-l-ummāl min ʻilm al-ḥisāb* (On What Scribes and Officials Need from the Science of Arithmetic). As the name implies, it was written for state officials, and therefore gives an insight into tenth-century life in Islam from the administrative point of view. Three more works demonstrate Abū'l-Wafā᾿'s interest in practical mathematics: *Fīmā yahtāju ilaihi as-sāniᶜ min aᶜmāl al-handasīya* (On the Geometrical Constructions Necessary for the Craftsman), written after 990; *al-Mudkhal al-ḥifzī ilā ṣināᶜat al-arithmāṭiqī* (Introduction to Arithmetical Constructions); and *Risāla al-shamsīya fī l-fawā'id al-ḥisābīya* (On the Benefit of Arithmetic).

On What Scribes and Officials Need, written between 961 and 976, enjoyed widespread fame. The first three parts, "On Ratio," "On Multiplication and Division," and "Mensuration," are purely mathematical. The other four contain solutions of practical problems with regard to taxes, problems related to harvest, exchange of money units, conversion of payment in kind to cash, problems related to mail, weight units, and five problems concerning wells. In this compendium Abū'l-Wafā᾿ systematically sets forth the methods of calculation used by merchants, by clerks in the departments of finance, and by land surveyors in their daily work; he also introduces refinements of commonly used methods and criticizes some for being incorrect. Considering the habits of the readers for whom the textbook was written, Abū'l-Wafā᾿ completely avoids the use of numerals. Numbers are written in words, and their calculations are performed mentally. To remember the results of intermediary steps, calculators bent their finger joints in conventional ways which enabled them to indicate whole numbers from 1 to 9,999. This same device was repeated to indicate numbers from 10,000 onward. All procedures, often quite complex, are only described by words. This treatise on practical arithmetic provides the model for all the treatises on the subject from the tenth to the sixteenth centuries.

He is cited as a source or an authority, but more often can only be discerned underneath. In the *Geometrical Constructions Necessary for the Craftsman* Abū'l-Wafā᾿ discusses a host of interesting geometrical constructions and proofs. He constructs a regular pentagon, a regular octagon, and a regular decagon. The construction of the regular pentagon with a "rusty" compass is especially noteworthy. Such constructions are found in the writings of the ancient Hindus and Greeks, but Abū'l-Wafā᾿ was the first to solve a large number of problems using this compass with fixed opening.

Renaissance Europe had a great interest in these constructions. The possible practical applications (such as making decorative patterns) may have been an additional motivation for studying things like a regular (or perhaps equilateral) pentagon inscribed in a square. However, the importance of such applications should not be overestimated. In proposing his original and elegant constructions, Abū'l-Wafā᾿ simultaneously proved the inaccuracy of some practical methods used by the craftsmen.

To honor Abū'l-Wafā᾿, a crater on the moon was named after him. He died in Baghdad in 997 or 998.

Abū Maʿshar

Richard Lemay

Arabic sources such as the *Kitāb al-Fihrist* give the date of Abū Maʿshar al-Balkī's death as 273 of the Hegira, which is AD 886, stating that he was over 100-years old. Since he was of Persian (Afghan) origin these may well be solar years rather than the lunar years of the Muslim calendar. Therefore his age at his death could have been reckoned as "over" 100 years if counted in lunar years in Muslim fashion, or else as 100 solar years. David Pingree claimed to have found the exact date of his birth to be August 10, 787 in a natal horoscope in Abū Maʿshar's *Nativities*. The trouble with this calculation is that Abū Maʿshar himself, in *Mudhākarāt* (Recollections), lamented the fact that he did not know the exact date of his birth and had to rely therefore on a "universal" horoscope he had drawn up. The *Mudhākarāt* then supplies the basic elements of this universal horoscope. Matching these data with Pingree's, it is probably safe to consider the year 171 H/AD 787 as his birth date.

Abū Maʿshar, known in the West as Albumasar, was born in Balkhī in Khurāsān, actually Afghanistan, and seems to have lived there and acquired a reputation as an astrologer much before he came to settle in Baghdad during the reign of the Caliph al-Maʾmūn (813–833), shortly after 820. He lived in Iraq until the end of his life in 886. He must have traveled, at least up and down the Tigris, since in the *Mudhākarāt* he is shown refusing to embark on the stormy waters of the Tigris. He died in Wasit, a city situated in the Sawād, midway between Baghdad and Basra.

Abū Maʿshar's early years are clouded in confusion because of an error committed by the earliest and most important Arab bibliographer, Ibn al-Nadīm (1970), in his *Kitāb al-Fihrist*. Writing in the late tenth century, nearly a century after Abū Maʿshar's death, al-Nadīm (d. ca. AD 987) apparently confused Abū Maʿshar the astrologer from Balkh with another Abū Maʿshar, called an-Najīh, who lived in Medina but died in Baghdad AD 787, the year of Abū Maʿshar's birth.

Once settled in Baghdad, where he spent the remaining 60 years of his life, Abū Maʿshar seems to have been involved in its cultural activity, but also in its tumultuous civic life at a time when "nationalisms" in the form of the *Shuʿūbiya* (non-Arabs) were raising their aspirations to cultural parity with the dominant Arabs. Abū Maʿshar's reputation as an astrologer, his newly found friendship with al-Kindī, and the credit he gained through astrological predictions assessing the power of rulers must have opened for him the doors of the political and learned elite of Baghdad. Al-Nadīm relates an episode in which Abū Maʿshar was punished with lashes by the Caliph for a realistic prediction that the Caliph disliked. Both Abū Maʿshar and al-Kindī, using an intricate system of astral conjunctions inherited from the Sassanian tradition, attempted to anticipate the duration of the Arab rule. In his *Risāla* (Epistle) on the duration of the rule of Islam, al-Kindī tried to comfort the ruling Caliph by giving the Arab rule a minimum span of some 693 years, longer than Abū Maʿshar's prediction. In fact Abū Maʿshar gives a total of 693 years, just as al-Kindī did. Still, in combination with the parallel scheme of the two maleficent planets Saturn and Mars affecting the meaning of the conjunctions of Saturn and Jupiter, Abū Maʿshar tended to reduce the duration to some 310 or 330 years only, which would bring the end of Arab rule closer, thus encouraging the aspirations of the *shuʿūbiyya*.

The *Mudākarāt* of Abū Saʿīd further tell us that, along with other astrologers, Abū Maʿshar accompanied the army of al-Muwaffaq in its campaign against the rebellious Zanj. Astrologers were used by both sides during these civic troubles. Abū Maʿshar's credit as an astrologer served him in these circumstances, for he may have been consulted by both sides in the Rebellion. At any rate he died in the city of Wasit, south of Baghdad, a city which had seen the farthest advance of the rebellious Zanj army and had been reconquered only shortly before by al-Muwaffaq.

The *Fihrist* credits Abū Maʿshar with 36 works, to which David Pingree adds six more. The list has remained fairly the same for all later bibliographers. This holds true for the original Arabic works as well as for the numerous translations into Latin, Greek, Hebrew, and medieval Romance languages. The uncertainty is due to a number of factors. Abū Maʿshar may have produced some works in several versions or editions. He has been imitated in a number of ways by later Arab authors, some of whom displayed his name prominently at the beginning of their own work, thus complicating the task of the bibliographer. Above all there is a lack of any systematic survey of Abū Maʿshar's production. In addition to the confusion still affecting the Arabic originals, a number of Abū Maʿshar's works were translated into so many media during the Middle Ages that the task of surveying the authentic remains is enormous. This illustrates the immense popularity enjoyed by Abū Maʿshar in the West.

Acoustics in Chinese Culture

Chen Cheng-Yih

A sound is perceived in terms of its pitch, loudness, and tone quality characteristics. The Chinese term for pitch is *yīn lü* or simply *lü*. Early mentions of pitch in connection to its function in ode singing, in musicology, and in the standardization of measures and weights are found in the *Yú Shū* (*The Book of Yú*). The Chinese used the terms *qīng* (clear) and *zhuó* (muddy) to describe, respectively, the high and low pitches. In remonstrating the decision of the High King Jǐng of Zhōu to have the Wǔ-Yì bell melted down and converted into the Dà-līn bell of lower pitch, minister Shan Mū Gōng stated in 522 BCE:

> The ear functions harmoniously within a certain range of high and low pitches. The determination of this pitch-range should not be left for individuals. For this reason bells constructed by our ancient kings never exceeded their corresponding size in *jūn* (unit) and weight in *dàn* (unit). This is where the specifications of measures and weights for pitches originated.

This statement, recorded in the *Guó Yǔ* (Discourses on States), reveals that the early Chinese were aware of the existence of an audible pitch range.

A description on the development of the 12 pitches preserved in bells from antiquity is provided by music master Zhōu Jiū. He says that the reason that ranges and degrees can be established for pitch is due to Shén Gǔ of antiquity, who investigated and determined the *zhōng shēng* (middle tone) as the reference. The degrees of the pitches and tuned bells are the standards observed by all officials. From the *zhōng shēng*, one first establishes three pitches, then levels them out evenly into six pitches, and finally brings them to completion in 12 pitches. This is the *dāo* of nature.

This suggests that the 12-pitch system was derived from "trichords". An early example of a trichord is provided by three jade stone-chimes unearthed from a pit of the Yin ruins (ca. thirteenth century BCE) at Anyang; they not only are capable of producing tones but also have their pitch names engraved on the stones.

Early evidence for pitch standardization mentioned in the Chinese text is provided by the common notes found among the unearthed musical instruments. The most significant archaeological evidence is provided by the pitch pipes unearthed in 1986 from a Chǔ tomb (M21) of the Warring States period located at the present Yǔtáishān in Jiāngling, Hūběi province. These pitch pipes, made of nodeless bamboo (open ends) with different lengths and diameters, are the earliest specimens currently available. Though broken, four of the pitch pipes still had readable inscriptions, providing not only the names of the pitches, but also explicit statements on assigning pitches through the usage of the character *dìng* (literally to fix or determine). From the measured frequencies of the unearthed Marquis Yǐ set-bells, one obtains for the Huáng-zhōng pitch a measured frequency of 410.1 vibs s^{-1} in the fifth century BCE.

In Chinese, the louder sound is called *dà* and the softer one *xì*. The modern Chinese term for loudness in acoustics is *yīn-liàng*. An early discussion on loudness is found in the *Guó Yu* on the arrangement of instrument in an orchestra, in which harmony and balance are considered essential.

An obvious question on loudness is its role in audibility. Lǎo Zǐ made some interesting observations which seem to have some bearing on the threshold of hearing. We have from the *Dào Dé Jīng* (Canon of the Virtue of Dào) the statement: That which is listened to but not heard is called *xī*. The term *xī*, as it is defined here, relates to the term *xī-shēng*, which Needham translates as "tenuous note".

At the time of Lǎo Zǐ, concepts such as frequency and intensity had not yet been developed. Lǎo Zǐ could not have distinguished the audibility of *xī-shēng* in relation to its frequency and intensity. But he probably was aware that most *xī-shēng* are low-pitch sounds and that their audibility depends sensitively on loudness. Thus, when he said that the loud sound contains *xī-shēng*, he was probably referring to the audibility of those *inaudible* low-pitch sounds at a louder level.

Tone quality is the perception of sound in relation to the dynamic structure of the sound. The Chinese term for tone quality is *yīn-zhì* and in classic usage simply *yīn*. The early Chinese acousticians identified tone quality with the sound-producing material and began to classify sounds in accordance with such materials. Eight distinct tone qualities known simply as *bā-yīn* (eight tones) are identified with eight such sound-producing materials.

Early mention of the "eight tones" is found in the *Yú Shū* and *Zhŏ Zhuàn*. Other than being responsible for instituting music with the two sets of six pitches, the Grand Music Masters (*Dà-Shī*) were also responsible for making sure that all music was composed in pentatonic intonations: *gōng, shāng, ju*é, *zhî*, and *yǔ*, and that all music was performed in eight tones: *jīn* (metal), *shí* (stone), *tǔ* (clay), *g*é (skin), *sī* (silk), *mù* (wood), *páo* (gourd), and *zhū* (bamboo).

Each of these sound-producing materials represents a basic tone quality. In 1936, Schaeffner commented that the *bā-yīn* was "probably the oldest extant classification of musical instruments in any civilization." Needham and Robinson compared the *bā-yīn* classification with the Greco-Roman classification of musical instruments, namely wind, stringed, and percussion instruments, and concluded that the Greco–Roman classification was more scientific. The point that needs to be emphasized here is that the *bā-yīn* classification was based on tone qualities and not on musical instruments, even though there is an intimate connection between the two. It is important to note that each complex tone has its own unique characteristic harmonic spectrum and wave form. There does not yet exist a satisfactory system for classifying tone quality. The fivefold classification of ideophones, membramophones, chordophones, electrophones, and aerophones is again a classification based on musical instruments.

In addition to the tone quality of sound due to the sound-producing materials, the ancient Chinese were also interested in the variation in tone quality coming from the configuration of musical instruments and the different ways of playing musical instruments. Twelve sounds are specified in the *Zhōu Lǐ* to identify tone qualities with the configurations of the musical instruments. According to the *Lü-Shì Chūn-Qiū* of 239 BCE, the techniques of exploiting timbre with overtones had reached a high level of art in *qín* (half-tube zither) playing. Indeed, in the playing the ancient lute (*gu qin*) with no frets and markings, each note could be played with a variety of subtleties in touch.

The Physical Nature of Sound

As described in the *Kǎo Gōng Jì* (The Artificers' Record), sound is produced by vibrations, and there is a relationship between the thickness of the vibrating walls and the pitch of the sound produced by the vibration.

In Chinese classic usage, the character *ji* means rapid (or fast) and *shū* means slow. Thus, sound produced by rapid vibration is called *yīn jí* (or *shēng jí*) and by slow vibration *yīn shū* (or *shēng shū*). Such technical terms are found in the description of acoustics of bells, stone-chimes, and drums in the *Kǎo Gōng Ji*. It is important to appreciate the relation between this terminology and the terminology for pitch. The terms *qīng* and *zhu*ó for high and low pitches represent the perceptive description of sound in relation to the rate of vibration, while the terms *yīn jí* and *yīn shū* represent the physical description of sound in relation to the rate of vibration.

An explicit statement on the direct relation between the physical and perceptive descriptions of sound is found in the *Guǎn Zǐ* (The Book of Master Guǎn), in which it is stated that the sound of rapid vibration has a high pitch.

According to the *Kǎo Gōng Jì*, Chinese bell-makers examined the audibility of a bell's sound at a distance and discovered that the audible distance of a strike tone depends on the interplay of the diameter and the length of the bell. Such an experimental investigation on the dependence of the audible distance of a bell's sound on the dimensions of the bell was a significant step toward a scientific inquiry into the physical nature of sound propagation. The early Chinese probably looked to the propagation of a disturbance in water as a mental image for the propagation of sound. This is suggested by the hydraulic terms, *qīng* (clear) and *zhuó* (muddy). Thus, the analogy between the expanding pattern of ripples on water and the propagation of sound in the air probably also began early in Chinese civilization. However, no extant record with explicit mention of this mental connection between waves in water and in air is available earlier than the work of Wáng Chōng of the first century AD.

An important physical phenomenon of sound that was discovered early in Chinese civilization is resonance. In the *Zhuāng Zǐ* (The Book of Master Zhuāng), there is a passage attributed to Lǔ Jù of Western Zhōu, in which he says that the striking of the *gōng* note of one zither causes the *gōng* note of the other zither to vibrate, and that the same is true of the *juē* note, because the notes are of the same pitch.

The resonance phenomenon of Lǔ Jù achieved wide recognition in ancient times. The principle of resonance was later summarized in the statement "*shēng-bǐ zē-yìng*." This contains two key technical terms, *bǐ* and *yìng*. The term *bǐ*, which literally means "comparison," is coined to represent "matching in pitch," a condition for resonance first pointed out by Lǚ Jù, and the term *yìng*, which literally means "respond," is coined to emphasize the sympathetic aspects of the vibrations in resonance. These technical terms became common in subsequent accounts of resonance in sound.

Terminology

1. *Zhen Jiu* (针灸)/acupuncture/acumoxology. The term "acupuncture," meaning "using needles to pierce" (*Webster's College Dictionary*), is translated from the Chinese term *Zhen Jiu*, in which *Zhen* means "using needling to pierce" and *Jiu* refers to burning Moxa[1] on the acupoints. Moxibustion refers to the application of heat stimulation with a moxa roll or cone on the point or affected site instead of using a needle. In Chinese, the term *Zhen Jiu* is often used as one concept, so, a new term *acumoxology* has been used to translate the original meaning of *Zhen Jiu*. The term "acumoxology" will be used if the text refers to both burning moxa and needling.
2. *Jing Luo* (经络)/meridian/channel/vessels. The English words meridian, channel, or vessel have been used to translate the Chinese term *Jing Luo*. Historically the concept of *Jing Luo* was related to arterial vessels; in this text the term vessel is used for the Chinese term *Jing Luo* instead of meridian or channel.
3. Chinese classic literature. There are often different English translations for the titles of the same Chinese classics. In this article, all Chinese classics are spelt first with Chinese Pinying and then by an English translation, as, for example, *Huangdi Neijing* (Yellow Emperor's Inner Canon). If the same title appears again in the text, only the Chinese Pinyin transliteration is used.

Sociohistorical Evolution of Acumoxology

Acupuncture is an ancient healing practice which appeared in different civilizations. Documents indicate that needling treatments were found in ancient Egypt, Greece, India, Japan, and China. Nevertheless, only the Chinese have nurtured this healing practice into a systemic medical modality which consists of clinical experiences accumulated for thousands of years and the theories gradually developed to explain these experiences. All branches of Traditional Chinese Medicine (TCM), herbology, tuina,[2] and Qigong[3] have absorbed some concepts from classic acumoxology.

Chinese archeological records suggest that stone needles (*bian shi*), the earliest tools for acupuncture, were invented to treat diseases during 8000–4000 BCE of the Neolithic Age. Later, bone, bamboo, bronze, and other metals like iron, silver, and gold were used to make needles. Today most of the clinical needles are made of stainless steel. *Mai Shu* (The Book of Vessels), the earliest document of acumoxology, appeared between the fourth and third centuries BCE. The first TCM classic *Huangdi Neijing* (Yellow Emperor's Inner Canon) discussed vessel theories, clinical principles of acumoxology, needling methods, and needling tools. However, *Huangdi Neijing* is neither systemic nor rigorously structured. It is a collection of medical

[1] Moxa refers to dried, pressed leaves of Mugwort (*Artemisia vulgaris*) burned on or above the skin to stimulate an acupuncture point or serve as a counterirritant.

[2] Tuina utilizes soft tissue manipulation, acupoints, external herbal medicines, therapeutic exercise, and structural realignment methods to treat a wide variety of musculoskeletal and internal organ disorders.

[3] Qigong is a Chinese healing art using a series of gentle focused exercises for mind and body.

treatises by authors of different times possibly from the period of Warring States (475–221 BCE) to the Han Dynasty (206 BCE–AD 220). The first book specifically devoted to acumoxology was *Huang Di Ming Tang Jing* (The Yellow Emperor's Canon of Bright Hall) in the Han Dynasty. Another book, *Jiu Fang* (Prescriptions for Moxibustion), came out in the period of Three Kingdoms (AD 220–280). Thus all the basic elements – the theories, acupoint system, methods of needling and moxibustion, and treatable diseases – were organized into a system of acumoxology.

The Ministry of Health of the Tang Dynasty (AD 618–907) designated acumoxology as one of the five medical specialties and appointed medical doctors to teach and practice acumoxology in a royal institute. The government of the Song Dynasty (AD 960–1264) published an official document of acumoxology, *Tong Ren Shu Xue Zhen Jiu Tu Jing* (Standard Atlas of Acupoints on Life-Sized Bronze Human Statue for Acumoxology), in AD 1026. This document clarified the location and indications of 354 acupoints and assigned them into 14 vessels. This is the first standardization of acumoxology in history. After the Song dynasty, a notable theoretical development in acumoxology includes prescriptions of acupoints according to the time of the day and seasons (*Zi Wu Liu Zhu*) or differential diagnoses[4] (*Bian Zhen Lun Zhi*) and a variety of needling manipulation techniques. Acumoxology as a medical practice declined after the Ming Dynasty (AD 1368–1643), especially when the Chinese agricultural culture confronted the Western industrial and scientific culture ever since the middle of the nineteenth century.

After the founding of the People's Republic of China (1949), application of modern science to traditional medicine was politically advocated and financially supported by the new government. Some of the best scientists and clinicians trained in Western science were encouraged to study and modernize traditional medicine. In 1972, successful cases in acupuncture anesthesia were reported in the US[5]; this increased interest in acupuncture in both professional circles and for the public. Acupuncture became the most studied subject of all alternative medical modalities internationally. Enormous quantities of research data have been obtained from laboratories and clinics in many countries and have justified the scientific basis of acumoxology. Because of this intensive research, the trend to biomedicalize acumoxology and integrate it into mainstream medicine began in both China and the West.

Historical Development of Acumoxologic Theories

How Acupoints Were Discovered

Ancient Chinese doctors believed that a vital force, *qi*, flowed inside the vessels of the human body. They felt the quality of qi pulsation at multiple pulsing points on the body and used this to diagnose diseases. They also needled these pulsing points to treat diseases. These points became the earliest acupoints. As clinical experience accumulated, effective but nonpulsing acupoints were discovered and recorded.

The Origin of Vessel Theories

Early acumoxologic theories were formed from empirical facts. For example, ancient doctors found that needling certain pulsing loci on the dorsum of the foot and medial part of the lower leg was more effective than other points in treating pain or other symptoms of the genitals, lower abdomen, and lumbar areas. Thus they drew lines to connect the effective needling points with the parts of the body that were most affected by the needling, making a visible representation which connected all the points and related body parts together. In this example the pulsing points on the dorsum, the medial leg, the genital area, the lumbar area, and up to the tongue were connected. They believed that these symptoms were related to the imbalance of the "liver," and thus the "liver vessel" was gradually formulated. However, different doctors at different times formulated different "liver vessel" maps.

The Historical Integration of the Various Vessel Theories into a Single System

Huangdi Neijing (Yellow Emperor's Inner Canon) integrated the various channel theories into one system. However, inconsistencies in this book reveal that the authors had differing medical experience from different historical periods. In the years that followed the appearance of the *Huangdi Neijing*, acumoxology continued to evolve by incorporating more theories, and an ever-increasing number of acupoints and channels, into the existing system. When clinical realities did not fit into an existing theory, the facts were often modified to ensure the continuance of the theory. New theories coexisted with old ones. Thus classical acupuncture as we know it today is made up of theories and clinical experiences that are valuable, but they are mixed with fallacious concepts and imperfect explanations.

[4] Differential diagnosis is the determination of which one of two or more diseases or conditions a patient is suffering from, by systematically comparing and contrasting their clinical findings.

[5] American interest was triggered in 1972 by a rumor that New York Times reporter James Reston had received acupuncture anesthesia for an appendectomy while visiting China during President Nixon's historic visit. Actually, he had had standard anesthesia and received acupuncture for postoperative cramps.

Daoist Philosophy Guided both Theories and Clinical Practice

"The universe and humans are one" (*Tian Ren He Yi*) is the central thinking model of Daoism. Its *Yinyang*[6] and *Wuxing*[7] (five phases: metal, wood, water, fire, and earth) models have been applied to the human body, its anatomy, pathophysiology, and acumoxology. All 14 vessels are classified into Yin and Yang vessels and within each vessel the important acupoints below elbow and knee are ascribed to five phases such as fire point, water point, etc. When treating diseases, the nature of Yin or Yang vessels and the phases of the points are synthesized to form the prescription according to the principle of Yinyang balance.

The "Pearls" of Classic Acumoxology Theory

Since the 1960s, international scholars and scientists have conducted research, but they still cannot verify the vessel entities. Both historical documents and clinical trials clearly show that the most valuable discovery in acumoxology theory is the interrelatedness between the parts of the body surface, and between the parts of the body surface and the internal organs. These are the immortal "pearls" of classic acupuncture. The classic 14 vessels are just tentative theories used by ancient medical sages to explain this interrelatedness of human body.

The Internationalization of Acumoxology

During the Tang Dynasty (AD 618–906), Korean and Japanese students were sent to China to study medicine and other subjects. Acumoxology, massage, and herbal medicine were first taught in a Korean medical school in AD 692. In Japan, specialized faculty taught acumoxology as part of a 7-year course in the Imperial medical school established by the emperor in AD 702.

Jesuit missionaries introduced acupuncture to Europe in 1683. Acupuncture was taught in French hospitals and was practiced by some doctors in Germany, The Netherlands and England. Acupuncture therapy has remained in European countries since the eighteenth century. An American doctor, William M. Lee, learned acupuncture from a British doctor and published his paper on using acupuncture for rheumatism in 1836. Sir William Osler, in his *The Principles and Practice of Medicine* (8th ed., 1909), suggested acupuncture therapy for low back pain. Acupuncture was reintroduced into the US in 1972 from China after diplomatic normalization between the two countries.

Since the 1950s, doctors of the former Soviet Union and Eastern European countries have studied acupuncture from China and they still practice acupuncture in hospitals today.

In 1975, three international acupuncture training centers were set up to train worldwide healthcare professionals in China. The World Health Organization (WHO) has offered enormous support to spread acupuncture therapy in developing countries. In 1989, WHO approved the *Standard International Acupuncture Nomenclature* which has been used worldwide. In 1994 and 1999, WHO issued the *Standard for Clinical Acupuncture Research* and *Guidelines on Basic Training and Safety in Acupuncture*.

Medical Differences Between Acumoxology and Chinese Herbal Medicine

There is a difference between acumoxology and Chinese herbal medicine, although they have absorbed theories from each other. First, acumoxology developed its special *Jing Luo* (vessel) theories, while Chinese herbal medicine applies *Zang Xiang* (Visceral concepts) theories. Second, the same acupoints can be applied to different symptoms, while herbs, more or less, have specific therapeutic indications. Third, the method of differential diagnosis is essential in herbal medicine while it is not necessary in acumoxology.

Medical Differences Between Acupuncture and Moxibustion

Acupuncture needling inoculates minor lesions inside the soft tissues including nerve tissue. This needling-induced lesion stimulates neuroimmune response involving the cardiovascular and endocrine systems. Fresh cells will replace this needle-induced lesion within 2–5 days. Most moxibustion has the same physiological effect as needling does, but no lesion is introduced into the tissue. Traditional pus-making moxibustion (*hua nong jiu*) burns the skin and makes huge superficial lesions which produce a longer effect.

Medical Differences Between Acupuncture and Western Conventional Medicine

In general, acumoxology therapy does not target any particular cause(s) of a symptom(s) or disease(s); it just activates the self-healing potential of the built-in biological survival mechanisms to normalize the physiologic processes and let the body heal. Acumoxology

---

[6] Yinyang is a Daoist symbol of the interplay of forces in the universe. In Chinese philosophy, yin and yang represent the two primal cosmic forces in the universe. Yin (moon) is the receptive, passive, cold female force. Yang (sun) is masculine, representing movement and heat. The Yinyang symbol represents the idealized balance of the forces; they demonstrate equilibrium in the universe.

[7] The theory of the five phases looks at five interrelated forces that have specific relationships to one another. Each of the elements has corresponding organs, emotions, colors, tastes, tissues, human sounds, and countless other correspondences. For example, an Earth person likes late summer, singing and sweet tastes.

treats the whole body and produces no side effects, but the efficacy is achieved within a physiologically healable limit. Western conventional medicine tries to eliminate or correct the causations of the diseases by manipulating the chemistry and biological structure of the body first. The body then recovers from the impairment of both the disease and the medical intervention. This strategy may be accompanied by some side effects.

Biomedicalization of Classic Acumoxology

The medical value of acupuncture has been recognized internationally, especially in cases in which Western medicine has been unable to cause healing, but it has been challenged for its scientific justification in both Western and Eastern countries as modern sciences predominate in every field. Since the 1960s, acupuncture has been the most researched subject of traditional folk medicine in both China and the West, from the molecular to the organismic level, using new technologies in anatomy, neuroscience and immunology laboratories and evidence-based, double blind, statistical methods in clinics. Sufficient data have verified that acumoxology shares the same biomedical basis with Western medicine, and also indicate that acupuncture can be understood, taught, and practiced in biomedical concepts. Historically acupuncture has been acculturated many times when it was adopted by different host cultures. Thus, during this new acculturation, the biomedicalization of classic acumoxology becomes both possible and necessary. In September 2004, two new biomedically oriented textbooks were published. *Acumoxology Course for International Students* was published in China and *Biomedical Acupuncture for Pain Management: An Integrative Approach* was published in the United States. The two textbooks emphasize the new developments and new trends in acumoxology while maintaining its traditional medical values and philosophy. The fact that they were published simultaneously represents the biomedicalization of acumoxology in both China and the West.

What Diseases Can Acupuncture Treat?/How Effective is Acupuncture Therapy?

Both clinical and laboratory data suggest that acupuncture and moxibustion are physiological therapies which result in self-healing, which is coordinated by the nervous system and mediated by the immune, endocrine, and cardiovascular systems. In 1979 WHO suggested a list of disorders and conditions for which acupuncture is effective, including neurological, musculoskeletal, respiratory, gastrointestinal, mouth, and eye problems. Nevertheless, WHO also made the statement that "this list was not based on controlled clinical research and cannot be considered authoritative nor does it reflect WHO's view in any way." This uncertainty can be clarified as we understand the physiological basis of acupuncture. Acupuncture does not target any specific symptoms or diseases but just normalizes physiologic processes to activate self-healing. The results of this self-healing depend on (1) the healability of the symptoms, and (2) self-healing capacity maintained by the patients. Thus, the same symptoms can be cured in some patients, or can be partially relieved in other patients but do not respond to acupuncture at all in a few patients. The information of healability may be obtained from medical examination. To estimate the self-healing capacity, readers may refer to the textbook *Biomedical Acupuncture for Pain Management: An Integrative Approach*.

Limitations of Acumoxology Therapy

As acumoxology normalizes physiological processes to activate self-healing, it works better for conditions resulting from physiological abnormalities. For example, if low back pain is caused by inflammation of soft tissues, acumoxology will cure it in most patients. If the low back pain is caused by a tumor of the spinal cord, acumoxology may provide only temporary pain relief. The former condition is an *acupuncture remedy*, while the latter is an *acupuncture-aided treatment*. In cases of acupuncture remedy, faster and more stable results can be obtained if conditions are treated at their early stage.

Questions Remaining

Today we understand acumoxology in terms of its physiological basis even better than some medical procedures used in conventional medicine, but, as in any field of science, more new questions arise after old mysteries have been clarified. There are many unanswered puzzles in acumoxology. For examples, what is the biological basis of the interrelatedness between different parts of human body as classic *Jing Luo* (Vessel) phenomena demonstrate? What symptoms or disorders are more amenable to acupuncture remedy or acupuncture-aided treatment? How are diseases related to particular acupoints? What acupoints should be selected for particular symptoms? How does needle manipulation influence the results? Clarification of these and other questions will improve clinical results of acumoxology.

Acyuta Piṣāraṭi

K. V. Sarma

Acyuta Piṣāraṭi (ca. 1550–1621), author of over ten texts, was an astronomer from Kerala in South India. It was he who enunciated, for the first time in Indian astronomy, the planetary correction called "reduction to the ecliptic" (the band of the zodiac through which the Sun apparently moves in its yearly course), in his work *Sphuṭanirṇaya* (Determination of True Planets), composed before 1593, which was later expanded into a full-fledged tract called *Rāśigolasphuṭānīti* (True Longitude Computation of the Sphere of the Zodiac).

Acyuta was popularly known as Tṛ-k-kaṇ tiyūr Acyuta Pisāraṭi. The first term indicated his birthplace, Kundapura, and the last the sect of Kerala temple functionaries to which he belonged. He was the pupil of Jyeṣṭhadeva, author of *Yuktibhāṣā*, an elaborate treatise on mathematical and astronomical rationale. He was a protégé of Ravivarmaṇ, King of Veṭṭaṭṭunāṭu in Kerala and the teacher of the poet and grammarian Nàrāyaṇa Bhaṭṭatiri of Melputtūr. Apart from one work, entítled *Praveśaka*, which was an instructive epitome of Sanskrit grammar, all his works were on astronomy. Acyuta is also referred to as a master of medicine and poetics.

Acyuta's work *Karaṇottama* is an astronomical manual in about a hundred verses, which, in five chapters, deals with the derivation of the mean and true planets, the eclipses, gnomonical shadow, and the phenomenon of the complementary situation of the Sun and the Moon. This work and its autocommentary are significant in that they set out several computational methods for securing greater accuracy, which had been kept secret by earlier teachers and were intended to be transmitted only orally to disciples. Acyuta's *Uparāgakriyākrama* (Method of Computing Eclipses) is also significant for its containing methodologies unknown to other texts. The *Horāsāroccaya* of Acyuta, in seven chapters, is an instructive epitome of the astrological text *Jātakapaddhati* (A Course of Horoscopical Science) of Srīpati (eleventh century).

It is noteworthy that Acyuta engendered an astronomical lineage, and the trail blazed by him was continued by several lines of scholars. One such line, of which there is documentary evidence, which continued for more than 250 years, runs thus: Acyuta (1550–1621); pupil: Tṛppāṇikkara Potuvāl (sixteenth century); pupil: Nāvāyikkulattu Āzhāti (seventeenth century); pupil: Pulimukhattu Potti (1686–1758); pupil: Rāmanāśān (eighteenth century); son-pupil: Kṛṣṇadāsa (Kṛṣṇanaśān (1786–1812). Later astronomers took up the innovative trends in Acyuta's works for rationalization and elaboration through short tracts, as evidenced by nine such tracts which have been identified and added as supplements to the edition of Acyuta's *Sphuṭanirṇaya*. This points to the impact made by Acyuta in the astronomical tradition of Kerala.

Agriculture: Ancient Methods

Alexia Smith

Today very few communities subsist upon hunting and gathering, with the majority of the world's population living a sedentary life dependant upon agriculture. The shift from gathering wild plants and hunting wild animals to dependence upon crop production and animal herding took place independently in different parts of the world at different times. The earliest development of agriculture is widely thought to have occurred around 12,000 years ago in the Fertile Crescent of Southwest Asia. The Fertile Crescent forms an arc leading up the Levant from the Negev Desert of Israel to southeastern Turkey, turns east along the Taurus–Zagros mountain chain, and then south between the Tigris and Euphrates rivers down to the Persian Gulf. Independent development of agriculture occurred later in South and North China, Central America, South Central Andes, the Eastern United States, sub-Saharan Africa, and perhaps Papua New Guinea.

Food Production Terminology

The ways in which societies throughout the world have organized food production varies greatly through time, and the terminology used to discuss early agriculture underscores the diversity of methods that can be used to produce or acquire food. In its widest sense, agriculture refers to the cultivation of crops and the rearing of animals. Animal husbandry refers to general animal rearing, whereas pastoralism describes a socio-economic specialization in production where animal rearing forms the primary economic endeavor of a community. The methods of production can vary widely, including nomadic pastoralism, which involves permanent migration and seasonal transhumance – where animals are moved periodically from a home base to pasture land. The term cultivation describes the preparation of land and tending of crops, which can include large- or small-scale crop production and slash-and-burn agriculture. Horticulture relates specifically to the production of fruits, vegetables, and flowers, and in preindustrialized societies was usually garden-based. Domestication is more difficult to define and there is no universally agreed upon definition. In general, however, domestication refers to the selection of desirable traits in plants and animals that leads to the genetic modification of a species, and reduces its ability to reproduce without intervention by people. Desirable traits may include reduced aggression in animals, allowing them to be controlled more easily, or ease of harvest and greater yields in plants. It is possible, therefore, to cultivate wild plants with domestication occurring only when selection processes affect natural reproduction mechanisms.

Evidence for Ancient Agriculture

Throughout the world, writing or notation systems developed well after the beginnings of agriculture, so there are no texts documenting the transition and our knowledge is based entirely on archaeological observations of plant and animal remains, changes in settlement size and patterns, storage facilities, and tools. Zooarchaeology examines ancient interaction with animals. The species, age, and sex of animal bones retrieved from archaeological sediments can be determined by reference to modern comparative skeletal material, and this information can be used to examine herding and hunting strategies. Paleoethnobotany or archaeobotany examines plant use in the past. Plant remains are preserved on archaeological sites predominantly through charring, an accidental process that renders them inert to bacterial or fungal decay; less frequently plant remains become preserved through waterlogging, desiccation, freezing, proximity to toxic metals, or indirectly by leaving an impression in ceramic vessels. Excellent preservation conditions are provided under waterlogged and desiccated conditions, although such finds are in the minority and are generally restricted to lakes and coastal margins or deserts. Charred remains are retrieved using flotation, whereby an archaeological sediment sample is placed in a large container of water and, following gentle agitation, the plant remains float to the surface where they can be collected. The remains are identified based on morphological similarity to modern reference material, and knowledge of crop and weed assemblages can be used to investigate a number of topics including crop domestication and methods of crop production, harvesting, and processing. Until recently, most paleoethnobotanical research had focused upon identifying cereal, legume, fruit, and weed seeds in the archaeological record but now, following pioneering work by Hather, increasing emphasis is being placed upon identifying tubers and investigating the role that vegetables played in the ancient diet. Such research is in its infancy, however, so the importance of horticulture in antiquity is likely underestimated.

Theories Explaining the Origins of Agriculture

A number of theories have been proposed to explain the origins of agriculture. Since farming was developed independently in different locations, the motives likely vary reflecting local social, cultural, environmental, and climatic factors. In Southwest Asia, the change occurred during a period of climatic amelioration after the Younger Dyras, a cold period marking the end of the Pleistocene and the beginning of the Holocene. Building upon work by Raphael Pumpelly, V. Gordon Childe argued in the 1930s that climatic deterioration forced people to concentrate within small oases and that these new conditions would have stimulated cultivation. His "Oasis" or "Propinquity" theory is not supported by paleoclimatic data, does not adequately explain the changes, and furthermore is viewed as too environmentally deterministic. To its credit, however, the theory stimulated much research on the origins of agriculture. In the 1960s and 1970s, Binford, Cohen, and Hassan put a number of related "Push" models forward. They argued that population growth or climatic change disrupted the food balance and provided the necessary incentive to begin cultivating crops. These models have also been criticized for being oversimplistic and monocausal as well as deterministic. Flannery expanded upon Binford's ideas and proposed a "Broad Spectrum Revolution." Citing data from Southwest Asia and Mesoamerica, Flannery argues that prior to the dependence upon agriculture, people greatly widened the range of plant and animals exploited, and developed new tool types, different methods of storage, and gained familiarity with other food resources. These changes created the necessary preadaptations for cultivation, which he argued most likely occurred in marginal areas on the fringe of production, where wild resources were less abundant.

The Broad Spectrum model is largely supported by both plant and animal data from Southwest Asia. Recent research at Ohalo II, a waterlogged site off the coast of the Sea of Galilee where preservation conditions are excellent, has underscored the importance of wild cereal collection by preagricultural groups approximately 23,000 years ago, well before the beginning of farming. Lastly, following critiques of the use of external factors and system analogies to explain change in the past, a number of social or "Pull" theories have been sought to explain the origins of agriculture. Bender and Hayden argue that domestication took place in resource-rich areas and that the ready availability of large amounts of specialty food may have led to social changes within preagricultural societies, placing greater emphasis on competitive feasting. This, in turn, would have elevated the demand for resources, acting as a precursor for cultivation and later animal herding.

The Rise and Development of Agriculture in Southwest Asia

The first domesticated crops in Southwest Asia include cereals (emmer wheat, *Triticum dicoccum* Schübl.; einkorn wheat, *T. monococcum* L.; and two-row hulled barley, *Hordeum vulgare* subsp. *distichum* (L.) Thell.), leguminous crops (lentil, *Lens culinaris* Medik.; pea, *Pisum sativum* L.; chickpea, *Cicer arietinum* L.; bitter vetch, Vicia ervilia (L.) Willd.), and flax (*Linum usitatissimum* L.), which together form the "founder crops" of Neolithic agriculture. Early farmers selected cereals with plumper, larger grains and ears that did not shatter easily, leading to greater yields and enhanced efficiency of harvesting. Transitional forms of domesticated plants and animals and their wild predecessors can be difficult to identify from the archaeological remains, but the available evidence suggests that the process took place quickly over several centuries.

Animal domesticates include sheep (*Ovis aries*), goat (*Capra hircus*), pig (*Sus scrofa*), and cattle (*Bos taurus*), each of which were ecologically and behaviorally suited to domestication due to their general diets, ability to breed in close conditions, social nature, and dominance hierarchy. Due to the selection of more docile animals, domesticated fauna tend to be smaller than their wild predecessors. The domestication of each species took place in different locations throughout Southwest Asia after communities had become sedentary and begun cultivating crops. Later a wide range of specialized pastoral practices was developed.

The adoption of agriculture in Southwest Asia was termed the "Agricultural Revolution" or the "Neolithic Revolution" by V. Gordon Childe, and it was truly revolutionary since it marked a drastic shift in the way people obtained food, placing greater emphasis on using land for production. It also involved the need to maintain and protect seed stores for the following year as well as ensure that animals were kept alive and well until they were deemed fit for slaughter. Intensive cultivation is associated with increased sedentism, which provides different opportunities for building social relationships and spacing births. Furthermore, with the accumulation of surplus crops, differential wealth could be accumulated, enabling parts of the population to be freed from farm labor. This in turn allowed for the development of institutionalized craft specialization and, some time later, the rise of urbanized state-level societies with social hierarchies, bureaucratic and administrative systems, long distance trade, monumental and public architecture, and some form of writing or record keeping.

The Construction of Cities and the Secondary Products Revolution

The first urban centers arose in Mesopotamia, the land between the Tigris and the Euphrates in modern-day Iraq around 5,500 years ago. Shortly later, urban centers developed in Egypt. Both developed along river courses and the use of irrigation to enhance crop yields is thought to have been instrumental in the rise of these city-states. Ancient irrigation canals dating between ca. 5,500 and 5,000 years ago have been located in Mesopotamia. The construction of earthen structures to control the natural flooding of the Nile banks in Egypt likely played a similar role. Concomitant with the development of cities in Mesopotamia and Egypt, an agro-economic shift took place in between these regions in the Levant, perhaps stimulated by enhanced trade with adjacent regions. The Mediterranean economy, including cultivation of cereals and legumes, viticulture and olive production, and herding of sheep and goats, together with use of animal drawn ploughs became widely established for the first time. Sherratt refers to these changes in agricultural production as the "Secondary Products Revolution," which placed greater emphasis on the use of animals for traction and for secondary products such as milk, blood, wool, and dung. Most early ploughs would have been constructed from wood, but because of their perishable nature, they do not readily preserve intact in the archaeological record. The earliest depictions of a plough, which likely postdate its invention, come from cylinder seals from Mesopotamia, dating to approximately 4,300 years ago, and terracotta figurines of yoke-bearing oxen from the Greek site of Tsoungiza dating to the Early Bronze Age. The ard, which scratches the surface of the land was developed first, with mould-board ploughs that turn soil and create furrows being developed much later. Prior to the invention of the plough, fields would have been prepared by hand, so the shift allowed larger tracts of land to be cultivated. This effect was intensified during the Iron Age, beginning around 3,200 years ago, with the manufacture of iron agricultural tools, rather than flint and bone sickles or wooden ards.

The exploitation of animals for milk and wool in Southwest Asia is reflected in animal bones that document the preferential culling of young males and the tending of a larger number of female animals to an older age. In order to release milk freely to people, lactating animals need to be separated from their young and become accustomed to being milked by hand, so initial attempts at milking were likely a perilous endeavor.

Zeder and McCorriston argue that the raising of sheep for wool fiber greatly modified the agro-economics of Southwest Asia, and led to a reduced reliance upon flax fibers; the local importance of wool as a commodity in northern Syria allowed urban centers that controlled its production to prosper. Concomitant with the rise of urban societies, the need for a recording system developed in order to log economic transactions. The invention of writing provides an additional window into agricultural production in antiquity. Clay tablets from Uruk in modern-day Iraq, dating to ca. 4,400 years ago, provide the earliest evidence of writing in the world with initial documents being used to list commodities. An extensive archive of cuneiform tablets was found at the site of Ebla in Syria, approximately 60 km south of Aleppo. These texts, dating to between 4,400 and 4,350 years ago, represent the earliest written reference to olive and grape production, although archaeological evidence of the plant remains predates the texts by almost a millennium. Since textual accounts and archaeological data provide different insights into past societies, this example demonstrates how the two records can be used to complement one another. Other cuneiform texts include the "Farmer's Instructions" from Mesopotamia dating to ca. 3,800–3,600 years ago. Civil has interpreted the text to be a Sumerian agricultural manual which outlines instructions from an old man to his son on how to prepare a field for irrigation; how and when to harrow, plough, sow seeds, inspect, harvest, thresh, and winnow the crop; maintain tools; as well as describing a desirable work ethic. It is likely that the text was used to teach scribes how to write Sumerian, since the content of the text would have been familiar to many.

Early Agriculture Outside of Southwest Asia

Following the development of agriculture in Southwest Asia, farming began to be practiced in Turkey and then Greece, followed by the rest of Europe. Models of this spread are debated, with some arguing for movements of people and other arguing for a transfer of ideas and new technology. New evidence based on plant data suggests that a complex mix of both was involved. Based on radiocarbon-dated finds of plant remains, the spread took place at an estimated rate of 1km/year, likely being adopted in fertile river valleys first.

Independent domestication of plants and animals took place in Southeast Asia approximately 8,000–7,500 years ago, with distinct modes of production evolving along the Yellow River in northern China and the Yangtze to the south. One of the most important domesticates from China is rice (*Oryza sativa* L.); rainfed lowland rice was grown initially, followed some time later by upland and deep-water rice. Due to the natural distribution of wild rice, which extends from India eastwards across China to the coast, the center of domestication was thought to lie in the southern part of China, but new finds of early domesticates in the Yangtze valley have expanded this range. Ongoing research and more extensive excavations are required until the debate regarding the location of rice domestication can be resolved fully. By approximately 7,000–5,000 years ago, rice production spanned large areas of Southeast Asia and India. Early tools found at the waterlogged site of Hemudu in China, dating to ca. 7,200 years ago, include two digging implements constructed from a water buffalo scapula (shoulder bone) attached to a wooden handle, but such finds are exceptional and as with other areas, the full range of early agricultural implements is unknown.

Further to the north, between the highlands and the plains along the Yellow River, rainfall tends to be lower and drought-tolerant species were chosen as the first domesticates. Here, broomcorn millet (*Panicum miliaceum* L.) and foxtail millet (*Setaria italica* [L.] Beauv) became important crops for Peligang communities just over 7,000 years ago. Dogs, pigs, chickens (*Gallus gallus domesticus* L.), and water buffalo (*Bubalus bubalis* L.) were the most important animal domesticates, although wild resources including various nuts, jujube dates (*Zizyphus jujuba* Mill.), and deer remained important components of the diet. It is likely that chickens were first domesticated just after 8,000 years ago in northern China.

Agriculture developed in the Americas later than in the Old World. In North America, early crops include goosefoot (*Chenopodium berlandieri* Moq.), sunflower (*Helianthus annus* L.), and marsh elder (*Iva annua* L.). Within Mesoamerica, most research has centered along the Oaxaca and Tehuacán valleys of Mexico; important domesticates include maize (*Zea mays* L.) derived from the annual grass teosinte, squash (*Cucurbita* spp.), beans (*Phaseolus vulgaris* L.), avocado (*Persea americana* Mill.), dog, turkey, and perhaps cottontail rabbit. Maize domestication is widely thought to have occurred around 7,000 years ago, but this date has recently been disputed; new radiocarbon dates of the oldest known domesticated corn cobs places them at approximately 4,600 years old. Cocoa (*Theobroma cacao* L.) also became an important domesticate in Mesoamerica. The Nuttall Codex, dating to AD 1051, depicts an early use ritual of cocoa. Further south in the Andes, llama (*Lama glama*), alpaca (*Lama *pacos*), and guinea pigs (*Cavia porcellus*) were herded. Important crops include quinoa (*Chenopodium quinoa* Willd.), and tubers such as oca (*Oxalis tuberosa* Mol.), mashua (*Tropaeolum tuberosum* Ruíz & Pav.), ullucu (*Ullucus tuberosus* Caldas.), and potatoes (*Solanum tuberosum* L.). Drawings of agricultural scenes by conquistadores in the 1500s depict the use of foot ploughs and hand hoes in the Andes.

Within Africa, agriculture first arose in the Nile Valley of Egypt, following the introduction of sheep, goat, cattle, and cereals, around 6,500 years ago from areas to the north. Independent innovation and domestication of local, indigenous species occurred between 5,000 and 3,000 years ago in a band between the Sahara and the equator, at a time when rainfall was higher than today. Important domesticates include cattle, sorghum (*Sorghum bicolor* [L.] Moench.), pearl millet (*Pennisetum glaucum* [L.] R. Br.), and much later, dating to around AD 200, African rice (*Oryza glaberrima* Steud.). African rice is still grown in parts of West Africa, although Asian varieties originally domesticated in China predominate today.

Continental Transfer of Crops

Throughout the world, the form that early agriculture took reflects, for the most part, an adoption of locally available plants and animals, with cereals such as wheat, barley, millet, and rice predominating in the Old World, and potatoes, maize, and squash predominating in the New World. There are numerous examples of people adopting non-native species throughout history, however, which demonstrates the dynamic nature of agricultural production and underscores how food production forms an integral component of social histories. The potato, for example, a native of Chile and Peru, was first introduced into Northern America and Europe during the late 1500s, after which time it became an important crop. By the 1800s, it formed the dominant staple in Ireland and the spread of potato blight resulted in the great famine that began in 1845. Tomatoes (*Lycopersicon esculentum* Mill.) were also introduced to Europe from Tropical America by Spanish conquistadors and Atlantic slave traders in the mid-1500s. Tomatoes were initially treated with suspicion due to their perceived similarity to deadly nightshade which was associated with witchcraft; they later became viewed as aphrodisiacs, rendering them the common name, "love apples." The introduction of maize, beans, cassava, and potatoes into West Africa during the Atlantic slave trade of the 1500s is particularly noteworthy. McCann provides a history of the adoption of maize throughout Africa and today it has become an important staple at the expense of indigenous crop. In Zambia and Malawi, maize contributes more than 50% of the calorific content of people's diet, greater than that in Mexico where the plant was originally domesticated, and this has resulted in a drastic narrowing of dietary breadth. Indeed, in all parts of the world, reliance upon agriculture has led to a more restricted diet than that consumed by hunting and gathering communities. Examination of paleopathology within early agricultural communities in both the Old and New worlds has shown that farming led to an initial decline in general health and nutrition.

Water Management

Through time, people have increasingly adapted their environment to grow the crops that they desire. Limits exist to the extent that the landscapes can be modified, and these limits have shifted through time as technology has evolved and as labor divisions and economic incentives have shifted. The choice of what and where to grow crops is not, therefore, always predicated upon environmental considerations, and social or economic factors can weigh more heavily. Nabatean farmers at Avdat in the Negev Desert of Israel, for example, situated their settlements at strategic locations along spice trade routes during the first century BC, and were able to grow crops in areas that received limited amounts of rainfall by using water harvesting techniques. Depending upon the timing and distribution of rainfall throughout the year, rainfed farming cannot generally be practiced in areas that receive less than 250 mm per annum. By clearing rocks from the hillsides and placing them in long lines running down slope, the thin soils were exposed to rainfall, encouraging them to slake and enhance runoff. Rainfall was then channeled down the slope into the valley bottom where walls constructed across the valley impeded the flow, minimized soil erosion, and enhanced infiltration of water into the soil allowing crops to grow successfully.

An equally ingenious method of water control was employed in South America where raised fields were used to grow potato. Raised fields have been found in dense concentrations in the Lake Titicaca area of Bolivia and Peru, and from above resemble a patchwork of fields. Raised fields were created by digging a network of ditches and placing the excess soil on top of the field to be cultivated. The fields provide optimal conditions for crop production in this area where weather conditions can be unpredictable; water can be maintained in the furrows between the fields and used for irrigation during dry spells, it can be drained away through the channels following heavy rainfall, and it also helps minimize diurnal temperature shifts, thereby reducing the risk of frost damage. There has been some interest in reintroducing this form of cultivation on a large scale today as part of the sustainable development movement, and while there are many benefits from an agronomic perspective, it is not clear how practical the construction and maintenance of raised fields would be from a social perspective because they require large investments of time. In the past they were likely constructed with corvée labor.

It is difficult to determine exactly when irrigation was first practiced because canals do not always preserve well and, additionally, preserved features can be difficult to date. Informal watering is likely as old as cultivation itself, particularly within food gardens close to the home, but more formal irrigation did not develop until much later. The earliest forms of irrigation would have employed water diversion structures such as deflection dams and gravity canals as seen in Mesopotamia; it was not until Roman times that engineering developed sufficiently to allow for water to be lifted from a river and distributed onto an adjacent field. Early examples of norias (water-powered wheels that scoop water), can be found in the more arid parts of the Roman empire including Syria, North Africa, and Spain. Horizontal wheels were also commonly used for irrigation during the Tang Dynasty (AD 618–907) in southern China, and may have been used as early as 200 BC. The Archimedean screw, invented by Archimedes during the 3rd century BC, uses a helix placed at a 45-degree angle within a tube to raise water when rotated. Despite these developments, as well as the invention of drip and sprinkler irrigation much more recently, floodwater farming continues to be a highly effective method of irrigation where topographic conditions are suitable. It was heavily utilized by the Hohokam of the Sonoran Desert in south Central Arizona, between AD 200 and 1450 to support large communities in an area of low rainfall.

Terracing

Other modifications to the environment include terracing and the cultivation of hill slopes. Due to erosion, ancient terraces are not always preserved, although examples do exist. Terraces can also be difficult to date, but based on embedded pottery finds, terracing may have been practiced in Southwest Asia during the Early Bronze Age around 5,000 years ago, perhaps being prompted by a greater demand for olive and grape commodities such as oil and wine associated with the rise of urban life in Egypt and Mesopotamia. Extensive tracts of terraced hillsides are also evident in the Peruvian highlands where numerous varieties of potatoes were grown, as well as throughout Indonesia where sophisticated methods of terrace maintenance and water use were developed and integrated into the social and religious calendar.

Soil Fertility Management

Assessing early methods of soil fertility management is more difficult since they leave fewer traces in the archaeological record and are not always documented in textual accounts. The practice of fallowing, or leaving land uncultivated for a year or more, is believed to have been an important method and it forms an integral role in slash-and-burn agriculture (swidden) that has been documented in tropical counties in Asia and Africa. In more arid areas, where slash-and-burn is not a feasible method of production, the need to maintain soil fertility was likely recognized following the first cultivation of crops, but little is known about the methods, if any, that were used. In northeastern Syria, Wilkinson observed scatters of pottery sherds surrounding large sites dating to the Bronze Age, which he interprets as non-perishable remnants of night soil or urban waste used to fertilize the fields. Since leguminous crops such as lentil, pea, and bitter vetch that fix nitrogen in the soil were important crops during the Bronze Age, it is also likely that crop rotations may have been used to maintain soil fertility, but it is difficult to assess this with any degree of certainty from archaeological evidence. It seems probable, however, that some form of crop rotation in Southwest Asia was practiced much earlier than the formalized introduction of the Norfolk four-course rotation of wheat, barley, clover, and turnips that was adopted in Europe, predominantly England, during the late 1600s and early 1700s.

More Recent Developments

Within the past century, the large-scale introduction of mechanized farming has greatly increased the efficiency of preparing land and harvesting crops. Mechanization has not been adopted uniformly throughout the world, however, and in many developing countries, animal traction is still relied upon for field preparation. The Green Revolution of the 1960s also markedly changed production following the introduction of high-yield varieties of wheat and rice throughout numerous developing countries, notably in Asia. These varieties required a strictly defined regimen of fertilizer and pesticide application for optimal growth. While many farmers enhanced yields, many of the poorer farmers whom the improved grain was intended to help were not always able to afford the prescribed chemical fertilizers and pesticides and, as a consequence, yields sometimes fell below those obtained from local varieties. While farmers have long recognized the benefits of local varieties for subsistence agriculture, the lessons from the Green Revolution prompted numerous agricultural development agencies and agricultural research stations around the world to compile seed banks to store diverse crop varieties for future generations.

The most recent, and potentially revolutionary, change in agricultural technology concerns the development of genetically modified crops. From agriculture's earliest inception, selection of species with desirable traits has led to genetic change; this selection became formalized with intentional cross breeding. The creation of genetically modified crops differs from cross breeding in that DNA is physically spliced, potentially from one species to another. Genetic modification offers enormous potential to develop crops that are able to grow productively under adverse conditions, or which contain medicines or vaccinations that can be used in remote areas without refrigeration. Such crops have not been widely accepted, however, and studies examining potential environmental, economic, and social impacts continue. It is possible to produce seed stock that will yield sterile grain that cannot be used to replant the following season. While this development protects the economic investments of the producer, it has raised enormous concerns among subsistence farmer who would not be able to use harvested crops for reseeding. The debate is likely to continue for some time.

In the eighteenth century, Reverend Thomas Malthus expressed his views regarding the balance between population growth and food production, claiming that due to the inelasticity of food supply, once population levels increased beyond the "carrying capacity" of the land, the surplus population would be eliminated either by direct starvation, or by positive checks such as misery and vice or moral restraint. Boserup counter-argued that population pressure would stimulate the creation of new methods of production that would enhance yields. The historical developments of agriculture through the ages demonstrate periodic innovation which has allowed the carrying capacity to increase. The relationship between population and carrying capacity is enormously complex and while people have continually adapted agricultural technology in order to enhance yields, as Amartya Sen has argued, social factors play an equally important role in ensuring that people are fed.

Agriculture in Africa

Paul Richards

According to the philosopher Hegel, Africa was the inert mass around which the history of consciousness pivoted in its journey from East to West. Even today one still encounters the view that sub-Saharan Africa is exceptionally backward in science and technology, and has no indigenous intellectual history worth the name. Judged by the conventional standards of modernity, e.g., statistics on literacy and education, Africa does indeed seem a "backward" continent; but against this we must consider the crucial part played by the African savannas in the story of human evolution; human intellectual development was shaped by challenges set by the African environment. The legacy is still perhaps apparent in the continent's exceptional linguistic diversity and an enduring facility among its peoples for coping with severe environmental challenge. Until recently, however, African indigenous knowledge of environmental resources has failed to register in conventional histories of science and technology, due in large part to the distinctive resource endowments and consequent agrarian history of large parts of the continent.

Population density, historically, has been low over much of sub-Saharan Africa, and was depressed further by the slave trade and the wars and epidemics associated with colonial conquest. This has meant an emphasis (contrary to the trend of agrarian history in Asia) on land-management strategies that efficiently deploy scarce labor, but in settings ill-suited to plough agriculture or mechanization (contrary to experience in Europe and North America). In place of labor-intensive leveling, drainage, and installation of irrigation, for example, African cultivators typically have sought to make use of diverse soil and land conditions as they find them. This requires emphasis on what might be termed "mix-and-match" approaches, e.g., maintaining different animal species in the pastoral herd, selecting a range of crop types adapted to different soil and land conditions, using different crop types in the same field (inter-cropping), or by ingenious dovetailing of a complex and varied portfolio of productive activities (hunting and gathering, shifting cultivation, tree-crop cultivation).

This emphasis on versatility above specialization has been of particular importance in those extensive tropical regions in sub-Saharan Africa blighted by insect-borne disease (notably malaria and sleeping sickness), climatic irregularities, poor soils, and lack of irrigation opportunities. Here, characteristically, human groups tend to invest heavily in the social "software" of agrarian relations rather than the "hardware" of technology and land improvement. Groups facing periodic drought may prefer to devote attention to the cooperative social relations that sustain an "optimal foraging strategy" rather than tie up large amounts of labor in costly land improvements such as irrigation systems. In an outright disaster social investments are portable, but land improvement is fixed and may have to be abandoned.

The knowledge and mental attitudes that support versatility among hazard-prone resource users do not lend themselves readily to the writing of conventional history of technology. Historians whose ideas have been formed against a background of more steadily evolving agrarian technological traditions in Europe and Asia have been at times tempted to conclude that African agriculture is deficient in technical expertise. Local knowledge tends to be regarded as makeshift and perhaps even irrational. Shifting cultivators and pastoralists, more anxious to meet the next challenge than celebrate past achievements, may have unwittingly reinforced these misperceptions. For Mende rice farmers in Sierra Leone several "traditional" techniques are colonial innovations – the local notion of tradition is simply "something that works." Sometimes, sensing potential damage to a good practical skill from wordy rationalization, African resource users may even seek to deny that they know anything useful about the topic under discussion. Outsiders end up perceiving a technological void where none exists.

Many schemes were set up during the colonial period to assist African farmers to climb across these imagined gaps in what was thought to be a fixed ladder of agro-technological progress. Colonial reformers concentrated at first on European innovations such as sickle and plough, only to be beaten back by African preferences for panicle selection in harvesting as a means to maintain the varietal distinctiveness of planting materials, or for the hand hoe as a superior means to maintain soil physical quality under difficult tropical climatic conditions. Later, it was supposed that Asia was the proper yardstick against which to measure the backwardness of African agrarian technology, and first steps were taken to transform African agriculture according to Asian experience. This culminated in efforts in the 1970s and 1980s to replicate the Asian Green Revolution in Africa, using fertilizer-responsive high-yield crop types under intensive management. Asia-to-Africa technology transfer repeatedly foundered on the issue of labor. Innovations for Asian farmers needed to be labor-absorbing, but for African farmers (not threatened, historically, to anything like the same extent by population pressure on land) labor-efficiency was often the criterion of greatest relevance.

During the colonial period in Africa a significant minority of long-serving agricultural officers came to appreciate that rural people did in fact have a considerable fund of valid practical knowledge of agriculture and the environment. This coincided with the rise of scientific ecology and related disciplines during the 1930s and 1940s; foresters, economic botanists, soil scientists, and veterinary officers were particularly active in recording African indigenous knowledge of agriculture and the environment, and in drawing parallels between these local concepts and emergent ideas in ecology and related disciplines. Perhaps the single most striking of these instances is the letter to the scientific journal *Nature* in 1936 by the Tanganyika-based soil scientist Milne, proposing the concept of the soil catena as a regularly recurring chain of soil types controlled by topography. African soils tended to be very old, and showed the influence of underlying rock types much less than in Europe. The concept of soil catena, by emphasizing topography and downplaying the role of geology, provided a much better guide to the way the soils had formed, and to how African farmers typically used their soils. Throughout the tropical zone, but especially where seasonal variations in rainfall distribution are most marked, farmers secure food supplies during the preharvest hungry season and spread their labor burdens by systematically planting up and down slopes, carefully matching different crops or crop types to the different soils within the catenary sequence. The catena rapidly became established as a basic organizing concept in tropical soil science throughout the world; Milne's letter to *Nature* makes clear its African roots by using the Sukuma terms employed by local farmers to categorize the different soils within the chain.

This is in stark contrast to earlier official thinking about land systems on the other side of the continent, in Sierra Leone. After famine in 1919, caused not by local agricultural incompetence but the loss of harvest labor resulting from the influenza that tracked colonial troops to their homes from the battlefields of Europe, the colonial governor Wilkinson sought (as he thought) to transform Sierra Leonean rice farmers from being shifting cultivators farming rain-fed up lands into permanent cultivators of irrigated valley-bottom lands along Asian lines. Moving local farmers from the tops to the bottoms of their valley slopes was for Wilkinson a shift of epochal proportions, through which the "ignorant" African would be able to catch up a 1,000 years of agrarian technological history in a matter of a few years. The official of the Madras Department of Agriculture in India employed by the Government of Sierra Leone to set things in motion requested to be sent home after nearly 2 years working with local farmers, on the grounds there was little if anything he could teach them that they did not know already, and that in any case they obtained better yields from similar resource endowments than farmers in Madras. However, the belief that there was something decisive about a shift from upland to valley-bottom farming survived into the modern period, and received a new boost from the example of the Green Revolution in the 1960s. This insistent categorical contrast on "uplands" and "wetlands" remains in stark contrast to local farmers' knowledge and practice in which seed types and labor resources are invested up and down catenary sequences, and across the upland–wetland divide, according to circumstances. Standing on the boundary between the rain-fed and water-logged soil types in their farms, Sierra Leonean peasants repudiate any gap between themselves and more technologically advanced farmers in Asia, and see instead only an opportunity for flexible adjustment to changing conditions. Recently, mathematicians have begun to provide formal tools with which to grasp the fuzzy logic that underpins this kind of cognitive flexibility, typical of African indigenous knowledge of environmental resources.

Rice farming on the western coast of West Africa is of considerable antiquity, and based on the domestication of the African species of rice (*Oryza glaberrima*). Due to contacts arising from the slave trade we have quite rich documentary sources concerning indigenous agricultural knowledge for this part of Africa at an early date, including a number of accounts from the seventeenth and eighteenth centuries specifying the way in which farmers matched planting materials to different soils, so spreading labor peaks and minimizing preharvest hunger. Today, rice farmers in the region continue to research this relationship whenever they encounter new material (e.g., accidental introductions, or new types that arise as spontaneous crosses). This knowledge of and interest in management of crop genetic resources is widespread in Africa, and is perhaps the single most important aspect of the legacy of indigenous agro-technological knowledge on the continent. Today it is threatened by social dislocation (including the effects of warfare) and agricultural modernization (including the spread of modern cultivars and labor-efficient harvesting technology).

African contributions to crop biodiversity management have been undervalued in the past, with some exceptions, because several of Africa's indigenous food crops are not widely known elsewhere (e.g., *Digitaria* millet in West Africa, *teff* in Ethiopia, and finger millet in eastern and central Africa). Vavilov recognized the Ethiopian Highlands as a major center of crop biodiversity, but a number of important crops originating in Africa are scattered more widely (e.g., African rice, white yam, sorghum, and oil palm). Greater recognition is still needed for the historical role played by Africa's farming populations in identifying, shaping, and conserving these genetic resources. In this context it is interesting to note the systematic efforts made by Thomas Jefferson in the 1790s to establish African rice in the United States. Jefferson was convinced that the hardy dryland cultivars selected and maintained by West African farmers would help reduce some of the health problems associated with rice farming in the coastal zone of South Carolina, and had a cask of upland rice imported from the coast of what is today the Republic of Guinea for distribution among inland planters in South Carolina and Georgia. Earlier, South Carolina rice planters had shown a preference for slaves from the coastal rice-growing regions of West Africa, and it is possible that the tidal-pumped wetland rice cultivation systems of the tidewater zone drew upon African technological expertise in this field. Historical examples such as these help correct the erroneous notion that the transfer of agricultural knowledge and technology between Africa and the rest of the world has been a one-way process.

During a period of aggressive modernization of African agriculture following the end of colonial rule the work of documenting and understanding African systems of resource knowledge and management, begun by ecologically oriented technologists in the colonial period, was kept alive only by a handful of enthusiasts. Special mention should be made of African pioneers such as George Benneh in Ghana and Uzo Igbozurike in Nigeria. However, interest in local knowledge systems expanded enormously in the 1980s and 1990s, after the failure of many "high-tech" schemes to promote rapid change in African agriculture. A number of agricultural and other scientists now see indigenous knowledge as a resource for orthodox science (farmer experimentation attracts particular attention). Recent studies have highlighted the specialist knowledge of Africa's women farmers, pointed to the complex ways in which indigenous technical knowledge of the environment is bound up with social relationships of production and consumption, and drawn attention to local knowledge in biodiversity conservation. The ratification of an international convention on biodiversity, adopted by the United Nations' Rio de Janiero Conference on Environment and Development in 1992, gives indigenous agricultural knowledge a new visibility, and status in international law. Questions of ownership and preservation of Africa's abundant legacy of indigenous knowledge now attract attention, though some concern has been expressed that this might serve to ossify such knowledge, and reduce its practical utility.

Agriculture of the Ancient Maya

Timothy Beach

The Maya are a diverse group of Native Americans, who speak 31 languages within the Mayan Language Family. They live in Southern Mesoamerica, in Mexico from Chiapas through Yucatan and south through Guatemala in the Peten lowlands and mountainous highlands and into Belize, Honduras, and El Salvador. Settlements started as early as 2,000 BCE along the mangrove coastal margins of the Pacific, but most settlements started after about 1200 BCE, with identifiable ceramics, and lasted through the Pre-Classic 1200 BCE to BCE 250 and the Classic Period from (BCE 250) to (BCE 850). Declines or transitions punctuated their history at the end of the Pre-Classic, perhaps in the Middle Classic, (BCE 500), the sharp decline often called the Maya "Collapse" in ninth century (BCE), and the population collapse due to the diffusion of European diseases and conquests starting in the sixteenth century. All but the last of these major transitions are regional, and the most famous is the Terminal Classic Collapse of the ninth century (BCE), which occurred in the central lowlands of Guatemala's Peten state and adjacent Belize, Honduras, and Mexico's Chiapas and southern Yucatan. Much of the writing about the Maya, including about its agriculture and environment, focuses on this Terminal Collapse and the Late Classic period (BCE 550–850) that preceded it though more and more publications are dealing with both the pre and post classic periods. The terminal classic in the central Lowlands represents an end to this intensive urban and agricultural civilization's great achievements in building, writing, art, astronomy, and agriculture, and the relatively quick return of tropical forests that enveloped the temples and terraces that had functioned for centuries.

The Maya World has two main geographic divisions: volcanic highlands and limestone lowlands. The highlands center on a series of north–south running and variably active volcanoes along the Pacific Coast side, which abut a complicated series of metamorphic and sedimentary rocks to their east. The Maya farmed these slopes and river valleys from Chiapas, Mexico into Guatemala, Honduras, and El Salvador. These uplands generally have deep and fertile soils, though rainshadow driven dryness, steep slopes, some poor soils, and seismic volcanic events have limited subsistence in different places at different times. The lowlands mainly refer to the limestone Yucatan platform ranging from Mexico, through Guatemala, to Honduras. Within this division are the karst plains of the northern Yucatan with no rivers but sinkholes, the faulted, karstic central and southern Yucatan, the more complicated geology to the south (including the granitic Maya Mountains); and the surrounding coastal zones with rivers and more coastal resources.

Climate also varies significantly across this region, from the semi-arid northwest Yucatan with about 500 mm of annual rainfall to the high elevations of the Maya Mountains that receive almost ten times more rainfall. Generally, the lowlands receive about 1,000 to 2,000 mm of rainfall and most of the region does have a distinct dry season from December to May that must be figured into every agricultural practice and adaptation in the region. These general regions all provide different potential resources and limitations for agriculture. One limitation for the whole region was recurring drought that corresponds to cultural declines especially with the Terminal Classic Collapse (Hodell et al. 2000).

Research into Maya agriculture is long and rich. The start of agriculture in the Maya World comes from the earliest evidence of maize in the floodplains of coastal Veracruz by about 7,000 BP and evidence from starch grains for root crops in nearby Panama comes about the same time (Piperno et al. 2000). This beginning of Mesoamerica's great triumvirate of staple crops – maize, bean, and squash – comes with the spread of extensive swidden or *milpa* farming and perhaps floodplain farming. This shows up in the Maya Heartland of Guatemala's Peten and nearby Belize from about 5,000 to 4,000 BP as increased charcoal and pollen from the weeds that usually accompany agriculture. Pollen from maize and manioc actually show up before 5,000 BP in Belize (Jones 1994; Pohl et al. 1996).

In the early twentieth century, scholars viewed swidden agriculture as the means for how the ancient Maya fed themselves because many had observed *milpa* farming across the region and studies showed that it provided a level of subsistence needed for the dispersed populations of a tropical forest civilization. In the 1960s, though, many scholars came to see the *milpa* as insufficient to feed the growing estimates of ancient Maya populations. Many regional surveys started showing more and more large-scale Maya sites that must have had high populations, and studies for decades had reported evidence for intensive forms of agriculture, including extensive, well-made terraces.

The agricultural staples of the Maya worlds were of course maize, beans, and squash, though there were a host of other possible and known crops like cassava, sunflower, amaranth, and many other fruits and vegetables, whether cultivated or collected. There were also sources of meat from turkeys, ducks, doves, deer, fish, and other animals, though what role they played in Maya agriculture and what proportion of Maya diets they made up is still not well known. Cacao was certainly an important commodity grown in different environments over much of the Maya Lowlands. Since we know from documents and archaeological evidence that the Maya and other Mesoamerican peoples highly prized cacao, scholars have tried to identify cacao in many possible ways: by noting the requirements of the crop, using ethnohistorical information, and looking for pollen and other fossil evidence. Tobacco, cotton, palms, and many others were nonsubsistence crops. This cornucopia of known foods has also fueled discussion of other possible staples to feed large populations and solve the riddle of Maya subsistence (Dahlin et al. 2006). Scholars have found evidence for use of many other crops like agave and many arboreal ones like ramon or breadnut (Gomez-Pompa et al. 1990).

Forms of Agriculture

We should note that we still know little about the agriculture of the ancient Maya, but many traditional and novel techniques are turning up more evidence with each field season (Beach et al. 2006b). Traditional research tools are still the backbone of research and include regional survey, sampling, mapping, and archaeological excavation. Adding to these methods have been an array of steadily improving geophysical, chemical, and biological methods. Each of these methods are whole subjects in themselves but we should not divorce a discussion of the methods from the findings, because techniques change and may make findings obsolete. For example, remote-sensing technologies have added to our breadth of knowledge, but some radar images have produced false-positive identifications for vast wetland agriculture in areas that are not even wetlands.

We can divide ancient Maya Lowlands agriculture into upland and lowland forms and outfield and infield forms. Upland agriculture occurred on well-drained and seasonally drained soils and lowland farms had to contend with seasonally or perennially high water tables. Outfields simply refer to fields at some distance from Maya sites and infields were agricultural areas within or adjacent to sites and thus more likely the focus of intensification techniques.

One type of infield in Maya societies is kitchen gardens or solares, which is still a common feature of traditional and indigenous communities. These, like similar farming systems around the world, are intensive, high input, close-to-home adaptations for growing crops. Kitchen gardens often use polycultural methods that grow as much on small areas as possible by arranging crops at different levels or canopies. Ethnohistorical studies have found that polycultural gardens produce about 11% of domestic caloric intake and few bulk staples, focusing more on dietary supplements, medicinals, ornamentals, and ritual objects. Archaeological evidence such as the size of walled areas around mounds may however, suggests greater pre-Hispanic contributions from kitchen gardens at certain periods (Beach et al. 2006b).

In uplands, milpa, or slash and burn farming, is the mainstay of nonintensive agriculture. A milpa is small farm that *milperos* slash and burn usually toward the end of dry season (from December to May). *Milperos* slash the tropical forest vegetation today with metal machetes (or more mechanized implements) but had to use stone tools in antiquity. They would slash vegetation, including girdling trees to make the vegetation dry enough to burn, and thus produce enough wood ash to enrich and prepare the seed bed for planting. They would usually plant multiple crops (e.g., corn, beans, squash, and chilies) in each milpa and indeed prepare more than one milpa every year to insure against the vicissitudes of climate (e.g., drought and hurricanes) and pests in these seasonally dry tropics. Each milpa might remain productive for 2 or 3 years and then weed competition and nutrient depletion would drive farmers along to new areas to slash and burn. Farmers might return to the old milpas after fallows of 10 or more years and restart the process. Although this is extensive agriculture, farmers might intensify this by shortening the fallow time, but this requires more labor for weeding and fertilizing (Beach et al. 2006b).

Upland agriculture occurred along slopes of varying degrees and, for any semblance of long-term sustainability, required conservation techniques to limit soil erosion in the Maya Lowlands, where the limestone soils were already thin, and in the Highlands, where slopes are much steeper and longer. We have substantial evidence that soil erosion, in lake sedimentation and buried depression soils, started early, by about 3,000 BP, in the Maya Lowlands. Rates of erosion only rise when major drivers of erosion occur and the main evidence for such drivers is the coincidence of weed and crop pollen, charcoal, and mineral sediments. These link deforestation and Maya farming together with increased runoff, caused by some combination of decreased transpiration and infiltration into soils. The increased erosion may have also coincided with another erosion driver, namely moving deforestation onto steeper slopes, where gravity can act to accelerate overland flow and all major types of water erosion. Modern evidence in this region shows that erosion rates are very high after deforestation and soils erode to bedrock surprisingly fast. Some scholars have even linked soil erosion with the Terminal Maya Collapse (Beach et al. 2006a).

Ancient Maya farmers, like early farmers everywhere, had to adjust their early pioneering experience. They had several options that all required more labor inputs: conservation techniques on slopes or management of flat or depression environments. The least laborious options would have been to farm flat areas, but there were too few flat areas that were not seasonally waterlogged around the settlement-carpeted limestone, karstic ridges of much of the central Maya Lowlands.

Upland Agriculture and Terrace Systems

In many places around the Maya Lowlands are large tracts of terraced lands. Indeed, travelers have mentioned terraces since at least the early twentieth century, and they have since identified many types of terraces that take advantage of specific slope situations. Terrace systems are intensive forms of agriculture that attempt to engineer slopes to make them sustainable. Indigenous terrace systems, starting more than 5,000 years ago, are nearly a universal human adaptation to farming on steep slopes, with several ancient terrace systems such as those in the Philippines, recognized as UNESCO World Heritage Sites. The factors that make steep slopes unsustainable are thin soils that cannot store enough water or nutrients and extremes of water: either too much destructive overland flow or too little to support crop needs during the dry season. Thus for terracing to be worth the heavy labor efforts, farmers must build up soils, minimize the impacts of overland flow, and maximize soil moisture for the growing season. Terrace systems also must return nutrients harvested in crops to maintain crop yields over time. Studies have thus attempted to find evidence for soil depletion coinciding with the Terminal Classic Collapse as well as find evidence for terrace soil maintenance from night soil, composted waste, and wetland organic matter (Turner 1974; Beach et al. 2002).

Terraces must function to slow the destructive force of overland flow, divert water away or to soils, help drain excess water, and dam up soils and potential fertility. There are surprisingly common terrace remnants left in the Peten after more than a thousand years and most tend to be engineered from limestone boulder dams, though some are earthen and some might have been vegetative hedges as well, which have left no obvious traces. The terrace dams were either single rows of large boulders or double rows of boulders with gravel, cobble, and ceramic fills. They often had gravel bases and cobble buttresses and some still testify to pre-Maya times with soils buried below the terrace dams and below soil sequences that filled in behind the dams unintentionally or by active human manipulation. Terraces occur in many slope positions: contoured around slopes, across channels, as boxes with little slope, around crests, and prominently at the base of slopes. Some landscapes have all types; others only have one. Since each has a different slope position, each creates a different microenvironment with different soil moisture conditions and aspects or orientations to the sun. In most cases a large part of the terrace system has eroded away, and, thus, our real evidence for an agricultural landscape integrated with diversion cannels is often only theoretical.

All of the terrace types are common, though box terraces are much smaller and more easily expunged by tree roots and slope wash. Some scholars have linked these systems with intensive nursery crops that could be replanted at some point in their lifecycle. Footslope terraces show up in many places because they are usually constructed of larger boulders that persist through time. These may have functioned to build up some areas above water tables in large, low elevation seasonal wetlands. Hence, we think the base of slopes that often ring depressions was an important focus of agriculture, where soil depth, fertility, and moisture could have been managed to lengthen the growing season. Likewise, upland sinkholes, called *aguadas* or *rejolladas*, could also have been a focus for agriculture because soil depths, fertility, and moisture could have been managed to lengthen growing seasons.

Some evidence exists for early terrace adoption, perhaps by 2600 BP, though most evidence of terracing coincides with the other large-scale building of the Late Classic period. Many sites in the Maya world, such as Caracol, La Milpa, the Rio Bec, Xunantunich, and the Petexbatun, had widespread terracing by the Late Classic period, though other notable sites like Copan and the Central Peten lakes region provide only meager evidence (Beach et al. 2002, 2006a, b; Beach and Dunning 1995).

Another form of upland soil management is field ridging, which looks like plowed furrows but required significantly more labor in Maya societies where beasts of burden were not available. Field ridging has been reported in many parts of Mesoamerica, but the most significant are the preserved fossil ridges in the ash covered, Maya Pompeii site of Ceren, El Salvador, which blankets a Classic Maya village from ca. BCE 650. The low ridges formed the seedbeds, and maximum air and water drainage could occur in the furrows. At Ceren, only one of eight excavated fields was in fallow, probably indicating much more intensive farming on these fertile, volcanic soils than could be possible in lowlands milpas that required years of fallow or heavy fertilizing and weeding (Beach et al. 2006a, b).

Lowland Intensive Agriculture

Lowland agriculture takes advantage of low sites where erosion is not significant, but water management is necessary to provide enough water in dry sites and enough root aeration in wet sites. These areas do not suffer from much erosion but all agricultural lands must still be fertilized for intensive long-term cropping.

One particular Maya region provides an interesting case study: the northwest Yucatan site of Chunchucmil. Here the soils are thin or nonexistent and the rainfall is spotty and low; yet this Maya site had many thousands of inhabitants around BCE 400–600, where today a few hundreds have trouble growing enough food. Milpa farming today produces only a small fraction of food requirements, but somehow high populations occupied this region ca. 1,500 years ago. Thus, either they imported food based on some other trade commodity or they used some extremely intensive systems. One line of evidence lies in the numerous polygonal wall systems around habitation mounds and surrounding empty lands. The walls only tell us that groups were trying keep predators or people out, and scholars are looking for every line of evidence about manufacturing and markets that might have functioned to provide trade goods for food from elsewhere. But these may also have been intensive kitchen gardens with traditional or special crops that were heavily fertilized with all possible wastes the site and organic matter from nearby wetlands. Modern farmers do enhance their solares this way, and we can balance subsistence for large ancient populations by maximizing infield, arboriculture, and surrounding outfield production (Dahlin et al. 2006).

Another type of agriculture that occupies the middle ground between uplands and lowlands is *bajo* or karst-depression agriculture (Dunning et al. 2002; Beach et al. 2002). This ranges from cropping that occupies the backslopes of small sinkholes of a hectare or less called *aguadas* or *rejolladas* to cropping into and around large seasonal sinks called *bajos* that are sometimes many square kilometers. Pollen of maize, cassava, and other crops in bajo sediments shows evidence of nearby agriculture, and excavation of surrounding terrace berms may show soil and water management in these "ecotonal" zones, i.e., regions that straddle two ecosystems.

Agriculture in these bajos was similar to agriculture in seasonally flooding valleys. In these environments, farmers had to manage water extremes, flooding in the wet season and insufficient soil moisture in the dry season. One globally widespread adaptation to such environments is a risky but productive technique called flood recessional agriculture. Farmers using this technique plant into the wet soils of receding floods to take advantage of plenty of soil moisture that might get a crop through the dry season. As does all farming to varying degrees, this plays the probabilities of potential drought and enough seed-corn to persist through recurrent floods. Farmers could also more actively manage soil moisture by ditching, draining, and damming.

Another option for intensive farming was manipulating perennial wetlands (Duzzader-Beach and Beach 2006). All over the Maya Lowlands perennial wetlands bear witness to a wide diversity of rectilinear features that look like cobwebs or other polygonal patterns from the air. Early on scholars suggested that these may be relicts of ancient Maya intensive wetland cultivation because the patterns look similar to the historical Mexica wetland plots or *chinampas* around the Basin of Mexico, which, like the terraces of the Aztec Realm, were highly productive systems. These *chinampas* are still very much working plots in Xochimilco on the outskirts of Mexico City, though today they are more for flowers and tourists than subsistence.

Farming wetland fields requires using plants that can grow in saturated soils or manipulating the soils and water table. Indeed, one explanation for the polygonal field patterns is that they are simply ditches to drain the fields and lower the water table below the root zone of typical crops. Thus such drained fields could function as long as there was a lower part of the landscape where water could be drained. A more elaborate model is a raised field, in which the ditches are built and the excavated soils and organic matter are used to build up and fertilize the soil plots. In both models, canals can be occasionally cleaned out and used to renew fields. In the Aztec fields, alder and willow trees were planted around the field edges to protect the sides from slumping and erosion (Armillas 1971). An even more elaborate model envisions a complex of farming and aquaculture akin to the productive but laborious Chinese rice paddy, aquaculture systems.

There are also more natural explanations for the polygonal wetland patterns. These range from human ditching in response to sea level rise and ground water rise to differential expansion patterns caused by a landscape building up from gypsum precipitating from saturated ground and surface waters. The first explanation sees wetland ditching as a Pre-Classic agricultural adaptation to wetland formation, though in the broader region other research teams saw the same patterns as evidence of Late Classic intensive cultivation with copious evidence for maize. The differential heave explanation does not discount the possibility of human modification of polygonal field patterns but argues for a landscape co-evolving from human and natural factors.

Another hypothetical use of wetlands for agriculture comes from the rock alignments of northeastern Yucatan. Perhaps these rock-aligned wetlands were used to raise algae or periphyton, which are cyanobacteria communities that have fertilizer and pesticide characteristics. Or, perhaps these were dryland plots created before sea level rise made these wetlands. In either case, Maya scholars have attempted to use every line of evidence and push the limits of science to come up with explanations for Maya subsistence. Sometimes they have pushed too far and too fast, but it was usually tin the spirit of seeking out explanations for the profound and vexing riddles of the past.

Debates about all forms of ancient agriculture underscore the difficulty of understanding ancient subsistence. We only have the lines of evidence and no historical accounts. Thus, we have vast terrace systems, walled fields, ridged fields, and numerous wetland polygons that coincide with millions of house mounds and massive buildings from especially the Late Classic. We have evidence of buried soils, elevated chemicals, fossil seeds, pollen, and other proxies of the past.

Since there are many types of intensive and extensive agriculture from around the Maya realm, many Maya scholars think the ancient Maya used heterogeneous types of farming, adapted for the different landscapes, soils, and climates of the region. Many Maya sites are on ecotones, such as at bajo edges and ridges that lie between two and more environments. Around the sites, evidence for many agricultural adaptations often occur. This makes us guess that, where possible, ancient Maya farmers tried to do with intensive systems what contemporary, traditional Maya farmers do in milpas: minimize risk by taking advantage of a diversity of sites. What is different about ancient Maya farming, however, are the many kinds of intensive agricultural systems with their extremely high labor demands.

Agriculture in China

Francesca Bray

China is a vast country covering roughly the area of Europe. Because much of it is steep mountains or fragile grasslands, only about 10% of China's total area is suitable for farming (see *Online resources* for some useful maps). However, intensive patterns of land use, increasingly refined over the centuries, sustained high levels of population and production throughout much of the imperial period. The modernization of farming in the West has characteristically involved increasing the size of farms or managerial units while substituting machines or other industrial products for human labor. In China the process was reversed: farms and equipment became smaller and inputs of human skills intensified. There is a fierce debate among historians as to how this long-term trend should be interpreted. Some see it as a "technologically blocked" system, incompatible with the emergence of capitalism, in which farming families had to work ever harder for smaller returns. Others argue that the farming system of China and the rural manufactures and commercial networks that grew up around it constituted a flexible and dynamic economic system which not only generated internal prosperity, but played a key role in stimulating and shaping the emerging global economy of the modern world (see BOX). The unusual quantity of agricultural treatises and economic or policy documents that have come down to us from the imperial era help fuel and complicate this important debate as to whether "modernity" is a Western or a worldwide phenomenon. In either case, the current social and environmental critiques of contemporary "productivism" and of the problems generated by industrial agriculture suggest the value of looking more carefully at such alternative paths to development as the progressive intensification of land-use typical of Chinese agriculture.

China has several different farming regions, ranging from the chilly plains of the Northeast where the main food crops are soybeans, sorghum, spring wheat, and corn, to the lush tropical gardens of Hainan Island where the year-round growing season allows constant cropping, including two crops of rice (Bray 1984: 9–27; ►http://www.1uptravel.com/worldmaps/china39.html). Broadly speaking, however, China has two distinct farming traditions that correspond to climatic zones. North China has sparse and irregular rain that falls mostly in the summer; the winters are long and cold. The uplands of the interior are formed of thick deposits of fertile loess; over the millennia the Yellow River has eaten away at the primary loess and deposited it as silt on the alluvial plains downstream. The main constraints on agricultural productivity in the Northern region are the relatively short growing season (between five and eight months) and the lack of water. It is seldom possible to grow more than one crop a year. The typical crops are those which do well with little water: millets, wheat, sorghum, cotton, and beans.

From the Yangzi plains south, the climate is semitropical. Rainfall is much heavier and spread throughout the year. As a result much of the natural soil fertility has been leached away, but irrigated rice fields counteract this effect. They build up their own fertile microecology that allows the same field to produce two or even three harvests a year, depending on the latitude. The growing season ranges from nine months to year round. Rice is the staple, grown everywhere in the Southern zone: other important crops are winter wheat, maize, sweet potato, sugar, tea, and cotton along the Yangzi.

The distinction between a Northern and a Southern tradition has its roots in prehistoric times. The earliest Chinese farming villages date from the sixth millennium BCE, much later than those of the Fertile Crescent. Archaeologists used to consider that farming diffused throughout the Old World from that single center; the current evidence suggests however that within China itself there were at least two independent centers of plant domestication. At the 5000 BCE Neolithic site of Banpo, in the loesslands of Northwest China, the dryland crop of Setaria millet was grown (Bray 1984: 434). The village of Hemudu, built in the marshes near the mouth of the Yangzi at the same period, grew large quantities of wet rice (Bray 1984: 481). Though some archaeologists believe they have now discovered evidence of domesticated rice in sites in Central and Southern China dating back as far as 10000 BCE (An 1999), most of the early evidence for farming in China is no earlier than Banpo or Hemudu.

Land was a scarce resource from very early times. Unlike the pattern of development in the West, where capital was invested in draft animals, equipment, and machines to substitute for labor, in China the historical trend was towards increasing the productivity of land through the application of skilled labor and cheap small-scale inputs. With one or two rare exceptions, economies of scale did not apply. The roots of this relationship between land, population, and labor developed very early in China's history.

From the sixth to the fourth centuries BCE, several states battled for control of all China; the states with most men to fight and most grain to feed them emerged as victors. A fiscal policy based on peasant contributions of grain, textiles, and services became the norm. A strong state was one with a large population of skilled farmers. As a political philosopher of the third century BCE put it: "Therefore it is said: 'Where a hundred men farm and one is idle, the state will attain supremacy; where ten men farm and one is idle, the state will be strong; where half farms and half is idle, the state will be in peril.' This is why those, who govern the country well, wish the people to take to agriculture" (*Shangjun shu*, trans. Duyvendak 1928: 191). This remained the basic view of Chinese statesmen through the unification of the empire in 221 BCE right up to the end of the Maoist era. For over 2,000 years officials encouraged farming and took an active role in developing and diffusing knowledge and techniques. They fostered labor-intensive peasant farming and tried to control the accumulation of land in the hands of the rich. Successive medieval regimes confiscated land from the wealthy and redistributed it to peasants to ensure that it provided a livelihood for as many people as possible.

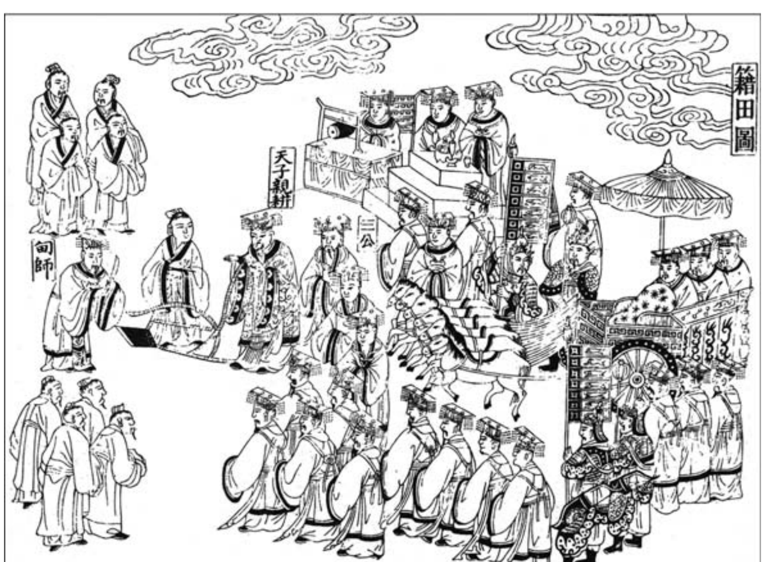
In part this intensity of land use was made possible by the particularities of Chinese farming systems. No arable land was wasted. There were few pastures in China proper. The main sources of animal protein were

Agriculture in China. Fig. 1 Water buffalo and herdboy. The sound of the herdboy's flute echoing up some distant valley was a common element in Chinese poetry, but here the agronomist Wang Zhen (see below) is illustrating the flute as one of the indispensable implements of a rice-farming household. Wang Zhen, *Nongshu*, Ming edition of 1530, 13/7a.

pigs, poultry and fish, and draft animals (oxen and mules in the North, water buffalo in the South) grazed on rough land (Fig. 1). The practice of fallowing seems to have died out as early as 2,000 years ago in parts of North China. Crop rotations alternated soil-enriching crops like beans with cereals; all human and animal waste was composted and returned to the fields. Medieval states in the North allocated approximately 6 acre of land to support a family. Land was even more intensively used in the South. By the seventeenth century, some fields in the South produced two crops of rice and another of tobacco or vegetables each year. In the early twentieth century families in the most densely populated regions lived off under a tenth of an acre of rice land.

The tax system meant that improving agriculture was a key concern in Chinese state policy from the very beginning (Wong 1997: 90), and many of the most important works on agriculture were written by members of the official elite in their capacity as civil servants (Fig. 2). Imperial compilations and works by civil servants aimed at a readership of local officials who would pass on the information to the farmers under their jurisdiction. They tended to stress practical details of husbandry, including innovations that could be introduced, and they emphasized subsistence production. Other works, written by landowners who ran their own farms, were written for fellow landowners; these works usually included discussions of labor, prices and estate management (Bray 1984: 47–80) (Fig. 3).

The earliest extant agricultural treatise belongs to the second category. It is entitled *Qimin yaoshu* (Essential Techniques for the Peasantry); the author, Jia Sixie, completed its ten volumes in around AD 535 (Bray 1984: 55–58). It describes the agriculture of the dry regions of the Yellow River plains. Perhaps its most striking features are the detailed descriptions of how careful and repeated tillage techniques (different depths of plowing, sowing with a seed-drill, harrowing and hoeing, all techniques requiring the use of several oxen or mules) were used to conserve soil moisture in a dry climate, and crop rotations were used to increase fertility. We can reconstruct much of the equipment mentioned by Jia from somewhat earlier tomb paintings, as well as archaeological discoveries of huge state iron foundries from the first century AD, that mass-produced cast iron plowshares, moldboards, and the iron shoes of seed-drills. Together with Jia's numerous citations from earlier Northern works, this evidence confirms that the *Qimin yaoshu* represented the culmination of a long Northern tradition of productive estate farming that was dependent on large acreages and heavy capital investment in equipment and draft animals. It was a form of centralized estate farming that



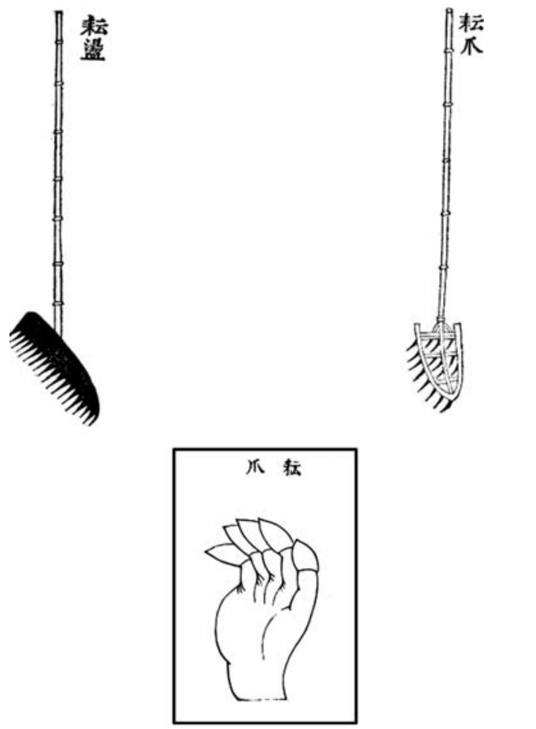
Agriculture in China. Fig. 2 Wang Zhen wrote his agricultural treatise of 1313 after service as magistrate in both Northern and Southern provinces; he hoped his work would help disseminate advanced technology and improved techniques. He begins with a section on the importance of official encouragement of farming. This included not only practical but also symbolic measures such as the New Year imperial plowing ceremony, where the emperor plowed a ceremonial furrow before the Temple of the God of the Soil in order to ensure good harvests throughout the empire. In this highly stylized rendering, an emperor of ancient times is shown holding the strut of a plow to the *left* of the picture. Wang Zhen, *Nongshu*, 7/4a–b.

Agriculture in China. Fig. 3 The harvest feast held by a landlord (shown seated right in front of his family altar) for his tenant farmers. *Bianmin tuzuan*, 1593 edition, 1/8a.

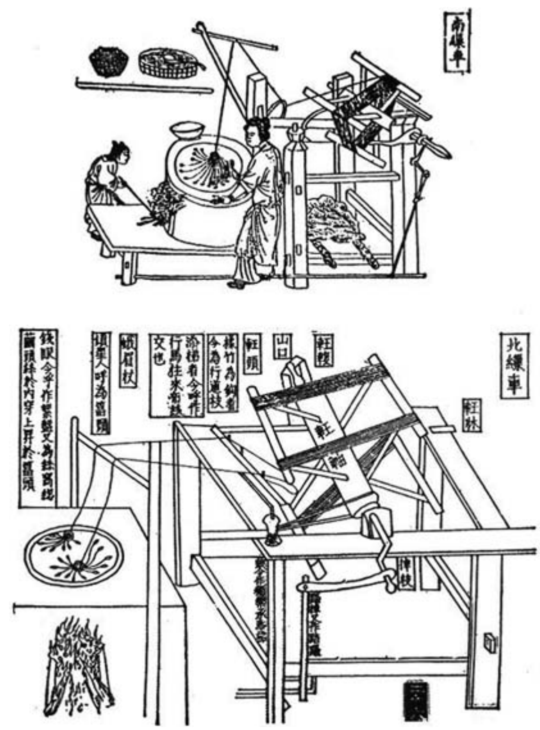
peasant farmers could not afford or compete with (Bray 1984: 587–97). The *Qimin yaoshu* was the last of the great works focused on the Northern system.

Repeated wars and invasions ravaged the Northern plains in medieval times. In the eleventh century the loss of the North to the Khitan finally established the Yangzi region as the political and economic center of Song dynasty China. The estates of the Northern aristocrats disintegrated, and as under-equipped peasant farmers did their best to scratch a living from a few acres of dry soil, the North became a backward region compared to the fruitful South. Migrants flooded into the Southern provinces from the North, and the state sought to encourage more productive agriculture by every possible means. Irrigation works were improved, seeds were handed out, information distributed, and cheap loans and tax breaks offered – the scope was similar to the Green Revolution of the 1970s, as was the impact on production (Elvin 1973; Bray 1986). One particularly fruitful venture was the introduction of quick-ripening rices from Vietnam that allowed rice farmers to double crop their fields, alternating winter wheat or barley with rice.

Several important agricultural works were published during the Song, but the landmark of the period dates from the Yuan (Mongol) dynasty. In 1313 Wang Zhen published a *Nongshu* (Treatise on Agriculture) several hundred pages long. His aim was to describe local innovations so that they could be adopted elsewhere (Bray 1984: 59–64). He included detailed woodblock illustrations of farming tools (Fig. 4), machinery (Figs. 5 and 6), irrigation equipment (Figs. 7 and 8), and various types of terraced or dyked fields that permitted the extension of farming into mountainous or marshy lands



Agriculture in China. Fig. 4 Varieties of tools for weeding rice fields depicted by Wang Zhen. On the *top left* is a simple rake. The hinged rake at the *right* was a new invention from the lower Yangzi which Wang described with great enthusiasm, hoping that it would relieve farmers of much back-breaking work going through the young rice on their hands and knees. The "weeding claws" at the bottom were made of bamboo and helped farmers grub up weeds at the roots. *Nongshu* 13/27–29.



Agriculture in China. Fig. 5 Silk-reeling machines typical of Northern China (below) and the Yangzi region (above). Rural women produced almost all the silk thread and much of the silk cloth in circulation at the time when Wang Zhen was writing, but later silk weaving moved into suburban workshops where most of the workers were men. *Nongshu* 22/26a–27b.

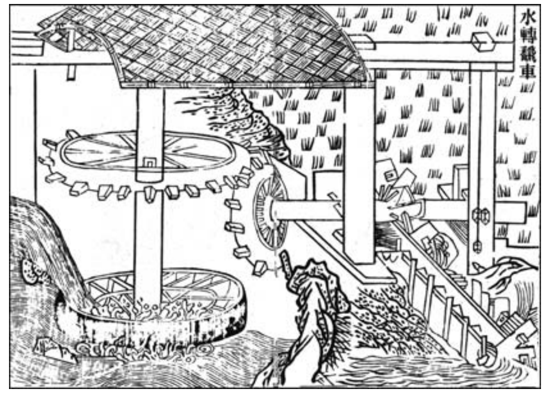
(Figs. 9 and 10). The treatise depicts a system of family farming in which poor peasants with little capital invested intensively in labor, skills, and low-cost inputs. This was the farming system that formed the basis for the commoditization and expansion of the rural economy in succeeding centuries (Bray 2000: 25–41).

Wang Zhen's *Treatise* was the paradigm for later works, including imperial compilations and the magisterial *Nongzheng quanshu* (Complete Treatise on Agricultural Administration) by the statesman Xu Guangqi, completed in 1639. Xu was a polymath and Christian convert who served for some years as Grand Secretary of China. The *Nongzheng quanshu* advocates a balance between the production of essentials (cereals for food and fiber crops for textiles) necessary for the health of the central state, and cash crops and handicrafts that would ensure a prosperous rural economy. Xu was also preoccupied with population pressure and the need to expand the arable area and improve yields; he devotes long sections of his treatise to land reclamation and improved irrigation techniques, to his own experiments with manures and commercial fertilizers such as lime and bean cake, and to crops like sweet potatoes that can be grown on poor land (Bray and Métailié 2001).

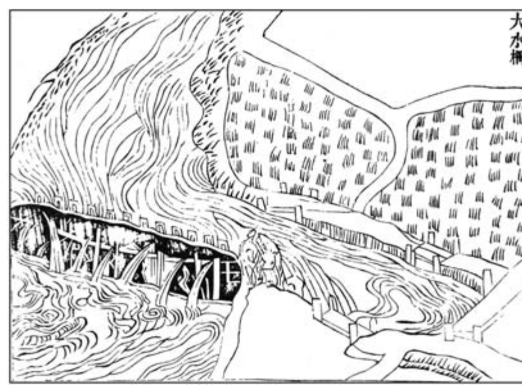
Landowners wrote a number of other works in the Southern tradition. In striking contrast to the *Qimin yaoshu*, however, the landowners themselves farmed only a few acres and rented the rest out to tenants. The main criteria for selecting a suitable tenant were his skills and experience, and his assiduity at work; capital assets were not a consideration as they would have been for a contemporaneous English capitalist landowner. The main difference between landowner and tenant lay in the ownership of land; it did not extend to differences in the scale of the farm, or in the range and size of equipment (Bray 1986: 113–119). In this highly intensive and skilled farming system there were no economies of scale, and anyone who owned more than an acre of rice land would seek a tenant to farm the

Agriculture in China. Fig. 6 Spinning wheel for making cotton yarn. When Wang Zhen was writing in the early fourteenth century, cotton was just beginning to replace other vegetable fibers as the most common everyday cloth, and Wang provides copious documentation about the techniques and equipment involved. *Nongshu* 25/6b.

Agriculture in China. Fig. 7 Chain pump operated by two men. These light, portable pumps could be made quite easily by local carpenters and they would be moved from field to field as each needed irrigating or draining. Wang Zhen, *Nongshu* 19/7a–b.

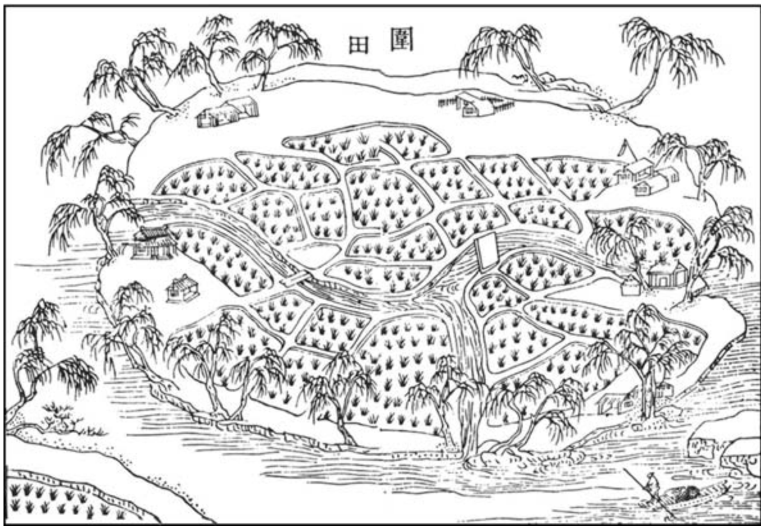


Agriculture in China. Fig. 8 Water-driven chain pump. Water mills were an essential element in medieval Chinese industry, as they were in Europe, and Wang Zhen also illustrates water mills of the kind used to power millstones, the bellows for metal foundries, and multiple trip hammers for fulling cloth or mixing clay for potteries. *Nongshu* 19/11a–b.



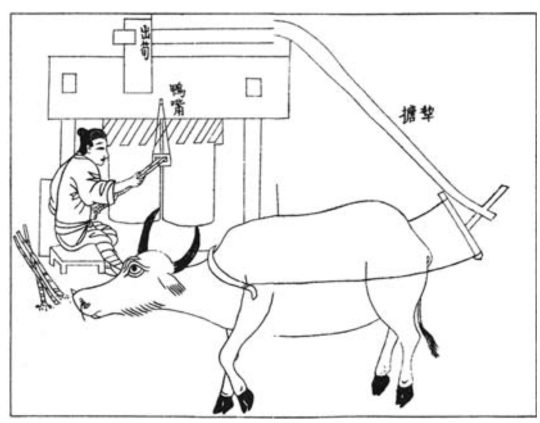
Agriculture in China. Fig. 9 A large sluice across a river, with irrigation channels leading off into padi fields. *Nongshu* 19/2a–b.

surplus. If levels of agricultural expertise were reckoned simply by the complexity of farm machinery or by levels of capital investment, then the farming methods of the eighteenth and nineteenth centuries might be reckoned a decline from those of 800 years earlier, for as average farm size diminished many peasants abandoned animal-drawn implements in favor of hand tools. However, if we look at the productivity of land, we see a different picture. Improvements in water control, in fertilizing (Fig. 11), in the spacing of plants and the breeding of varieties enabled China's peasant farmers to increase the total output of crops at a rate that kept up with population growth until about 1800 (Perkins 1969; Li 1998a, b). This intensive small-scale farming also supported a diversified rural economy of small industries and handicrafts that fed



Agriculture in China. Fig. 10 A polder (protective dyke) surrounding a block of rice fields reclaimed from swamp or the shallows of a river. Drainage channels run through the middle, and houses nestle among the willow trees planted along the high surrounding dykes. This illustration from 1742 is based on an original in Wang Zhen's *Nongshu*. *Shoushi tongkao*, 1742 edition, 14/5b.

Agriculture in China. Fig. 11 Fertilizing the rice seedlings in the nursery bed before transplanting. *Gengzhi tu*, Yongzheng imperial edition of 1742, 1/8b.



Agriculture in China. Fig. 12 Sugar mill with vertical rollers, depicted in Song Yingxing's technical treatise on crafts and industries *Tiangong kaiwu* of 1637. This type of mill had apparently come into use in the chief sugar-exporting regions of China, namely the Southeastern provinces of Fujian and Guangdong, shortly before Song wrote his book. Song describes a variety of sugars, some for internal trade and some for export to Europe. *Tiangong kaiwu*, 1637 edition, 6/2a–b.

into national and international trade networks (Rawski 1972; Gardella 1994; Daniels 1996; Marks 1998; Mazumdar 1998; Bray 2000; Pomeranz 2000) (Figs. 12 and 13).

Agriculture in China. Fig. 13 Picking cotton. A group of young women is hard at work, while a granny and a little boy, helpfully carrying a wicker basket round his neck, look on. This is from a short illustrated work written by the Provincial Governor of Zhili (the Beijing region) in order to encourage rural women to take up cotton production. Wood block print of 1808 based on the original painting of ca. 1765. *Shouyi guangxun*: 1/14b–15aBox.

The great inventions of Chinese agriculture are anonymous, the collective achievements of peasants recorded by servants of the state. Many important innovations occurred in the densely populated heartlands where pressure on land was most intense. There has been a tendency for Chinese historians past and present to assume that political and technical superiority went together, and that the Chinese taught civilization to the barbarians. However, several features crucial to Chinese high farming came not from the center but from the periphery. The technique of transplanting rice, fundamental for the development of intensive wet farming, was practiced by Thai-speaking populations in the Canton and Tonkin regions when they were conquered by China 2,000 years ago (Bray 1984: 279). Terraced fields probably spread northwards into China from Vietnam and Yunnan, reaching the Yangzi region by the fourteenth century (Bray 1984: 123–26). Tea was introduced from Tibet and Western Sichuan some time before the eighth century (Smith 1991). The techniques of cotton cultivation and processing were introduced to the Lower Yangzi from Hainan Island around the thirteenth century (Kuhn 1988).

Although there was no indigenous development of experimental agricultural science or engineering, Western agronomists found much to admire in traditional Chinese farming in the early twentieth century, particularly its careful husbandry and sustainability. Also traditional agronomic strengths such as crop breeding, have allied fruitfully with modern science. For example, Chinese geneticists used their vast range of local rice varieties to develop the first semi-dwarf high-yielding *indica* strains in the 1960s, several years before "miracle rices" were released by the International Rice Research Institute in the Philippines (Harlan 1980).

Extra: Chinese Agriculture and the "Great Debate"

Until recently comparative historians of economics or of science and technology tended to treat non-Western civilizations like China (or the Islamic world, or the Mayan empire) as *failed* or *blocked systems*. The most interesting question to ask about them was: Why did they fail to follow the European pattern of historical progress to industrialization, capitalism and modernity? Even Joseph Needham, who dramatically documented so many fundamental contributions of Chinese civilization to early science and technology, believed that China's creativity and ingenuity ground to a halt in about 1400. Needham was inclined to blame this on the mindset of the governing elite ("bureaucratic feudalism"). In 1973 Mark Elvin published a highly influential study in which he argued that the problem lay primarily with the technologies and organization of production, beginning with farming and the associated system of household manufactures. Unlike in early modern Europe, Chinese landlords and merchants saw no reason to invest in new technology in order to increase production or profits because smallholder farmers and household manufacturers, who were already highly productive, were always able to raise output a little more by increasing the family's inputs of labor. Elvin argued that by about 1400 or 1500 this system of small-scale commodity production had reached a point of technical stagnation and diminishing returns to labor, an "involutionary" system or "high-level equilibrium trap" that precluded indigenous transformation and encouraged overpopulation, impoverishment and the devastation of the environment. Only the forced confrontation with the modern Western powers in the nineteenth century offered China the opportunity to break out of this trap (Elvin 1973). In the mid-1980s Philip Huang began to elaborate on Elvin's analysis and on Chayanov's theories of peasant self-exploitation through the lens of farm management and market participation, to lay out a theory of late imperial China's "growth without development" (Huang 1985, 1990; see also Goldstone 1996).

Since the late 1990s a revisionist trend has come to prominence, stimulated by scholarship that has reconsidered the roots, nature and trajectories of the Industrial Revolution in the West. Jan de Vries' concept of "industrious revolution" suggests close parallels between early modern Europe, China and Japan. De Vries (1994) argues that between roughly 1550 and 1850 households in northwestern Europe steadily increased their working hours and allocated more of their labor to specialized production for the market. This was not "involution," however, for they freed time for this work by purchasing some goods that they had previously made for themselves. The profits they made by their sales allowed them to purchase more consumer goods. Though they sacrificed some leisure hours, this brought them higher living standards. Historians and social theorists including André Gunder Frank (1998), Bin Wong (1997, 2003) and Ken Pomeranz (2000, 2003) have argued that this was also true of much of China through the late imperial period.

A slightly different angle is taken by historians whose research suggests that sometimes increased farming output was achieved without additional labor. There were a range of improvements in farming technology that did not involve labor-saving machinery per se yet made it possible to raise farming output without increasing labor inputs (Bray 1986, Li 1998a, b, Shiba 1998). The steady expansion of inter-regional or international trading networks allowed growing numbers of rural households to specialize in commercial production while buying food and other necessities on the market (Gardella 1994, Daniels 1996, Mazumdar 1998, Marks 1998), and government policies for monitoring and regulating grain distribution and prices helped reduce the risks of such market dependence (Marks 1998, Wong 1997, Hamilton and Chang 2003). Local specialization was another factor that could raise output without necessarily leading to involution.

The revisionist historians stress that until at least 1800 China was the world's chief producer and exporter of manufactured goods. It was trading from a position of strength: from the sixteenth well into the eighteenth century, three quarters of all the silver produced in the world ended up in China (Atwell 1998, Brook 1998, Flynn et al. 1999). Not only was China a key actor in generating the economic configurations of world trade that catalyzed the rise of the modern West (Frank 1998, Arrighi et al. 2003), but life expectancy and living standards of rural households in around 1800 compared favorably with those in the most advanced regions of Western Europe at the time (Pomeranz 2003). Hamilton and Chang (2003) go so far as to claim that from as early as 1500 China should be thought of as a mass-consumption society. Moreover, many of the revisionist scholars argue, early modern China's political, social and economic institutions were not inherently incompatible with or antagonistic to industrial capitalism, nor even to today's global capitalism: the legacy of the late imperial era is clearly visible in China's national and international reflorescence today (Hamilton and Chang 2003; Arrighi et al. 2003).

The debate continues to rage, and given the patchy nature of the data both for Europe and for China it is likely to continue to seethe for some time. Often we find strong disagreements over the interpretation of the same data. In his magisterial new study of China's environmental history, for example, Elvin (2004) presents levels of deforestation in 1800 as proof that population growth and path-driven technologies had trapped China into a situation where it was probably more environmentally degraded than northwest Europe at the same time, while Pomeranz (2003) represents what he sees as roughly similar levels of deforestation in France and China around 1800 as a triumph of the Chinese political economy and its sustainable resource use.

The critical rethinking of the long-term logics of economic and technological development which we see in the revisionist scholars' work clearly owes much to the questioning of "master narratives" in postcolonial theory and critical studies of science and technology. Social and environmental critiques of productivism, together with new models of productive efficiency that emphasize decentralization, smaller scale and flexibility, provide a broader intellectual context for these new perspectives on the achievements or shortcomings of the imperial Chinese agrarian economy, as does China's meteoric rise as an economic and industrial powerhouse since the economic reforms of 1979.

Some Online Resources

►http://depts.washington.edu/chinaciv/ is the Web site of the *Visual Sourcebook of Chinese Civilization*, prepared by the social historian of China Patricia Buckley Ebrey, with the assistance of Joyce Chow, Lenore Hietkamp, Kevin Jensen, Robert Lin, Helen Schneider, Cyndie-Lee Wang, Kim Wishart, Cong Zhang and Lan Zhang. The project was funded by the National Endowment for the Humanities, the Freeman Foundation and the Chiang Ching-Kuo Foundation. The Web site provides useful historical timelines and geographical background, and it presents the main periods of Chinese history from the Neolithic up to the present by selecting two key themes (such as tombs, or calligraphy, or weapons) for each period. The illustrations (maps, photographs and art works) are excellent. As good background for the history of agriculture in China, under "Geography," "Land" (►http://depts.washington.edu/chinaciv/geo/land.htm) you will find a series of maps showing topography, climate, etc. If you follow through to "China proper" and then to "Outer China," among the photographs you will see images of the farming landscapes typical of China's regions, and of typical crop plants and farming techniques (plowing, transplanting rice with a machine, picking tea, herding).

Another useful online source for maps of China and its contemporary provinces, with good information about regional history, contemporary economics, climate, agriculture, cuisine, etc., is the Web site of the *South China Morning Post*, the Hong Kong English-language newspaper: ►http://china.scmp.com/map/

For brief accounts of Chinese history from its origins up to 1988, try ►http://www-chaos.umd.edu/history/toc.html

On contemporary economic issues concerning Chinese agriculture, see the UC Davis site ►http://aic.ucdavis.edu/research1/chinaeconomics.html

China Facts and Figures provides useful statistics on contemporary agriculture in its section on "Economy"; the English-language Web site for 2003 is ►http://www.china.org.cn/english/eng-shuzi2003/

The Food and Agriculture Organization (FAO) webpage on China ►http://www.fao.org/countryprofiles/index.asp?lang = en&ISO3 = CHN is an excellent source for a wide range of studies and statistics on contemporary agricultural issues in the People's Republic of China, including themes like sustainable development. It also offers a useful set of interactive maps which include maps showing elevation, slope, precipitation, length of growing period and major environmental constraints as well as more conventional maps of political boundaries, population, communications, etc.

Agriculture in India

R. K. Arora

The Harappan culture related to the earliest agricultural settlements in the Indian subcontinent is dated between 2300 and 1700 BCE. The crops of the Harappan period were chiefly of West Asian origin. They included wheat, barley, and peas. Of indigenous Indian origin were rice, tree cotton, and probably sesame. Rice first appeared in Gujarat and Bihar, not in the center of the Harappan culture in the Indus Valley. There is some rather doubtful evidence that African crops were also grown by the Harappans. There is a record of sorghum (*jowar*) from Sind and *Pennisetum* (*bajra*) from Gujarat. The earliest record of the African cereal, *Eleusine coracana* (*ragi*) is from Mysore, about 1899 BCE. The Southeast Asian crops of importance to India are sugar-cane and banana, and they both appear in the early literary record. Crops of American origin include maize, grain amaranths, and potato. The dating of the introduction of maize is uncertain, the characteristics and distribution of some forms being such as to lend support to the view that they reached India in pre-Columbian times. Crops of the Indian subcontinent have influenced the agricultural development of ancient Egyptian, Assyrian, Sumerian, and Hittite civilizations through their early spread to these regions of the Old World. The Buddhists took several Indian crops and plants to Southeast Asian countries, and there was much early exchange of plant material with Africa. The Arabs distributed crops such as cotton, jute, and rice to the Mediterranean region in the eighth to tenth centuries AD. There was also a reciprocal exchange of several New World domesticates.

Agriculture Today

India is characterized by a wide variety of climates, soils, and topographies. It is rich in biodiversity and a seat of origin and diversification for several crop plants such as rice, millets, pigeon pea, okra, eggplant, loofah, gourds, pumpkin, ginger, turmeric, citrus, banana, tamarind, coconut, and black pepper. Because India is ethnically diverse, traditional agriculture is still practiced in many places. There are about 100 million operational holdings, and the country has over 20% of the world's farming population.

India has different ecosystems such as irrigated, rain fed, lowland, upland, semideep/deep water, and wasteland. Agriculture is primarily rain fed (rain dependent); it supports 40% of the human population, 60% of cattle, and contributes 44% to the total food production. Owing to differences in latitude, altitude, variation in rainfall, temperature and edaphic diversity, great variety exists in crops and cropping patterns.

There are two important growing seasons in India: the *Kharif* or the summer season, especially important for rice; and the *Rabi* or the winter season in which major crop grown is wheat. The *Kharif* crop is primarily rain dependent, and the *Rabi* is relatively more reliant on irrigation. The *Kharif*/rainy season cropping patterns include major crops such as rice, sorghum, pearl millet, maize, groundnut, and cotton. The *Rabi*/winter season cropping patterns include important crops like wheat, barley and to some extent oats, sorghum, and gram/chickpea. Mixed cropping is also practiced, especially during the kharif season. Pulses, grain legumes, and oilseeds are grown with maize, sorghum, and pearl millet. Brassica and safflower are grown mixed with gram or even with wheat. Under subsistence farming, on small holdings, mixed cropping provides food security and is consumption oriented.

India is the major producer of a number of agricultural commodities including rice, groundnut, sugar-cane, and tea. Food grains constitute roughly two-thirds of the total agricultural output. These consist of cereals, principally rice, wheat, maize, sorghum, and minor millets. India is the second largest producer of vegetables next to China. Mango accounts for almost half of the area and over a third of production; banana is the second largest and is followed by citrus, apple, guava, pineapple, grape, and papaya. Of nonfood cash crops, the most important are oilseeds especially groundnut, short staple cotton, jute, sugar-cane, and tea.

Owing to improvements in recent years there has been widening of inter-regional disparities in agricultural production and productivity. Regions such as the north and north-west and the delta regions of peninsular India have prospered under assured irrigation, but dryland and semiarid regions have not done so well.

Agriculture in the Islamic World

LUCIE BOLENS

The success of classical Islamic agriculture is due to the adaptation of agrarian techniques to local needs, and this adaptation itself is due to a spectacular cultural union of scientific knowledge from the past and the present, from the Near East, the Maghreb and Andalusia. A culmination more subtle than a simple accumulation of techniques, it has been an enduring ecological success, proven by the course of human history.

In the definitions which open the *Kitāb al-filāḥah* (Book of Agriculture), this function is said to be blessed by God because it has as its end the production of the sustenance of life. Agriculture consists of restoring to the earth what has been furnished by harvesting from it, by fertilizing, watering and making efforts to avoid the problems caused by excessive heat. This restoration to the soil implies a knowledge of the whole – the soils, the plants, the most suitable tools. Balance (*mizān*) is the aim, or reciprocity between what is taken from the earth and what must be given back in order to make this vital alliance with Nature endure.

The complex union of facts with the general conjunction of the Mediterranean world between the eleventh and the fifteenth centuries means that a de-positioning of history is indispensable for understanding a crisis as well as a success. No progress is linear, and it is always useful to draw inspiration from the aleatory nature of history, in order that this discipline, fundamentally cultural, may also have a practical impact.

The successional right of the four Islamic judicial schools permits "holdings" according to a customary right which is similar to the right to private property of the Romans. Royal power encouraged territorial expansion among the princes of the blood and high officials of the state.

From a historical point of view, the important thing is the fact of reciprocal information throughout the *Dār al-Islām* (the Islamic world). There emerges the impression of a coherent school and a general movement – of people, goods and ideas – from the East to the Islamic West.

The ancient tradition, prolonged and recovered from the ancients (*al-Alwālī*), integrated the ideas of fourth century scholars like Aristotle, Dioscorides, Galen and Anatolius Democritus with those of the botanists of the ninth century and contemporary scholars of geoponics, the art and science of cultivating the earth. If the mysterious *Filāḥat al-Nabaṭiyyah* (Nabataean Agriculture, by Ibn Wahshiyyah, ca. 1000) traces the origins of agriculture back to Adam, those who lived in the classical age were equally inspired by knowledge obtained from anonymous farmers who retained the memory of ancient ways. Tradition and scientific curiosity have not always been at odds with each other.

On a religious level, the earth and water, as in the Hebraic tradition, belong to no one person; they belong to God. Historical accounts of Islamic expansion distinguish between Arab lands and lands situated in the conquered countries. Under the early caliphs, Arab lands were surveyed and registered. A basic tax was established, ten *dirhams* for a *jerib* of grapes, eight *dirhams* for a *jerib* of palm trees, six on a *jerib* of sugar cane, two on barley. The *jerib*, a unit of measure, equaled 360 cubits, according to al-Mawardī. The lands of people who freely converted to Islam were subject to a deduction of a tenth, *dīme*, varying according to province and century from the eighth to the twentieth centuries. In Andalusia, the tax was one-fifth. After the Reconquista, the farmers there continued to be called *quinteros.*

Lands which were forcibly conquered were redistributed. Al-Wanshārisī, a fifteenth century Maghreb legal expert, notes numerous examples for studying classical Islamic agriculture in Andalusia and the Maghreb.

Collective lands, *jema'a*, existed in certain parts of *Dār al-Islām*, used for the movement of flocks of large and small grazing stock. Cultivated land was also divided up legally and parceled out.

"Tributary" lands were conquered lands lying outside Arabia, beginning with Syria (Sham). They were considered lands not belonging to anyone, the property of the state or the caliph. By contrast, they were left to their former owners, according to a right of use. A land tax called *kharaj* was paid to the Treasury (*bayt al-māl*) and the amount of tax was set according to the quality of the soil. From the 700s, the principle was applied in the form of a supplemental tax to Jews, Christians and Sabeans, being the *Ahl al-kitāb* (People of the Book), or *dhimmis.*

Individual land holdings were called *iqtā;* they were lands grafted to a private individual according to clauses which were more or less restrictive depending on rents. All lands which the caliph gave to his subjects so that they might transform and cultivate them were so designated. *Waqf* lands were lands granted by private individuals to mosques, hospitals, schools and other charitable institutions. They are often translated as charitable properties. They were not subject to land speculation.

All these lands, except for the *waqf* properties, could be the object of commercial transaction – sale, rent, or purchase – which had nothing to do with feudal land statutes. In the twelfth century, the Sevillian Ibn Abdūn, in his *Treaty of Ḥisbās*, encouraged personal appropriation of land as a means of stimulating economic growth.

The information which appears in the documentation needs examining. It is based on experimentation which resulted in the shattering of prior philosophical premises. Empiricism appeared to be the condition of renewing knowledge and techniques. Ibn al-ʿAwwām writes: "I affirm nothing which seems right to me without having proven it in numerous experiments". In agriculture, the results refer to the practical successes of sheaves of grain, fruits, or taxes.

The theory of climates, *al-iklim*, compares Andalusia with Iraq and makes pertinent constant reference to Nabatean agriculture.

"Indeed", writes Ibn al-ʿAwwām, "what suits our country is the result of what comes from the concordance of tradition with experimental results". The respect for ecological balance – *mizān* – between the soil, the micro-climate, and various cultivated plants guarantees the success of the harvest. The "weather" governs the results, and the seasons are stated in the "Calendar of Seville" according to their names in Syrian, Persian, Hebrew and in indigenous romance languages. More subtle than a syncretism, it was a question of a whole society.

Islamic agriculture had, at first, been Arab agriculture, since Islam first appeared in the Arabian peninsula, among the Bedouins and camel drivers. Around the big cities, agriculture was the agriculture of the oasis, a natural miracle brought about by the presence of water in a desert of sand and stones. The history of agriculture in Islamic countries, established over a long duration as Fernand Braudel has described, is made up of a fundamental unity. The first great geo-climatic regions were sub-arid dominants around the Mediterranean basin. The Ummayyad empire, then the Abbasid empire, finally integrated the sub-tropical regions with temperate ones. However, the essential originality of Islamic agriculture is still linked to the Mediterranean regions and to the fluvial valleys. The first Islamic empires and the caliphate of Andalusia owed their agriculture to the great rivers carrying water and fertilizing silt (alluvium); the Tigris, Euphrates, Nile, Guadalquivir and the Guadiana all gave both soil and waterless, sun baked lands.

Between the seventh and the thirteenth centuries, the displacement of peoples and technical skills gave rise to a migration of cultivated plants, from the East towards the West, from subtropical zones towards the Mediterranean basin, from the monsoon regions to semi-arid lands; from China towards Persia, passing through India; and from Afghanistan towards the Fertile Crescent and the Maghreb, creating in its passing the gardens of Sicily and of Andalusia. Just as the ancient Romans constructed aqueducts and waterworks to provide food on a scale for the cities and municipalities which were their centres of power, so the Islamic empire, founded on caravan cities, also wove a net across the countryside of hydraulic equipment for agricultural adaptation, for example *acequias* [an earthern channel that conveys water], *qanats* [a water management system] and *norias* [a stone grinding wheel]. In spite of the progressive climatic diversification which occurred as the area ruled by Islamic law increased, from the Sudan to the Caspian seaports, from the Straits of Gibraltar to the boundaries of the Ottoman Empire and to India, the determining character of their agricultural system remained the adaptation of irrigation to local and regional needs and the spread of plant species away from their original ecosystems.

The spread of agricultural land and the intensification of irrigation in sub-Iberian regions which tended to be hot and very humid sub-arid areas were spectacular. Legal aspects of land holding were closer to those of Rome and Byzantium than the medieval West. Individual property ownership was actively encouraged.

Technological and cultural methodologies were informed by the need for renovation while remaining empirical. Among the agrarian jobs, that of the autumn harvest is characteristic in that the human job prevails over the financial investment. The swing plough was preferred over the heavy Brabout plough of the French colonist; not exposing the deep beds of cultivated land to erosion and intense heat was the golden rule of ecology in Andalusia. In the golden Andalusian age, this protection of the Mediterranean soils was subject to laws of a scrupulously careful ecology. The *mishā*, a heavy, hand-held spade was the tool for restoring the soil. The object of such agriculture was closing the soil, not opening it.

Among agricultural systems, the biennial rotation of crops is essential for maintaining fallow fields. Biennially or by a more complex number of years, but always by an even number, the rotation of crops shows a deep understanding of the plant world. The refertilization of soil, the base of all agriculture, comes about through the joint knowledge of plants and soils, the mastery of botanical and edaphic science. In Andalusia, well before the era of the English physiocrats of the 1800s, this agriculture revolution was closely based on high level of knowledge of the life sciences and on a love of nature which was the common gift of both the Islamic and the Hebraic tradition.

Certain plants modified dietary habits, for example sorghum, a common basis of diet in Asia and Africa; rice in flooded areas; sugar cane which is used for preserving and for therapeutics; the eggplant transported by the Jews in the second diaspora; citrus fruits from China; durum wheat from Africa, a nutritional mainstay in the form of bulgur and couscous; watermelons; and banana trees, acclimated in Egypt before arriving in the Maghreb and Andalusia.

The cultivation of other plants influenced styles and types of clothing throughout the Islamic regions. There was cotton, introduced to Andalusia after the arrival of the Kurd Ziriyab in the 900s, dye plants which brought a passion for Persian and Indian colours to the puritanical Berbers, and perfume which supplied the base of a whole range of products, such as lotions, salves, and soaps, and which was manufactured from the almost limitless supplies of fragrant flowers from Turkey and Morocco.

With a deep love of nature and a relaxed way of life, classical Islamic society achieved ecological balance, a successful average economy of operation, based not on theory but on the acquired knowledge of many civilized traditions, a society which wanted to live without the spectre of famine and hunger.

Colonialism seriously upset the traditional agricultural balance in order to increase profitability for the colonizers. This has been widely written about and is proven today by global economic realities. In the 1900s, colonial settlers and city authorities (wrongly) interpreted the indigenous practice of transhumance (moving flocks of animals from one area to another) as non-ownership of land. This distortion of a multisecular custom of complement between plant and animal husbandry (for example, in the Maghreb) caused grave damage to the native economy. Colonial agriculture thus found pseudo-legal advantages in a vast redistribution of land, which brought great economic benefit to the colonial settlers who had come out from the cities and towns.

We are witness today to the slow recovery of agrarian balance in former colonies like Algeria.

Agriculture in Japan

Mutsuyasu Ito, Kouichi Hiraizumi

Land in Japan has distinctive characteristics which make it suitable for organic produce. Because of this, agriculture has been the basis of most economic activity over the last 2,000 years. Historically, Japan was predominantly agricultural, but with the remarkably rapid growth of its economy after the Second World War, the country has been transformed into a heavily industrialized society. The Japanese have been abandoning their traditional food culture, which depends on rice plus other supplemental foods such as miscellaneous grains, vegetables, mountain plants, fish, and other sea products. They have instead been paying enormous sums of money to incorporate Western protein-rich foods from all over the world into their cuisine. In the meantime, rice consumption has decreased dramatically in the last 40 years, and the daily intake of nutritious foods such as meat, milk, and other dairy products, has increased remarkably, leading to a high demand for luxury foods. Within the Japanese agricultural sector, only rice is produced to the level of national self-sufficiency, while only 50% of the products derived from animals – themselves raised by feed concentrates which are nearly 100% imported – is supplied domestically (Table 1).

The early postwar effort to increase the production of food to meet human requirements actually led to a serious problem from around 1960, when the economy as a whole began to boom and agriculture began to decline. One of the present concerns connected with Japanese agriculture is the degradation of the rich, green nature of the country that the people had long admired as "the land of vigorous rice plants" (*Mizuho no Kuni*). At present, rice cultivation narrowly survives with the increased abandonment of agricultural fields and the deterioration of environments which the Japanese people had created over the past 2,000 years.

Geography, Climate and Resource Potential

The Japanese archipelago covers a rather wide area of sea. It includes 6,854 islands that extend from subtropical Ishigaki (24°N, 123°E) to the northernmost point of Hokkaidō at Wakkanai (46°N, 142°E). In this broad area are diverse landscapes and meteorological conditions, but most of the area has a temperate, monsoonal climate. The total land area is less than 400,000 km^2 (one-thirtieth of the territory of China),

Agriculture in Japan. Table 1 Domestic supply, importation, and domestic demand of various foodstuffs in Japan[a]

and the four main islands of Hokkaidō, Honshū, Shikoku, and Kyūshū are dominated by steep mountains that reach to around 1,000 m or even more above sea level. Because of the mountainous nature of the islands, the amount of flat land suitable for cultivating crops is less than 15% of the total area of land (Table 2).

In spite of its more or less cold winter, Japan benefits from a longer warm season and yearlong, ample rainfall, both of which are indeed useful for high-yielding crop cultivation. However the condition also accelerates harmful weed generation that disturbs pure stand formation of cultivated crops. The generally warm, moist climate, which provides high organic produce – almost equivalent to that of tropical rainy forest areas – has led to forests being the dominant vegetation throughout the archipelago. The geographical features present Japanese farmers with a difficulty in scale development of their farming, forcing them to make continual attempts to improve yield potential per unit area.

Origins of Japanese Farming Based on Paddy Rice

Despite the rich potential for organic produce, the actual start of paddy rice cultivation did not occur until several thousand years after its origin in the Yangtze River basin in the nearby Asian continent. Around 2,400 years ago, when the *Jōmon* Period (ca. 10,000 BCE–ca. 400 BCE; this period was dominated by hunting and gathering with straw-rope patterned [=*Jōmon*] pottery culture) ended, the arrival of the new immigrants from the continental mainland brought techniques for cultivating rice in paddies. As the *Yayoi* Period (ca. 300 BCE–ca. 300 AD, so-called from the place in Tokyo where the new type potteries were first unearthed) started, it replaced the lifestyle based on hunting, fishing, and gathering with one based on the cultivation of rice. Because irrigation techniques had been rather primitive when rice culture was introduced, swampy areas of mountain streams and basins, where water stagnated, were primarily used for cultivating rice. However, wooden farm implements such as hoes and spades were already very popular for working with improved *japonica* rice varieties, and even some ironware was used.

Soon after the introduction of paddy rice in northern Kyūshū in the fourth or fifth century BCE, paddy rice production and its associated technology are known to have moved eastward into the Kinki district where the Yamato Court later gained supremacy over all of Japan. At least 2,000 years ago, they had arrived in the Kanto district (around modern-day Tōkyō) and subsequently moved into Tōhoku (northern Honshū). The large *Yayoi* remains of paddy fields discovered at Taruyanagi in Aomori prefecture, at the northernmost end of Honshū (42°N), demonstrate that the diffusion of rice cultivation was very rapid and took only several hundred years at most, despite the large distance and different climates between northern Kyūshū and northernmost Honshū. Through experiments, Sato (1992) has endeavored to show that domestically improved thermo-sensitive varieties, which ripened early, were probably responsible for this rapid progress of rice cultivation in cooler areas.

Agriculture in Japan. Table 2 An abstract of land size, vegetations and agricultural land use in Japan

Item	Area (km^2)	Ratio (%)
(A) Total land size of Japan	377,887	–
Hokkaidō	83,407	22.1
Honshū	231,097	61.1
Shikoku	18,795	5.0
Kyūshū	42,144	11.2
Okinawa (Ryūkyū Islands)	2,264	0.6
(B) Forests[a]	249,180	65.9
(C) Natural grasslands[b]	4,158	1.1
(D) Secondary grasslands[b]	12,852	3.4
(E) Managed grasslands[b]	5,327	1.4
(F) Arable lands[a]	47,360	12.6
Those used for paddy rice	25,920	6.9

Agricultural Development in Ancient and Medieval Japan

The beginning of the *Yayoi* Period could be thought of as the dawn of agriculture in Japan, albeit with low productivity in poorly drained, wet rice fields. The remains of the Yoshinogari archeological site in northern Kyūshū demonstrate that the agrarian society of that time had a state-like political structure in which social stratification and classes resulted from individuals' riches or poverty. Agriculture is thought to have brought about these social arrangements.

After that, much higher technology for agriculture developed in the subsequent Kofun Period (ca. 300–700 AD; *Kofun* refers to tomb mounds prepared for rulers). The social and technological progress came with the introduction of advanced iron implements (hoes, plows, and spades led to deeper soil tillage), maintained waterways, and the orderly planting of rice, all of which resulted in higher yields and the further expansion of arable land. These developments were probably accompanied by a change from using stone knives to clip off the developed heads of genetically diverse rice population to using sickles to harvest the above-ground shoots of genetically identical crops with their heads attached.

Because of these developments, the Yamato Court was able to carry out social, economic and political reforms known as the Taika Reform of 645 AD (*Taika* is the name of the era between 645 and 650, which was first recorded in Japan) that promoted a centralized state similar to that in China at the time. In 701, the legal system, known as *Ritsuryō* (Criminal and Civil Laws) was established to govern the whole country, except for Hokkaidō (which was not yet Japanese territory). Under the *Ritsuryō* system, canal improvements, reclamation of new paddy fields, and rezoning of regular-size fields were all planned by the central government in an effort to significantly increase agricultural production. Since then, Japanese people depended greatly on rice as their main food and supplemented it with various other grains and plants. They did not raise livestock for consumption because Buddhism became the official religion in the eighth century. These characteristics of farming and cuisine that date to the period of consolidating central power in the archipelago continued over the centuries until very recently.

Although the best yields of rice in the Nara Period (710–794) were supposed to be less than 1,000 kg per hectare (one-sixth of the present yield in Japan), that figure is surprisingly high when compared to yields of wheat in England during the same period (Evans 1975). The introduction of rice was also advantageous for efficient food supply at the time because it required basically no fallowing of fields if they were regularly fertilized.

Governmental power under the Ritsuryō system, however, began to collapse in the middle of the Heian Period (794–1192) as private territories of powerful aristocrats, temples, shrines, and clans emerged as *shōen* (manors). The formation of *shōen* inspired owners to reclaim further arable land, especially from swampy areas. The farmers gradually supplied their own iron tools, which had previously been monopolized by the rulers. More precise management of water for the paddies came into existence, and agriculture appears to have become much more intense in all the rural areas. Attempts at double-cropping in paddy fields were undertaken in some areas to supplement yields in lean years. As central rule became weaker and weaker because of the social changes in the late Heian Period, officials in district branches, and the wealthy farmers, began to arm themselves, and their influential leaders formed bands of warriors known as *samurai*.

After a long struggle between samurai bands in various areas, the remaining two most powerful bands – the Genji and the Heishi – fought for national supremacy in the twelfth century. The war finished with the Genji in power and the beginning of the Kamakura Period (1192–1333) in which Japan was ruled by a samurai government. In this feudal period, a relationship developed between lords and vassals from the samurai class, in which the latter usually engaged in agriculture and managed the farmland as well as providing military service during wartime.

The establishment of manors and the intensification of agriculture in each locality resulted in a further rise of agricultural output that led to a second boom in land reclamation for paddies, and surplus agricultural products were gradually commercialized to create markets in various regions. The increasing economic strength of the lower classes, however, weakened the central power of the samurai government and drew Japan into a period of civil wars in the latter part of the Muromachi Period (the reign of second shogunate Muromachi, 1336–1573).

Unique Development of Japanese Farming During the Edo Period

Feudal lords in various regions began fighting each other in an era that has come to be known as the Sengoku Period (1467–1573; *Sengoku* refers to warring states). During this time, improving agricultural production and expanding arable land were the greatest concerns of the feudal lords (*Sengoku Daimyō*; *daimyō* originally meant “great paddy-field-owners”) because of the possibility of imminent warfare. They took control of paddy fields in their territories, even in hilly diluvial areas, by using the construction skills they had earned through their preparation for civil war. After taking over the entire country, Hideyoshi Toyotomi implemented a cadastral survey *(Kenchi)* known as *Taikō-Kenchi* (Hideyoshi was known by the title of *Taikō*) from 1582 to 1598. The survey involved measuring fields, ranking their productivity to estimate a tax base, and registering their landowners. It established the *kokudaka* (productivity, *koku* being a unit of measurement for rice) system in which the arable lands were legally graded in terms of average productivity. This brought an end to the system of direct rule by the feudal lords and determined land tenureship for small farmers.

Ieyasu Tokugawa defeated the Toyotomi family in the Battle of Sekigahara (1600) and completed the process of unifying Japan after the civil wars by establishing a new shogunate. Under the Tokugawa family, Japan in the Edo Period (1600–1867) flourished in seclusion from other countries, and each of the surviving *sengoku daimyō* was regulated by a *shōgun* (military general). Because the *daimyō* could no longer acquire more territory because of the strict Tokugawa regulations, the only way that they could expand their power was to reclaim land or to improve their fields to get better yields. This led to improved irrigation systems within the big river basins and diluvial tablelands that could not previously be well controlled, and also to improved technology for crop cultivation.

Despite the overall developments in agriculture, however, the farmers who got their own lands through *Taiko kenchi* were not allowed to move or even to choose another livelihood under the rigid feudal system. Furthermore, most of their harvested rice was collected by the *daimyō* as a tax, which left the farmers with relatively little rice and therefore, a spartan existence. The tax was usually paid in kind by harvested rice at the rate of 30% at the beginning of the period, and later it went much higher. "Don't let the farmers survive well but don't kill them either," is thought to be the principle of Tokugawa's governing policy throughout the Edo period. Under such a severe regime, and because of it, many farmers made remarkable improvements in technology for raising field crops other than rice, especially for those which were cultivated upland. The use of human manure as a fertilizer was a profound development at this time, as were the thorough use of resources and technological improvements in recycling that are informative even for today's societies.

During the Edo Period, many books called *nōsho* (writings on agriculture) were written, and some of them were even published in xylography and distributed widely. Publications to describe agricultural technology and various local varieties contributed to further technological improvements and an examination of traditional varieties. In a sense, an original agricultural science, rooted in the traditional culture of Japan, came into existence, and the most notable work in the first half of the Edo Period was the *Nōgyō Zensho* (Complete Writings on Agriculture, 1696) by the lordless samurai Yasusada Miyazaki (1623–1697) in northern Kyūshū. This was a practical textbook that was based on Miyazaki's comprehensive knowledge acquired over years, while the basic style of the book followed the famous Chinese *Nóngzhèng Quánshū* (Complete Book on the Administration of Farming, 1639) which was written by Xú Guāngqǐ late in the Ming Dynasty. Miyazaki had long regretted that the life of farmers required hard labor and low incomes because of their paucity of knowledge about the principles of agriculture, so he published information about the available scientific principles and technology that was easily put to use anywhere in the country. His book greatly influenced agriculture throughout the Edo Period, and it was reprinted repeatedly over 150 years, almost until the end of the Edo Period.

The Tokugawa shogunate built many roads which originated in Edo (present-day Tōkyō) or Ōsaka in the seventeenth century. Various sea routes for shipping were also established, so an integrated system of transportation throughout all of Japan was progressively built. Because the *daimyō* wanted to sell their rice to merchants and encouraged the cultivation of other cash crops to be marketed, transportation became very important, especially between regions. Nagatsune Ōkura (1768–1860?), one of the most famous scholars of agriculture late in the Edo Period, wrote many volumes on agriculture and particularly wrote textbooks about cash crops. He also prepared manuals on agricultural equipment, and wrote about plant protection. The books he wrote were useful, as agricultural production techniques were then thriving. The application of these techniques resulted in the prosperous cultivation of rapeseed, cotton, and other industrial crops in the Kinki district and the rise of the processing industry near Ōsaka that increased the amount of merchandise available for distribution.

Despite the remarkable growth in productivity, farming throughout the Edo Period still depended on human power. Although plowing with draft animals was practiced to some degree in and around the Kinki district, it did not spread throughout the country, partly because the traditional long-soled plows were less efficient than hoes for deep tillage in paddies to get higher yield with a higher level of fertilizer use. Hence, labor-intensive cultivation continued to dominate and relied on specialized hoes and spades. In his *nōsho* (An Investigation of Usefulness of Various Agricultural Tools), Nagatsune Ōkura precisely illustrated a diverse range of hoes modified for various purposes or soil conditions.

Another example of prosperous development of farming was found in sericulture, the process of raising silkworms and producing silk yarn from their cocoons, in the late Edo Period. Instances include thermal management of silkworm development and crossbreeding of various productive strains. These later contributed to the further development of sericulture and silk spinning industries in the following Meiji Period.

Modernization in Agriculture After the Collapse of the Tokugawa Shogunate

In the second half of the nineteenth century, under the pressure of Western powers, Japan opened itself to international relations. The Tokugawa regime lost its ability to govern effectively, and the feudal system finally came to an end in 1868. The new government under the restored emperor began to modernize Japan along contemporary Western lines. As Japan had no particular source of revenue except for agriculture at that time, and since 80% of the population belonged to the agrarian class, the collection of land taxes was of great concern to the new government. Introducing Western agricultural technology (*Taisei nógaku*) was therefore an urgent project for the government, which wanted to increase the wealth and military strength of the country in order to catch up with the European powers and the United States in a short amount of time.

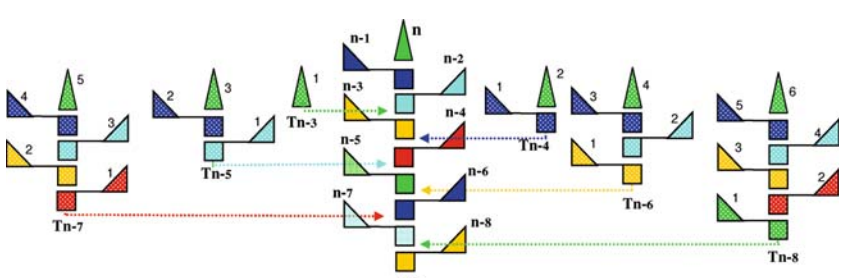
However, the Westernization of Japanese agriculture at the very outset was not as successful as it was with industrialization. British scientists who specialized in agriculture, and who were among the first foreign experts to be invited into the country, did not do well at solving problems facing Japanese agriculture. They simply tried to bring their own style of agriculture without any modification and did not consider the different state of affairs that existed between Japan and their homelands. However, a few European scientists used a different approach to developing Japanese agriculture by evaluating traditional technology and knowledge. For instance, excellent researchers such as Max Fesca from Germany made a huge effort at scientifically analyzing traditional Japanese techniques of cultivation, applying Western technology to suit the needs of Japanese agriculture and developing new technology for practical cultivation. So-called *rōnō* (*rōnō* refers to farmers with outstanding farming knowledge), who had fully mastered the knowledge and skills of traditional agriculture, also played an active part in the modernization of traditional agricultural technology and its extension throughout the country in the late nineteenth century.

In the early twentieth century, Japan had nearly completed establishing a public system of education and scientific research based on Western models. As centralized power became stronger through and after the First World War, research at institutes and universities contributed to the remarkable increase in agricultural production from 1920 to 1940. Studies on the genome of wheat strains by Hitoshi Kihara, the autumn deterioration of paddy soils by Matsusaburō Shioiri, and the selection of the famous Nōrin No. 10 wheat variety (*Nōrin* is the abbreviation for the Ministry of Agriculture and Forestry) by Gonjirō Inatsuka, were all world-renown accomplishments prior to the Second World War.

Through repeated crossing with various native varieties from Mexico, the Nōrin No. 10 later obtained high yielding dwarf varieties, which increased wheat production in developing countries dramatically through the "Green Revolution". Also pursued was the concept of "synchronism in tillering and tiller development in rice, wheat, and barley crops" established by Tsukuda Katayama, which led to precise technology for monitoring the growth and improving the yield of grain crops (Fig. 1). In Western countries, "phyllochron" (leaf appearance interval) studies have been initiated in the last 30 years to take precise control of the growth of improved wheat and other crops. In fact, Katayama and his students had completed the principle of phyllochronic development of grain crops more than 50 years ago; the original studies, written mostly in Japanese, were hardly read by Western researchers. The abovementioned scientific achievements principally contributed to much higher productivity, which had remained unchanged in traditional, labor-intensive agriculture in Japan.

The Dramatic Transformation After the Second World War

Warfare throughout the 1930s to 1945 in the Far East came to an end with the unconditional surrender of the Japanese Empire. This defeat gave the Japanese people an opportunity to replace an autocratic system with a representative democracy akin to those in Western Europe. A thorough land reform was undertaken under the auspices of the occupying powers, mainly the United States, and among its achievements were the abolition of the parasitic landlordism (*jinushisei*) and



Agriculture in Japan. Fig. 1 A schematic illustration of Katayama's Concept on tillering regularity in rice, wheat and barley plants – the synchronism in tillering and tiller development. Mother shoot (MS), which forms her leaves in constant interval in any order, generally bears her daughter tillers regularly in parallel with successive leaf formation of MS, so that the new tiller appearance at the age of "*n*"th leaf emergence of MS usually becomes apparent at the leaf axil of *n*–3 and the tiller develops further with homologous leaf formation, resulting in successive increase in leaf number in lower daughter tillers. Thus the grain crop plant is an integrated unit of synchronously appeared tillers in various orders and synchronously developed leaves on synchronized tillers while showing different appearance. In the figure, (Δ) indicates the top elongating leaf on any time. (⊾) denotes the expanded mature leaf attached to any node (□) of MS or daughter tillers. Arrow is the position of the leaf axil with which successive daughter tiller is subtended. Daughter tillers are numbered acropetally with the codes as…Tn-5, Tn-4, and Tn-3, being subtended by… "*n*–5"th, "*n*–4"th, and "*n*–3"th leaves of MS, respectively. Number noted by each leaf of daughter tiller indicates the leaf position as counted from the initial foliage leaf of each tiller. Leaves with the same color denote the synchronous emergence (and analogy in size) on different tillers. The Katayama's Concept shown above had been very useful tool for developing the intensive technology in rice plant cultivation in Japan during the Postwar period.

the creation of independent farmers, mainly from the ranks of the previous tenant farmers. The newly created independent farmers struggled to improve their yields of rice, even though their small, scattered landholdings put them at a severe disadvantage.

Among the early postwar developments was the almost entirely Japanese original machine called the *kōunki*, a cultivator which reduced the amount of hard work required from farmers and stimulated agricultural growth in the first decade after the war (Fig. 2a). Remarkable progress was also made in the technical development of farming materials such as pesticides, insecticides, herbicides, plastic films used for soil mulching and simplified greenhouses, all useful for small-scaled, intensive agriculture in Japan. Advances in efficient fertilization, such as top-dressing at the ear-formation stage proposed by Shingo Mitsui, led to stable, high rice yields as well. When the farmers achieved an abundant harvest of 12 million tons of rice in 1955, the government declared that the country was in "no postwar situation any longer!"

From 1955 to 1973, when an international oil crisis interrupted its progress, Japan experienced rapid economic growth. The labor force for this growth was supplied principally by a rural-to-urban migration so that the number of agricultural workers fell from 15 million (38% of the entire work force) in 1955 to 6.7 million (13%) in 1975. This transfer of labor from agriculture to manufacturing originally comprised younger sons and brothers of independent farmers, but later, other members of households began to take on part-time work outside agriculture and, by 1965, the ratio of farmers with side jobs exceeded 40%.

In 1961, the Basic Agricultural Law (*Nōgyō Kihonhō*) was enacted, after a massive outflow of people from the countryside had become apparent, and aimed to make farmers economically self-reliant with incomes about the same as those for urban laborers. Administering the law concentrated on improving the productivity and efficiency of labor in agriculture through mechanization; the government did in fact succeed in improving agricultural labor productivity.

Thus, rapid economic growth after the Second World War improved the standard of living for farmers – much more quickly than had been the case in Western Europe – and they have been relieved of a lot of heavy

Agriculture in Japan. Fig. 2 Characteristic improvement of small-sized machines that facilitate labor intensive cultivation in rice-growing paddy fields in Japan. (a) *Kōunki*, the innovative cultivator that was intensively developed and iteratively refined during the postwar period in order to improve labor efficiency in small-sized fields covered with heavy and wet soils. The improved machines achieved the easier and quicker farming practices in labor intensive agriculture, relieving farmers who had previously been forced to work very hard using manpower alone. (A scene showing students from Hokkaido University, 1976. Photo taken by Michiaki Ito, Niigata University. Used with his kind permission) (b) An early type of rice transplanter machine under development. The crawling machine was being used to research labor efficiency in a paddy field in Hokkaido University (1968). A series of extensive projects for the innovative development of rice transplanters was made in late 1960s in order to lighten the heavy labor burden that required almost 100 persons/hectare/day for transplanting rice seedlings by hand. (Photo taken by Michiaki Ito, Niigata University. Used with his kind permission.) (c) Improved rice transplanter in action in the paddy rice fields of a part-time farmer that owns 3 or 4 hectares of land. Those part-time farmers normally complete routine tasks in 3 or 4 days during holidays in May. (d) A rice combine harvester in action to harvest the yield of a well ripened rice crop, being easily operated by an aged farmer (Niigata, September 2004). Rice harvesting, which was once one of the most labor-intensive farming activities, is now usually completed by low numbers of people – around one person/hectare/day or less.

labor by such machines as four-wheeled tractors, rice transplanters (Fig. 2b,c), and rice harvesters (Fig. 2d) (the last two being Japanese originals) as well as various unique farming tools useful for Japanese intensive agriculture. However, the changes also created a serious inconsistency for the existence of traditional agriculture. The population of farmers decreased dramatically to about 6% of the Japanese total in the past half century, and most of them are living as part-time farmers dependent to a large extent on other industries. In the meantime, Japan has been simply exhorting the agricultural sector "to be efficient economically", hence its output of such crops as wheat, barley, soybeans, and buckwheat gets beaten in international competition. Rice cultivation now narrowly survives but is dependent on being located in optimal environments as well as the official policy of protection. The current, apparently irreversible trend foreshadows the increasing abandonment of agricultural land usage, further alienation of seminatural environments and the inevitable decline of Japan's agricultural practices and traditions which had been developed over almost two millennia.

Agriculture in the Pacific

William C. Clarke

The environments where traditional agriculture was practiced in the Pacific Islands ranged from frost-prone but gardened mountain slopes at 8,500 ft (2,600 m) in Papua New Guinea to tiny atoll islets lying scarcely above the reach of the waves in the always warm equatorial ocean. Heavy downpours almost everyday keep some places in the Pacific Islands permanently humid; short wet seasons followed by long dry spells characterize the rainfall in other places. Still others with almost no rainfall are true deserts. Some single islands contain this whole range – the big island of Hawaii, with its high, massive volcanoes and its sharply contrasting windward and leeward coasts, is a notable example of such climatic variety. A comparable dissimilarity exists in Pacific Island soils, with some young volcanic soils being highly fertile, whereas on atoll islets the only natural soil material may be rough coral rubble, which is alkaline, has a very low water-holding capacity, contains little organic matter, and is unable to supply plants adequately with many of the nutrients required for vigorous growth.

Traditional Pacific Island agriculturalists met this wide range of often challenging conditions with an even wider range of agronomic techniques and crops, which enabled food production on all but the most barren islets or at the highest elevations of the larger volcanic and continental islands. This universe of agroecosystems included elaborate terracing and irrigation to grow the water-loving taro, massive drainage works to grow less water-tolerant crops such as sweet potatoes, mulching and composting to enrich the soil and to slow water loss, planting crops in built-up mounds of soil to encourage cold-air drainage and so lessen frost damage, planting in excavated pits to reach the water table on dry atoll islets, and (in systems of shifting cultivation) the use of forest or woodland fallow – planted in some places, spontaneously natural in others – to restore fertility to soils after they had been gardened.

The Origin and Evolution of Pacific Island Agriculture

When, from the sixteenth century onwards, European explorers began to encounter the sophisticated Pacific Island agriculture then practiced, it was not surprising that some of them believed they had sailed to a Garden of Eden, where breadfruit trees and coconut palms provided food without work, and where only a little labor was needed to make irrigated terraces of taro bear heavy harvests of starch-rich corms or tilled beds of sweet potatoes produce many baskets full of nutritious tubers. Initially, Europeans saw this productive agriculture as though it were some sort of a divine gift given to the Pacific Islanders, who had been favored with gardens and orchards that yielded unchangingly through time and that remained continuously in harmony with local environments. It is now clear on the basis of the extensive research into Pacific prehistory carried out only over the past few decades that such a view is far from accurate.

Pacific Island agriculture has never been static. It has been evolving constantly from its beginnings, as migration led people to new environments where there were previously unknown wild plant species, as the agriculture itself changed the environment, as the need for food expanded with growing island populations, as new crop plants were introduced, or as the agriculturalists experimented and introduced productive innovations. The Pacific Island agriculture first seen by Europeans was only an instant snapshot of a long and very dynamic history.

Twenty-five years ago it would have been asserted confidently by many scholars that Pacific Island agriculture had originated in southeast Asia and that Pacific Island cultivated plants had been domesticated in that same hearth. All that the ancestors of Pacific Islanders had done was to carry the Asian techniques and crops with them as they dispersed to the farther oceanic islands. It was recognized that the sweet potato and a few other less important crops did not fit this scenario, having been shown to have originated in the American tropics. However, the presence of these exceptions was explained away by various, often fanciful, theories of migration or simply as the result of introductions by Portuguese or Spanish voyagers during the fifteenth and sixteenth centuries – though recent archeological research in the Cook Islands (central eastern Polynesia) shows the sweet potato to have been present there by about AD 1000.

We know now that although some plants of Southeast Asian origin and domestication were transferred without significant change far into the Pacific (some species of yam, for instance), there is also evidence in support of early indigenous domestication and development of agriculture in the Pacific, specifically in western Melanesia (Solomon Islands and the island of New Guinea). The length of occupation there (at least 40,000 years in New Guinea) is more than sufficient for the experimentation necessary for independent domestication. And chromosomal and paleobotanical studies now indicate that plants that may have been domesticated in this region include sago, one type of *Colocasia* taro, one kind of banana, sugar cane, *Canarium* (a nut-bearing tree), *Saccharum edule* (a relative of sugar cane with an edible inflorescence), *kava* (the ritual and social drink still important in many parts of the Pacific Islands), and a variety of other plants, including several fruit trees. This attention to trees and the creation of orchards is a characteristic of food production all across the Pacific and was probably carried by itinerant colonist-cultivators from its place of origin in western Melanesia to Polynesia and Micronesia.

Further, especially strong evidence for the early development of agriculture to the east of southeast Asia comes from an archeological study in the Papua New Guinean highlands at a place called Kuk. A great deal has been written about Kuk, and the evidence has been interpreted in various and changing ways, but there is general agreement that Kuk demonstrates a long history of agricultural development, beginning about 9,000 years ago and involving, among much else, an ever-growing complexity of drainage works and water control in a large swamp, changes over time in cropping combinations from mixed gardens to taro monoculture to sweet potato dominance, responses to deforestation and land degradation brought about by shifting cultivation on the surrounding slopes, and the development of planted or encouraged tree fallows. Kuk, as well as evidence from prehistory elsewhere in the Pacific, shows that a dynamic agronomic and botanical science has long existed in the Pacific, in terms both of basic understanding and applied techniques. The origins of agriculture in the Pacific can now be said to have a time depth comparable to that of better known sites in southwestern Asia and tropical America.

No less mistaken than the view that traditional agriculture has been static in the Pacific Islands is the view that it has always been in harmony with its environment. Rather, as in the history of any dynamic agriculture, there have been episodes of deforestation, serious soil erosion, land degradation, and crop failure. Pacific Islanders did what all peoples, especially pioneers, do: in their efforts to make a living, they actively manipulated, modified, and, at times, degraded the ecosystems in which they lived, producing environmental changes that in turn required ecological adaptations and social adjustments. Considering the whole landscape, the most widespread of the human-induced changes in the prehistoric Pacific has been deforestation, with the cleared forests replaced by grasslands that required cultivation techniques different from those associated with forest-fallowed gardens. In many places, fire-maintained fern grass savannas underlain by infertile, eroded, or truncated soils came into existence or were extended by agricultural activities. This distinctive plant – soil complex is known as *toafa* in several Polynesian islands and as *talasiga* in Fiji. These dramatic landscape changes resulting from pioneering clearance for agriculture did not, however, bring unmitigated environmental degradation. Rather, in many places, they resulted in what has been termed "landscape enhancement," whereby the eroded soil transported down the slopes filled in the lower valleys and created swampy zones that were ideal sites for what came to be sustained yield, intensive cultivation of wetland taro. Other responses included the development of dryland cultivation techniques to cope with the changed agricultural environment, irrigated terracing, and an elaborated use of trees.

Traditional Agriculture in the Pacific Islands

The wide range of agricultural systems and techniques devised by Pacific peoples over millennia can be considered as ways of solving the agronomic problems presented by the great variety of island environments. For instance, in forested areas of low population density, soil fertility was maintained by simple no-tillage shifting cultivation wherein natural forest fallow rehabilitated the soil after gardening. Where forest was diminished, leguminous or other nitrogen-fixing trees (such as *Casuarina* spp.) were encouraged or planted. In grasslands a variety of mulching and composting techniques were developed. On atolls where soil was poor or absent and rainfall often low, Islanders created an ingeniously productive and sustainable agricultural environment for the giant swamp taro (*Cyrtosperma chamissonis*) by excavating a pit to reach the water table ("the freshwater lens") below the coral rubble and building up fertile soil in the pit by composting leaves of breadfruit and several other wild or semidomesticated trees as well as seaweed, pumice, and other materials.

The management of wet and dry conditions by irrigation and drainage was widespread and ranged from very simple ponds and small ditches to elaborate, kilometer-long, stone-lined channels and extensive hillside terracing. Irrigation and drainage were not necessarily spatially exclusive in that the ditches that drained water away from sweet potato beds were used to provide a moist growing site for taro and other water-loving crops. Water control may also have been used to control insect pests. As population densities increased or as political control expanded enabling greater labor mobilization, some systems of wet cultivation of taro in Polynesia became very intensive, productive of yields as high as from 30 to 60 metric tons per hectare.

The agricultural tool kit of the traditional Pacific was simple, mostly derived from unprocessed natural materials: wood, plant fiber, stone, shell, and bone. Wooden spades were elaborated in places where tillage and swamp cultivation was common. Wooden hoes were made here and there but were rare. The paramount agricultural tool was the digging stick. Used for loosening soil, digging roots and corms, making holes for planting and house posts, or as poles for carrying burdens, digging sticks ranged in size from heavy, two-meter, two-man tools used cooperatively to turn grassland or swampland sod to the light sticks used by girls to open shallow holes in soft forest soil. They remain widely in use today, and modern technology has yet to find a better tool for planting taro.

Before being replaced by steel tools, stone adzes and axes were effective in opening vast areas of forest and were far more sophisticated than they might seem at first glance. For instance, the cutting edges of stone axes might be facetted and asymmetrical to make resharpening more effective and to prevent the blade sticking in the tree during felling. Wooden spades and the way they were handled had similarly subtle attributes.

Organization of agricultural labor varied across the Pacific, with, for example, men doing the clearing but women most of the gardening in Melanesia, whereas in Tonga and Samoa in Polynesia men carried out all the agricultural tasks. Traditional Pacific livestock comprised the pig and chicken. Pigs were of great importance ritually and socially in many places and were a way to "bank" the food produced in tuberous starchy vegetables, which did not store well. During the periods when pigs were being accumulated for ceremonial feasts, considerable land and agricultural labor would be devoted to producing their food.

Like all traditional agriculturalists, Pacific Islanders possessed an enormous store of knowledge about both the domesticated and the wild plants and animals in their environment. This indigenous knowledge was organized by means of complex folk taxonomies that provided a framework for pleasurable intellectual activity as well as serving practical purposes. Similarly, aesthetics was a part of Pacific Island science of agriculture and land use management. Pacific people in traditional landscapes enjoyed the arrangement of productive diversity all around. Medicine here, perfume there, fiber in the hibiscus stem, fruit, timber, edible leaves, and so forth. There is a strong aesthetic pleasure in these observations of utilitarian diversity. As Malinowski (1935) wrote about the Trobriand gardens he made famous in Papua New Guinea:

> The gardens are, in a way, a work of art. Exactly as a native will take an artist's delight in constructing a canoe or a house, perfect in shape, decoration and finish, and the whole community will glory in such an achievement, exactly thus will he go about the laying out and developing of his garden. He and his kinsmen and his fellow-villagers as well, will be proud of his labours… During all the

successive stages of the work, visits are exchanged and mutual admiration and appreciation of the aesthetic qualities of the gardens are a constant feature of village life.

In the Pacific, as elsewhere, the complexity of traditional agriculture has undergone a simplification in modern times. Polycultural gardens of subsistence crops have been replaced by monocultural stands of commercial crops such as coconuts, ginger, coffee, and citrus. Intensive systems of irrigated taro or dryland yam cultivation have fallen out of use, often replaced by the less demanding cassava (manioc). On the other hand, with the current interest in locally based sustainable development, there is a growing concern to revive some of the indigenous traditional systems that served Pacific Islanders well in their past.

Agriculture in South and Central America

Karl H. Schwerin

Conquest of South and Central America by the Spanish and Portuguese in the sixteenth century was rapidly followed by the introduction of Old World crops. These included both those familiar to European farmers, such as wheat, barley, oats, and many temperate vegetables and fruits catering to European food tastes, as well as tropical crops from Africa and Asia, such as bananas and plantains, sugar cane, and rice. At the same time many American crops were carried to the Old World – the most important being maize, potatoes, manioc, beans, and squash.

From the time of conquest to the present, agriculture in this region has been dichotomized between small-scale subsistence farming and large-scale monocrop operations producing for profit. Their development is summarized here.

Some native agricultural methods continued, such as swidden agriculture in temperate and tropical forested regions, field cultivation with the foot plow in the Andes, and intensive *chinampa* agriculture in central Mexico. Other techniques such as terracing declined, or as with raised fields, disappeared altogether. The small

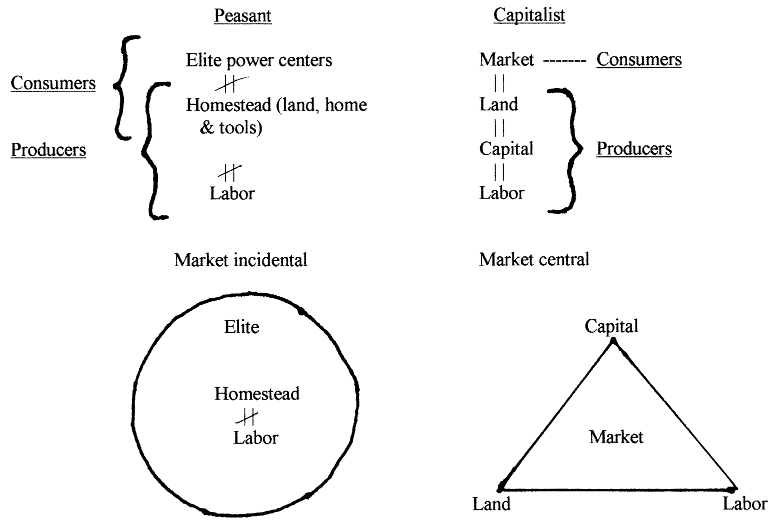
farmers incorporated some European crops as staples – wheat in Mexico (principally among mestizo farmers), barley in the Andes, onions, cabbage or collards almost everywhere. Bananas and plantains spread rapidly throughout the tropics. Agricultural technology continued much as before contact, perhaps because it was appropriate to traditional agriculture which, though small-scale, was highly productive.

Although early colonial institutions such as the *encomienda, corregimiento*, and *repartimiento* were designed to exploit native labor and mineral resources, they also produced surplus foodstuffs to support the European population, mining, and colonial administration. As native populations declined, large land holdings were granted to Spanish and Portuguese immigrants. Some were cultivated dilatorily, but others were transformed into plantation enterprises producing sugar, tobacco, cacao, indigo, or cochineal (a red dye obtained from the crushed dried bodies of female cochineal insects, used to color food and drinks and to dye fabrics) (also cattle, sheep, and horses) which soon supported a lucrative trade with the home country. Most plantations were dependent on slave labor. Sugar, consumed raw or distilled into *aguardiente* or rum, became the principal economic enterprise in Brazil and the Caribbean, and was particularly dependent on slave labor.

By the eighteenth century mining became concentrated in a few rich areas. Agriculture acquired more importance in the colonial economy. Land grants were increasingly cultivated to supply colonial needs for food grains and raw materials such as cotton. The *hacienda* became the vehicle for accomplishing this production. Labor was secured through mechanisms such as debt peonage and was administered in such a way that it was almost impossible for the individual laborer to break free.

After independence early in the nineteenth century, slavery was gradually abolished throughout the Americas. The hacienda, however, continued as a major system of ensuring agricultural labor. It only began to disappear with the Mexican Revolution of 1910. Though much less important today, it continues to operate in some Andean countries and in parts of Brazil.

The nineteenth century was marked by widespread expansion of agricultural capitalism in the form of plantation systems producing a wide variety of crops for industrial and consumer markets in Europe and North America. These included *henequen* (fiber obtained from the leaves of the henequen agave plant, used in making rope, twine, and coarse fabric) from the Yucatan, bananas in Central America, and sugar in the Caribbean and Brazil. Coffee, one of the most profitable crops, was widely introduced, from Mexico



Agriculture in South and Central America. Fig. 4 The peasant economy versus the capitalist economy.

to Brazil. In Mexico and parts of Central America, small farmers produced it; in Costa Rica and Colombia medium sized farmers were the rule; elsewhere large coffee *fincas* predominated. Particularly in the latter case, land was intensively exploited, without efforts at conservation or improvement, leading to rapid deterioration in soil quality and declining production. Where land was abundant, the response was to clear virgin land and plant new coffee groves. Uruguay and Argentina became major world producers of wheat, owing to the rich Pampean soil. In both Brazil and the pampas, immigrant labor was employed to clear the land, in exchange for temporary usufruct of part of the cleared area. Evicted after a time in favor of the landowner, some immigrants acquired their own (usually smaller) farms, but most withdrew to the cities, leaving only the larger *fincas* and *estancias* as significant agricultural producers.

Several different systems of agricultural exploitation can be identified in this region today. Yet agriculture has declined in importance in national economies throughout the century, dropping precipitously since 1980. Only in Central America, Mexico and Brazil is 15–30% of the work force still farming, in most countries only 10% is still employed in agriculture, which represents less than 10% of the GDP for the region.

The persistent dichotomy between large, extensively cultivated holdings (*latifundio*) and small, intensively cultivated properties (*minifundios*) survives today. Though these are sometimes geographically separated, they frequently occur interspersed with each other interacting as a symbiotic whole. This dichotomy is also

A

at the root of many economic and social problems. Although precise data on distribution of agricultural landholdings have not been reported since the 1970s, the extreme bimodal distribution has probably not changed significantly. In El Salvador, Guatemala, and Peru more than 90% of agricultural landholdings were under 10 ha, yet represented only about 30% of the area. In contrast, 26% of the area in Guatemala and 61% of the area in Peru were larger than 1,000 ha, yet represented less than 0.5% of the holdings.

Some small-scale specialized farming techniques survive in scattered locales, such as localized irrigation systems, *chinampas* in the Valley of Mexico, drained fields among the Karinya in eastern Venezuela (Figs. 1 and 2), or terraces and lazy beds in Mesoamerica and the Andes. Traditional methods of agriculture generally promote ecological stability both because environmental disturbance is minimal and because the agroecosystem is stable. Unfortunately, development, modernization, and institutional pressures from the larger society often lead to abandonment of these techniques, in spite of their suitability to local conditions and often exceptional productivity. Thus most irrigation has been modernized and commercialized and relies on pumping, reservoirs, and lined canals. Yet there are efforts in some places to reintroduce ancient agricultural techniques, like ridged fields in the Titicaca Basin, which have proven superior to current practices. Many traditional practices should be preserved in order to exploit their productive advantages, utilize marginal microenvironments, maintain crop diversity, and minimize production risks.

Swidden agriculture or shifting cultivation is still widely used in forested regions. It may support as many

as 50 million people. It is relatively productive and successfully integrated into the ecological regime of the tropical forest, yet requires less labor than many other methods. It is a technology that does not require capital investment or energy subsidies. When associated with sparse populations its environmental impact is minimal, perhaps even beneficial by stimulating renewed forest growth. When intensified to the point that the forest can no longer replace itself, swidden may produce widespread environmental degradation. Rapid population growth throughout Latin America has spurred migration in search of farmland in lowland tropical forests from the Peten and the Caribbean coast to the Amazon basin. Resulting widespread deforestation has had serious ecological repercussions.

supplementary food, condiments, herbs, medicinal remedies, fuel, fertilizer, and ornamental plants (Fig. 3).

Peasant farmers conduct most small-scale agriculture. A true peasant owns or controls his land, runs his own operation and makes his own decisions independently. The primary production objective is for subsistence and survival. Peasants do not think in capitalist terms, but instead are oriented around the homestead (land, home, tools), which cannot be converted or exchanged for other means of production (see Fig. 4). Because cash is

Agriculture in South and Central America. Fig. 29 Peons harvesting *mellocos* (*Ullucus tuberosus*). Hacienda El Colegio, Cañar, Ecuador. September 1969. Photo by Karl H. Schwerin.

limited, the peasant cannot afford to take risks; he often resists trying new crops and techniques; technology remains traditional (paleotechnic).

The strength of peasant farming is its heterogeneity and diversity. Planting a variety of crops, in several locales, under varying conditions, minimizes risk. The most important crops are starchy staples – grains or root crops – and legumes; perhaps supplemented by a high value cash crop – tomatoes, coffee, or narcotics (Figs. 5–17).

Large holdings can be roughly divided into haciendas, estancias, plantations, and agroindustrial enterprises. Hacienda organization represents a unique adaptation to abundant land and scarce capital. Labor to work the estate is attracted by offering small subsistence plots to local smallholders or landless laborers (most commonly known as *peons*). Traditionally little or no

CHARACTERISTICS OF THE PLANTATION

Distinguishing Characteristics of the Plantation

1. Sharp separation of classes
2. Capitalistic enterprise
3. Monocrop specialization
4. Continuous commercial production

(2–4:) Hacienda lacks these, tends toward self-sufficiency

plantation - A capitalistic type of agricultural organization in which a considerable number of laborers are employed under unified direction and control in the production of a staple crop for sale to an external market. (Sidney Mintz)

Contrasts Between the Hacienda and the Plantation

Hacienda	Plantation
abundant land	pervasive control of the land
scarce capital	abundant capital
pervasive control of labor	scarce labor, often mobile
tries to avoid wages	relatively high wages
ownership by family or traditional institution (church, government)	ownership by company or corporation
personalistic & paternalistic	universalistic & impersonal
economically inefficient	economically efficient
paleotechnic	neotechnic, often highly mechanized
produces for domestic market	produces for external market
participates in regional and national power structure	participates in international power structure

wages exchanged hands; today real wages may actually be paid, although they are often seriously in arrears because capital remains scarce. For the same reason haciendas try to be self-sufficient in terms of basic needs. They also tend to be inefficient, relying on antiquated technology and cultivating only a small area of the best land, leaving the rest uncultivated or in the hands of the workers. Yet their production of staple cereals and tubers, or milk, meat, and wool may contribute significantly to national economies. Hacienda property may be viewed more as a basis for prestige or a hedge against inflation than as an income producer. For this reason, as well as scarce capital, haciendas also tend to resist innovation. Most surviving haciendas are found in highland areas of the Andes and Mesoamerica,

though they have also been the object of land reform from Mexico to Bolivia, Peru and Ecuador (Figs. 18–29).

Estancias are large holdings devoted to livestock production found mostly in the Southern Cone and northern Mexico, although in recent years cattle production has expanded rapidly in the Amazon lowlands and Central America to feed the North American demand for hamburger and processed meats.

The modern plantation contrasts with the traditional hacienda in that it is fully and efficiently operated with large amounts of capital (see Fig. 30). The plantation generally concentrates on monocrop specialization with the aim of continuous commercial production, usually for export. Although their proportion of total agricultural production has been declining, plantation crops such as sugar, coffee, bananas, pineapples, oil palm, cotton, tobacco, maize, and wheat continue to be the major source of foreign exchange for several countries (Figs. 31–38).

Large farms in central Chile, Northern Mexico, and Central America have also adopted this mode, producing fruits and vegetables for the winter market in North America. Production and marketing of feed products (maize, sorghum and millets, soybeans) and oilseeds (safflower, soybeans, cottonseed) have become important in Brazil, Argentina, Colombia, Guatemala, El Salvador, and Mexico. Commercial farming is almost always profitable, but profits increase exponentially with the size of the operation. They generally practise monocropping with chemical additives such as fertilizers and pesticides. Since larger commercial farmers participate in the international economy, they can survive bad years by falling back on economic institutions (loans, savings, insurance) to carry them through.

The North American Free Trade Agreement (NAFTA) has had serious repercussions in Mexico. Imports of agricultural products produced cheaply by large US and Canadian agribusinesses has undercut the production of small and medium sized farmers in Mexico, forcing many to abandon the land, often moving to the cities in search of alternative employment.

Agriculture in South and Central America. Table 2 Export and industrial crops for Latin America showing principal exporting countries, 1999

	In thousand metric tons	Export value (millions of US dollars)
Cotton (Brazil, Argentina, Paraguay)	1,164	261
Sugar cane	539,308	4,457
Coffee	3,693	7,912
Bananas	22,279,000	2,816
Maize (Argentina, Paraguay)	13,183	832
Soybeans (Argentina, Brazil, Paraguay)	5,141	2,481
Wheat (Argentina)	14,500	999

From *Statistical Abstract of Latin America*. v. 38, 2002 and *International Trade Statistics Yearbook*, 2001.

Social consequences of these developments are that the peasantry is losing control over its productive processes and is being transformed into a rural proletarian underclass that is being exploited as the primary labor force. These factors have deeply transformed production relations within the agricultural sector, resulting in the modern agroindustrial complex. As a result of increasing commercialization of agriculture, the production of cash crops for export and industrial use has expanded at the expense of the production of basic food crops, leading to significant imports in many countries of basic foodstuffs (Tables 1 and 2).

Efforts at agricultural modernization vacillate between large, capital intensive projects and smaller "appropriate" technology, designed especially for small farmers. However, the bias is toward large-scale projects that are highly visible and politically profitable, but which are often viable only for the short term. In any case they are rarely beneficial to the small farmer.

Agroforestry in Africa

Arnold Pacey

Agroforestry is not a new idea; it is merely a new word used by scientists to describe ancient land use practices operated by farmers in many parts of the world. Other names stressing different aspects of the same technique include forest farming, forest interculture, layered gardening, and multistorey farming. The latter word has been used in West Africa to refer to a system where crops are produced from the same area of land at several levels or storeys, ranging from tops of trees (oil palms, for example), to ground crops beneath the trees, and to root crops below ground (yams, cocoyams, cassava).

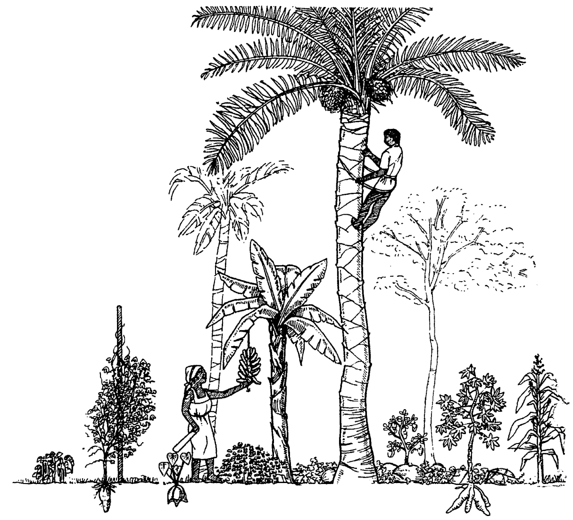
Rediscovery of such farming methods during the last third of the twentieth century was linked to a realization that imported western techniques in tropical Africa had often led to soil erosion and loss of fertility. Cleared fields planted with single crops in the western manner left the soil acutely vulnerable to damage by heavy seasonal rainfall. By contrast, trees gave protection against erosion during rainstorms, while their leaf litter helped maintain soil fertility.

During the 1980s and 1990s, professionals working on this topic, notably at the International Council for Research on Agroforestry (ICRAF) in Nairobi, came to see agroforestry as a holistic approach to land use, using combinations of trees and shrubs with crops, pastures, or animals. What this means in practice depends on climate and environment, for there are different traditions of agroforestry in semiarid tropical regions, in rainforest areas, and in more temperate zones.

In the West African Sahel, traditional customs of retaining and using sparse tree cover in coordination with livestock raising and cropping tended to moderate the effects of high temperatures and low rainfall and to conserve plant nutrients while making possible a diversity of products, not all of which would suffer when droughts led to crop failure. Whilst many tree and shrub species were involved, one tree in particular, *Acacia albida*, was of such value in the western Sahel that it was often regarded as sacred, and there were severe punishments for its unauthorized felling. Because it is a leguminous, nitrogen-fixing species, yields of millet and sorghum sometimes increased greatly when grown in fields which had a scatter of trees of this type. Its leaves and seed pods were a nutritious fodder for livestock. Materials were obtained from it for the preparation of medicines, and its timber was useful in building.

Another species of importance, particularly in Sudan, was *Acacia senegal*, which produced gum arabic, and was grown in conjunction with millet and other crops in a 20-year rotation. With the disruption of this and other cropping systems, sometimes in favor of more "modern" methods, the productivity of the land, and the number of people it could support, was greatly reduced.

In rainforest areas, the retention of tree cover on land where crops are grown is even more important. Oil palm is particularly valuable in West Africa as a tree yielding a valuable crop yet also offering protection of the soil against erosion, and banana may be grown in the same context (Fig. 1). Crops grown at ground level under these trees traditionally include a great variety of beans, squashes, and leafy vegetables, with cereals in more open, sunnier glades.



Agroforestry in Africa. Fig. 1 A form of agroforestry in West Africa sometimes known as multistorey farming. The upper storeys are represented by oil-palm and banana crops. Below that is the cereal crop, maize (corn). Nearer ground level are beans and melons, whilst in the "basement" are the main root crops. Left to right the latter are yams, cocoyams and cassava. This somewhat compressed view does not reflect realistic spacing, in which maize would be in open glades and more shade-tolerant species under trees. Illustration by Hazel Cotterell based on sketches by Arnold Pacey. Reproduced from *Technology in World Civilization*, by Arnold Pacey, MIT Press 1990, p. 200.

Many early innovations in agroforestry arose when crops were introduced into new areas. Thus over the last 1,500 years, African agroforestry has incorporated bananas and the Asian yam from Indonesia, then later, cassava and other crops from the Americas. Recently, though, agroforestry has been researched and repackaged by scientists, then taught to farmers by extension workers as if it were something new, with its origins in traditional practice heavily disguised.

One example of an innovation that arose from scientists' observing traditional practices is "alley cropping". This is said to have arisen when an Indonesian scientist working in Nigeria saw farmers planting a tree species on fallow land to speed the regeneration of the soil. He was led to experiment with trees that could be cut back prior to planting a corn crop, but which would grow up again quickly after the crop was harvested. The Alley Farming Network for Tropical Africa (AFNETA) was set up in 1989 to promote sustainable cropping systems based on alley farming and other ideas drawn from agroforestry practice, and in the 1990s it was developing and disseminating such farming methods in 20 African countries.

Agroforestry: Agri-Silviculture

Harold Olofson

Agri-silviculture is the intercropping of timber and fuelwood species and/or fruit and other useful trees with vegetables and other crops in a common space, at the same time. It may characterize a harmonic swidden (see Agroforestry: Harmonic Swiddens) where fallow periods are sped on their way toward full fertility and a forest architecture by the purposive planting and protection of leguminous and fruit trees in the cropping period or afterwards. Or it may be found in permanent farms. In the first case, we can refer to such swiddens as accelerated swiddens, to be distinguished as a term from the Food and Agriculture Organization's "accelerated fallow" to refer to swidden fallows which, because of population pressure, must be planted to food crops before they have recovered full fertility. In agri-silviculture, the sylvan component of the field is cultivated through practices like weeding and thinning. Agri-silviculture is an example of Alternative Forest-like Structures (AFS) because of the presence of arboreal species which provide some values of the forest. It is also a simultaneous polyculture. Indigenous examples follow.

Within swiddens themselves we frequently find that swiddenists are making efforts to encourage reforestation at a very early stage by interplanting forest trees and tree crops. These are then simultaneously harmonic, polycultural swiddens, as well as examples of agri-silviculture. Agri-silviculture is one type of indigenous agroforestry that seems identical with some of the ideas which modern agroforestry has adopted. From various anthropological sources on the Lingnan Yao of Kwangtung Province, China, which were written in the first third of this century, a summary of their agri-silviculture has been constructed.

> The first year after burning, a swidden is used mainly for mountain rice and maize; the second year for sweet potatoes; and the third year for taro. Simultaneously with the first planting, seedlings of various economically important trees are put in the ground. At the end of three years, these are large enough to discourage further growth of weeds and grasses. The swidden is thereafter fallowed for 18 or 19 years until the trees are large enough to be cut for timber (Lebar et al. 1964: 82–83).

They go on to say that cedar and bamboo are also planted in the swidden. The Lingnan Yao apparently have had a symbiotic relationship with the Han Chinese. The Yao are skilled neither in timber extraction nor in woodwork. In exchange for allowing the Chinese to take most of the timber and other forest products, the Yao receive rice, paper, cloth, salt, guns, and the skilled carpentry of the Chinese. Thus while the Yao grow the timber, the Chinese cut it and transform it into useful shapes (Lebar et al. 1964: 82–83). A search should be made for indigenous agroforestry models among other South China cultural minorities.

Acceleration appears to begin with selective weeding in the swidden so that forest tree seedlings that have established themselves can survive. In his description of the Tsembaga Maring, Rappaport noted that one is chided for stepping on what is called "the mother of the forest" – tree seedlings that are appearing in the swidden but not recognized by the visitor (Rappaport 1971: 122).

For the Siane of New Guinea, Salisbury provides this description of the importance of *Casuarina*:

> Casuarina trees [*Casuarina equisetifolia*] provide wood for fencing, fuel, and house building, and their growth as a secondary tree cover is facilitated by the weeding of garden sites. This prevents the growth of kunai-grass, which would crowd out young casuarina roots. If the casuarinas are given a chance to establish themselves, their shade often prevents the spread of the sun-loving *kunai*. The growth of casuarinas is deliberately encouraged, and gardens are often made when a boy is born, with the explicit expectation that this will provide a crop of timber for the boy at the time of marriage, and so enable him to build a house and

> fence a garden for his wife. Occasionally, too, casuarina seedlings are deliberately planted in areas which no windblown seeds could reach. This happened, for example, in 1941 when Antomona clan of Emenyo tribe returned to their devastated village site, where all trees had been ring-barked following their rout and expulsion in a war. Thus casuarina trees may be considered "cultivated" plants (Salisbury 1962: 43).

Thus it was considered enough to completely conquer an enemy by ring-barking all of the casuarinas in his territory. This would mean that the vanquished would have to retreat up to the high mossy forests to make their swiddens, while their forest areas lower down might run the risk of grassy invasion, since ghost-fear would prevent these areas from being immediately assimilated into enemy territory (Salisbury 1962: 48).

These accounts reveal that traditional swiddenists are frequently capable of long-term future orientation when it comes to forest regeneration, but primarily in the context of viewing the trees that are so protected and preserved as being useful to people.

Given the right economic conditions, this propensity to accelerate swiddens can evolve into a completely stable form of horticulture with the establishment of orchards. This has been described for the Cuyunon of Palawan Island, Philippines. Many of them have made this transition since the 1930s as a response to the flourishing nearby market and port of Puerto Princesa. As an ethnographer describes it,

> Orchards are usually established as an adjunct to swiddening. A farmer systematically intercrops his newly-planted swidden with tree crops and then controls regeneration of herbaceous secondary growth until the tree crops are established (Eder 1981: 95).

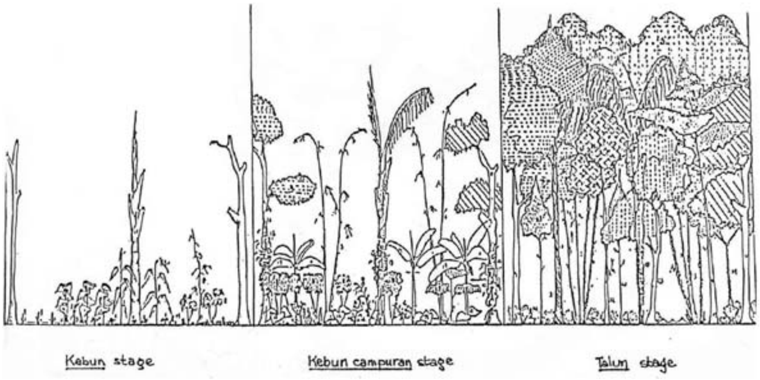
The land used for tree crops, which are mostly fruit of many different species, is in this example taken right out of the swidden cycle.

Cairns (ca. 1995) discovered that the nitrogen-fixing (even though nonleguminous) *Alnus nepalensis* (an alder) enables the Angami Naga shifting cultivators of the Himalayan foothills in northeast India to accelerate their swiddens without causing ecological damage. Oral histories collected from village elders revealed that this has been going on for 500 years, ever since alders invaded the originally opened fields and always seemed to enhance the growth of crops planted near them. The Angami came to protect individual alders (which coppice prolifically and thus are good renewable sources of firewood) and their seedlings, and through the centuries actively to plant them in their fields. This intensification of their agroforestry was probably a response to the fact that the fields had to be clustered near the village due to the hostility of neighboring communities of head-takers. Swiddenists had to be able to retreat quickly to their walled villages.

Over two years of cropping, the alders are pollarded for firewood twice, at the reopening of the fallow and again twelve months later. This is to allow sunlight to reach the staple crops of upland rice and pearl millet, and others. The alders are then left to grow and dominate the tree canopy in the next fallow period of two years. During that fallow, the trees' "extensive roots draw nutrients from a large soil area and return them to the surface in high volumes of nutrient-rich litterfall" (Cairns 1995: 7). As a result, Cairns maintains, the Angami Naga do not remember ever having suffered from this rapid succession of fallow and cropping periods. It is made possible by the presence of the alders, and "without the need of outside technologies, investment capital, or excessive labor inputs." This system is a model for how to stabilize shifting cultivation.

The Huastec Indians of Veracruz State, Mexico, manage stands of forest trees named by them *tel'om* (Alcorn 1981: 409–410). These are particularly closely managed in communities sited near markets. This can be done by adding shade-loving coffee trees into the forest, in places where some forest trees have been cut down to allow space for them. Those trees and vines which are particularly useful for construction are spared. In the shade of the coffee trees, cassava and chili peppers are planted. Furthermore, a species of valued medicinal palm, mango, and citrus trees may be added. The *tel'om* includes both primary and secondary species, as well as useful species introduced from other plant communities. The managed forest is used by women and children for food gathering and play, and streams running through it are sites for bathing and laundering. Within a range of humanly managed plant associations moving from crop field to natural forest, the *tel'om* approaches the forest in structure, but Huastec culture has turned it into a multiple use artifact which can persist for many years as a stable ecosystem. Having originated as an enriched fallow, it need never be opened again for swidden.

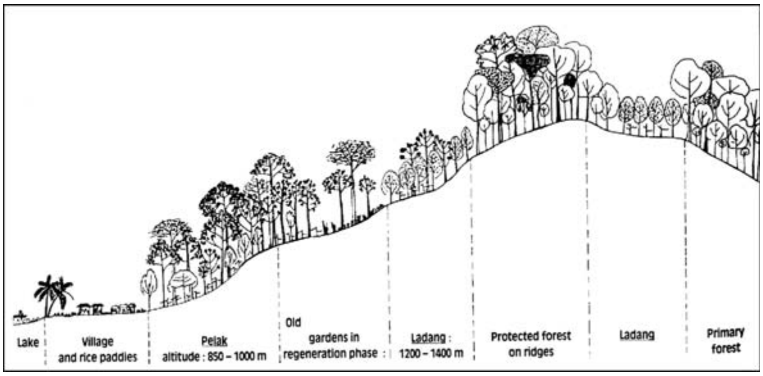
Closely related to the *tel'om* conceptually are the "village-agroforests" of the Sundanese in West Java, Indonesia. Named *talun-kebun*, these cover up to 50% of a village's cultivated land (Christanty 1982, Michon et al. 1983, see Figs. 1 and 2). Thus they are not to be confused with mixed dooryard gardens, which these farmers also have, for they are found further away from the residences. Architecturally imitative of the tropical forest ecosystem in their structure and bio-diversity, Michon et al. (1983: 118, 120) say that they "should be described in the same way as natural forest ecosystems" as well as "in terms of an agricultural lay-out." As in the *tel'om* of the Huastec, the Sundanese *talun-kebun* preserves wild vines, bananas, and trees. Annuals and



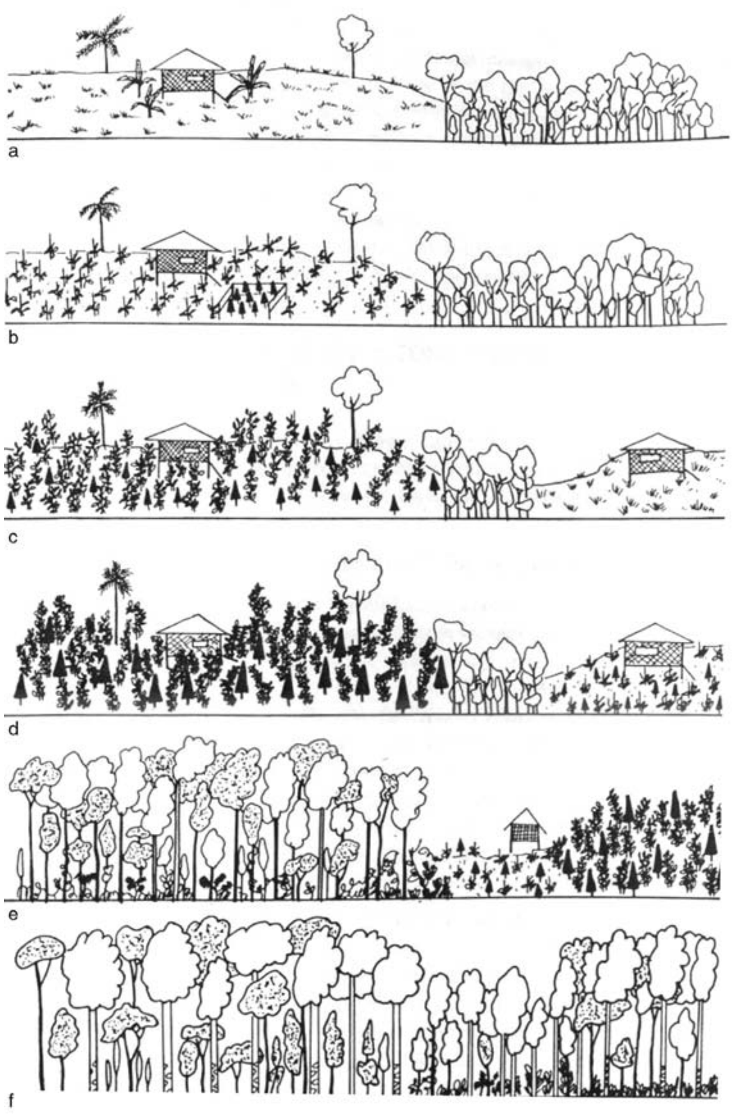
Agroforestry: Agri-Silviculture. Fig. 1 Successional stages in the *talun-kebun* agroforest of the Sundanese, West Java. (From Christanty 1982, 20).

Agroforestry: Agri-Silviculture. Fig. 2 Partial profile of a *talun-kebun* agroforest of the Sundanese, West Java. (From Michon et al. 1983, 126 ff).

perennials are mixed with wild and domesticated plants and livestock (chickens, sheep, and goats) as well. Crop species can reach up to 250 in number. This richness prevents the spread of plant pests and diseases and "represents an invaluable gene pool on an island [Java] where original forests have about disappeared" (Michon et al. 1983: 118–119). Like the *tel'om*, the *talun-kebun* evolved out of the fallowing phases of an older shifting cultivation, no doubt in response to increased population pressure.



Agroforestry: Agri-Silviculture. Fig. 3 Schematic diagram of land use in Semarang village, at the edge of Kerinci Seblat National Park, Sumatra, Indonesia (*ladang* = swidden). (From Aumeeruddy 1994, 22).



Agroforestry: Agri-Silviculture. Fig. 4 From rice field to coffee plantation to damar (*Shorea javanica*) agroforest in Krui, Sumatra. (From Michon et al. 2000, 184).

Agroforestry: Agri-Silviculture. Fig. 5 Profile of an agroforest showing an association of timber, legume, and cinnamon tree crops, Jujun, Kerinci, Sumatra. (From Aumeeruddy 1994, 28–29).

Much study has been done recently of indigenous agroforestry in Sumatra, Indonesia that has been able to restore biodiversity to the forest by incorporating cash tree crops into village forest gardens (Aumeeruddy 1994; Michon et al. 2000; see Figs. 3, 4, and 5).

In the agri-silvicultural form of accelerated swidden, crops may sometimes support the trees. This can occur if some of the crops are nitrogen fixing. But more importantly, food crops that are interplanted with tree seedlings have the function of giving the farmer quick returns, which he may require before he is willing to go into the venture of a long-term investment in the form of trees interplanted with his crops.

Agroforestry: Field-and-Grove Systems

Harold Olofson

This is the most interesting, complex, and varied form of indigenous agroforestry. The fields can be either harmonic or disharmonic swiddens, accelerated swiddens (agrisilviculture or agroforestry rotations), irrigated or nonirrigated permanent fields, or combinations of these. But they are interspersed with groves of trees that may vary along a range from predominantly wild forest species that are consciously conserved to groves largely composed of domesticated tree species planted by people. These two components may alternate or be scattered in a highly productive mosaic across the landscape of a village, district, or watershed. There may also be a tendency over a long period for some fields to become groves, and some groves to become fields, with both components thus slowly migrating across the landscape, producing in effect a very long-term agroforestry rotation. I was able to find four different types of field-and-grove systems in the literature available to me.

The Field-and-Forest

In some countries having temperate climates, these have been a feature of indigenous agroforestry. In England, patches of trees are known as copses when they are composed of species that can be managed by coppicing (cutting back trees regularly to encourage more growth). Larger woodlots and forests have been preserved for centuries as a source of game, deadwood for fuel, honey, and visual pleasure (see Rackham 1985). But in more definite examples of the "field-and-forest," forest resources may be more consciously pulled into the support of agriculture than they usually are in swiddening systems, where the forest tends to take on the passive role of a growing fertilizer reserve. The forest becomes more markedly a component of an agroecosystem.

In many areas of Japan, it is the custom to maintain a forest adjacent to wet-rice fields so that litter from the forest floor can be annually incorporated into the pondfield soils. This may in some measure account for the traditional high productivity of Japanese rice farmers. But the groves are subject to premature aging as a result of the fact that they are not allowed to reabsorb their own litter as food (Kira 1976: 36–7).

Some fascinating examples of field-and-forest relationships are described by Wilken (1977) for Mesoamerica. As in Japan, in western Guatemala and Mexico he observed the "transfer of the forest floor to the fields." Leaf litter is scattered onto the fields and turned into the soil to improve its structure and moisture retention. The litter may first be placed on the stable floor, where it picks up nitrogen content from the urine of livestock. Also, forest materials may be transported to the field to provide protective micro-climates, in the form of mulches to reduce radiation and evaporation from the soil and absorb the impact of raindrops, or actual shelters in the form of leaves and branches to perform similar functions and to allow cash crops to become gradually attuned to the open field. Wilken uses the term "forest structure mimicry" to describe the protective uses of litter and also the custom of letting leguminous trees or pines to simply invade the fields, leading to an eventual replacement of the field by a grove.

Wilken, like Kira, points out that the practice of forest litter removal may have deleterious effects on the forest. However, one could easily imagine long-term experiments to determine the best system of leaf-litter removal management so that no section of the forest floor is harvested year after year, thereby at least prolonging the life of the grove.

The Field-and-Sacred Grove

A second variant of the field-and-grove type of indigenous agroforestry is found primarily among shifting cultivators who maintain forests, which they believe are inhabited by spirits or deities. These are thought of as fiercely defending their homes by visiting illness on human intruders. An excellent example is found in the Philippines among the Tagbanuwa on the island of Palawan, described by Fox (1982: 163–76; for India see Gadgil and Vartak 1976). When a Tagbanuwa selects a site in the forest for making a swidden, it must be first determined by a religious practitioner (the shaman) whether there are malevolent spirits (*panya'ɨn*) who claim the place. He or she enters the forest alone, makes an offering, and perhaps experiences a trance or dream in which an answer is received from the spirits. If the results are negative, the area becomes untouchable, and swiddens cannot be opened in it for the lifetimes of the shaman and the shaman's spouse. Another way of testing a potential site is described by Katherine Warner.

> …A potential site was further tested for the presence of a *panya'ɨn* by sticking a piece of bamboo into the ground. The next day when the bamboo was pulled out, if there was dirt sticking inside it, it was said that it was a *panya'ɨn*'s area and that sickness would come if it was planted. Interestingly, the test that showed the presence of the forest spirit on another level gave information on the texture and suitability of the soil. If the soil is hard and stays in the bamboo, it is not quite ready to be planted, whereas if it is soft and fine textured it will fall out, indicating not only the absence of *panya'ɨn* but also the suitability of the soil for planting (Warner 1981: 20).

The result in Tagbanuwa country has been a patchwork effect of swiddens, fallows, secondary growth, bamboo groves, useful grasses, and sacred groves, which has led to a harmonic and productive system that allowed the Tagbanuwa to live in what for swiddenists are quite large villages without depleting the nearby land. The numerous ecotones (well-defined boundaries typical of closed communities) also have insured the abundance of wildlife and game. But unlike the systems described by Wilken, forest material cannot be moved to the field, as sickness and death might follow the breaking of the taboo against trespass. However, the groves provide seed, which can reach the centers of swiddens easily since the Tagbanuwa do not arrange their swiddens in clusters. With the death of the shaman or the migration of his village, his taboo would be forgotten, and a later shaman might come in and determine the former sacred patch to be safe for swiddening. The long-term effect of this again was an agroforestry rotation between fertile sacred groves and cultivated areas.

In field-and-sacred grove systems, forest resources are not used consciously in support of agriculture. But the existence of the grove is preserved so that it can be truly available to play eventually its integral role in shifting cultivation along with all forest vegetation as the "beginning and end" of the swidden cycle, as Warner has expressed it in a nice way (1981: 27).

Apel (1996) describes the complex forest management of the villages of the Dai minority people in Yunnan Province, China. The bulk of their forests are "amenity forests," which provide an aesthetic setting for each village, an expression of a value rare in tropical Asia. Watershed forests are "used forests," recognized as providing construction timber and an adequate supply of water for each village and its rice pondfields. "Forests without special functions" are another kind. All types of forest have high species diversity. About 5% of forests are considered sacred. There are three kinds of these. "Sacred natural woodlands" are wild and have been considered sacred since animist, pre-Buddhist times and are situated on hilltops adjacent to villages. Hunting, tree felling, and collecting are all forbidden there. "Sacred groves," purposively planted near Buddhist temples, are biodiverse, providing sanctuary for rare plants, and yield fruits for Buddhist monks. "Forest cemeteries" must be kept separate from the village at an elevation well below it. Conceptually distinct from all of these are individual "sacred trees," especially the strangling fig (*Ficus altissima*) with its many striking features, which can be planted in sacred Buddhist groves, found wild on hilltops as the homes of spirits and sites of sacrifice to them, or scattered throughout the "used forest." In the latter case, there is a taboo against felling the *Ficus* for use, and they serve a positive ecological function in assuring that frugivores (birds and mammals) have a food supply available to see them through periods of wider food scarcity, thanks to the characteristic of figs to bear fruit at different times. Apel claims that the taboo against cutting down the strangling fig thus prevents local degradation of the forest through overexploitation.

McWilliam (2001) has gathered significant evidence to say that probably all communities on the Island of Timor historically recognized, and many still do recognize, within the districts belonging to them, sacred (*lulic*) forests or groves, existing within government forest land, which they protect against shifting cultivation. Today, much of Timor's forest has been denuded of vegetation, and sacred groves remain as relicts of the wider forest. Depending on the traditions of the varied cultures concerned, sacred groves may have been preserved as the "mythic origin places of local clan groups" and sites of religious sacrifice to those founding ancestors (McWilliam 2001: 97). McWilliam makes a case for East Timor government support of these "forest custodial communities" as entry points for "negotiated reforestation activities," the responsibility for which can be shared between Timorese government and villages. The basis for this survival of sacred groves, he contends, is a tradition of "rural land management and protection" which "provides a powerful source of moral authority and ecological knowledge" that could lead to sustainable conservation programs. This bold suggestion could be true for places other than Timor, as well.

The Field-and-Woodlot: The Ifugao Pinugo

The most striking example of a field-and-grove system is that of the Ifugao of the Cordillera Central mountain range in northern Luzon, Philippines. This system, which may be 1,000-years old, has been described by Harold Conklin (1980; for a review article on this see Olofson 1980). The Ifugao are best known for their wet-rice terraces and irrigation technology on steep terrain. But few know that their woodlots, or *pinugo* as they call them, among pondfields, or at higher elevations, are almost as interesting. Sweet potato swiddens, too, are found at high elevations of a watershed. The most instructive aspect of the Ifugao woodlot is that it is made out of grassland (and secondary forest) through an intermediate swidden stage. To the Ifugao, making a swidden is the logical first step in reforestation. In the swidden stage, the land being used is not owned by the one making the swidden; he only has the right to use its products. But when a family member decides to grow a woodlot on this swidden, it becomes recognized by all families in the watershed that it is now owned, as a piece of land, by that individual, and its boundaries will be clearly demarcated for all to see.

The Ifugao woodlot is itself an agrisilvicultural system. The only kind of economic plant not grown appears to be vegetables and tubers, if Conklin in his account has mentioned everything. But there are plantings of trees for firewood and for the provision of building materials, utensils, furniture, tools, and religious figurines; fruit trees and grove crops such as betel nut; bamboos and rattans; and medicinal plants. According to Conklin, the species diversity exceeds that of the natural forest. The woodlot is weeded, pruned, and thinned as it grows. It has in fact grown out of an accelerated swidden. And, it might be added, that as a woodlot is harvested and ages, it reaches a later stage in its cultural successional sere.

Oftentimes, the Ifugao cluster their swiddens together, perhaps to defend them better from wild pigs by digging trenches on the edges of the cluster. When the swiddens are converted into woodlots, the cluster is more ecologically sound as a forested expanse than would be a single cluster alone.

Besides supplying the Ifugao with numerous products, which make woodlots second only to pondfields in economic value, the woodlots are overtly recognized by the Ifugao as supportive of the terraces, though not by the use of tree litter as fertilizer (this comes from the floor of the public forest). They are well aware, rather, of the fact that they aid crucially in conserving the water needed in irrigation, and in preventing soil erosion and land slippage. Conklin found that even children could talk about this. In addition, when the woodlot becomes aged and completely harvested it can be reconverted to swidden, at which time its soil should be particularly fertile for sweet potato.

The Field-and-Mixed Home Garden

Of some importance as indigenous agroforestry are field-and-grove systems in which the grove component is the mixed tropical "dooryard," "kitchen," or "home" garden. The dooryard garden represents a distinct agricultural enterprise with its own integrity and often with crucial connections to the farm component. Such gardens are similar to harmonic, polycultural swiddens, except that more important in them are fruit trees, which provide a protective canopy under which other plants are grown, and that perhaps as a result of the need for closed nutrient cycling as in forests, have become permanent. Stuart Schlegel (1979) in his description of the home gardens of the Tiruray of Mindanao finds that they are in fact a terminal stage in swidden. They would thus in Tiruray be an equivalent to the Ifugao woodlot, which also develops out of swidden, except that the Ifugao woodlot may be some distance from the house.

Home gardens are of great significance on the world's most densely populated island, Java, where they are called *pekarangan*. First of all, this is due to their ability to protect the soil through forest mimicry. Among the first to note this was the geographer Karl Pelzer (1945: 43–47) drawing on the work of Ochse and Terra in Indonesia. Then, according to an economic anthropologist, who was also including *talun-kebun* (village-agroforests) in her statistics,

> [For Java] … garden land … makes up anywhere from 15–75% of the cultivable land area, may provide more than 20% of household income, and more than 40% of a household's caloric requirements (Stoler 1978: 86–87).

Another interesting statistic comes from Terra (1966), who found that once well established and continuously producing throughout the year, the home garden grove in Java requires only 5-man days of labor per year for its upkeep. Finally, Indonesian ecologists, noting that dooryard gardens in some overfarmed areas of Central Java "look like green oases in a desert of eroded hills," have characterized them as the last line of defense against ecosystem degradation (Soemarwoto et al. 1976: 194). These same observers go on to suggest that they could be expanded spatially to become *talun-kebun* and begin a rehabilitation of these same uplands. In this last regard, Central Javanese home gardens are fulfilling the same function as has been reported for sacred groves in western India (Gadgil and Vartak 1976) by representing the last patches of forest-like cover in the landscape.

Pelzer believed that mixed home gardens were not well developed in the Philippines. But recent work by Sommers (1978) has shown that they are rather widespread there, and the problem remains of diffusing them further to the many households where they are yet nonexistent or underdeveloped.

From descriptions such as Stoler's, it is clear that Javanese home gardens are an alternative forest structure (AFS).

> They often lack the orderly appearance of other forms of cultivation. They seem a haphazard array of scattered trees, untended plants, crawling vines, and decaying vegetation. In fact the lack of orderly rows and clean swept vegetation is precisely what allows *pekarangan* to produce its own natural fertilizers, and remain erosion-free even in critical watershed areas of poor land use. The multileveled "disorder" functions in part to prevent unnecessary organic waste found under other systems of cultivation (Stoler 1978: 88–9).

She goes on to mention timber trees as one of their products.

By viewing home gardens as part of a field-and-grove system, we throw them into a wider context. The ways in which they are related to the staple field, livestock, and other gardens are probably many and varied, but not covered systematically in the literature in any one place. One thing that stands out from putting together scattered references on the dooryard garden, especially in the context of shifting cultivation combined with stable residences, is its role as an experimental site for new varieties of vegetables and even staples borrowed from neighboring people or visitors. If these do well in the dooryard, they may be grown on a wider scale and even tried out in the main field. For example, among the wet-rice growing Bontok in northern Luzon, Philippines, where sweet potato grown in swiddens is calorically more important than rice grown in mountain terraces, new varieties of sweet potato are planted first in the *doran,* which is found around the house. This area acts as a reserve for all kinds of cuttings, and also has fruit trees, green vegetables, and other root crops. From the *doran*, the cuttings may be transplanted to swiddens or fed to pigs (Yen 1974: 92, 95, 96).

This brings us to the connection between home gardens and livestock. Among the Ikalahan of northern Luzon, papaya, chayote, and sweet potato vines from the dooryard go into the special pig's cauldron in the kitchen where cooked food is prepared for them daily (Olofson 1984). The Ikalahan pig, however, is allowed to roam freely to hunt for mast on the forest floor during the day, so it cannot contribute collectible manure for the maintenance of the dooryard plants. Among the Bontok, however, pigs are kept near or under the house and their manure can be collected and added to compost which goes into rice fields and which helps to account for the high productivity of Bontok wet rice without capital inputs (Sajise and Omengan 1981).

In the entry on harmonic swiddens, we noted that a number of South American Amazonian Indian groups have experimented with swiddens of much-less-than-expected species diversity, swiddens often polyvarietal in nature, to perhaps find other ways of providing some of the values of the tropical rainforest to the cropped field. Among the Siona–Secoya, one of these groups, Vickers (1983) found that home gardens had sparse and discontinuous canopies; they are also not the best examples of the AFS. However, it is important to note that Lathrap earlier (1977: 729–736) had much to say about highly diverse mixed-home gardens among people like the Shipibo and Desana and found that they may have been very significant in the evolution of agriculture among South American Indians. It is worth quoting from him at a little length.

> The house garden functioned as an experimental plot. New species of plants brought in from the forest or received through contact with other ethnic groups would be introduced into the house garden in a conscious effort to evaluate their potential as useful cultigens. The composition of the house garden was dynamic; …the potential of [new] species was constantly being investigated…. I would argue that the important food crops of Amazonia were ennobled in the context of these experimental plots…. Under the artificial growing conditions and a degree of artificial selection, they were genetically modified so as to become the supremely efficient food producers of the tropical forest system at the time of the contact period (Lathrap 1977: 733).

Agroforestry: Field-and-Interstitial Support Trees

Harold Olofson

In this type of agroforestry, trees in groves or rows are separated spatially from crops, but are in a common field with them. The trees may be planted in arrangements interstitial (with small openings or gaps) to crop fields, for example, as field borders, or along the contours of a slope. In a variation, the trees and crops may be rotated in a field. In this agroforestry rotation, the trees interplanted in a mixture with crops may be cut back (coppiced) to allow crops to grow in the sun, and in a later phase allowed to take over and dominate the field for a period when their products are needed. This last essentially entails a rotation or alternation – or "separation" – of trees and crops through time. In all variations, the trees support the crops, as well as yield products of their own.

Spatially Interstitial Trees

There are many examples of trees that are spatially interstitial:

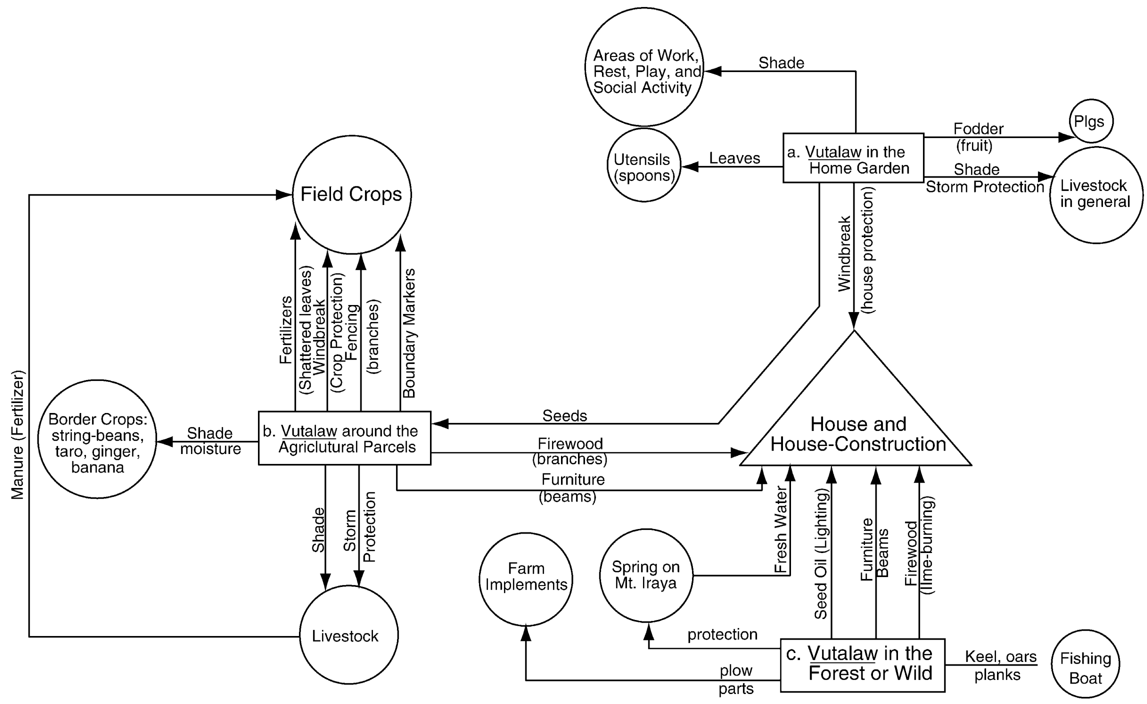
1. The planting of Osage orange in the American Great Plains as a hedge to protect fields from animals and then, as they grew, as a windbreak (Smith and Perino 1981);
2. The growing of ipil–ipil for fertilizer or firewood on rice bunds in Pangasinan, Philippines (interview data);
3. A living fencerow of *Cestrum nocturnum*, guava, and forest trees to prevent the passage of pigs from a pigsty into a swiddening area among the Ikalahan of northern Luzon, Philippines (personal observation);
4. The use of ipil–ipil in contoured rows to prevent erosion on steep corn farms in Cebu (National Academy of Sciences 1977: 72–3);
5. The planting of teak on fallow boundaries by the Yoruba of Nigeria to claim ownership of the fallow (John Wyatt-Smith, personal communication), and thus probably prevent premature cropping by others; and
6. The planting in Batanes, Philippines of palo maria (*Calophyllum inophyllum*) as living fencerows on parcel borders to mark boundaries, provide shade for cattle, windbreaks for crop protection in a typhoon-battered region, firewood, fencing material, and moist soil for plantings of ginger and beans (Rede-Blolong and Olofson 1997: 110–2; see Fig. 1).

Of special interest is the use of trees to reclaim soil to fixate sand dunes, thus adding to the total arable land. A good example is the construction of living fencerows in seasonal floodplains by the Indians of Sonora, Mexico. These are arranged in such a way that they are able to capture arable soil from seasonally torrential watercourses that would otherwise erode away the area in which the fencerows have been planted. The trees are planted so as to impede the flow of water, allowing soil particles in the water to sink to the bottom of the stream (Nabhan and Sheridan 1977). While this type of agroforestry involves the use of residual, leftover, or boundary spaces, such trees can be of the utmost importance; they can be used to reverse the deleterious forces of nature.

Interstitial arrangements involving livestock occur where spatially interstitial trees provide fodder. A case in point occurs in Jalajala, Rizal, Philippines, where native ipil–ipil growing between (and within) upland parcels is collected and brought down to sites situated on a level lakeside plain in order to stall- or force-feed milch cows (Olofson 1985: 322).

Temporally Interstitial Trees, or the Agroforestry Rotation

An interesting system that falls into this rubric has been described for the Atoni language speakers in the province of Amarasi in southwestern Timor. The system is a relatively recent innovation, but originated within and has been strongly supported by traditional institutions. It is a many-faceted response to famines caused by slash-and-burn on poor soils in a climate with a 9-month dry season, and to the spread of *Lantana camara*, which was interfering with the attempt to develop a livestock industry in the resulting savannahs, because it is poisonous to cattle:



Agroforestry: Field-and-Interstitial Support Trees. Fig. 1 The participation of the *vutalaw* (*Calophyllum inophyllum*) in the Ivatan agroecosystem. From Rede-Blolong and Olofson (1997: 115). By permission of *Philippine Quarterly of Culture & Society*. Thanks to Fr. Herman van Engelen for his help in constructing this illustration.

> With the systematic use of [*Leucaena leucocephala*], which had been known in Timor for centuries as a fallow plant, a significant agroecological change took place in Amarasi. An *adat* regulation pronounced in 1932 by the local ruler (*raja*) in accordance with his council obliged every farmer in Amarasi to plant rows of this leguminous plant with at least 3-m spacings along the contour lines on his shifting plot before abandoning it. This was intended to reduce erosion, to encourage new plant growth, and to improve soil fertility by making use of the nitrogen-fixing properties of this legume. In order to put the necessary pressure behind these regulations, each farmer was threatened with a heavy fine for failing to comply (Metzner 1981: 96).

In 1948 the government officially adopted this custom law as its own, and by 1951 *Lantana* had been significantly reduced by the ipil–ipil (*lamtoro* in Atoni), so that land-use zoning, also originating in *adat* decisions taken by the raja in 1938, could be most efficiently implemented to aid in the separation of farming and grazing areas (Metzner 1981: 96–8).

It can be assumed that the ipil–ipil was planted late into the swidden because of its rapid growth, so that a succession of food crops and ipil–ipil took place, rather than a mixture, in the initial phase. In one area this use of ipil–ipil led to a situation where the farmers could make a labor-saving innovation that eventually resulted in almost permanent cultivation.

> Once the *lamtoro* poles and leaves are cut they are not burnt but left on the field as mulch. Into this mulch layer maize and other crops are planted. Weeding is limited to cutting off the fresh shoots growing from the roots of the legume left in the ground. Similarly the cut-off shoots remain on the field as mulch. Since the soil is neither hoed nor turned the thin layer of topsoil is hardly disturbed. According to the farmers…even after seven years of continuous cultivation yields were not lower than those expected from newly cleared *lamtoro* plots (Metzner 1981: 100).

In this system, the growth of the trees and crops alternate over time in the same space. In most swiddens, the forest stage of the swidden cycle primarily functions as a source of fertilizer to be released by the next burning, of shade to eliminate weeds, and of seed for reforestation of fallow areas. Here the fast growth of the ipil–ipil as well as the soil enrichment caused by nitrogen fixation adds significantly to these functions, making the next cultivation of the plot possible much sooner as well as extending the cropping period. This last, in turn, makes it possible to delay fallow and to allow adjacent ipil–ipil fallows to grow more. For this reason, agroforestry rotations of temporally interstitial trees that nourish the soil could be called forms of accelerated swidden.

It is important to note here that while the tree component is kept "submerged" or cut back during the cropping phase, so that we cannot speak of a mix of growing trees and crops, this example is still one of a simultaneous polyculture. The underground portions of the ipil–ipil still play a positive role in generating nitrogen and holding the soil.

Agroforestry: Harmonic Swiddens

Harold Olofson

Forest swiddens are clearings made in a forest by shifting cultivators, to be planted to crops. They are generally of two types, depending on the cultural traditions of the cultivators: harmonic and disharmonic.

Harmonic swiddens are found among many indigenous cultivators, and are essentially a form of agroforestry. In fact, when they are designed and managed in such a way as to enable rapid recovery of the forest after a brief period of use during which their soil fertility is depleted, they are good models for modern agroforestry. As integral agroforestry paralleling Conklin's (Conklin 1961) famous classification of types of shifting cultivation, they are embedded in cultures into which members of a society are born, as part of their plan for survival. Making harmonic swiddens is learned as part of growing up in indigenous societies where they are integral to the tradition of cultivation. One of the effects of harmonic swiddens which is often "in the awareness" of their practitioners is to accelerate the recovery of the forest structure which was eliminated in the process of making a swidden in the forest, once they have to leave the swidden. This is done by paralleling or imitating in the swidden that forest structure which they have felled, or one which exists nearby. They attempt to harmonize the structure of the swidden with the nature of the environmental context in which they live. Such swiddens can be called Alternative Forest Structures (AFS). The AFS can have up to five characteristics that aid in identifying it as forest alternatives. The first three were clearly described by the anthropologist Geertz (Geertz 1963; Harris 1971).

1. There is a high diversity index of plant species in the swidden, as in the natural forest. In contrast to monoculture, which specializes in one species only, there are many species and varieties planted in the field. Thus, a swidden is a simultaneous polyculture (coined by Kass 1976: 6), but a complex, not a simple one. This term covers patterns involved in mixed cropping, intercropping, interculture, interplanting and relay-planting. Also in contrast to monoculture, there are relatively few representatives of any species.
2. The vegetation is stratified into soil-protecting canopy layers, two or four in number, but usually less than in a tropical forest climax.
3. As in the natural forest ecosystem, the tight cycling of nutrients within the bounded agroecosystem is quite rapid. As has been said for the tropical forest, the AFS cannibalizes itself by quickly reabsorbing its own litter into its root systems. While this is widely believed to be true for some of the AFS described below, there is a need to confirm this through detailed agroecological studies.
4. Oldeman nicely analyzes the fourth analogy. According to him, especially in older forests, "the death of forest patches is a perfectly natural mechanism which constitutes the motor of all vegetational dynamism" (Oldeman 1981: 79). Numerous accidents through time, such as earthquake, exposure to storm winds, or the formation of goblet-shaped clearings or *chablis* by the falling of single, large, old trees cause the forest to take on the appearance of a mosaic of points on a successional sere. As Rambo (Rambo 1981: 36) has put it, man may purposefully and systematically manipulate the forest – through an eco-catastrosphe of felling and burning – to deflect the natural succession on a site back to more open conditions and thus cause a patch to enter a succession which he himself designs. Geertz called

this "putting the forest through its paces." Thus, like patches in the forest many AFS will be located on some point along a sere. Oldeman points out how it requires a good deal of art and science to preserve with some stability the analogical relationships between the cultivation cycle and the natural cycle, and to replace the wild species by domesticated ones that fill the "same functional and structural niche as their wild precedents" (Oldeman 1981: 81). Like the forest, swiddens also have phases in their histories.

5. The overall effect is one of resonance between the AFS and the surrounding natural forest. The structure of the forest is imitated, planting materials may actually be brought in from the forest, and forest wildlife may flourish at the ecotone (boundary) with the AFS. In these ways, the AFS may act to reinforce the forest ecosystem.

Disharmonic swiddens may have evolved from harmonic ones, with the farmer learning to specialize to the point of monoculture or near-monoculture, with one species such as sweet potato, upland rice, or corn dominating in the field. In this process, the swidden loses its stratified canopies and there is a dangerous reduction of plant cover in the clearing during the cropping stage. Or, disharmonic swiddens may be cleared by land-hungry, lowland migrants to the hills or forests who may be people who have little knowledge of indigenous practices, who did not grow up in cultures traditionally skilled in forest farming.

Disharmonic swiddens have no resonance with the surrounding forest other than attracting wildlife; they bring on the threat of soil erosion through heavy rainfull impacting on the bare soil, grassy intrusion, and a decrease of nutritional diversity in the family diet. The harmonic swidden is much more capable than the disharmonic of regenerating into natural forest during the fallow period.

Swiddens can be found on a continuum of incipient to advanced indigenous agroforestries. In the first, trees may not be a major component of the swiddens, but species of fruit trees are usually present. These incipient agroforestries may be seen as evolutionary precursors to indigenous agroforestries which put more stress on trees, usually always to support the crops. Swiddens of this nature have been reported widely for traditional peoples. For the T'boli of Mindanao, Rice has made this observation:

> Usually there are three or more different crops on a given piece of land at all times and as each crop ripens and is harvested its place is taken by another. A well-developed system of inherited agricultural knowledge governs which seeds are to be planted together and in which months they can be planted for most effectiveness. This… tends to maintain the soil fertility longer since at least one legume is usually in the soil to stimulate nitrogen fixation. Second, the land is covered more continuously and heavily, and erosion and weed control are thus more effective… (Rice 1981: 77).

For the Tsembaga Maring of New Guinea, one anthropologist has described the forest-like structure of their swiddens.

> In the garden as in the forest, species are not segregated by rows or sections but are intricately intermingled, so that as they mature the garden becomes stratified and the plants make maximum use of surface area and of variations in vertical dimensions. For example, taro and sweet potato tubers mature just below the surface; the cassava root lies deeper and yams are the deepest of all. A mat of sweet potato leaves covers the soil at ground level. The taro leaves project above this mat; the hibiscus, sugarcane and [*Setaria palmaefolia*] stand higher still, and the fronds of the banana spread out above the rest. This intermingling does more than make the best use of a fixed volume. It also discourages plant-specific insect pests, it allows advantage to be taken of slight variations in garden habitats, it is protective of the thin tropical soil and it achieves a high photosynthetic efficiency (Rappaport 1971: 121–2).

The Tiruray of Mindanao have been described as having another kind of what I call resonance between the forest and the cultivated areas. This involves a virtual exchange of planting materials between the two sites. Four bamboo species, the fruit tree *Averrhoa carambola*, narra, and *Gendarussa vulgaris* are taken from the forest and planted in swiddens, gardens, at the edge of watercourses, or right at the forest boundary, while the candlenut (*Aleurites moluccana*) is planted directly in the forest (Schlegel 1979: 171–9, 194–205).

In harmonic swiddens, trees support the domesticated plants grown in the clearing by first bringing about more fertile soil conditions and then by being sacrificed through burning for fertilizer. It is difficult to see, however, how nutrients from the clearing do much in their turn to make the forest prosper. Perhaps on the edges of swiddens, where some slash or crop residues may be thrown from the swidden into the forest, or where rainwater is eroded down from the swidden, nutrients may re-enter the nutrient cycle of a small section of forest. On the field itself, only crop residues remain to act as a source of nutrients for the returning forest. It may be that young trees are able to make incredibly efficient use of such small amounts of nutrients, for on soils in which domesticated plants no longer flourish, secondary growth will oftentimes thrive.

The Lacandon Maya of Chiapas, Mexico plant numerous varieties of fast-growing root and tree crops prior to the planting of corn in their *milpas* (swiddens); these prevent soil erosion and nutrient leaching in the newly cleared field. During the rains, many other species of tubers, trees, cereals and vegetables are planted. Of great interest is the observation that the Lacandones have learned to plant several of these crops only when certain "indicator" species in the primary forest begin to flower. For each planted species, the corresponding flowering forest species is called the "foot" of that crop. "Such a system coordinates the agricultural cycle with current environmental conditions, rather than with a fixed calendar that makes no provisions for annual variations in temperature and precipitation" (Nations and Nigh 1980: 9–11, see Table 1). Thus the Lacandones tune in to what ecologists would call the forest's information flow. This could also be described as the dispersion of crop cycles through time.

There is also, among the Lacandones, dispersion of plants in space through their swiddens. This prevents large clusters of single species and so emulates the high species diversity index of the forest, ensuring that the swidden "becomes a living mass of food-producing plants which occupy the entire cleared area both above and below the soil." These dispersions in space and time enable the plants to escape their herbivorous predators, and make possible a sustained yield of food throughout the year (Nations and Nigh 1980: 11).

The Lacandones have evolved a swidden system wherein a swidden is only cultivated for short periods, and few weedings are done. This allows secondary species to establish themselves quickly on sites that are abandoned, so that re-opening of that space to cultivation can take place after only two or three years of fallowing, since forest growth will have been enough to provide sufficient ash fertilizer after burning. Not only that, but wild species are encouraged, and a variety of other useful plants are deliberately seeded into the *acahual* (fallow) to accelerate the reappearance of the forest (Nations and Nigh 1980: 15).

The Lacandones recognize the forest as the principle factor in regulating itself. The strategy is thus to "farm" in the forest… not to replace the forest in order to farm (Nations and Nigh 1980: 20).

All of the above is not to imply that all shifting cultivators have harmonic swiddens, as defined previously. Newcomers to forest farming do not have the required knowledge for managing forest-friendly swiddens. But traditional, integrated swiddenists also may not have swiddens that are Alternative Forest-Like Structures. Anthropological research prior to 1983 among Amazonian Indian groups living near the Equator in South America found a number of tribes without them, interspersed among those who do. In 1983, the journal *Human Ecology* published a symposium of papers on these groups, wherein the authors attempted "appropriate descriptions" of them, which were summarized by Beckerman (Beckerman 1983a). The research found, instead of harmonic features, monocropping, planting of different monocrops in concentric circles around the swidden (in one culture, the family house was always cited in the center of the swidden), and polyvarieties of the staple cultigen (usually many varieties of cassava [manioc] mixed together). In the symposium, attempts were made to explain how these arrangements were able to perform some of the functions of the Alternative Forest-Like Structure. For example, the different varieties of cassava planted in Jivaroan gardens have a "variation of branching pattern, leaf shape, and growth period …promoting effective vertical and lateral exploitation of available light, warmth, and moisture" (Boster 1983: 62) that would be much the same as that achieved by the mixture of distinct species. Beckman notes that the simultaneous monocrops planted in an annular fashion among the Bari (Beckerman 1983b) and the Candoshi (Stocks 1983, see Fig. 1) are done so that the tallest plants are in the outer ring and the shortest in the center ring, creating a downward gradient of crop elevations from the edge to the center – a "funnel-like" effect in the garden. Stocks suggested that this arrangement reduces the shading of a shorter crop by a taller one; protects interior crops from pests by placing crops that are valued less by people but which taste best to pests on the outer rim, thus preventing satisfied pests from continuing on into the center; nourishes the crops on the edge better by placing them next to the forest; and/or disperses crops across a range of "micro-edaphic variation". Beckerman suggested that these and other hypotheses needed agronomic field testing before they could be accepted.

Another possibility springs to mind. In the evolution of agriculture there must have been people who initiated the practice of planting whole fields to one or a few favored staples. The first experimental monocultural fields could have been forest swiddens. Could these Amazonian Indian groups have been among the first to move in this direction? Their heavy reliance on the cassava as their staple food could have supplied a motive. The Amazonian swiddens discussed above may well represent a frozen stage in that transition, a stage continuing on today in those societies.

Swiddens of the South American rain forest which are Alternative Forest-Like Structures happened to be among the earliest studied, particularly by geographers, for example those of the Yanomamo people found in the Upper Orinoco of Venezuela (Harris 1971). Treacy (Treacy 1982) has also written of them among the Bora in southern Colombia. He makes the following very

Agroforestry: Harmonic Swiddens. Table 1 "Foot" indicator plants: Wild forest species whose flowering provides information flow to the Lacandon Maya. From Nations and Nigh 1980, p. 12.

Crop				Indicator Species		
Month	Region	English	Latin	English	Latin	Lacandon
January	South	corn	Zea mays	barbasco	Paullina pinnata	mäsh ak'
February	North	watermelon	Citrullus vulgaris	corkwood	Heliocarpus donnell-smithii	halo

nice point for them: "...the notion that shifting cultivation fields are 'abandoned' with fallowing needs reassessment" because fruit trees, planted in the Bora swidden, continue to grow for a long period of time after final crop harvesting and the ground around them is regularly weeded to prevent competition with fast-growing secondary forest species (Treacy 1982: 16).

Agroforestry: Special Systems

Harold Olofson

Certain indigenous agroforestry systems do not fit easily into a Western-science classification of such systems because, anomalously, they do not have as major components either a field of agricultural food crops or grazing livestock. Instead they involve, on the one hand, specific conserved species of forest vegetation, or sizeable conserved sections of forest, and on the other, such animal food sources as fish or bees in the place of domesticated animals or plants (although other agricultural or even agroforestry types may be found elsewhere in the village or district under consideration). Bee culture, however, is considered a branch of agriculture in some places (Commonwealth Agricultural Bureaux 1980). Existing forest species are simply maintained as a support for either aquaculture or apiculture. These systems are not well known.

Aqua-Silviculture

The evidence for an indigenous aqua-silviculture, or combination of aquatic resources with managed forest vegetation, is thin. One possibility is a system described by Joly (1981) for a mixed Hispanic and Indian group living along rivers in upland Panama. These people train a species of riverine fish (*Brycon chagrensis*) to feed on the leaves of *Piper auritum* placed as bait in a system of stockades in family-owned pools during periods of low water. The fish absorbs the pleasant flavor of the leaves and the stockades facilitate the trapping of the fish.

It is somewhat questionable whether the plant *P. auritum* can be included in a discussion of silviculture, which pertains primarily to trees. Although Joly's discussion is unclear, it seems that this herb is not a part of the gallery forest found adjacent to the pools. It is apparently gathered from secondary forest vegetation growing away from the river and brought to the feeder devices. It is, however, at the very least a conserved forest resource, for when clearings are made for swidden, "clumps" of the plants are left untouched. If it requires shade, then other forest trees are involved in its conservation.

The Uanano Indians in the Uaupes River Basin in the Brazilian Amazon rainforest provide another example of indigenous aqua-silviculture. They take care to preserve particularly the forests along major rivers, by prohibiting the practice of shifting cultivation on the river margins. They know that if they interfere with those trees, they will harm the rivers' fish populations, their major source of protein.

A Western science explanation can be made for what the Uanano perceive in doing this. The rivers in the Uaupes Basin are all blackwater rivers, full of tannins produced by the rainforest plant species as a protection against herbivores. Rains wash these tannins from the litter on the forest floor into the drainage system, where they prevent the growth of microflora which fish feed upon. These rivers generally have low levels of nutrients and primary phytoplankton. But during rainy seasons of high water in the rivers, the fish are able to swim into the forest with the rising river waters and feed on the vegetable matter (leaves, fruits, flowers, seeds, and microflora) and small animals (insects and their larvae, arachnids, crustaceans, and worms) that they can find there as "floating and decomposed matter and mud." Observing this, the Uanano are "acutely aware" that preservation of the forest will save for them the fish as well (Chernela 1982).

Another example of aqua-silviculture has been noticed in a lakeside community in the Philippines, where the finally branching tree *Streblus asper* is maintained in farmers' parcels. Branches are cut and submerged in the lake water for a time necessary to capture shrimp which come to shelter among them (H. Olofson, fieldnotes, Jalajala, Rizal, Philippines).

Api-Silviculture

When forest resources in the form of nectar-producing flowering trees and other plants are consciously conserved in order to support domestic beekeeping and honey production, we have what could be called an indigenous api-silviculture. Essential to the recognition that api-silviculture exists is the knowledge that a beekeeping people can name flowering forest species important in honey production and also conserve them by, for example, not cutting them for swidden.

The protection of nectar-producing forest trees occurs among the swiddening Iraya of northern Mindoro Island, Philippines. Another aspect of their traditional conservation is the restriction of honey collection to the waxing period of the moon, thus forcing bees to swarm and to build up new hives with honey in the waning of the moon. Such customs may be stimulated by the fact that the Iraya look upon honey as a shamanic medicine (Revel-Macdonald 1971). But the Iraya are "honey hunters," not beekeepers, having to look for such new hives by observing the flight directions of bees after those bees partake of river water. (The term "honey gatherers" would be most properly reserved for those people who know of permanent hive sites, such as those located on known cliff faces, to which they can return year after year.)

It would seem logical that if honey-hunters protect relevant trees, so also there must be examples of indigenous beekeepers who do. A good description of ritualized domestic beekeeping among the Yucatecan Maya is given in Weaver and Weaver (1981) but only the plant *Gymnopodium antigonoides* is mentioned as a recognized nectar source; they do not say whether it is protected. However, Chemas and Rico-Gray (1991) say that the Yucatecan Maya are able to identify 12 species of wild trees and weeds that are good sources of nectar foraged by bees to produce honey. They can rank these in terms of quantity, odor, flavor, color, and viscosity of the honey produced, as well as the quality of their pollen and nectar. They have a good knowledge of the flowering phenology of these trees, and know how very dry and very rainy seasons, very humid and very cool years, affect the honey produced by bees. They find that the management of honey and pollen-producing vegetation need be only minimal. In their area, forest cutting has led to the forest being composed of mainly young trees. But this may have done little damage to the annual honey production cycle, since bees prefer to visit younger successional stages of forest growth anyway, as well as roadside plants.

The conservation of interstitial trees or of bee pasture useful to bees would be essential to growing populations who combine farming and beekeeping, since otherwise the nectar sources would give way to the spread of crop land (see Editorial 1981).

Agroforestry: Systems with Animals and Grasses

Harold Olofson

Silvipasture

Silvipasture is an agroecosystem which involves a necessarily precise combination of forest trees, livestock, and selected grasses.

It is difficult to locate references on indigenous communities which have achieved the combination of forest-grazing consciously involving silviculture. For example, one would not expect to find this among pastoralists, who have in the course of cultural evolution branched off from a way of agricultural life involving both domesticated animals and plants to concentrate on domestic animals alone – full-time pastoralists are not usually planters. They are known to graze their animals among forest trees, and to use those trees for shade for their livestock, but it is difficult to find reference to their actually having planted those trees. This type of agroforestry appears to be a very recent conception.

If they can be accepted as a people who are now, in this day, "indigenous" to their homeland, some nth-generation Caucasian New Zealanders are a good example of temperate-climate silvipastoralists (Stover 1979). Silvipasture, interestingly enough, was discovered almost accidentally and simultaneously by imaginative, private farmers and private company employees in the 1960s, not by scientific research. Observations of their schemes led to serious consideration of silvipasture in the Forestry Development Conferences of that country in the 60s and 70s and silvipasture was then realized as a way of reversing the historical depletion of timber resources caused by clearing land for cattle and sheep. As a response to increased timber prices, and to the lowering prices for meat and wool,

> Farmers … have come to see trees not only as shelters for livestock both winter and summer and as sources of fuel and locally needed posts, but as another potential cash crop, albeit, a slow-growing one, that might share growing space with grass (Stover 1979: 441).

The New Zealanders' view of the role of livestock is reminiscent of the rationale for the food crops in accelerated swidden or food-tree crop interplantings. In the latter, the crops provided the short-term returns necessary to stimulate the willingness to plant and wait for trees on the same space, as among the Ifugao in Northern Luzon, Philippines. In New Zealand, the farmers see that the animals provide income to cover interest costs during the period before the trees can be harvested. Silvipasture in New Zealand involves allowing livestock into well-established forest, once the potential relationships are well understood; planting trees into well-established pasture; or sowing grass among tree-seedlings on run-down land.

Agri-Silvipasture

A remarkable indigenous system involving the mix of three components – livestock, trees, and a staple crop, is found among the Fur of Sudan. This permanent system is made possible by the unique characteristics of the savannah tree *Acacia albida* (Radwanski and Wickens 1967). Unlike almost all other trees, this legume sheds its leaves at the start of the rainy season, and plots of millet or sorghum placed directly under the trees quickly benefit from the rapidly decaying leaves, at a time when sunlight is able to reach the crop through the tree canopy. In the dry season, the trees are in leaf, providing shade for the plots below, and keeping down the temperature of the soil which is able to retain more water than otherwise. During this fallow period, livestock may be allowed to graze and rest in the shade under the trees, especially when a storm blows down the nutritious fruits of the acacia. The livestock in turn fertilize the area. They are also fed with the leaves and fruits of the tree especially collected by the Fur as fodder. And the combination of animal manure and *Acacia albida* leaves makes nitrogen plentifully available under the trees.

Agroforestry in the Pacific Islands

William C. Clarke

The planting of trees together with the cultivation of annual crops, a combination now generally termed agroforestry, has been strongly promoted in recent years as a way to prevent land degradation and to increase total production of food and useful products from a unit of land. Throughout the Third World, development agencies and government departments of agriculture and forestry have been advocating agroforestry as a way to harmonize forests with farming, or as a way to make up, at least partially, for the destruction of natural forests and their replacement by pasture or by fields of annual crops. In the Pacific these modern, aid-funded attempts to promote agroforestry are ironic, for they take place in a region where agroforestry systems were developed thousands of years ago and where hundreds of species of trees are still used in a be wildering variety of ways.

At least a few trees even have a place in the popular imagination about the Pacific Islands. If asked what particularly characterizes the landscape of the islands, most people would think of a line of coconut palms overhanging a beach beside a coral-reef lagoon. They might also envision the stately and strikingly beautiful breadfruit tree, whose yield of starchy fruit so enchanted Captain Cook and his companions on the first European visit to Tahiti and subsequently led to Captain Bligh's famous voyage to Tahiti in H. M. S. *Bounty* to collect breadfruit cultivars for the West Indies. These conceptions of coconut palms and breadfruit trees in Pacific landscapes are accurate enough, but they only begin to suggest the full significance of trees, both domesticated and wild, in the lives of traditional Pacific peoples.

Recent chromosomal and paleo-botanical studies in the Melanesian islands of the western Pacific reveal that the domestication of plants extends back in time there for thousands of years, thus demonstrating that agriculture evolved endogenously in the Pacific region, rather than being solely or mainly the result of a direct transfer from southeast Asia, as had been believed previously. Plants that may have been domesticated in western Melanesia include – aside from important short-term crops such as *Colocasia* taro and sugar cane – a remarkable number of trees or shrubs. This early emphasis on arboriculture – the cultivation of trees and shrubs – was eventually transported all across the Pacific by the voyaging colonist cultivators, to be incorporated into production systems everywhere and to beget the typical tree-filled environs of human settlements in Polynesia and Micronesia.

Archaeological evidence for a well-developed arboriculture at least 3,500 years ago comes from the Mussau Islands, which are now part of the country of Papua New Guinea. Tree species already in use then included: coconut, two or three species of *Pandanus*, *Inocarpus fagifer* (the "Tahitian chestnut," which remains one of the most important Oceanic arboricultural species), *Canarium indicum* (a nutritionally substantial "almond"-producing tree in Melanesia), *Spondias dulcis* (the vi-apple, now of very wide distribution in the tropical Pacific), and other useful trees such as *Pometia* (which provides edible fruit, medicine, and other products), *Pangium* (seeds edible after treatment to remove the poisonous component), *Terminalia* (edible "beach almond," useful timber), *Burckella* (edible fruit), and *Calophyllum* (timber favored for many uses, sticky sap used for caulking canoes). There is also evidence for the early domestication in the Pacific of several species of sago palm (used in some places to produce starch for food, elsewhere its leaves used as long-lasting house thatching), one kind of banana, and kava (a sprawling shrubby plant, the pounded stems and roots of which are used to make the ritual-social drink long important in many parts of the Pacific).

Over 400 species of trees or tree-like plants have been identified as having widespread or localized economic, cultural, and ecological importance in the Pacific Islands. The adoption of these many kinds of trees for human purposes is the cumulative result of a selection process that occurred over thousands of years and that involved both the domestication of previously unknown species encountered when Pacific voyagers landed on uninhabited islands as well as the deliberate transport from island to island of plants already known to be useful. The trees and their products served Pacific peoples in a great variety of ways. For instance, ecologically, trees provided, among other services, shade, erosion control, wind protection, beach stabilization, soil improvement, and frost protection (at high elevations in New Guinea). Cultural and economic uses included, among many others, house timber, firewood, tools, weapons, fishing equipment, abrasives (for example, the "sandpaper" leaves of some fig species), gums and oils, fiber, beverages (for example, the fluid from coconuts, immensely important for drinking on dry atoll islets), caulking, stimulants, medicines, and love potions and perfumes. Many Pacific trees are also of great importance nutritionally. For example, in various places people depend heavily on one or a combination of staple foods from coconut, breadfruit, bananas, sago palm, or several species of *Pandanus.* Many other species provide supplementary and snack foods. Although many tree foods are energy-rich in carbohydrates or vegetable fats or both, it is in other nutritional essentials that they often excel, compared with the starchy root-crop staples. Several fruits are excellent sources of provitamin A; others provide B-complex vitamins or are rich in vitamin C. Most seeds and green leaves from trees (which are widely eaten) are good sources of plant protein and various micronutrients. Spices and sauces derived from tree products can also be of great nutritional and culinary significance. An oily sauce made from the huge red fruit of a *Pandanus* species in highland New Guinea provides a rich, nutritious condiment for many otherwise bland foods. Or coconut milk or cream (squeezed from the coconut flesh) is widely used in cooking in coastal areas, and in places is aged or fermented with sea water and other flavorings to make a tasty sauce that enhances local cuisines.

The multipurpose nature of many Pacific trees in providing a diversity of different products or services to people is well exemplified by the breadfruit. Its straight trunk is valued for canoe hulls; the inner bark is used to make bark cloth in some areas; the tree's thick, milky sap is used for caulking canoes, as adhesive for bark cloth, and as chewing gum; its large leaves are used as plates and for wrapping food for cooking in earth ovens; the dried inflorescence is burnt as a mosquito repellant; and the fruit is eaten cooked as a staple or important supplementary food in most areas of Polynesia and Micronesia and as a supplementary food in Melanesia, where seed-bearing varieties are often more important than the seedless varieties used as a staple food in Polynesia.

Like most trees, the breadfruit's production of fruit is seasonal, so that people dependent on it for food can expect periods of food shortage recurrently each year. Pacific-Island peoples developed two solutions to this problem. First, high intraspecies diversity had been developed in breadfruit (and most other domesticated crops) by centuries of observation, selection, and transportation of promising varieties from place to place. As only one example of the prolific number of named cultivars that might have been accumulated within a single species, the volcanic island of Pohnpei in Micronesia is reported to have 150 named varieties of breadfruit. Generally, each of the many cultivars followed its own distinct calendar, so that production of breadfruit on atolls and high islands of Polynesia and Micronesia (or, to give another example, the yield of *Pandanus* fruits in highland New Guinea) is staggered over a much longer period than would be available from a single cultivar or individual tree. The second way in which the availability of food from breadfruit was extended over the year was by the pit fermentation of the fruit so that it could be stored. Unlike grains, there were few Pacific-Island indigenous foods except yams (*Dioscorea* spp.) that if unprocessed last long in storage once harvested. Because harvested breadfruit lasts only a few days, a way had to be found whereby the seasonal surpluses could be accumulated for later use. The method developed was pit storage. After the ripe fruit was peeled and cored, it was preserved by a process of semianaerobic fermentation, involving intense acidification, which reduces the fruit to a sour paste that lasted in storage for decades. The pits, which served both as fermentation chamber and storage area, were dug in clay soil to prevent water seeping in and then lined with stones, woven mats, and a variety of leaves to keep soil from mixing with the breadfruit paste. Modern food analysis shows that the fermented product contains more carbohydrate, fat, protein, calcium, iron, and B vitamins than the fresh fruit. The pits of breadfruit paste also provided a reserve food supply after tropical cyclones, or hurricanes, devastated gardens and orchards or during times of warfare. Packages of the baked fermented paste wrapped in leaves also provided a portable, long-lasting food for sea voyages.

Although trees had a great significance in people's lives almost everywhere in the traditional Pacific, the hundreds of species utilized were combined in a great variety of unique agroforestry systems, each distinct to particular locales spread over hundreds of islands, each with a unique environment and each occupied by a distinct group of Pacific peoples, with their own particular history and set of agricultural techniques. In forested areas of low population density where shifting cultivation was practiced, a mixture of certain trees might be planted in old gardens, creating orchards that produced food, fiber, and other products for decades while also serving as a kind of fallow for the gardened soil, which eventually would be reused. The spontaneous secondary forest in such areas came to be everywhere dotted with valuable trees, remnants of past orchards and gardens. Elsewhere, in drier, more heavily populated areas where complex irrigation channels had been built to bring water to permanent plots of taro, there might also be permanent and highly diverse tree gardens surrounding the irrigated plots and shading the villages. On atolls, with their severe environmental constraints, a particularly intensive form of agroforestry had been developed to support the often high population densities. Spread through a matrix of planted coconut palms, which were particularly common and immensely useful on atolls, were a variety of other domesticated trees including species of *Pandanus*, breadfruit, and a native fig. As in much of the Pacific, what might look like an untouched natural forest to an uninformed eye was in reality a managed agroforest in which almost every tree was known and owned by an individual or a family and served at least one valuable purpose if not several. Unfortunately, a variety of present-day socio-economic factors and changes are leading to a decline of traditional agroforestry in the Pacific region.

Aida Yasuaki

JOCHI SHIGERU

Aida Yasuaki, also called Aida Ammei, was born in Yamagata, Japan on February 10, 1747 (March 20, in the present calendar). Aida studied mathematics under Okazaki Yasuyuki, a mathematician of the *Nakanishi-ryu* school, from the time he was 15 years old until he reached the level of the *Tianyuanshu* technique (Chinese Algebra system).

Then he went to Edo (now Tokyo), in September 1769 and became a son-in-law of SUZUKI Seizaemon, a Samurai of the Shogun. Aida changed his name to SUZUKI Hikosuke and worked as a *Fushin' yaku*, a civil engineer. Here he came to know KAMIYA Teirei, a student of FUJITA Sadasuke (1734–1807). Fujita was a mathematician of the *Seki-ryu* school who wrote the *Seiyo Sampo* (Exact Mathematics, 1781) which was one of the best mathematical textbooks of that time.

Aida decided to become a mathematician, retired from his work, changed his name back to Aida Yasuaki, and asked Fujita if he could teach mathematics. Fujita did not accept Aida's offer because he was concerned about mistakes in Aida's *Sangaku*. (*Sangaku* is a picture board with mathematical drawings, mostly of geographical problems. They were hung on the walls of shrines and temples for praying for mathematical progress.) Aida grew angry with Fujita and wrote the *Kaisei Sampō* (Counter-argument with Seiyo Sampo, 1785).

He then founded the *Saijō-ryū* school, and both schools disputed mathematics with each other for about 20 years. This encouraged Japanese mathematics to progress to a high level. Aida published eight books, nearly 2,000 chapters of manuscript. He taught mathematics to WATANABE Hajime (1767–1839), SAITO Naonaka (1773–1844), ICHINOSE Korenaga (fl. 1819), and KANDO Seii (nineteenth century).

Aida died at Edo (Tokyo) on October 26, 1817 (December 4 in the present calendar).

The strong point of the *Saijo-ryu* school was in systematic algebraic symbols. Aida created the original symbol for "equal," which was the first use of equal in Eastern Asia. He wrote the *Sampo Tensei-ho Shinan* (Mathematical Instruction of "Tensei-ho" (or the Tenzanjutsu technic in the Seki-ryu school)), which is one of the most systematic books describing the Japanese algebraic system.

Aida's mathematical method was similar to SEKI Kowa's. Aida studied the characteristics of irrational numbers. First, Aida computed the approximate value of irrational numbers by a sort of "Horner's method" (Horner 1819); then he computed the value of the continued fractions. An example of the root 2 is as follows:

Approximate value	Continued fraction
$\sqrt{2} \approx 1.4142$	1, 2, 2, 2, 2, 2, 1…
$\sqrt{2} \approx 1.414213$	1, 2, 2, 2, 2, 2, 2, 2, 1…
$\sqrt{2} \approx 1.41421356$	1, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 2, 1, …

Aida then calculated the continued fractional value of prime numbers smaller than 100. He also used the inductive method.

Ajima Naonobu

SHIGERU JOCHI

Ajima Naonobu (1739–1796), also called Ajima Chokuen, was born at Edo (now Tokyo) in 1732. Ajima's father was eighty *Pyo*[1] and a samurai warrior of Lord Shinjo,[2] in Dewa (now Yamagata prefecture). Ajima studied mathematics first under IRIE Masataka, a mathematician of the *Nakanishi-ryu* school, then under YAMAJI Nushizumi (also called Yamaji Shuji 1704–1772), who was the third president of the *Seki-ryu* school and an astronomer at *Bakufu Temmongata* (Shogun'sAstronomical Observatory). Then Ajima became an accountant of Lord Shinjo, at the rank of 100 *Koku*.

Yamaji made the *Horeki* (*Kojutsu*) *Reki* calendar (Calendar Made in Horeki Era 1754), which was used from 1755 to 1797; however, this calendar was not very accurate. In order to make a new luni-solar calendar, in 1762 he started to observe the sky with FUJITA Sadasuke (1734–1807), his assistant. When Fujita was appointed *Sangaku Shihan* (Professor of Mathematics) of Lord Arima (1714–1783) in 1768, he retired from the Shogun's Observatory. After that, Ajima helped Yamaji to observe the sky and taught astronomy at Yamaji's astronomical school. are Ajima wrote four astronomical manuscripts: *Jujireki Bimmo* (Introduction of the "Works and Days Calendar"), *Anshi Seiyo-reki Koso* (Professor Ajima's Studies for Western Calendars), *Ajima Sensei Bimmo no Jutsu* (Methods of Professor Ajima's "Bimmo") and *Koshoku Mokyu Zokkai* (Introductions of Eclipses (of the Sun and Moon)). These manuscripts were probably students' notes of Ajima's lectures.

The Lunar crater of "Naonobu" (4.6S 57.8E) commemorated him and was named in 1976.

Ajima's works for pure mathematics were studies for logarithms, computing the values of spheres, and series. Ajima and other Japanese mathematicians studied Western mathematics indirectly, that is to say, through Chinese books such as the *Shuli Jingyun* (Mei Juecheng (1681–1763), 1723, China). Ajima studied logarithms from this book, and then made a table of logarithms whose values are from 0.9 to 10^{-12}, 108 items. When Ajima used this table and these formulae:

$$\log = \log X + \log Y \quad \text{and} \quad \log 0 = 1,$$

he could compute all logarithmic numbers up to 12 decimal places.

Ajima expanded Japanese mathematicians' traditional method *Tetsu-jutsu*, which uses a sort of inductive method. (*Tetsu-jutsu* was created by TAKEBE Katahiro (1664–1739), second president of the *Seki-ryu* school.) Ajima computed the value of a sphere. In this case, he solved a sort of integral equation using *Tetsu-jutsu* twice.

Ajima also wrote the *Sansha San'en Jutsu* (Methods of Three Diagonals and Three Circles).

After Yamaji died, Ajima became the fourth president of the *Seki-ryu* school (or fifth, because Fujita was sometimes counted as the fourth). Ajima died in Tokyo, April 5, 1798 (May 20, 1798, current calendar).

[1] *Pyo* was an annual salary of 60 kg of rice, and 80 *pyo* was the same salary as a landlord of an 80-person village, or *Koku* would earn.
[2] Lord Shinjo belonged to the Tozawa family.

Al-Battānī

Julio Samsó

Abū ʿAbd Allāh Muḥammad ibn Jābir ibn Sinān al-Raqqī al-Ḥarrānī al-Ṣābiʾ was an extremely important Islamic astronomer of the ninth to tenth centuries. He was probably born in Ḥarrān before 858, and had Sabian ancestors. He lived most of his life in Raqqa (Syria) where he made most of his observations, but there is also evidence that he visited Baghdad and Antioch.

Apart from a few astrological tracts which have not been studied so far, he compiled (after 901) his *al-Zīj* (astronomical handbook with tables) also called *al-Zīj al-Ṣābi'* (Sabian *Zīj*), a work which marks the stage of full assimilation of Ptolemaic astronomy in Islam. This process had produced its first results ca. 830 with the *zījes* which were the consequence of the program of observations undertaken in Baghdad and Damascus under the patronage of Caliph al-Maʾmūn. Al-Battānī's *zīj* contains a set of instructions for the use of the numerical tables which have an essentially practical character. We do not find in them careful descriptions of the Ptolemaic models implied in the tables, and the author makes surprising simplifications, such as not describing Ptolemy's model for Mercury or not mentioning the equant point around which the mean motion of the center of the epicycle takes place. Nevertheless he describes, sometimes very carefully, the observations he made in Raqqa between 887 and 918, which allowed him to establish new and more precise mean motion parameters, a new eccentricity (0;2,4,45°) for the Sun and Venus, the longitude of the apogee (82;17°) of these two celestial bodies, a very accurate determination of the obliquity of the ecliptic (23;35°) (the band of the zodiac through which the Sun apparently moves in its yearly course), measurements of the apparent diameters of the Sun and the Moon, and their variation in a solar year and anomalistic month, respectively. These new parameters show a clear improvement over those of Ptolemy and led al-Battānī to establish some important corrections on Ptolemaic theory such as the mobility of the solar apogee, the fact that the obliquity of the ecliptic is not a fixed value, and the possibility of solar annular eclipses.

Apart from the *Almagest* and the *Planetary Hypotheses* (used by Battānī to determine the geocentric distances of the planets), Theon's *Handy Tables* constitute a major Ptolemaic influence in the *zīj*: the planetary equation tables (with the obvious exception of those for the equation of the center of Venus), for example, derive from Theon, and al-Battānī's work constitutes one of the important instruments for the diffusion of the *Handy Tables* during the Middle Ages. The *zīj* was translated twice into Latin (by Robert of Ketton and Plato of Tivoli) in the twelfth century, as well as into Spanish (thirteenth century) under the patronage of Alfonso X. It influenced strongly the Latin version of the *Alfonsine Tables*, was known in Jewish circles through the summary made in Hebrew by Abraham bar Ḥiyya (d. ca. 1136), and was quoted by European astronomers until the seventeenth century. Al-Battānī died in 929.

Al-Bīrūnī

Abdul Latif Samian

Abū Rayḥān Muḥammad ibn Aḥmad al-Bīrūnī was born on Thursday, 3rd of Dhū al-Hijjah, 362 H (4th September AD 973) at Madīnah Khwārizm. His exact birthplace is still a matter of controversy. It is conjectured that he was born in the outskirts (*bīrūn*) of Kath, at al-Jurjāniyah, Khwārizm or at a place called Bīrūn, as implied by his nickname al-Bīrūnī. The only clue given by al-Bīrūnī was that he was born in a city in Khwārizm. The name Abū Rayḥān was given to him because of his love for sweet fragrance. Al-Bīrūnī died on 443 H (AD 1051).

He knew Persian but preferred Arabic, because the latter was more suitable for academic pursuit. Most of his numerous books and compendia were written in Arabic. He received some of his early education under the tutelage of the astromathematician Abū Naṣr Manṣur b. ‘Alī b. Īrāq al-Jilāni (d. ca. 427 H) and ᶜAbd Al-Samad b. ᶜAbdal Samad from Khwārizm. This is in addition to his formal elementary religious education at the *madrasah*, an institution where Islamic sciences are studied.

Al-Bīrūnī’s first patron was the Sāmānid Sultan Abū Ṣālih Manṣūr II, who reigned in Bukhara until the city was invaded by the Ghaznavid Sultan Maḥmūd in 389 H (AD 999). Later al-Bīrūnī went to Jurjān to the court of Abu’l Haṣṣan Qābūs b. Washmjīr Shams al-Ma’ālī (r. AD 998–1012), under whose patronage he wrote *al-Āthār al-bāqiya min al-qurūn al-khāliya* (Chronology) which was completed in 390 H (AD 1000). Al-Bīrūnī found the Sultan indiscriminate and harsh. His next sojourn was in Khwārizm and Jurjāniyah, in the service of the Sāmānid Prince Abu’l Abbas al-Ma’mūn ibn Muḥammad II. Under his partonage, al-Bīrūnī received great respect. It was during this period that al-Bīrūnī met the physician ‘Abu Sahl ᶜIsa b. Yaḥaya al-Jurjāni. His *Taḥdīd nihāyāt al-amākin li taṣḥih masāfāt al-masākin* (Determination of the Coordinates of Cities) was completed in AD 1025.

His *Kitāb fī taḥqīq ma li’l-Hind* (Book on India) was finally published in 421 H (AD 1030). The Ghaznavid Sultan Maḥmūd invaded and conquered the city in 407 H (AD 1017). Al-Bīrūnī’s other book, *Kitāb al-tafhīm li-awā’il sināᶜat al-ṭānjīm* (The Book of Instruction in the Art of Astrology), which was dedicated to Rayḥānah, daughter of al-Ḥassan, was written in Ghaznah, AD 1029. Al-Bīrūnī’s *magnum opus*, *al-Qānūn al-Masᶜūdī fī al-hay’ah wa’l-tanjīm* (Canon Masudicus), an astronomical encyclopedia comprising 11 treatises divided into 143 chapters, was completed at a later date, in 427 H (AD 1035) and was dedicated to the son of Maḥmūd, Masᶜūd. Apart from emphasizing the importance of astronomy, he gave accurate latitudes and longitudes and also geodetic measurements. His *Kitāb al-jamāhir fī maᶜrifat al-jawāhir* (Mineralogy) was completed less than a decade later (about 435 H/AD 1043) and was dedicated to the Ghaznavid Prince Sultan Shihāb al-Dīn Abu’l Fatḥ Mawdūd b. Masūd, Sultan Maḥmūd’s grandson. His *Kitāb al-ṣaydanah fi’l-ṭibb* (Materia Medica or Pharmacology) was written toward the very end of his life.

Al-Bīrūnī lived during a period of intense scientific activity. Among his contemporaries were Ibn al-Haytham (AD 975–1039) and Abu ᶜAli al-Husayn ibn ᶜAbd Allāh ibn Sīnā (370 H/AD 980–428 H/AD 1027). Others include Abū Nasr Mansūr ibn ᶜAli ibn Irāq who was one of al-Bīrūnī’s patrons, Abū al-Hassān ᶜAli ibn Sāid ᶜAbd ar-Raḥmān ibn Aḥmād ibn Yūnus who was an astronomer of distinction (d. AD 1009), and Abū Sahl ᶜIsa ibn Yaḥya al-Masīhi al-Jurjāni (d. AD 1000) who was a close associate of al-Bīrūnī’s and wrote 12 books under his name.

Al-Bīrūnī was a philosopher–scientist, but science prevailed over philosophy and he appeared not to have identified himself with any school of philosophy. It was reported that he started doing astronomical observation as early as 18-years old.

In addition to his *Kitāb al-tafhīm* (Astrology) and his *Kitāb fī ifrād al-maqāl fī amr al-ẓilāl* (The Exhaustive Treatise on Shadows) we can also find remarks which reflect his conception of nature in his other works. As an example, the introduction to his *Kitāb al-jamāhir fī maᶜrifat al-jawāhir* consists of 15 *tarwīhāh* (philosophical reflections) which give his view on the attitude of man toward nature. It is more than a book on pearls and precious stones.

According to al-Bīrūnī, God creates nature from nothing (*creatio ex-nihilo*). Concerning his views on the relationship between man and nature, in his introduction to *Taḥdīd nihāyat al-amākin* (The Determination of the Coordinates of Cities), al-Bīrūnī explicitly refers to the *Qurʾānic* verse, “And contemplate the wonders of the creation in the Heavens and the Earth,” “Our Lord: Not for naught hast Thou created (all) this” (Ch. 3: 191). Moreover, al-Bīrūnī contends, “This noble verse contains the totality of what I have explained…” In other words, this particular *āyāt*, out of all the other *Qurʾānic* verses, is of paramount importance to his scholarly life.

The element of transcendence is evident in al-Bīrūnī’s outlook on nature. One of his major postulates is that God creates nature; al-Bīrūnī envisages from the very beginning the affinity between natural phenomena and their metaphysical causes. God creates nature through the *Qurʾānic* injunction of *kun fayakun* (Ch. 17: 163). Nature and her phenomena are nothing but the manifestation of God’s initial creative act that is verbal. But God’s creative act is also continuous. God always intervenes. It is different from the Cartesian worldview where God stops to intervene after the initial act of creation.

The laws of nature (*sunnat ‘Allah*), which are the laws of God and which to al-Bīrūnī warrant examination, are possible because of the appearance of permanency in them. The affinity between nature, the created, and God who is the Creator points also to the element of the sacredness of nature. The study of nature through contemplation and action ought to be done within the parameters of religion, which to al-Bīrūnī is Islam. Therefore there is an esoteric and exoteric utility to religion in studying nature. In addition to the esoteric utility of studying nature, al-Bīrūnī emphasizes the exoteric aspect too. Again, in *Kitāb Ṭāḥḍīḍ* (The Determination of the Coordinates), he states, “The Jews also need a direction, because they turn in their prayers to the Temple in Jerusalem… The Christian need the (direction of) true East because their elders…prescribed to them that they should turn to Paradise in their prayers."

Prayer (*ṣālat*) is one of the fundamental principles of Islam. It is well known that Muslims offer their prayers facing the *qibla* in Mecca. The problem for Muslims all over the world is to ensure that they are facing the correct direction in their prayers. This is an example of what can be viewed as the exoteric aspect which al-Bīrūnī attempted to solve.

Another example is determining the time for prayer. Al-Bīrūnī devoted a whole chapter in his *Kitāb fī ifrād al-maqāl fī amr al-zilāl* (The Exhaustive Treatise on Shadows) to this problem. Studying nature should not be for the sake of studying nature; there must be a greater purpose sanctioned by religion, and in this case it is to solve the problem faced by Muslims in offering their prayers.

Al-Bīrūnī places truth as one of the noble aims of contemplating nature. "I must assay all aspects of this statement, because I do not refuse to accept the truth from any source, wherever I can find it" (*Taḥdīd*). Studying nature is akin to an investigation to find out the truth. The external world can provide truth. Thus al-Bīrūnī maintains, "There is a great difference between an investigator of truth [who studies nature] and a follower of tradition." God says: "Are those equal, those who know and those who do not know" (*Taḥdīd*).

Al-Bīrūnī never uses the word "science" in the sense that the word is understood today – that knowledge which is exact, objective, verifiable, deductive, and systematic. The closest term that he ever used is the Arabic word *ᶜilm*, which also means knowledge. *Al-ᶜilm* in the language of the *Qurʾān* and Sunnah (traditions of the Prophet) implies knowledge which makes man conscious of God, of His attributes, of the eternals, of the next world, and of the return to Him.

Science, to al-Bīrūnī, is a problem-solving activity. Scientists seek solutions to problems. Solving problems, which to al-Bīrūnī is analogous to "untying knots," (*Kitāb fī ifrād al-maqāl*), is the main activity of scientists. That science is a problem-solving activity and a scientific problem is a problem circumscribed by the Holy *Qurʾān* and Sunnah which needs to be solved in order for a Muslim to improve his *taqwa* (God consciousness) can be discerned by examining, in particular, the Introductions of his major books. We can see in these cases that this concept of religion is fundamental in shaping his attitude toward science as a problem-solving activity. His *India*, for example, was written "as a help to those who want to discuss religious questions with them, as a repertory of information to those who want to associate with them."

In another work, *Taḥdīd nihāyat al-amākin* (The Determination of the Coordinates), he clearly states another aspect of a scientific problem. "Geography is very essential for a Muslim for knowing the right direction of *qibla*." Finding the direction of the *qibla* is an example of a scientific problem which is circumscribed by the *Qurʾān* and Sunnah.

The evaluation of the problems tackled, except in the *Taḥdīd*, is not given post hoc or ad hoc. It is not the case that al-Bīrūnī solved scientific problems before thinking of their necessity, their worthiness for the *society*, viz., their legitimacy from the *Qurʾānic* and Sunnah point of view. Concerning geography and astronomy, he states: "…For whoever determines the longitude and latitude of this country with precision will thereby enable him to find out…times which are needed…for fasting." Realizing the comprehensiveness of Islam as a complete way of life, he adds, "…the usefulness here exceeds specific religious matters and extends to worldly affairs." Clearly, there is a sacred orientation in scientific problems. Scientists *qua* scientists should solve problems in a manner which brings them closer to God that can "yield His satisfaction (*riḍā*)."

In yet another book, *The Exhaustive Treatise on Shadows*, we can see very clearly his orientation toward scientific problems. In studying shadows, not only did he analyze shadows of this world, but also shadows in the Hereafter. He investigated in detail their differences, similarities, and the nature of their existence. He differentiated between shadows in Heaven and shadows in Hell. Thus al-Bīrūnī showed that there is a "revealed perspective" on scientific problems which the scientist should take into account. The scientist should always be mindful of the connection that the problems have to this world and to the Hereafter. The science of astronomy, for example, has its origin from the prophet Idrīs. These are examples of scientific problems in the Holy *Qurʾān* and Sunnah that from al-Bīrūnī's point of view merit investigation.

There is an element of transcendence in seeking scientific solution. Al-Bīrūnī is always conscious of God while solving problems. He strives to be among those who "…remember Allah, standing, sitting and reclining and consider the creation of the heavens and the earth, (and say): O Lord; Thou created not this in vain." Examples are abundant in his writings where he invokes God's help. In *India*, he beseeches God to "help him to a proper insight into the nature of that which is false and idle, that he may sift it so as to distinguish the chaff from the wheat."

Generally speaking, within the schema of contemplation, al-Bīrūnī solves problems mathematically. He considers himself a mathematician more than anything else. In *al-Qānūn al-Masūdī*, he says: "…I belong to a branch of mathematics (*riyāḍhi*),… and have been known by it and may intention never exceeded it…"

There are two complementary aspects of his problem solving: one is the "external" and the other is the "internal." The "external" aspect involves more of the external senses as opposed to the "internal" aspect. The "internal" aspect heavily involves the processes of mathematical abstraction by the internal senses.

Man has to look for information, for evidence, in nature. This is an external aspect of his problem solving. "Human reason needs data and no human being can be an exception from the need of phenomena in which the mind functions" (*Kitāb al-Taḥdīd*). Al-Bīrūnī's statement urging his readers to observe and collect data about observables shed some light on his approach to mathematical inquiry: that the process of mathematization, from the external aspect that is, should have empirical import. There are two parts related to his external aspect of this problem solving (as an act of contemplation) that warrant elaboration. First is al-Bīrūnī's view on the manner in which one arrives at a theory and second in his perspective on theory choice.

Al-Bīrūnī attaches great importance to intense observation and putting exhaustive effort into procuring, comparing, analyzing, and synthesizing data (which includes both oral and written reports) in arriving at a theory. In fact in his *Kitāb fī ifrād al maqāl* (The Exhaustive Treatise on Shadows), he cautions people against "ignoramuses" who do not spare much effort but simply "attribute to God's wisdom all that they do not know of the physical sciences." The physical world is out there to be studied in order for us to internalize the greatness of God. Observation is essential to all scientific endeavors, including medicine. Al-Bīrūnī says, in the *Kitāb fī ifrād*, "through the frequency of observations he will gain in resource, both intellectual and intuitive."

To begin with, one has to define his object of study. In the case of geology, he needs to focus his observation on "the rocks and vestiges of the past." Observation involves seeing. Unlike Aristotle, who believed that vision was made possible by emitting rays from the eyes, al-Bīrūnī believed that rays were emitted to the eyes by the object themselves. Images are then formed in the eyes. There is no objective observation. Seeing is an experience. It is a not physical state. A retinal reaction is a photochemical excitation, a physical state. Scientists—and not their eyes—see. Al-Bīrūnī admits the possibility of the observation made by his contemporary, the astronomer Abū Saᶜid of Sistan, even though al-Bīrūnī preferred the geocentric theory. Unlike al-Bīrūnī, the latter was a proponent of the heliocentric (the sun is the center of the universe) theory. Al-Bīrūnī saw the sun rising but Abū Saᶜid saw the horizons of the earth changing in the East at dawn.

Al-Bīrūnī underscored the importance of observation not only in studying geology, but also in mineralogy. One should have keen eyesight, more so than others. Without good eyesight, it would be difficult for them to observe the minute differences and similarities in metals and precious stones.

It is through sight that mathematicians can observe nature and contemplate. Observation, which is an integral part of al-Bīrūnī's problem solving, is not only for the sake of accumulating information. Observation is done within the schema of contemplation. For example, in his *Kitāb ifrād al-maqāl* (The Exhaustive Treatise on Shadows), he quotes a *Qurʾānic* verse (Ch. 77: 31) and states: "If one meditates on the verse, he will find two of the attributes of the shadow in the masculine form…" In his *Kitāb al-jamāhir* (Mineralogy), he says: "Sight connects what we see to the signs of Divine Wisdom in creatures and demonstrates the existence of the Creator from his creation."

Sight and hearing are two of the most important sense perceptions for gathering data for scientific inquiry insofar as observation is concerned. Both are integrated "in the heart, which is the seat of intelligence."

Reports are equally important as observation. The scientist gathers his data from documented reports. Reports are written in several languages. Al-Bīrūnī's preference for Arabic is not without a strong reason. Through etymological examination of the names of things, the scientist can be more informed about them. For example, there is the word *falāk* in his explanation about celestial motion. He writes in *Kitāb al-tafhīm* (Astrology), "The celestial sphere…is called *falāk* on account of its circular movement, like that of a whirl of a spindle…"

It is interesting to note that in so far as history of science is concerned, al-Bīrūnī preferred written tradition to immediate observation and he recommended *comparing* reports. Al-Bīrūnī lamented his predecessors who did not scrutinize their data.

After focusing on the problem, al-Bīrūnī collects data which are then compared and analyzed or synthesized, mainly through experiment or verbal verification (questioning the transmitters) or both, depending upon the field of study. In al-Bīrūnī's pattern of problem solving, the stage of theorizing comes only after one has exhausted all reasonable efforts in procuring data and in comparing the results of previous or contemporary researches. It is only after he is satisfied with the amount of information relevant to the problem that he goes "from the known to the unknown, from the near distant to the far" – to wit, the inductive and deductive process.

Examples are abundant throughout his works which demonstrate this exhaustive effort. In his study of astronomy, after procuring data, he examines solutions offered by others. His study entitled "A Number of Topics Dealing with Shadows" is a case in point. In it he discusses methods for computing the length of daylight at any time of the year used by Brahmagupta, Vijayanandin, and Yaᶜqūb ibn Tāriq besides three other methods of Babylonian and Persian origin.

In the fourth chapter of *al-Qānūn al-Masᶜūdī* (Canon Masudicus), he compared results obtained by Ptolemy and one Yaᶜqūb al-Sehri and thereafter made the trenchant remark, "Both the methods give results correct to the second order but Ptolemy understood what he did, whilst Yaᶜqūb did not known what he was doing." In mineralogy, there were extensive etymological considerations in his analysis of minerals. He revised the findings of others. He did the same in his studies of medicine in his *Kitāb al-ṣaydanah* (Materia Medica or Pharmacology).

In his analysis of societies such as in *Kitāb fī taḥqīq ma li'l Hind* and *al-Āthār al-bāqiya* (India and Chronology), in subtopics where experiments could not be conducted, where most of the data is not in the form of direct observation but through oral and written reports, he examines witnesses to remove distortions in addition to comparing reports to ensure that they are as correct and accurate as possible. His emphasis is on the comparative method. In his *al-Āthār al-bāqiya*, he writes on most, if not all, of the festivals of various creeds and religions found in the regions of the Caliphate. In *Kitāb fī taḥqīq* he compares the beliefs and lifestyles of the Hindus with Buddhists, Manicheans, and Zoroastrians to what others wrote about them. Similarly in his study of the circumference of the earth, al-Bīrūnī examines the previous results obtained by astronomers under the patronage of Ma'mūn al-Rashid (AD 813–833), the Abbāsid Caliph. He discovers that they reached different results. Dissatisfied, he conducted experiments in the area of Ghazz, Turks, and Jurjān.

In the external aspect of al-Bīrūnī's pattern of scientific problem solving, the problem of theory choice from his view occurs when there are several possible theories (as viable solutions) to a specific problem. In particular, the problem arises when al-Bīrūnī compares possible explanations in order to find a good one. Al-Bīrūnī does have some criteria which determine his choice and these criteria help him in formulating a good theory. What is more interesting is that these criteria reflect his scientific acumen and his conception of God (as the "perfect scientist").

An important criterion to al-Bīrūnī is accuracy. That accuracy dictates the choice of one theory instead of another is partly because accuracy is less equivocal compared to other characteristics such as simplicity or fruitfulness. The predictive and explanatory power of theories depends on their accuracies. Al-Bīrūnī knew that accuracy is almost synonymous with exactness which certainly involves measurements. The finer the measurement, the higher the degrees of accuracy. Al-Bīrūnī's treatment on measurements, on inventing measuring instruments such as the *Yamīni* ring, the *Ustuwani* which he used "to measure the height of heavenly bodies, their apogees, time, depth of well or rivers and heights of walls, towers and hills..." His expertise with *al-dahj*, *sarqālah al-ma'*, *Sirāj al-Khādim*, and *naqshah*, and a particular machine that found the exact prayer times which he constructed for the mosque in Ghaznah, points to the importance of accuracy to him. More important than that, the striving for accuracy on the part of the scientist reflects al-Bīrūnī's understanding that perfect scientific knowledge belongs to no other but God because it is only He that measures perfectly.

In addition to accuracy, another criterion is novelty. Al-Bīrūnī believed that a good theory should be able to disclose new relationships of previously unnoted phenomena. A theory should help the mathematician to discover "new" aspects of God's creation, increasing his awareness of God as *al-Khāliq*, the Creator who creates everything unceasingly. An example to illustrate this is al-Bīrūnī's study of the variation in the length of the year related to the motion of the apogee where he gives the theorem "that the apogee and the perigee are the points at which the apparent velocity reaches its extreme values."

However the most important criterion is truth. Truth to al-Bīrūnī is more than a regulative principle; it is *the* regulative principle. The notion of truth is central to his conception of problem solving. We can find that truth permeates at all stages in his pattern of problem solving outlined above. Al-Bīrūnī did not view truth as an illusive notion which, construed as such, is irrelevant to science. After focusing on a particular problem, he begins his inquiry in *al-Āthār al-bāqiya* (Chronology) by asking God to "help [him in] perceiving and realising the Truth, and facilitate its pursuit and lighten its courses..." In collecting as much relevant information as possible to the problem, he states in *Taḥdīd* (The Determination of the Coordinates): "I do not scorn to accept truth from whatever source I can find it." He even reminded himself in *India* to "speak the truth, even if it were against yourselves." In *Chronology*, al-Bīrūnī perceives truth as that which is "enjoined by the holy scriptures on mankind [and] possesses its own intrinsic beauty just like justice..."

Al-Bīrūnī's notion of truth is not equivalent to the popular conceptions of truth. It cannot be construed as correspondence theory of truth favored by realists. Neither can it be categorized under the coherence theory nor the pragmatic theory of truth per se. These are the reductive approaches to truth. Truth, to al-Bīrūnī, must be seen from the perspective of the *Holy Qurʾān dan Sunnah* since the *Qurʾān* is revealed as a "guidance" (*huda*). Therefore it is interesting to note that whenever a theory which is a result of his rigorous approach is not consistent with a new discovery of an "irregularity" of nature, it points not so much to its falsity but more so to Divine Wisdom.

In light of the importance of contemplation to al-Bīrūnī, it needs to be emphasized that although al-Bīrūnī construes science as an activity of problem solving, the scientist himself is not obsessed with the problems. Rather he is obsessed with the relationship between himself and God. It is God that is central in this problem-solving activity. Therefore solving scientific problems is only a consequence of his consciousness and conception of God.

To recapitulate, nature to al-Bīrūnī is the handiwork of God. The activity of deciphering nature, of solving scientific problems, can be an act of *ʿibādah*, a "sacred" act which can raise the status of the scientist in the eyes of God. Scientific activity to al-Bīrūnī is an activity bounded by the parameter of religion. In his quest to gain understanding of nature, he believed that one should be conscious of Divine Wisdom, which is manifested in nature and all its intricacies. It is both a theoretical and practical activity of solving problems. As a very prolific and multidimensional scholar, al-Bīrūnī did serious work in almost all branches of science in his time and his 146 treatises range from 10 to 700 pages each.

Al-Bīrūnī and Geography

Akhtar H. Siddiqi

The geographical knowledge of the Muslims, in part derived from the Greeks and others, and contemporaneously developed and advanced by themselves, had reached a very high level of development by the tenth century. It is in this development that the work of al-Bīrūnī is significant. Al-Bīrūnī presented a critical summary of the total geographical knowledge up to his own time. He made some remarkable theoretical advances in general, physical, and human geography. Al-Bīrūnī did not confine himself to a simple description of the subject matter with which he was concerned. He compared it with relevant materials and evidence, and evaluated it critically, offering alternative solutions.

George Sarton identifies al-Bīrūnī as one of the great leaders of this period because of his relative freedom from prejudice and his intellectual curiosity. Although his interests ranged from mathematics, astronomy, physics and the history of science to moral philosophy, comparative religion and civilization, al-Bīrūnī became interested in geography at a young age. He is considered to be the greatest geographer of his time.

In the area of physical geography, he discussed physical laws in analyzing meteorology and climatology. He wrote of the process of streams development and landscape evolution. He introduced geomorphological enquiry to elucidate a history of landscape. He developed the mathematical side of geography, making geodetic measurements and determining with remarkable precision the coordinates of a number of places. Some of his noteworthy contributions to geography include: a theory of landform building processes (erosion, transportation, and deposition), proofs that light travels faster than sound, explanations of the force of gravity, determination of the sun's declination and zenithal movement, and discussion of whether the Earth rotates on its axis. He described various concepts of the limits for which he seems to have had recourse to contemporary sources not available to earlier geographers. He made original contributions to the regional geography of India.

In the study of physical phenomena, including landforms, weather, and geology, al-Bīrūnī adopted the methods of the physical sciences and drew conclusions with scientific precision. Al-Bīrūnī developed a schema for physical geography: (a) terrestrial conditions, describing the shape and size of the Earth; (b) cosmic concepts, dealing with the measurement of the circumference of the Earth and the establishment of the exact location of places; and (c) classification of natural phenomena either in accordance with their nature or with their position in time and space. He studied phenomena in time (chronological science) and also tried to study them in space. In his view, geography was an empirical science.

Based on available knowledge concerning the surface of the Earth, he deduced and described the shape and forms of land surface. Al-Bīrūnī examined questions concerning the Earth's shape, size, and movement.

He explained running water as the most effective agent by which the surface of the land is sculpted. He further asserted that as the rivers of the plains of India approached the sea they gradually lost their velocity and their power of transportation, while the deposition process along their beds increased proportionately. Al-Bīrūnī considered the changes in the course of a river a universal phenomenon. He also recognized the influence of the sun upon the tide and suggested that heavenly bodies exert a gravitational effect on the tides.

Al-Bīrūnī recognized that the heat of the atmosphere and the Earth's surface is derived from the sun through the transfer of energy by rays, and that it varies with the length of time that the Earth is exposed to the rays. He recognized the wind's force and velocity and argued that the wind, in all its phases, is determined by certain causes.

Al-Bīrūnī noticed the peculiarities of the Indian monsoon, observed the time of its breaking, and described its westward and northward movements and the unequal distribution of rain in different areas of India.

Finally, he added that the habitable world does not reach the north on account of the cold, except in certain places where it penetrates into the north in the shape, as it were, of tongues and bays. In the south it reaches as far as the coast of the ocean, which in the east and west is connected with what he calls the comprehending ocean (*India*, Vol. I, p. 196).

In short, al-Bīrūnī recognized geography as an empirical science, and he dealt with the terrestrial globe as a whole. He stressed its nature and properties. He also tried to investigate the causes of global phenomena and described them as they existed.

Al-Biṭrūjī

Julio Samsó

Al-Biṭrūjī (fl. 1185–1192) was an Andalusian astronomer whose complete name seems to be Abū Isḥāq (ibn?) al-Biṭrūjī, Nūr al-Dīn. Nothing is known about his biography apart from the fact that his name probably derives from the region of Los Pedroches, near Cordoba, and that he was a disciple of the philosopher Ibn Ṭufayl (ca. 1110–1185). The latter was already dead when al-Biṭrūjī wrote his only known work, the *Kitāb fī-l-hayʾa* (Book on Cosmology), which seems to have been read by the anonymous author of a book on tides dated in 1192. On the other hand, al-Biṭrūjī's treatise was translated into Latin by Michael Scott in Toledo in 1217.

Al-Biṭrūjī was a member of the Andalusian school of Aristotelian philosophers composed of Ibn Bājja (1070?–1138), the aforementioned Ibn Ṭufayl, Ibn Rushd (Averroes, 1126–1198), and Mūsā ibn Maymūn (Maimonides, 1135–1204). All these authors criticized Ptolemaic astronomy due to its mathematical character which did not agree with Aristotelian physics. Al-Biṭrūjī was, however, the only one who made a serious, although unsuccessful, attempt to create an astronomical system which could have a physical reality. In it he uses homocentric spheres in the Eudoxan tradition which he combines with materials derived from the Toledan astronomer Ibn al-Zarqāllu (Azarquiel, d. 1100). It is interesting to remark that al-Biṭrūjī's dynamics are not exclusively Aristotelian but also use Neoplatonic concepts such as the impetus theory which he seems to have been the first to introduce into Western Islam. Al-Biṭrūjī's system was soon known in Western Europe and became very popular among Scholastic philosophers of the thirteenth century, who considered it a serious alternative to Ptolemy.

Alchemy in China

Fabrizio Pregadio

In China, as elsewhere, alchemy is a science based on cosmological doctrines, aiming to afford (a) an understanding of the principles governing the formation and functioning of the cosmos, and (b) the transcendence of those very principles. These two facets are complementary and ultimately equivalent: the alchemist rises through the hierarchy of the constituents of being by "exhausting" (*jin* or *liao*, two words also denoting "thorough knowledge") the nature and properties of each previous stage. He thus overcomes the limits of individuality, and ascends to higher states of being; he becomes, in Chinese terms, a *zhenren* or Authentic Man.

While historical and literary sources (including poetry) provide many important details, the bulk of the Chinese alchemical sources is found in the *Daozang* (Daoist Canon), the largest collection of Daoist texts. One fifth of its approximately 1,500 texts are closely related to the various alchemical traditions that developed until the fifteenth century, when the extant Canon was compiled and printed. Later texts are included in the *Daozang jiyao* (Essentials of the Daoist Canon) and other minor collections. Modern study of the alchemical literature began in the present century, after the Canon was reprinted and made widely available in 1926. Among the most important contributions in Western languages are those of Needham (1978), Sivin (1968, 1976, 1980, 1990), Ho (1985), Baldrian-Hussein (1984), and Robinet (1989).

Though the underlying doctrines remained unchanged, Chinese alchemy went through a complex and not yet entirely understood development along its 20 centuries of documented history. The two main traditions are conventionally known as *waidan* or "external alchemy" and *neidan* or "internal alchemy." The former, which arose earlier, is based on the preparation of elixirs through the manipulation of natural substances. Its texts consist of recipes, along with descriptions of ingredients, ritual rules, and passages concerned with the cosmological associations of minerals and metals, instruments, and operation. Internal alchemy developed as an independent discipline around the middle or the late Tang period (618–906). It borrows a substantial part of its vocabulary from its earlier counterpart, but aims to produce an elixir – equated with transcendental knowledge – within the alchemist's person.

At the basis of both traditions are traditional doctrines of metaphysics and cosmology. Chinese alchemy has always been closely related to the teachings that find their classical expression in the early "philosophical" texts of Daoism, especially the *Daode jing* and the *Zhuangzi*. The cosmos as we know it is conceived of as the final stage in a series of spontaneous transmutations stemming from original nonbeing. This process entails the apparent separation of primeval Unity into the two complementary principles, *yin* and *yang*. Once the cosmogonic process is completed, the cosmos is perceived as subject to the laws of cosmology, *wuxing*, the Five Agents or Phases. The alchemist's task is to retrace this process backward. Alchemy, whether "external" or "internal," provides him with a support, leading him to the point when, as some texts put it, "Heaven spontaneously reveals its secrets." Its practice must be performed under the close supervision of a master, who provides the oral instructions (*koujue*) necessary to an understanding of the processes that the adept performs with minerals and metals, or undergoes within himself.

In order to transcend space and time – the two main features of the cosmos as it is ordinarily perceived – the alchemist should take extreme care of their correspondences to the work he performs. Space is delimited and protected by talismans (*fu*), and the laboratory (*danwu* or "chamber of the elixirs"), and instruments are properly oriented. According to some texts, heating must conform to minutely defined time cycles. This system, known as "fire times" (*huohou*) and sometimes described in painstaking detail, allows an adept to perform in a relatively short time the same work that Nature would achieve in thousands of years – in other words, to accelerate the rhythms of Nature. Bringing time to its end, or tracing it back to its beginning, is equivalent: in either case time is transcended, and the alchemist gains access to the eternal, constant present that precedes (or follows, though both terms become inadequate) the time of cosmogony and cosmology. The same is true with space: its center, where the alchemist places himself and his work, is a point devoid of dimension. From this point without space and time he is able to move at will along the axis that connects the higher and lower levels of being ("Heaven," *tian* and the "Abyss," *yuan*).

Among a variety of procedures that the sources describe in an often allusive way, and in a language rich in metaphors and secret names, two stand out for their recurrence and importance. The first is based on lead (*yin*) and mercury (*yang*). In external alchemy the two substances are refined and joined in a compound whose properties are likened to the condition of primal Unity. In internal alchemy, lead becomes a cover name for the knowledge of the Dao (pure yang, *chunyang*) with which each being is fundamentally endowed, but which is obscured (i.e., transmuted into yin) in the conditioned state. Mercury, on the other hand, represents the individual mind. The second most important method, which is proper to external alchemy, is centered on cinnabar (yang). The mercury contained therein (representing as such the Yin principle contained within the yang) is extracted and newly added to sulfur (yang). This process, typically performed nine times, finally yields an elixir embodying the luminous qualities of pure yang. This yang is not the complementary opposite of yin, but, again, represents the one before its apparent separation into the two complementary principles.

The final object of both disciplines is represented as the preparation of an elixir commonly defined as *huandan* (lit., elixir of return). This expression, recurring in the whole literature, originally denotes an elixir obtained by bringing the ingredients back to their original condition through repeated cyclical operations – an operation comparable to the process that the adept performs within himself with the support of the alchemical practice. The word *dan* (elixir) also denotes cinnabar, suggesting that the process begins and ends on two corresponding points along an ascensional spiral. This synonymy also shows the centrality of cinnabar in external alchemy, where this substance plays a role comparable to that of gold in the corresponding Western traditions. This role is taken by lead in internal alchemy. Both lead and gold, in their turn, are denoted by the word *jin*. The value of gold, and the word "gold" itself, is therefore mainly symbolic in China: the elixir, whether external or internal, and whatever its ingredients, is often defined as "gold," and Golden Elixir (*jindan*) is a name of the alchemical arts.

The extant *waidan* sources suggest that the two main methods outlined above acquired progressive importance in the history of the discipline. In the *Huangdi jiuding shendan jing* (Book of the Nine Elixirs) and other texts dating from the first centuries AD, cinnabar is never the main ingredient of an elixir, and the lead–mercury compound – sometimes replaced by refined lead alone – is only used as a layer in the crucible together with other ingredients. In these methods, the substances undergo cycles of refining in a hermetically sealed crucible. This process consists of a backward reenactment of cosmogony that brings the ingredients to a state of *prima materia*. The elixir can be finally transmuted into alchemical gold projecting on it a minute quantity of the native metal. Important details on the early phase of Chinese alchemy are also found in portions of the *Baopu zi neipian*, written around AD 320 by Ge Hong. Its descriptions of processes that can be compared with extant sources are, however, often abridged and sometimes inaccurate.

During the Tang dynasty, the *waidan* tradition reached one of its peaks with Chen Shaowei (beginning of the eighth century), whose work describes the preparation of an elixir obtained by the refining of cinnabar. Each cycle yields a "gold" that can be ingested, or used as an ingredient in the next cycle. In the second part of the process, the final product of the first part is used as an ingredient of a *huandan*. Among the representative texts of this period are several collections of recipes, one of the most important of which was compiled by Sun Simo. The first half of the Tang dynasty also marked the climax of contacts between China and the Arabic world. These exchanges may be at the origin of the medieval word *alchymia*, one of whose suggested etymologies is from middle Chinese *kiem-yak* (the approximate pronunciation of the modern *jinye* or "Golden Liquor") with the addition of the Arabic prefix *al-*.

While the Tang period is sometimes defined as the golden age of external alchemy, it also marked the stage of transition to internal alchemy. This shift, sometimes taken to be only due to the multiplication of cases of elixir poisoning, or to the influence of Buddhism, requires further study to be properly evaluated. The very incidence and relevance of cases of accidental poisoning (which claimed their toll even among Emperors) suggest that external alchemy had lost, at least to some extent and in some contexts, its soteriological character, and that its practices had become known outside the legitimate transmission. Some masters may, therefore, have transmitted their doctrine modifying the supports used for the practice. In internal alchemy, the adept's person itself performs the role which natural substances and instruments play in external alchemy. In doing so, this discipline avails itself – in ways and degrees that vary, and which require further study to be correctly understood – of traditional Chinese doctrines based on the analogies between macrocosm and microcosm, of earlier native contemplative and meditative disciplines, and of practices of Buddhist origin (apparently of Tantric character, through the possible medium of the Tiantai school).

Among the forerunners of internal alchemy is the Shangqing (Supreme Purity) tradition of Daoism, as practiced for example by Tao Hongjing. Based on revelations of the late fourth century, this school attributed particular importance to meditation, but also included the compounding of elixirs among its practices. (Shangqing represents in fact the first example of close relations between alchemy and an established movement of "religious" Daoism.) The relevant sources exhibit the earliest traces of the interiorization of alchemy. Among the texts used in this school is the *Huangting jing* (Book of the Yellow Court), a meditation manual often quoted in *neidan* texts.

In Song and Yuan times, the history of *neidan* identifies itself with that of the lines of transmission known as Southern Lineage (*nanzong*) and Northern Lineage (*beizong*). The respective initiators were Zhang Boduan (eleventh century) and Wang Zhe (1112–1170). Both schools placed emphasis on the cultivation of *xing* and *ming*, which constitute two central notions of internal alchemy. *Xing* refers to one's original nature, whose properties, transcending individuality, are identical to those of pure being and, even beyond, nonbeing. *Ming* denotes the "imprint," as it is, that each individual entity receives upon being generated, and which may or may not be actualized in life (the word also means "destiny" or "life," but neither translation covers all the implications in a *neidan* context). The Northern and Southern lineages, and subtraditions within them, were distinguished by the relative emphasis given to either element. The textual foundation of both lineages was provided by the *Zhouyi cantong qi* of Wei Boyang, and the *Wuzhen pian* (Awakening to Reality), a work in poetry by Zhang Boduan.

During the Ming and Qing dynasties the *neidan* tradition is known to have divided into several schools, but their history and doctrines are still barely appreciated. One of the last greatest known masters of this discipline was Liu Yiming (eighteenth century), who, in his works, propounded an entirely spiritual interpretation of the scriptural sources of his tradition.

Alchemy in Islam

Karin Ryding

Arabic alchemical writing and documentation emerges in approximately the second half of the eighth century (750–800 AD), a period that witnessed substantial growth in intellectual activity and methodological refinement for all the known sciences. With the rapid expansion of the Islamic empire, knowledge from civilizations such as the Greek, Persian and Indian was melded and shared by means of the new lingua franca, Arabic. The unifying force of the Arabic language enabled scholars of diverse ethnic and disciplinary origins to exchange ideas, to transmit those ideas to their students, and to develop conceptual frameworks for exploring and expanding knowledge of the natural world. The Arabic term *al-kīmyāʾ* appears morphologically to be non-Arabic in origin, most likely a borrowing from Syriac *kīmīyā*, which may derive from Greek *khemeia*, or *khymia*, prefixed with the definite article *al-* in Arabic (Ullman 1965: 110; Wild 1965: 4). This word has survived as the term for the entire pre-modern tradition of proto-chemistry. Nonetheless, this era within the Arabic/Islamic cultural tradition remains little explored and poorly understood within mainstream history of science.

Arabic alchemical writings show influences of Egyptian, Greek, Sabaean, Syriac, Persian, and Indian cultures. Hermetic and gnostic influences are abundant, as many Arabic alchemical texts combine description and analysis of naturally occurring substances and chemical experiments with firm admonitions to adepts on the need for purity of heart, behavior and intent in order for transformation to occur.[1] The texts evidence not only cultural syncretism, but also interweave practices for psycho-spiritual transcendence with procedures to transform natural substances. The distinctive discourse of Arabic alchemical texts is variable in style. Sometimes it is descriptive, didactic, and straightforward, other times complex, highly abstract, mystical, and profoundly arcane.

That alchemy was well established as a branch of scientific study is attested by the fact that two 10th-century Arabic encyclopedia authors, al-Nadīm and al-Khwārizmī, each have extensive chapters on alchemy. Both chapters are available in English translation (Dodge 1970; Ryding 1994). Al-Nadīm focuses on the history, personalities, and scholarly works of the alchemists, whereas al-Khwārizmī concentrates on the instruments, substances and procedures involved in alchemical operations.

The earliest Arab contributor to alchemical science is reputed to have been the Umayyad prince Khālid ibn Yazīd ibn Muʿāwiya ibn Abī Sufyān (ca. 665–704) (Nadīm 1970, chapter on alchemy). Tradition says that he was instructed in alchemy by a Christian monk named Morienus/Marianus. A Latin manuscript entitled the *Booklet of Morienus Romanus, of old the Hermit of Jerusalem, on the Transfiguration of the Metals and the Whole of the Ancient Philosophers' Occult Arts,* appeared in Paris in 1559 with the notation that the original translation from the Arabic was dated 1182. Stavenhagen (1974) has details on the manuscript as well as the English translation. Documentation of al-Khālid's alchemical interests is sketchy; no works of his on the topic have been discovered, and some scholars consider al-Khālid's reputation for alchemical scholarship unjustified (e.g., Ruska 1924).

The central figure in Arabic alchemy is the semilegendary Jābir ibn Hayyān, who is said to have lived in Mesopotamia during the second half of the eighth century and died around 810–815 AD (Holmyard 1923: 47). Nadīm gives Jābir's full name as (Abū Mūsā ʿĀmī) Abū ʿAbdallāh Jābir ibn Ḥayyān ibn ʿAbdallāh al-Kūfī, known as al-Ṣūfī (Nadīm 1988: 420). Elsewhere his name is given as Abū Mūsā, and he is variously described as Tūsī, Tartūsī or Tarsūsī, Harranian and from Khorasān (Holmyard 1923: 47). Major Arab biographers (including Nadīm, Qifṭī, and al-Kutubī) consider him a genuine historical personage (Qiftī 1903: 160–1; Al-Kutubī 1973). Sarton considers him "the most famous alchemist of Islam," calling the era 750–800, the Age of Jābir ibn Ḥayyān" (Sarton 1927: 521).

There has been debate as to the extent of Jābir's authorship of what is referred to as the Jābirian corpus, with Kraus, Mieli, Ruska, and Plessner asserting that these works are largely attributable to an early Ismaʿīlī sect in the late tenth century (Kraus 1986, also Plessner and Kraus 1968; Plessner 1980), whereas Holmyard, Stapleton, and more recently, Corbin and Lory, give substantially more credence to the authorship of the historical Jābir.[2] The Jābirian manuscript matrix may include later accretions

[1] See Affifi (1949), Plessner (1954), and Corbin (1964: 179–183) on hermeticism in Arabic sciences. For more on the Arabic *corpus hermeticum* see Klein-Franke (1973). On Islamic gnosis see Corbin (1975), and for Egyptian hermeticism in particular, see Fowden (1996).

[2] See especially Corbin (1986: 68–69), where he discusses the work of Paul Kraus, "notre regretté collègue" who, he states, "fût entraîné sur sa lancée à un certain extrémisme." (our sorely-missed colleague, who was drawn by his impulsiveness to a certain degree of extremism.) He goes on to state that "il se trouve que depuis trente ans la théorie traditionnelle a trouvé de vigoureux défenseurs, dont les recherches ont sérieusement ébranlé la thèse extrémiste de Paul Kraus." (For 30 years the traditional theory has found vigorous defenders whose research has seriously weakened the extremist thesis of Paul Kraus.) See also Holmyard (1923), Corbin (1964: 184ff); Lory's introduction to Corbin (1986: 20ff); Stapleton (1936), and Sezgin (1971: 132–269). Cf. Hachmi (1961), Macuch (1982), Mahmūd (1975), and Burnett (1992).

from commentators and imitators, with a core of authentic older writings.

Whether or not the original Jābir is the source of all the manuscripts attributed to him in Arabic, and whether or not any of those writings constitute the source of the contributions of the European Geber has not yet been established, since the extant Arabic manuscripts have not been compared thoroughly or systematically with those in Latin of the European Geber. On this topic, see Holmyard's introduction to Russell (1678, 1928), esp. pp. xvii–xxi and on the European Geber see Newman's extensive 1991 analysis.

As Manfred Ullman states (1965: 112),

> Arabic alchemy holds a key position in the development of chemical thinking as a whole. However, in glaring contrast to its importance, it has been regrettably neglected by research until now. Most of what historians of science have written on the Arabic alchemists is second-hand, based on obsolescent literature and disfigured by gross errors. A vast and fertile field lies here open to research; access to it, however, is not easy.

Ullman (1965: 113) cites three components of the theoretical foundations of Arabic alchemy (1) The quicksilver–sulfur method for synthesizing gold, calculating the true proportions of quicksilver and sulfur in gold and endeavoring to reproduce those proportions; (2) The doctrine of "the relations of quantities" (used especially in the Jābirian texts). This took the form of speculation on the concept of balance, especially the "balance of letters", a form of phonosymbolism wherein the letters of the Arabic alphabet are attributed certain weights (in dirhams) and qualities (dryness, moisture, heat, cold) that correspond proportionately to the contents of minerals and metals as they occur in the names of those metals (Kraus 1986: vol. 2, 223–236). Thus the name of a particular metal such as lead (*usrub*) reflects exactly the essence of that metal; (3) Formulating the elixir (*al-ʾ iksīr*) that, when added to base metals, has the power to transform them into gold or silver, or to grant everlasting life.

Other major contributors to the vast alchemical literature of Islam include Abū Bakr Muhammad ibn Zakariyā al-Rāzi (Rhazes) (ca. 864–925 or 935), whose work in alchemy "takes a new, more empirical and naturalistic approach than that of the Greeks of Djabir" (Goodman 2001), Muhammad Ibn Umayl (ca. 900–960), and Aydamīr ibn Alī al-Jildakī (fourteenth century). Translations of all these texts, starting with Jābir, are sorely needed.

Al-Damīrī

Emilia Calvo

Al-Damīrī Muḥammad ibn Mūsa ibn ʿĪsā was born in Cairo, Egypt in AD 1341. Although he began work as a tailor, he soon decided to study with the leading teachers of the time such as Bahāʾ al-Dīn al-Subkī, Jamāl al-Dīn al-Asnāwī, Ibn ʿAqīl, and others. He became a professional theologian and taught in different centers such as al-Azhar University, achieving a great recognition for his preaching and his ascetic life. A very religious man, he made the pilgrimage to Mecca six times between AD 1361 and 1367 and died in Cairo in AD 1405.

The majority of al-Damīrī's works are conventional commentaries and epitomes of earlier works such as the one on al-Nawawī's *Minhāj* (a manual of Islamic law). He also wrote sermons and treatises on canon law. Most of these works seem to be lost. His most famous work is *Hayāt al-ḥayawān* (Life of the Animals), a zoological dictionary which contains information on the animals mentioned in the *Quʾrān* and in the Arabic literature. It includes not only the zoological aspects, but also everything related to the animals mentioned.

The work contains 1,069 articles describing a lesser number of animals because the same animal is occasionally described twice using two different names. The animals are described in alphabetical order and usually contain seven sections (1) grammatical and lexicographical peculiarities of the name, (2) a description of the animal according to the leading authorities, (3) Muslim traditions in which the animal is mentioned, (4) juridico-theological considerations regarding the animal, (5) proverbs about the animal, (6) the medicinal properties of the products derived from the animal, and (7) rules for the interpretation of dreams in which the animal appears.

There are three versions of this work: the large (*al-kubrā*), the medium (*al-wusṭā*), and the small (*al-ṣugrā*) and it has been republished several times and translated into Persian and Turkish.

Al-Farghānī

Ahmed Bouzid

Al-Farghānī, Abu-l-ʿAbbas Aḥmad ibn Muḥammad ibn Kathīr was born in Farghana, Transoxania and died in Egypt, ca. 850. He was a famous astronomer during the time of the ʿAbbasid caliph al-Maʾmūn and a contemporary of al-Khwārizmī, al-Marwarudhī, al-Jawharī, and Yaḥya ibn Abi-Manṣūr. He was well known in the Latin Middle Ages under the name of Alfraganus, thanks principally to his widely read book, *Compilatio astronomica* (also called *Liber 30 differentiarum*, Book of the 30 Chapters), which is a summary of Ptolemy's *Almagest*. The work still survives in Arabic under the following titles: *Jawāmiʿ ʿilm al-nujūm wa'l-ḥarakāt al-samāwiyya*, *Uṣūl ʿilm al-nujūm*, *ʿllal al-aflāk*, and *Kitāb al-fuṣūl al-thalāthīn*. The *Jawāmiʿ* (sometimes translated as *Elements*) provided the medieval reader with a rather comprehensive account of Ptolemy's astronomy through a well-organized, accessible, and nonmathematical presentation. The work was translated into Latin at least twice in the twelfth century: by John of Spain (John of Seville) in 1135, and by Gerard of Cremona before 1175. The *Jawāmiʿ* was also translated into Hebrew during the thirteenth century by Jacob Anatoli. Copies of this translation exist today in Berlin, Munich, Vienna, and Oxford, among other places. In 1590, drawing from Anatoli's translation, Jacob Christmann published the third Latin version of the book in Frankfurt-am-Main. A later Latin translation of the text, along with al-Farghānī's original Arabic, was published in 1669 by Jacob Golius. Widely circulated in the West during the Middle Ages, the *Jawāmiʿ* was frequently referenced by medieval writers, and it is generally accredited today for having contributed considerably to the propagation of knowledge on the Ptolemaic system. In addition to the *Jawāmiʿ*, al-Farghānī wrote on the astrolabe. A number of his manuscripts on the subject survive under the following titles: *Fīṣanʿ at al-asṭurlāb*, *al-Kāmil fi'l-asṭurlāb*, and *Kitāb ʿamal al-asṭurlāb*.

Al-Fazārī

Boris Rosenfeld

Abū Isḥāq Ibrāhīm ibn Ḥabīb ibn Sulaymān ibn Samura ibn Jundab al-Fazārī (d. ca. 777) was a Muslim astronomer and the first Muslim constructor of astrolabes. He was the author of many scientific works whose manuscripts are not extant, but the Arabic historians Abū'l-Faraj Muḥammad ibn Nadīm al-Warrāq al-Baghdādī (d. 993) in his *Kitāb al-fihrist al-ʿulūm* (Bibliography of Sciences) and Jamāl al-Dīn ʿAlī ibn al-Qifṭī (1173–1248) in his *Taʾrīkh al-ḥukamā* (History of Sages) mention one mathematical and five astronomical works by al-Fazārī:

1. *Kitāb fī tasṭīh al-kura* (Book on the Projection of a Sphere onto a Plane)
2. *al-Zīj ʿalā sinī al-ʿarab* (Astronomical Tables According to Arabic Years)
3. *Kitāb al-ʿamal bi'l-asṭurlāb al-musaṭṭaḥ* (Book on the Use of the Plane Astrolabe)
4. *Kitāb al-ʿamal bi'l-as ṭurlābāt dhawāt al-ḥalaq* (Book on the Use of Astrolabes with Rings)
5. *Kitāb al-miqyās li'l-zawāl* (Book on the Gnomon for the Noon)
6. *Qaṣīda fī ʿilm al-nujūm* (Poem on the Science of Stars)

His son Muḥammad translated an astronomical work *Brāhma-sphuṭasiddhānta* by the sixth century Indian astronomer and mathematician Brahmagupta from Sanskrit into Arabic. The Arabic name of this work, *Sindhind*, came from the word *siddhānta*, astronomical texts, and the Arabic name for India, *Hind*. The extant fragments of *Sindhind* have been translated into English by David Pingree.

Alfonso X

Julio Samsó

Alfonso X, King of Castile (1252–1284) and a patron of literature and learning, made an important effort to recover Arabic and, very especially, Andalusian astronomical materials by translating them first into Spanish and later into Latin. His collaborators were one Muslim convert into Christianity, eight Christians (of whom four were Spaniards and another four Italians) and a very important group of five Jews. Alfonso failed in his attempt to integrate in his team a Muslim scientist of the importance of Muḥammad al-Riqūṭī but his interest for us here lies in the fact that his translations preserve Andalusian astronomical works which would have been lost otherwise. This is the case, for example, of the *Libro de las Cruzes* (Book of Crosses), a late Latin astrological handbook translated into Arabic in the early ninth century and revised, in the eleventh century, by a certain ᶜUbayd Allāh. Other works which are only known through his translations are the *Lapidario* (a book on the magical applications of stones) written by the otherwise unknown Abolays, the two books on the construction of equatoria written by Ibn al-Samḥ (d. 1035) and Ibn al-Zarqāllu (d 1100), ᶜĀlīibn Khalaf's book on the use of the plate for all latitudes (*Lámina Universal*, Toledo, eleventh century) and Ibn al-Zarqāllu's treatise on the construction of the armillary sphere. Other works which are, apparently, originals contributed to the European diffusion of Arabic astronomical ideas: the famous *Alfonsine Tables*, extremely popular between the fourteenth and the sixteenth centuries, were strongly influenced by the *Tables* of al-Battānī and marked a turning point in the development of late Medieval European astronomy.

Algebra, Surveyors'

Jens Høyrup

Around 1930, a mathematical technique very close to later second-degree algebra was discovered in Babylonian cuneiform tablets, most of them dating from the early second and a few from the late first millennium BCE (the "Old Babylonian" and "Seleucid" periods, respectively). Although the texts did not say so in any way, it was supposed that the technique was purely arithmetical, and that its "lengths," "widths," and "areas" were metaphors designating numerical unknowns and their products. The geometry of Euclid's *Elements* II was then believed to represent a Greek geometrical reinterpretation of the arithmetical results of the Babylonians, necessitated by the discovery of irrationality.

A more sophisticated analysis of the Old Babylonian texts shows that the arithmetical interpretation does not hold water. For instance, the texts distinguish sharply between two different concepts that had been understood as one and the same "addition"; two different "subtractions"; two different "halves"; and no less than four different "multiplications." Instead, a nonmetaphorical interpretation as "naïve cut-and-paste geometry" imposes itself. A problem where the sum of the area and the side of a square is said to be 3/4 is solved as in the illustration given later: The square itself represents the area. From one of its sides a "projection" 1 is drawn, which together with the unknown side contains a rectangle with an area equal to the side – the total area of the square itself and this rectangle is thus 3/4. This projection is bisected, and the outer half is moved so that the two halves together contain a square of area equal to

$$\frac{1}{2}\cdot\frac{1}{2}=\frac{1}{4}.$$

This small square completes the gnomon into which the original area 3/4 is transformed as a larger square of area

$$\frac{3}{4}+\frac{1}{4}=1.$$

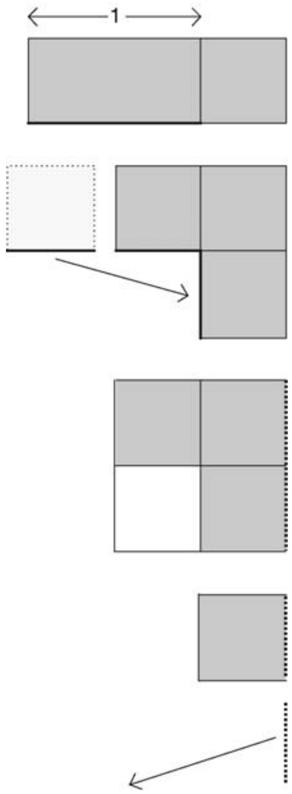
The side of this completed square will then be $\sqrt{1}=1$. "Tearing out" that rectangular length 1/2, which was moved around leaves

$$1-\frac{1}{2}=\frac{1}{2}$$

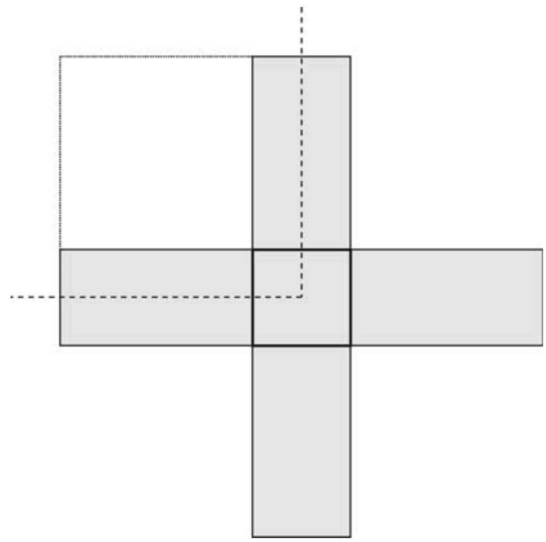
for the side.

With this technique, the Babylonian scribe school teachers solved problems of much higher complexity than the present one – in non-normalized problems (e.g., if 2/3 of the area plus 1/3 of the side equals 1/3) a change of scale is introduced, but apart from that everything goes by cutting and pasting – the approach is always "naïve" (as opposed to "critical") in the sense that everything can be *seen* immediately to be true. No explicit argument proves that, for example, the two halves of the bisected rectangle really contain a square when arranged as in Fig. 1.

A few texts, apart from using the terms for "lengths," "widths," and "areas" of fields, hint in other ways at surveying practice. An important example is this



Algebra, Surveyors'. Fig. 1 The sum of the area and the side of a square equals 3/4.



Algebra, Surveyors'. Fig. 2 The four fronts and the area. The dotted lines show the solution: one-fourth of the total area is taken and completed as a square.

problem: "Concerning a field: I have added the four fronts (sides) and the field (the area)." The formulation is unique in mentioning the sides before the area, and so is the solution, which refers to a configuration where a rectangle with length 1 is glued to each side of the field (Fig. 2).

Certain treatises from the Islamic Middle Ages reveal a close connection to this cut-and-paste tradition. The best known is al- Khwārizmī's *Algebra* (*Kitāb al-mukhtaṣar fī ḥisāb al-jabr wa'l muqābalah* – The Book of Summary Concerning Calculating, restoration, and Equation) from the early ninth century AD. The algebraic technique itself is arithmetical and at most obliquely if at all connected to the Babylonian tradition. However, in order to prove the correctness of his algorithms – first the one for "square and ten roots equal 39" – al-Khwārizmī makes use precisely of the diagrams of the figures shown, the second with completion in all four corners instead of quadrisection.

Less widely discussed is a *Book on Mensuration*, written by an otherwise unidentified Abū Bakr. The text is known from a meticulous Latin translation made in the twelfth century by Gerard of Cremona, and contains in its first half a large number of problems similar to those known from the Babylonian texts, both in mathematical substance and method and in the very characteristic grammatical format. However, the differences that are also present and systematic reveal that the Babylonian scribe school "algebra" is not the source. Instead, both the scribe school and Abū Bakr appear to have drawn on a surveyors' tradition, which had been present at least in Central Iraq, and probably in a wider region, from the early second millennium BCE onward.

This tradition nurtured and transmitted a stock of recreational problems with appurtenant techniques for their solution. Those that can be determined with some certainty were of the same quasialgebraic nature as the Babylonian problems cited earlier.

If we designate by Q a square area and by s its side, by A a rectangular area and by l, w, and d its sides and the diagonal, we may be fairly sure (from what is common to the scribe school and Abū Bakr together with other medieval sources) that the following problems were present (Greek letters stand for given numbers, which cannot be safely determined because the Babylonian and the Medieval tradition give different values – question marks indicate doubtful presence):

$$s + Q = 110; \qquad Q - s = 90,$$
$$4s - Q = \alpha(??); \qquad A + (l \pm w) = \alpha, \qquad l \pm w = \beta,$$
$$4s + Q = 140; \qquad Q - 4s = 60(?),$$
$$A = \alpha, l \pm w = \beta; \qquad A = \alpha, d = \beta.$$

For two squares Q_1 and Q_2, one of which was probably thought of as located concentrically within the other, the four problems $Q_1 + Q_2 = \alpha$, $s_1 \pm s_2 = \beta$ and $Q_1 - Q_2 = \alpha, s_1 \pm s_2 = \beta$ were dealt with. All problems are of the second degree (although $Q_1 - Q_2 = \alpha$, $s_1 \pm s_2 = \beta$ reduce trivially to the first degree, since $Q_1 - Q_2$ is easily seen in a diagram to equal $[s_1 + s_2] \times [s_1 - s_2]$).

Since Abū Bakr's treatise contains the problem $d - s = 4$, we may guess that the subscientific tradition solved this problem by equating the diagonal of the 10×10 square with 14. Abū Bakr gives the exact solution $s = 4 + \sqrt{32}$, whereas the Babylonians (who always worked backward from known solutions in their "algebra") eliminated this "unscientific" problem in the same process as they transformed the restricted stock of surveyors' riddles into a genuine, systematic discipline and into something that can legitimately be regarded as an *algebra.*

The Seleucid cuneiform "algebra" texts have traditionally been understood as faithful continuations of the Old Babylonian tradition. Close scrutiny of the texts shows even this to be a half truth. Indeed, the Old Babylonian mathematical tradition lost its higher, algebraic level when the scribe school system collapsed around 1600 BCE, and only the directly applicable level survived in an environment whose professional pride was based on other aspects of its practice. The surveyors' tradition, however, survived, and appears to have supplied the material for an algebraic revival in the later first millennium at the level of scholar scribes. In the meantime, the surveyors had developed more sophisticated methods – e.g., calculating the heights of triangles and using this for area determination instead of restricting themselves to practically right triangles laid out in the terrain. The most important Seleucid algebraic text also reads as a catalog of new problems and methods for the treatment of rectangles, some of them quite refined (e.g., determining the sides from $l + d$ and $w + d$ or from A and $l + w + d$).

The surveyors' tradition influenced not only Late Babylonian scribal mathematics and Medieval Islamic mensuration but also ancient Greek geometry and arithmetic. What is reflected in *Elements* II is, indeed, not Babylonian "algebra" in general but very precisely *that part of Old Babylonian algebra which it shared with the surveyors' tradition* – whence one may conclude that the real inspiration was *not* Old Babylonian scribal mathematics – long since forgotten – but the still living stock of surveyors' riddles. Proposition l, it turns out, justifies the geometrical addition of rectangles which have one side in common, whereas propositions 2 and 3 concern the special cases where sides are subtracted from or added to square areas. Propositions 4 and 7 are used, e.g., in two different but equivalent solutions to the problem of finding the sides of a rectangle from the area and the diagonal. Proposition 6 explains the solution of all problems $Q \pm \alpha s = \beta$ (including "the four sides and the area") and $A = \alpha$, $l - w = \beta$, while proposition 5 has a similar relation to rectangular problems $A = \alpha$, $l + w = \beta$ and to $\alpha s - Q = \beta$. Proposition 8, which is used nowhere else in the *Elements*, is associated with the concentric inscription of one square into another, and propositions 9 and 10 are connected to the solution of the problems $Q_1 + Q_2 = \alpha$, $s_1 \pm s_2 = \beta$.

What the Greek text does is not merely repeat the traditional solutions – in fact, it presents us with theorems, not with problems to be solved. But the theorems are *critiques* of the traditional "naïve" procedures, showing that what is immediately "seen" is indeed correct and can be proved within the axiomatic framework. The proofs fall into two parts, the first of which establishes the equality of areas and that the quadrangles which are believed to be squares are indeed so. Then on firm ground, the second part goes through the traditional cut-and-paste procedure.

Propositions 11–13 are connected to matters found in Abū Bakr's treatise, and the textual evidence suggests that at least propositions 12 and 13 (the generalized Pythagorean theorem) were originally developed independently of the Greek theoreticians, as part of the "new" stage of the surveyors' geometry. Propositions 1–10, on the other hand, are completely untouched by the innovations. This critique thus seems to go back to a moment when the "new" development had not yet taken place, or not yet reached the ears of Greek geometers (we may point to the late fifth century BCE, the epoch of Hippocrates of Chios and of Theodoros).

Book I of Diophantos' *Arithmetic*, which also contains undressed versions of favorite arithmetical recreational problems, embraces a few problems of the second degree – as it turns out, arithmeticized versions of $A = \alpha$, $l \pm w = \beta$ and $Q_1 + Q_2 = \alpha$ $s_1 \pm s_2 = \beta$ (all four belonging to the original surveyors' stock). As can be seen from certain passages in Plato, Diophantos' work builds at least in its terminology upon a tradition reaching back to Greek calculators of the fifth century BCE or earlier. The present simple problems can be assumed to belong to the early ingredients of this tradition, which then agrees with the chronological conclusions that could be drawn from *Elements* II.

A single Greco-Egyptian papyrus (probably second century AD) shows that the "new" diagonal-centered group of surveyors' problems circulated among the mathematical practitioners of the Greco-Roman orbit at this later moment, without being adopted into the corpus of scientific mathematics. In China, on the other hand, they appear to turn up in the *Jiuzhang suanshu* (Nine Chapters on Arithmetic) (one of them in a dress which with high probability points back to Babylonia and thus shows the Chinese problems to be borrowed). In the later Chinese tradition, however, this interest disappears again.

"Naïve" geometry is also to be found in the Indian *Śulbasūtra* geometry (mid-first millennium BCE), and a few commentaries to later Indian algebraic works might suggest a fundament in something similar to our surveyors' tradition. The evidence, however, is too shaky to allow any conclusion, except in the case of the ninth century Jaina mathematician Mahāvīra, whose *Gaṇita-sāra-saṅgraha* contains indubitable borrowings from it, and even treats material stemming from the Bronce Age phase, the preseleucid Late Babylonian phase and the Seleucid phase in separate sections of its geometry chapter. Apart from that and from its role for the emergence of Babylonian "algebra" and for that of Greek metric geometry as found in *Elements* II, the only literate mathematical culture where the anonymous surveyors gained real influence is thus that of medieval Islam. Its reflection in al- Khwārizmī was already mentioned, to which it may be added that al-Khwārizmī's borrowed geometric proofs were taken over by numerous algebraic authors until the mid-sixteenth century – one step in Cardano's solution of the third-degree equation makes use of a three-dimensional generalization of this diagram, another of the solution of the rectangle problem $A = \alpha$, $l + w = \beta$. Within the mensuration tradition, the twelfth-century Abraham bar Ḥiyya (Savasorda) betrays familiarity with the surveyors' quasialgebraic riddles, in a version which shows him to be independent of Abū Bakr); so does Jean de Murs' fourteenth century *De arte mensurandi*.

As the technique was taken over by scientific mathematicians, the reason to uphold a distinct naïve-geometric tradition disappeared. Abū Bakr had already solved many of the problems in two ways, first by naïve geometry and then by *al-jabr* – the originally sub-scientific discipline committed to writing and made famous by al- Khwārizmī. Abraham bar Ḥiyya, for his part, refers to *Elements* II in his solutions. Nonetheless, the riddles themselves continued to be attractive. They are important in Leonardo Fibonacci's *Pratica geometrie* (1220), which draws on Abraham bar Ḥiyya, on Gerard of Cremona's translation of Abū Bakr, and on at least one other work belonging to the tradition. And they turn up again in Luca Pacioli's *Summa de arithmetica geometria Proportioni: et proportionalita* (1494), which still asks for the side when "the four sides and the area" equals 140, with the same anomalous order of the members as in the Bronze Age. The last shimmering of the tradition is in Pedro Nunez' *Libro de Algebra en Arithmetica y Geometria* (1567), after which every trace disappears, together with the knowledge that such a tradition had ever existed.

From the beginning some 4000 years ago, the surveyors' riddles were algebraic in the sense that the solutions follow steps that correspond to those of a modern solution by means of symbolic algebra. They were also algebraic in the sense that their method was *analytic:* the unknown side of the square is treated as if it were known, and submitted to such operations that at the end it is isolated and thus known – precisely as a modern x.

However, the surveyors' technique lacked two essential characteristics of modern equation-algebra (characteristics which, by the way, modern equation-algebra shares with the Old Babylonian scribe school "algebra"). First, it was no general method for finding unknown quantities; the measurable lines and areas which it manipulated were never used as representatives of something else. It was, and remained until it was taken over and reshaped by the written traditions, a collection of sophisticated riddles with no practical purpose beyond itself. Second, it always dealt with the entities which are naturally present in the geometrical configurations of which it spoke: *the* area, *the* side or *the four* sides, etc. It is never, as we may find it even in those of the Old Babylonian scribal texts which otherwise come closest to the background tradition, "one half of the length and one third of the width" of a rectangle. This is also the reason that its problems are – with one very late and thus dubious exception – always normalized, and a supplementary reason that it did not develop into an all-purpose algebra. We may therefore, legitimately, speak of a surveyors' "algebra" – but not of a surveyors' algebra without quotes.

Algebra in China

LAM LAY YONG

Arithmetic and geometry are the two oldest branches of mathematics. Algebra has its beginnings from both of them when attempts were made to generalize operations and relationships. Initially, such ideas were expressed in words; in the course of time, they were represented by some form of notation. The symbols facilitated the methods which in turn generated new concepts and methods. For instance, we are now able to solve with ease any arithmetical problem involving what we call a pair of linear equations in two unknowns through the use of the notational equations $ax + by = c$ and $dx + ey = f$. Around AD 825, Muḥammad ibn Mūsā al-Khwārizmī wrote a book expressing equations in words. In order to arrive at a solution, the two sides of an equation were manipulated through two main operations which he called *al-jabr* and *al-muqābala* – the name "algebra" was derived from the first word.

In ancient China, arithmetic developed through the use of the rod numeral system. Arithmetic was fully developed – not only were the methods of addition, subtraction, multiplication, and division known, but also the manipulations of the common fraction and the decimal fraction were commonplace, and methods such as those involving proportion and the Rule of Three were widely used. This article will describe very briefly how the mathematicians were able to generalize arithmetical operations and relationships which resulted in general methods of solution. The period covered will be from antiquity to the beginning of the fourteenth century. Traditional mathematics in China was at its height during the thirteenth and early fourteenth centuries; this was a time in Western Europe when the importance of the new arithmetic that evolved from the Hindu–Arabic numeral system was just beginning to be realized.

It might seem strange and improbable that the ancient Chinese were able to find general methods of solving equations since they did not compute through a written system but through the use of rods. However, the rod numeral system was extremely sophisticated and flexible, and the positions where the numerals were placed usually represented certain mathematical concepts. For example, let us consider a set of linear equations in three unknowns which we now write in the following manner:

$$a_1x + b_1y + c_1z = d_1,$$
$$a_2x + b_2y + c_2z = d_2,$$
$$a_3x + b_3y + c_3z = d_3.$$

The ancient Chinese would notate such a mathematical concept by placing the numerical values of the *a*s, *b*s, *c*s, and *d*s in rod numerals in the following matrix form:

$$\begin{matrix} a_3 & a_2 & a_1 \\ b_3 & b_2 & b_1 \\ c_3 & c_2 & c_1 \\ d_3 & d_2 & d_1 \end{matrix}$$

The positions occupied by the rod numerals were important – the positions in the first row represented the first unknown, and those in the second and third rows represented the second and third unknowns, respectively.

The aim of the method was to obtain a group of zeros forming a triangle in the top left diagonal half of the matrix through a process of elimination with two columns at a time. Thus the elimination process would result in zeros for the positions which were occupied by a_3, a_2, and b_3 of the above matrix. After this was attained, the third unknown was derived from the third column from the right. This result would be able to derive the second unknown from the second column, and the solutions would in turn derive the first unknown from the remaining column.

The method is called *fang cheng* and can be found in the eighth chapter of *Jiu zhang suan shu* (Nine Chapters on the Mathematical Art). The whole chapter is devoted to the solutions of such equations which include a problem involving five equations in five unknowns and another involving five equations in six unknowns.

The matrix notation was derived through an evolution of a fundamental tradition that used positions occupied by rod numerals to represent concepts or things. Besides the placement of numerals involving the common fraction, problems related to proportion were solved by similar operations. The ancient Chinese were familiar with what is now called the Rule of False Position which, for them, originated from the solution of the concept of a pair of linear equations in two unknowns. The method is called *ying bu zu* and is the precursor of the *fang cheng* method.

The procedure for finding the square root of a number was derived from the geometrical division of a square into smaller areas. This was then arithmetized through the placement of rod numerals to become a general method. The offshoot of this method was the solution of what we call a quadratic equation of the form $x^2 + bx = c$, where b and c are positive. The ninth chapter of *Jiu zhang suan shu* has a problem involving an equation of this form. Besides the method of finding the square root, the book also gives the method of finding the cube root of a number. Knowledge of this method led to the solution of a cubic equation of the form $x^3 + ax^2 + bx = c$, where a, b, and c are positive.

The seventh-century work *Jigu suanjing* (Continuation of Ancient Mathematics) by Wang Xiaotong has problems involving such equations.

The struggle to solve other types of quadratic equations besides the one mentioned above was depicted by the thirteenth-century mathematician Yang Hui, who quoted from the works of Liu Yi of the eleventh century – Liu Yi's works are now no longer extant. Though the concepts of the different types of quadratic equations were initially derived from a variety of geometrical considerations, the arithmetization of their operations through rod numerals revealed certain patterns and similarities which enabled the emergence of a general method of solution.

In his explanation of the development of the polynomial equation and its solution, Yang Hui quoted another eleventh-century mathematician, Jia Xian. He pointed out that Jia Xian was familiar with the triangular array of numbers now known as the *Pascal triangle* and was the first to realize its close relationship with the procedure of root extraction. From here, Jia Xian laid the foundation for a ladder or algorithmic method of finding the root of a number of any degree. This eventually provided the breakthrough to finding a solution of any numerical polynomial equation.

It was Qin Jiushao's detailed and systematic methods of explaining the problems in his book, *Shushu jiuzhang* (Mathematical Treatise in Nine Sections), that established beyond doubt the competence of the Chinese mathematicians to solve numerical equations of higher degree. Among the problems in the book, there are three that are involved with equations of the fourth degree and one of the tenth degree. These equations are of the following form:

$$-x^4 + 763200x^2 - 40642560000 = 0,$$
$$-x^4 + 15245x^2 - 6262506.25 = 0,$$
$$-x^4 + 1534464x^2 - 526727577600 = 0,$$
$$x^{10} + 15x^8 + 72x^6 - 864x^4 - 11664x^2 - 34992 = 0.$$

Yang Hui, Li Ye, and Zhu Shijie were the other thirteenth-century mathematicians who were also familiar with the algorithm method of solving a polynomial equation of any degree. This method is now generally accepted as similar to that put forward by Horner in 1819.

The Chinese were able to express the complex concept of a polynomial equation through the placement of rod numerals on the counting board. This notational representation was called *tian yuan shu* (Technique of the Celestial Element) in which an equation was formulated in terms of the unknown called *yuan*. An equation of the form

$$a_0x^n + a_1x^{n-1} + \cdots + a_{n-1}x + a_n = 0$$

was represented in rod numerals in a vertical line as follows:

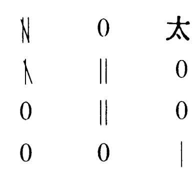
$$\begin{array}{l} a_n \\ a_{n-1} \\ \vdots \\ a_1 \\ a_0 \end{array}$$

The positions occupied by the rod numerals had meanings – the first row signified that the rod numeral was a constant and the other rows in the downward direction signified that the numerals were the coefficients of the unknown in increasing power.

From here, Zhu Shijie in his *Siyuan yujian* (Precious Mirror of the Four Elements), written in 1303, proceeded to express polynomial equations in two, three, and four unknowns with rod numerals. For instance, the equation in two unknowns

$$(-x-2)y^2 + (2x^2 + 2x)y + x^3 = 0$$

is expressed as follows:



The slanting rod indicates that the numeral is negative. In the first column from the right, the character *tai* indicates the constant of the equation, which in the above case is zero. This column, which is similar to the notation of a polynomial in one unknown, represents $0 + 0x + 0x^2 + x^3$. The second column represents $0y + 2xy + 2x^2y + 0x^3y$, and the last column represents $-2y^2 - xy^2 + 0x^2y^2 + 0x^3y^2$.

Zhu Shijie gave examples to show how a set of simultaneous polynomial equations of varying degrees up to four unknowns could be reduced to an equation in one unknown, and thereby finding the solution. For example, he illustrated how the set of equations of the form

$$-2y + x + z = 0,$$
$$-xy^2 + 4y - x^2 + 2x + xz + 4z = 0,$$
$$y^2 + x^2 - z^2 = 0,$$
$$2y + 2x - u = 0$$

was reduced to the following single equation in one unknown:

$$4u^2 - 7u - 686 = 0.$$

In *Siyuan yujian*, Zhu Shijie excelled in another area in algebra: he gave correct formulae for the sums of higher order equal difference series. They are of two types which may be described in the following manner. First type:

$$
\begin{aligned}
&1+2+3+4+\cdots+n=\tfrac{1}{2!}n(n+1),\\
&1+3+6+10+\cdots+\tfrac{1}{2!}n(n+1)\\
&\quad=\tfrac{1}{3!}n(n+1)(n+2),\\
&1+4+10+20+\cdots+\tfrac{1}{3!}n(n+1)(n+2)\\
&\quad=\tfrac{1}{4!}n(n+1)(n+2)(n+3),\\
&1+5+15+35+\cdots+\tfrac{1}{4!}n(n+1)(n+2)(n+3)\\
&\quad=\tfrac{1}{5!}n(n+1)(n+2)(n+3)(n+4),\\
&1+6+21+56+\cdots\\
&\quad+\tfrac{1}{5!}n(n+1)(n+2)(n+3)(n+4)\\
&\quad=\tfrac{1}{6!}n(n+1)(n+2)(n+3)(n+4)(n+5).
\end{aligned}
$$

Second type:

$$
\begin{aligned}
&1\cdot 1+2\cdot 2+3\cdot 3+\cdots+n\cdot n=\tfrac{1}{3!}n(n+1)(2n+1),\\
&1\cdot 1+2\cdot 3+3\cdot 6+\cdots+n\cdot\tfrac{1}{2!}n(n+1)\\
&\quad=\tfrac{1}{4!}n(n+1)(n+2)(3n+1),\\
&1\cdot 1+2\cdot 4+3\cdot 10+\cdots+n\cdot\tfrac{1}{3!}n(n+1)(n+2)\\
&\quad=\tfrac{1}{5!}n(n+1)(n+2)(n+3)(4n+1).
\end{aligned}
$$

It was Shen Guo (1032–1095) who initiated the study of this type of series and he was followed by Yang Hui and Zhu Shijie – their basic technique was related to the piling of stacks.

The foundation of algebra, as we know it today, and its impetus for growth arose from the successful development of arithmetic based on the Hindu–Arabic numeral system. In the earlier civilizations, there were various beginnings of algebra which also depicted the struggle to find expressions for arithmetical operations and geometrical relationships. The development of algebra in China has proved to be unique and significant with its growth being maintained continuously until the Ming dynasty (1368–1644).

The essential ingredient that fostered the growth of algebra in traditional China was the rod numeral system. What was extraordinary about it was its notation: the position of each digit of a numeral represented the place value of that digit, such as units, tens, hundreds, and so forth. This notation of a number freed the mind of unnecessary work and enabled arithmetic to be developed to the fullest. The same kind of thinking in the use of the positions of rod numerals to represent concepts or things made possible the subsequent evolution of algebra.

Though the Chinese used rods to develop algebra, the results obtained manifested numerous similarities with our early algebra. In the solution of a set of simultaneous linear equations, the ancient Chinese invented the matrix notation and the *fang cheng* method of elimination. About 1,500 years later, Seki Kowa and Leibniz initiated the study of determinants – Seki Kowa knew of the *fang cheng* method.

In searching for a general solution of a polynomial equation, Jia Xian drew attention to a triangular array of numbers which we now call Pascal's triangle. The method that the Chinese used to solve the polynomial equation was rediscovered by Horner half a century later. The concise notation of expressing the concept of a polynomial equation led Zhu Shijie to invent a notation to express a set of polynomial equations up to four unknowns. He gave examples to show how to solve them. In eighteenth-century Europe, it was Étienne Bezout who initiated the study of solving a pair of polynomial equations in two unknowns. Zhu Shijie's formulae for the series of higher order equal difference series also showed that he was a few centuries ahead of his counterparts in Europe.

It is ironical that the use of rods, which enabled the expansion and sustenance of algebra in China for over one and a half millennia, was also the reason for its decline. The rods were used not only for the development of mathematics but also for computation. By the Song dynasty (960–1279), a faster-paced society could not tolerate the time required for manipulating the rods. The demand for quicker computation led to the invention of the abacus. However, the abacus was only suitable for swift calculations and had neither the potential to foster the growth of mathematics nor the capacity to allow for the conceptual retention of what had already been developed in mathematics. The replacement of the rods by the abacus signaled the demise of traditional mathematics.

Since ancient times, the Chinese mathematicians had been using a base ten place value numeral concept in the rod numerals, and so it would not have been difficult for them to adopt this concept in a written form. If they had made such an adoption during the switch to calculation with the abacus, there would have been a smooth transference of mathematical concepts from the rod medium to the written medium. However, such an adoption was only made when western mathematics entered China beginning with the arrival of Matteo Ricci in 1582. The consolation from this erroneous turn of events was that during the sixteenth and seventh centuries many Chinese were still knowledgeable in traditional mathematics, and they helped greatly to lighten what would have been a tremendous upheaval in the change to the new mathematics.

Algebra in India: *Bījagaṇita*

Takao Hayashi

Bījagaṇita, which literally means "mathematics (*gaṇita*) by means of seeds (*bīja*)," is the name of one of the two main fields of medieval Indian mathematics, the other being *pāṭīgaṇita* or "mathematics by means of algorithms." *Bījagaṇita* is so-called because it employs algebraic equations (*samīkaraṇa*) which are compared to seeds (*bīja*) of plants since they have the potentiality to generate solutions to mathematical problems. *Bījagaṇita* deals with unknown numbers expressed by symbols. It is therefore also called *avyaktagaṇita* or "mathematics of invisible (or unknown) [numbers]." Algebraic analyses are also employed for generating algorithms for many types of mathematical problems, and the algorithms obtained are included in a book of *pāṭī*. *Bījagaṇita* therefore also means "mathematics as a seed [that generates *pāṭī* (algorithms)]."

Extant works in *bījagaṇita* include chapter 18 (*kuṭṭaka* only) of Āryabhaṭa's *Mahāsiddhānta* (ca. AD 950 or 1500), chapter 14 (*avyaktagaṇita*) of Śrīpati's *Siddhāntaśekhara* (ca. AD 1050), Bhāskara's *Bījagaṇita* (AD 1150), Nārāyaṇa's *Bījagaṇitāvataṃsa* (before AD 1356, incomplete), and Jñānarāja's *Bījādhyāya* (ca. AD 1500). Śrīdhara's work (ca. D 750), from which Bhāskara quotes a verse for the solution of quadratic equations, is lost. Chapter 18 (*kuṭṭaka*) of Brahmagupta's *Brāhmasphuṭasiddhānta* (AD 628) has many topics in common with later works of *bījagaṇita*, but the arrangement of its contents is not so systematic as that of the later works, and an unusual stress is placed on *kuṭṭaka* as the title of the chapter suggests. *Kuṭṭaka* (lit. pulverizer) is a solution to the linear indeterminate equation: $y = (ax + c)/b$.

The symbols used for unknown numbers in *bījagaṇita* are the initial letters (syllables) of the word *yāvattāvat* (as much as) and of the color names such as *kālaka* (black), *nīlaka* (blue), *pīta* (yellow), etc. The use of the color names may be related to Āryabhaṭa's *gulikā* (see below). Powers of an unknown number are expressed by combination of the initials of the words *varga* (square), *ghana* (cube), and *ghāta* (product). A coefficient is placed next (right) to the symbol(s) to be affected by it, and the two sides of an equation are placed one below the other. A dot (or a small circle) is placed above negative numbers. Thus, for example, our equation, $5x^5 - 4x^4 + 3x^3 - 2x^2 + x = x^2 + 1$, would be expressed as:

yāvaghaghā 5 *yāvava* $\dot{4}$ *yāgha* 3 *yāva* $\dot{2}$ *yā* 1 *rū* 0,

yāvaghaghā 0 *yāvava* 0 *yāgha* 0 *yāva* 1 *yā* 0 *rū* 1,

where *rū* is an abbreviation of *rūpa* meaning an integer or an absolute term. The product of two (or more) different unknowns is indicated by the initial letter of the word *bhāvita* (produced): e.g., *yākābhā* 3 for $3xy$.

These tools for algebra had been fully developed by the twelfth century, when Bhāskara wrote a book entitled *Bījagaṇita* (AD 1150), the main topics of which are "four seeds" (*bījacatuṣṭaya*), namely (1) *ekavarṇasamīkaraṇa* or equations with one color (i.e., in one unknown), (2) *madhyamāharaṇa* or elimination of the middle term (solution of quadratic equations), (3) *anekavarṇasamīkaraṇa* or equations with more than one color, and (4) *bhāvitakasamīkaraṇa* or equations with "the product" (i.e., of the type $ax + by + c = dxy$).

At least part of this algebraic notation was known to Brahmagupta. He uses the words *avyakta* (invisible) and *varṇa* (color) for denoting unknown numbers, when he gives his rules concerning the same four seeds as Bhāskara's, in chapter 18 (*kuṭṭaka*) of his *Brāhmasphuṭasiddhānta*. The details of Brahmagupta's algebraic notation are, however, not known to us.

Bhāskara, a contemporary of Brahmagupta, did know the word *yāvattāvat* meaning an unknown number, but it is not certain if he used it in equations, because he expresses the equation, $7x + 7 = 2x + 12$, without the symbol *yā* as:

7	7
2	12

in his commentary (LAD 629) on the *Āryabhaṭīiya*. In the same work he refers to four seeds which are said to generate "mathematics of practical problems" (*vyavahāragaṇita*) having eightfold of names beginning with "mixture," but what kinds of seeds he mentioned by the names *yāvattāvat*, *vargāvarga* (square?), *ghanāghana* (cube?), and *viṣama* (odd), are not exactly known. Similar terms (*yāvattāvat*, *varga*, *ghana*, and *vargavarga*) occur in a list of ten mathematical topics given in a Jaina canon, *Sthānāṅga* (Sūtra 747), which is ascascribed to the third century BCE.

Āryabhaṭa used the term *gulikā* (a bead) for an unknown number when he gave his rule for linear equations of the type $ax + b = cx + d$ in his *Āryabhaṭīya* (AD 499). All the equations to which he gave solutions (including *kuṭṭaka*) are linear, although his rules for the interest and for the period of an arithmetical progression presuppose the solution of quadratic equations.

Brahmagupta gave many theorems for *vargaprakṛti* (lit. square nature), i.e., the indeterminate equation of the second degree: $Px^2 + t = y^2$, but it is Jayadeva (the eleventh century or before) that gave a complete solution for the case $t = 1$ (the so-called Pell's equation).

Bījagaṇita reached its culmination in the twelfth century, when Bhāskara gave solutions to various types of equations of higher degrees by means of *kuṭṭaka* and *vargaprakṛti*. After him significant developments in the field of *bījagaṇita* are not known.

Algebra in Islamic Mathematics

MAT ROFA BIN ISMAIL (*with the collaboration of* OSMAN BAKAR AND KAMEL ARIFIN MOHD ATAN)

The word *algebra* is derived from the Arabic *al-jabr*, a term used by its founder, Muḥammad ibn Mūsā al-Khwārizmī, in the title of his book written in the ninth century, *al-Jabr waʾl-muqābalah* (The Science of Equations and Balancing). Algebra is also known as "the science of solving the unknowns in equations."

The simplest equation with one unknown is of the form $ax = b$, with a and b as constants x here is called *al-jadhr* of the equation. Al-Khwārizmī enumerated six standard second-degree equations in his *al-Jabr wa'l-muqābalah*:

$$ax^2 = bx, \quad ax^2 = b, \quad ax = b,$$

$$ax^2 + bx = c, \quad ax^2 + c = bx, \quad ax = bx + c.$$

Also, he provided solutions to these equations using algebraic and geometrical justifications.

The main aim of al-Khwārizmī's algebra was to provide the Muslim community with the necessary arithmetical knowledge essential in their daily calculation needs, such as in matters pertaining to heritage and legacy, transaction, sharing and partnership, loss and profit, irrigation and land-acreage, and geometrical problems. Al-Khwārizmī devoted about half of his *al-Jabr wa ʻl-muqābalah* to such problems.

Abū Kāmil Shujāʿ ibn Aslam of Egypt (AD 850–930) gave his treatise on algebra the name *al-Jabr wa ʻl-muqābalah*, the same title as al-Khwārizmī's. This treatise gives commentaries on al-Khwārizmī's six standard quadratic equations using Euclid's lemmas in geometry to justify the existence of two roots for a general quadratic equation. In the twelfth century, Abū'l-Fath ʿUmar bin al-Khayyām listed 39 standard cubic equations in his *Risāla fi'l-barāhīn ʿalā masā'il al-jabr wa ʻl muqābalah*, and solved them by intersecting suitable conic-sections (circle or semicircle, parabola, hyperbola, and ellipse) using Apollonius's theory of conics. The solutions to the equations were represented by intersections of the curves, but he failed to identify the exact numerical solutions. Many attempts had been made toward finding the geometrical solutions of cubic equations before ʿUmar al-Khayyām mentioned them in his book, such as those by al-Māhāni and Abu'l-Jūd.

Also in the twelfth century, Sharaf-al-Dīn al-Ṭūsī examined the cubic equation species classified by ʿUmar al-Khayyām and provided their solutions through a systematic study of the minimum and maximum values of their associated functions. He gave the number of real solutions of a cubic equation in terms of its coefficients.

In the third portion of his *Kitāb fi ʻl-al-jabr wa'l-muqābalah*, Abū Kāmil discussed indeterminate problems (*mu ʻādalah siālah*) of the second degree. Some of these were of Greek origin and could be found in the *Ṣinā ʻah al-jabr* by Diophantus, the translation of *Arithmetica* by Qusṭā ibn Lūqā. The problems were then cited by Leonardo Fibonacci in his book *Liber abaci*. Abū Kāmil concentrated on enumerating the possible solutions of simultaneous equations in his *Ṭarāʾif al-Ḥisāb*. They were based on the problem of determining the number of birds that could be purchased with 100 dirhams. Somebody is to buy 100 fowls, given that, for example, a rooster costs five units, a hen 3, and chicks are sold three for one unit. Problems of this type gave rise to a system of equations of the form:

$$x + y + z + u + v = 100 = ax + bx + cz + du + ev.$$

In the case of $a = 2,\ b = 1/2,\ c = 1/3,\ d = 1/4,\ e = 1$, Abū Kāmil gave 2,696 possible integer solutions. The analysis marks the birth of a field in algebra which is known today as linear algebra.

Extraction of square and cubic roots became an important subject of discussion in arithmetic and algebra books, or *Ḥisāb al-Hindī* based on Indian Mathematics during the heyday of the Muslim mathematicians. The rule for the extraction of roots was then based on binomial expansion of the form $(a + b)^n$. Al-Ṭūsī listed the coefficients in the expansion of $(a + l)^n - a^n$ for some n, in his *Jawāmiʿ* and arranged them in a triangular form which he called *manāzil al-ʿadad*. This triangular arrangement came to be known in the West as Pascal's triangle, after Blaise Pascal, the famous French mathematician who published his *Traité du triangle arithmétique* in 1665. Such an arrangement was also drawn up by al-Karajī in one of his books. This was further mentioned by Samuʿīl (or Samauʿal) ibn ʿAbbas, also called al-Maghribī (eleventh century), in his *al-Bāhir fi ʻl-jabr*. ʿUmar al-Khayyām did write a book on the extraction of cubic and fourth roots, but the book is assumed to be lost. The extraction of the fifth root was carried out by al-Kāshī in the fifteenth century in his *Miftāḥ al-Ḥisāb*. He gave a numerical example of extracting the fifth root of 44,240,899.506,197 (order of trillions).

In the expansion of an algebraic term raised to a certain power, the concept of the negative number is extremely important. Muslim mathematicians made a substantial contribution to the development of this concept. Abū'l-Wafā al-Būzjānī in his *Ma Yaḥtaj ilayh al-kuttāb wa ʻl-ʿummāl min ʿilm al-ḥisāb* considered debts as negative numbers. For example, the calculation for 35 + (−20) = 15 was written as 35 + *dain* 20 = 15 − (*dain* = debt). Abū Kāmil, as a commentator on the *al-Jabr wa ʻl-muqabalah* of al-Khwārizmī, explained the application of positive and negative signs for the purpose of expanding the multiplication $(a \pm b)(c \pm d)$. This resulted in his rules:

$$(+)(+) = + = (-)(-), \quad (+)(-) = (-)(+) = -.$$

These rules are embodied in his famous work *Kitāb al-jabr wa ʻl-muqābalah*. Al-Karajī showed clearer examples illustrating operations with negative quantities in his al-Fakhrī. These rules are implicitly used throughout the book:

$$a - (-b) = a + b, \quad (-a) + b = -(a - b),$$
$$(-a) - (-b) = -(a - b), \quad (-a) - b = -(a + b).$$

Samuīl and Ibn al-Bannāʾ al-Marrākushi then made some finer rules about calculations involving negative numbers in their works, *al-Bāhir fi ʻl-jabr and Kitāb al-jabr wa ʻl-muqābalah*, respectively.

The art of proving became an important part of mathematical science. The direct and proof by contradiction methods are two important tools in proving mathematical statements. In some cases, however, they fail to work, especially in proving formulae containing integral terms. In this case, the method of *istiqrāʾ*, or proof by induction, is an appropriate one to use. Al-Karajī wrote an article by that name to explain this method. Samuīl and Ibn al-Haytham used it to prove some formulae on infinite series. A good example of the employment of proof by contradiction was given by

Abū Jaᶜfar al-Khāzin to establish some properties of right-angled triangles. These can be found in the treatise *Risālah fi ʻl-muthallathāt al-qāᶜimat al-zawāyā* or in the *Tadhkirat al-aḥbāb fī bayān al-tuḥābb* of Kamāl al-Dīn al-Fārisī. The contradiction method based on the logical property "if (statement *a* is true) then it implies (statement *b* is true)" is equivalent to "if (statement *b* is not true) then (statement *a* is not true)." The converse, however, is not always true. This type of reasoning is characteristic of discussions in *manṭiq* or logic.

To explain the method of *istiqrāʾ*, Samuᶜīl proved the case $n = k$ through the assumption that the case $n = k - 1$ is true. For example, to prove $a^3b^3 = (ab)^3$, Samuᶜīl started with the assumption of $a^2b^2 = (ab)^2$ (which had been proved before), then multiplied both sides by (ab) to obtain $(ab)(a^2b^2) = (ab)(ab)^2 = (ab)^3$. Using the proposition mentioned earlier, i.e., $(ab)(cd) = (ac)(bd)$, he obtained $(ab)(a^2b^2) = a^3b^3$. Although in this demonstration, Samuᶜīl used particular numbers instead of a general *k*, he successfully showed the method of *istiqrāʾ* correctly as we understand it today. Some writers, however, continue to attribute the method to Pascal or Bernoulli in the seventeenth century (Yadegari 1978).

The inherent idea in the use of logarithm is to expedite the multiplication process by converting it into an addition one. This is done by employing the rules of exponent. Abūʾl-Ḥasan al-Nasawī wrote a book on the idea in Persian which was later translated into Arabic with the title *al-Muqniᶜ fi ʻl-Ḥisāb al-Hindi*. Ibn Yūnus (eleventh century), a well-known Egyptian astronomer, discovered the role of the trigonometric relation

$$\cos(a)\cos(b) = \frac{1}{2}[\cos(a+b) + \cos(a-b)]$$

in transforming the process of multiplication into addition. For example, suppose one wishes to obtain the product of 35.84 and 54.46. Since cos(69°) = 0.3584 and cos(57°) = 0.5446, then (35.84)(54.46) = 1951.5 by using this identity. This formula had been proven earlier by Abū'l-Wafā al-Būzjānī (d. 998) in his commentary on the *al-Majesṭi* (*Almagest*) of Ptolemy.

The expression of a fraction in the decimal form, based on an extant manuscript, goes back to *Kitāb al-fuṣūl fī al-Ḥisāb al-Hindī* of Abu'l-Ḥasan Aḥmad al-Uqlīdisī. It was written in the year 341H (AD 952). Uqlīdisī operated on the number 19 by consecutive halvings. First, he obtained (using his symbol) 9′5 then 4′75, 2′375, 1′11875, and finally 0′59375 (some commas indicating separations of hierarchy were dropped in the manuscript). Subsequently, Samuᶜīl al-Maghribī gave a clearer idea of the notion of decimal fractions in his *al-Qiwāmi fi ʻl-Ḥisāb al-Hindī.* This book was written in the year AD 1172. The quotient of 210 by 13 was expressed as follows:

Integer	Parts of 10	Parts of 100	Parts of 1,000	Parts of 10,000	Parts of 100,000
16	1	5	3	8	4

The square root of 10 is expressed as 3.16227, a clear definition of a decimal fraction, as the number 16,227 is considered part of 1,000,000, with 3 as a whole number. More precisely, 3.16227 means:

$$3 + \frac{1}{10} + \frac{6}{100} + \frac{2}{1,000} + \frac{7}{100,000}.$$

Jamshīd al-Kāshī (fourteenth century) expressed the decimal fraction in both al-Khwārizmī's and the astronomers' system in the article "*al-Risāla al-muḥīṭīyyah.*" He gave the value of 2π as 6.2831853071795865 (in al-Khwārizmī's decimal system) or as 6–6, 16, 59, 28, 1, 34, 51, 46, 15, 50 (in the astronomers' sexagesimal system).

The method of writing numbers as decimal fractions later appeared in the West in Stevin's *de Theinde* or its French version, *La Disma*, in 1585. To indicate the integral and fractional portions of the number, Stevin employed a stroke to separate the two. He is considered the founder of the decimal fraction by some writers in the West.

Nicomachus in his *al-Madkhal ilā ᶜilm al-ᶜadad* (an Arabic translation of *Introduction*) gave the four first perfect numbers: 6, 28, 469, and 8,128. Ismail al-Māridīnī (twelfth century) added some others to the list of perfect numbers: 6, 28, 496, 8128, 1130816, (2096128), 33550336, 8589869056, 137438691328, (35184367894528). Actually, the two numbers in brackets are not perfect. This mistake is due to the difficulty in determining the primality of a number.

One can observe from al-Māridīnī's list that it is hard to find an odd perfect number. The numbers seem to be even, and the first digit (remember that Arabs write from the right) of a perfect number obtained by the formula is always 6 or 8. Indeed, the perfect numbers described by the formula $(2^{n-1} - 1)2^n$ are always even, since they are the product of even and odd numbers. However, many think that odd perfect numbers do exist. Euler, centuries later (1849), in his paper in *Tractus de numererum doctrina*, described a necessary condition for the existence of an odd perfect number, but it was not a sufficient condition.

Other types of numbers that became the subject of scrutiny of Muslim mathematicians are the deficient and abundant numbers. The mathematicians supplied some criteria to identify these numbers:

- Every odd number less that 945 is deficient.

- Every even-times-even number has factors less than itself.
- The first abundant number is 12, and the first odd one in this class is 945.
- If $2^n S$ is a perfect number, then $2^{n+1} S$ is an abundant number, and $2^{n-1} S$ is a deficient number.

Kamāl al-Dīn al-Fārisī (d. 1320) in his treatise, *Tadhkirah al-aḥbāb fi bayān al-tuḥābb* supplied the rule to find pairs of amicable numbers (*al-a'dād al-mutaḥābbah*) in a systematic way. Thābit ibn Qurra (836–901) developed the theory of amicable numbers and provided a technique to find such pairs in his *Risālah fi'l-a'dād al-mutaḥābah*. Al-Fārisī reached the same conclusions through somewhat different paths. He based his new technique on the systematic knowledge of the divisors of a composite number and their sum. A pair of amicable numbers is defined as a pair of numbers (a, b) with the properties that the sum of all possible proper divisors of a is equal to b and the sum of all possible proper divisors of b is equal to a.

Ibn Ṭāhir al-Baghdādī defined a new variety of numbers known as equivalent numbers or numbers of equal weight (*mutaʾadilan*) in his *al-Takmila fi'l-Ḥisāb*. According to him:

> If we have a given number and wish to find two numbers, the parts of which make up this number, we reduce it by one and split the result into two prime numbers, then two others, and so on, as many times as we can. The product of each pair is a number equivalent to the given number. Thus if we are given 57, we split 56 into (3.53), (13,43), etc. The products of 53 by 3 and 4 by 13 are numbers such that the sum of the parts of each is 57 (Saidan 1977).

Equivalent numbers had not been studied by al-Baghdādī's contemporaries, nor by mathematicians for a few generations after him, until the time of Muḥammad Bāqir al-Yazdī (seventeenth century). Al-Yazdī, in his *ʿUyūn al-Ḥisāb*, considered such numbers and chose evenly even numbers to be decomposed as al-Baghdādī had done. In this way it was convenient for him to establish some properties of equivalent numbers, such as: if p and q are prime numbers, then p and q are of equal weight. It was felt that numbers of this kind needed more attention and to be examined further as they exhibited interesting unique behaviors.

The problem of finding the sides (x, y, z) of a right-angle triangle was studied and addressed by many Muslim mathematicians, including Samuʿīl (twelfth century) and Abū Jaʿfar al-Khāzin (tenth century). Al-Khwārizmī considered some basic problems related to a right-angled triangle. These problems became the source of his algebraic problems in his *Kitāb a-jabr wa 'l-muqābala*. Samuʿīl in his *al-Bāhir fi 'l-Ḥisāb* showed that any triple of the form

$$\left(a, \frac{(a^2 - b^2)}{2b}, \frac{(a^2 + b^2)}{2b}\right)$$

with a, b, c being appropriate positive integers, would describe right-angled triangles. Earlier, al-Khāzin had considered such problems in his *Risālah fī al-muthallathāt alqā 'imat al-zawāyā al-munṭaqat al-adḷāʿ*. He showed that it was not possible that any triple (x, y, z), with x and y being odd (or evenly even) could be the sides of a right-angled triangle with z as an integer. Al-Khāzin then used the results to study the problems of the form $x^m + y^n = z^p$ with m, n, and p some small positive integers. He left out some cases, however, such as $m = n = p$ 3 or 4, for such problems have no solutions. Problems of these types were examined centuries later by de Fermat (1736).

The problem of splitting a cube into three other cubes, i.e., to find the solution of the equation with three unknowns, $x^3 + y^3 + z^3 = n^3$, was discussed by Ibn Ṭāhir al-Baghdādī (tenth century) in *Takmila fi 'l-Ḥisāb*. He gave the answer as

$$(x, y, z) = \left(\frac{n}{2}, \frac{2n}{3}, \frac{5n}{6}\right).$$

This problem then reappeared in the works of Barbareta (1910).

Algebra in the Malay World: A Case Study of Islamic Mathematics

Mat Rofa Ismail, Kamel Ariffin Mohd Atan

The Malay World comprises countries which are now known as Malaysia, Indonesia, Brunei, Singapore, Thailand, Philippines, and Kampuchea. This part of the world is also known as *Nusantara* or *Pascabima*. Ptolemy, the Egyptian geographer, visited the Malay world in the second century AD and called it "Golden Chersonese" (*Semenanjung Emas* in Malay – a beautiful golden peninsula) for its beauty and greenness. Indian travelers once referred to it as *Sunarvabumi*, which can be translated in the same way. The significance of this area in ancient history as a meeting place for sea travelers between east and west is due to its strategic location between India and China.

The region went through its own history under many religious influences such as Hinduism, Buddhism, and Islam. It is recorded that Islam came to this region in the very early period of the Umayyad caliphate when a Srivijayan king embraced Islam during the reign of Caliph Umar ibn al-Aziz (AD 717–720). Since then, Islam gradually became an important religion in the region. Religious matters, such as compulsory charity (*zakat*), inheritance problems (*farā'iḍ*), and crescent sighting to mark a new month in the lunar calendar needed knowledge of systematic mathematical calculation. For these purposes, the works of al-Khwārizmī, Ibn al-Bannā', al-Turtūsī, Ibn al-Hā'im, Ulugh Beg and Ibn al-Yāsamīn in algebra, mathematics and astronomy were frequently cited by the Malay scholars.

Text books in algebra and arithmetic, such as *Khulasah al-Ḥisab* (A Concise Treatise on Mathematics) by al-'Amili, *Talqīḥ al-afkār* (Combining Ideas) and *al-Urjūyah al-Yāsaminiyyah* (The Poem of al-Yasamin) by Ibn al-Yāsamin, *Tuḥfah al-a'dād li dhawī al-rushd wa al-rashād* (A Special Arithmetic for the Wise and the Rightly Guided) by Ibn Hamzah al-Maghribi, *Kashf al-asrār* (Unveiling of Secrets) by al-Qalsaldi, *Talkhīṣ al-ḥisab* (Purification of Mathematics/Understanding Mathematics?) by Ibn al-Bannā' al-Marrakushi, and *Murshid al-ṭālib ila asna al-mutalib* (Student's Guide to Excellence in the Pursuit of Knowledge) by Ibn al-Ha'im, were among frequent quoted references by Malay writers (see Zain 2001).

The beginning of the history of Islamic mathematics can be traced to the late eighth century. Among the earliest Muslim mathematicians was al-Khwārizmī (780–850 AD) who introduced a new system of numbering which greatly simplified the Roman one which had been widely used previously. The decimal system (*a'shariyyah*) provided simplification in carrying out basic arithmetical operations. In the Islamic tradition of knowledge, religious scholars who were experts in the field of theology were also conversant with and masters of other areas of knowledge. These included astronomy, medicine, the arts, logic, and rhetoric. Among those who fall into this category are al-Kindī (born 796 AD), al-Battānī (858–929), Ibn al-Haytham (965–1038), al-Bīrūnī (973–1048), and Ibn Sīnā (eleventh century). By the fourteenth century Islamic civilization was already very rich in its mathematical knowledge. Scholars moved to other fields besides basic mathematics.

The treatise by Ibn al Bannā', entitled *Raf'u al-ḥijāb 'an A'māl al-Ḥisāb* (Unveil the Cover in the Arts of Mathematics) or *Khulasah al-ḥisab* by al-'Āmili, discussed the subject of basic arithmetic and algebra. For example, the discussion of permutations and combinations in the book of Ibn al-Bannā' (fourteenth century) marks the first advance made by Islamic mathematics since the time of al-Khwārizmī. Islamic scholars continued to be active and productive in the field of mathematics until the seventeenth century, when their involvement waned due to backlash in the political arena during that period and subsequent to it. Until that time many outstanding treatises were produced and became references not only by contemporaneous scholars, but also by mathematicians in the subsequent centuries. They played an outstanding role in shaping and providing directions for the future development of mathematics in the world. Muslim works were brought into Europe by early scholars by translating Arabic treatises into Latin. Leonardo Fibonacci was among the pioneers in this pursuit. Centers of learning set up in places such as Cordova, Toledo, and other places in Spain became the focal point of convergence for western scholars to study Islamic mathematics.

Islamic mathematics came into the Malay world through the efforts of Malay religious scholars who had gone to the Middle East to study Islamic theology. They mastered the mathematics of the day in its original form and in an integrated manner with branches of theology. Whatever was learnt in the Middle East was brought back and disseminated to students in traditional schools. Among the works collected and brought back were books on a variety of branches of mathematics which had been their references during their study, especially in Mecca, Medina, and the University of Al-Azhar. Some of the scholars became writers and produced mathematical works based on their learning experience. Many of the written works were in the form of leaflets, short notes, and letters, written in Malay using the Arabic script. These works came down to us through the descendants of these scholars. Though only a few manuscripts survived, they give us a glimpse of the serious efforts and quality of work of the early Malay scholars in mathematics.

The documentation of Islamic mathematics in the Malay World has to date not been completed. The earliest known record of a treatise in logic by a Malay writer, entitled *'Ilm al-Manṭiq* (The Art of Logic), is dated 1593. However our search for such treatises in mathematics written in the region mainly concentrated on surviving documents that are dated later than the eighteenth century.

The records tell us about the existence of a number of Malay mathematicians for the period between the nineteenth and mid-twentieth century. They were mathematicians who were also scholars in religious studies. Our early survey (Ismail 1995) showed that they originated mainly from Fatani/Patani (in southern Thailand), Sumatera Indonesia, and Kelantan Malaysia. Some were also of Riau and Kampuchean origin. They were highly respected by the Malay community then and now because of their knowledge in religion as well as in other scholarly areas. Syeikh Daud al-Fatani (b. 1720 AD), for example, was regarded as one of the great Malay scholars during that period. So were Syeikh Abdul Kadir al-Fatani (b. 1817 AD), Syeikh Muhammad Nur al-Fatani (b. 1873), Faqih Wan Musa al-Fatani (second half of nineteenth century), and Syeikh Wan Ahmad Mohamad Zain al-Fatani (1856–1908). Another Malay scholar was Ahmad bin Abdul Latif al-Khatib al-Minangkabawi from Sumatra, Indonesia. He is regarded as the greatest Malay mathematician of the nineteenth century. Syeikh Tahir Jalaluddin (1867–1957), also of Sumatran origin, who later settled down in peninsular Malaysia, was regarded as a fine Malay astronomer towards the end of the nineteenth century. So was 'Umar Nuruddin al-Kelantani.

Mathematical works by Ahmad bin Abdul Latif al-Khatib al-Minangkabawi entitled *'Alam al-Ḥussāb* (The Banner for Mathematicians) (1892) and *Rauḍat al-Ḥussāb* (The Garden for Mathematicians) (1890) became the models for others to follow in the Malay world then. *'Alam al-Ḥussāb* was a Malay version of the Arabic *Rauḍat al-Ḥussāb*. Al-Khatib was the first Malay *imam* (prayer leader), *khatib* (Friday prayer's speaker) and religious teacher in Masjid al-Haram Mecca, appointed by The Holy Land's authority. Many of his students came from the Malay region. In these two books were mathematical topics of the period found in the Muslim world, which included number theory, algebra, geometry, trigonometry, approximation theory, and discussions on daily problems especially those arising from Islamic practices (*fiqh*) and the like. The contents of these works reflected the discussions and debates that took place in the period that began in ninth century and ended in the seventeenth, especially on the works of Muhammad bin Musa al-Khwārizmī produced during the late eighth and early ninth centuries. Also included were those by Abu Kamil Shuja' al-Aslam (tenth century), Abu Bakar al-Karaji (eleventh century), Ibn Yasamin (twelfth century), Ibn al-Bannā' (fourteenth century), Ibn Hamzah al-Maghribi (sixteenth century), and Baha'uddin al-'Amili (seventeenth century).

Umar Nurudin's work on the distribution of properties left behind by deceased members of the family was entitled *Pelajaran Membahagi Pesaka* (Lessons in Distribution of Inheritance) (early nineteenth century). His other works include *Syams al-Fathiyyah fi A'amāl al Juyūb* (The Guiding Light to Success in the Art of Trigonometry) or *al-Jaibiyyah* (The Art of the (Trigonometrical) Sine) (1925), *Rubu' al-Mujayyab* (The Quadrant of the (Astronomical) Sine) (date unknown), and *Miftāḥ al-Ta'alīm* (The Key to Teaching and Learning) (1924). In the early twentieth century a scholar by the name of Muhamad Nur al-Ibrahimi, from Sumatra Indonesia, wrote a treatise on logic called *'Ilm Mantiq* (The Art of Logic) (1931). Sheikh Muhammad Nur Ibrahim of Kelantan wrote a book *Bantuan Ketika Bagi Orang yang Membahagi Pusaka* (A People's Guide to Inheritance Problems) (1936). Earlier, in 1932 he published a book entitled

Pilihan Mastika pada Menerangkan Qiblat dan Ketika (Selected Gems in the Calculation of the Qibla Direction and (Prayer) Times), on the exact Qibla location in Mecca. Syeikh Tahir Jalaluddin, of Sumatran origin, wrote a book on the mathematical method of determining Muslim prayer times, entitled *Pati Kiraan pada Menentukan Waktu yang Lima dengan Logaritma* (The Essence of Calculations Related to the Five Prayer Times Using Logarithms) in 1938. He also authored two other books on astronomy and wealth distribution. His book on astronomy, *Risā'il fi'l-Falak* (Treatises on Astronomy), contained an article by Abdul Rahman Kelantan bin Muhamad al-Battul which was dated 1826. In our view, this may be the oldest extant treatise on astronomy ever found in the Malay language.

An arithmetic text written by Abd Qadir ibn 'Ali al-Sakhawi, known as *Matn al-Sakhawiyyah* (The Shortened Version of Sakhawi), was rewritten by Sheikh Wan Ahmad bin Muhammad Zain of Patani with some significant commentaries and footnotes towards the end of the nineteenth century. This book was a standard text in arithmetic and algebra among new students in Islamic schools. The commentator mentioned the book by Ibn al-Ha'im as one of the references in his commentary.

The philosophy of learning mathematics in the Malay Islamic world is closely linked to the concept of the relationship between Allah, The Supreme Being and man, his servant. A Muslim is always conscious of this relationship and of the fact that whatever he has at his disposal must be directed to the expression of his enslavement to Allah. Hence in the pursuit of knowledge he is always aware of his role and the roles of knowledge in glorifying the Supreme Being and the confines of his activities in this pursuit. Islam places high priority on the importance of learning. It is a religion whose understanding relies greatly on the grasp and the depth of one's knowledge of the physical and nonphysical world. Hence the learning of mathematics became necessary in a Muslim's life, as this subject is a tool in enhancing one's understanding of the world. If one is aware that the world is a creation of Allah, one's understanding of the greatness and infinite wisdom of Allah will be further heightened by grasping the mathematics principles that describe Allah's creations. Also the knowledge he has mastered will make him better able to contribute to the development of his society, which is also consonant with the teachings of the religion. Hence the positions of scholars and intellectuals rank high in an Islamic environment.

Among the daily activities in a Muslim society is the conducting of business transactions. Bartering, weighing, and using other means were characteristic activities in Muslim markets. All of these are closely connected to the ability to compute based on agreed principles. In his book *'Alam al-Ḥussāb*, al-Khatib gave examples of the units of measures which were in use during that time. These include *sen*, *ringgit*, and *rupiah* as currency units, *pikul*, *kati*, *saga*, *kundi*, and *bungkal* as weights measures, *hasta* and *depa* for length units and *cupak*, and *gantang* for volume. Further discussions on the topic of measures according to al-Khatib can be found in his book in Arabic entitled *Sulh al-Jama'atain* (Conciliation of the Two Parties). Quizzes were also included in al-Khatib's books. They ranged from topics on multiplication and division to determinations of square roots based on real life problems. Among the topics covered in this book are *permulaan ḥisāb* (elementary arithmetic), *haqiqah bilangan* (on counting principles), *hitungan sahih* (on the integers), *kumpulan* (addition), *kurangan* (subtraction), *pukulan* (multiplication), *jenis–jenis pukulan* (types of multiplication), *bahagian* (division), *nisbah a-muttaṣilah ḥisābiyah* (arithmetic progression), *al-muttaṣilah handasiyah* (geometric progression), *kaifiat mengetahui yang majhul* (systems of equations), *tabādul* (permutations), *kaifiat bilangan kali–kali mungkin* (combinations), *amal dua yang tersalah* (approximations method; golden rule), *al-jabr wa al-muqabbalah* or *amal dengan bertemper dan berkebetulan* (the term in Malay for the *algebra* of al-Khwārizmī and solutions to quadratic equations), *misāḥah* (plane geometry), and *al-mizan* (modular congruence). Most of the topics covered by this book are taught in modern day Malaysia. An interesting feature of this book, which was also admitted by the author, was the striking similarity between its content and that of the book *Khulāṣah al-ḥisāb* written by al-'Amili (seventeenth century) which was one of the many links in the chain of Islamic mathematical tradition which had begun from the time of al-Khwārizmī. Al-Khatib's approach in the teaching of mathematics was almost exclusively influenced by the traditional methods of teaching from the scholars of the early Muslim period which clung to the descriptive way of solving problems. Although symbolism was already introduced in the Islamic world as early as at the time of al-Khwārizmī and further popularized by Abu Kamil, al-Maghribi and later by al-Qalsaldi in Spain (fifteenth century) Malay Muslim mathematicians were not responsive to the idea of adopting the symbolism approach (Ismail 2004). Descriptive representation of mathematical problems is the special feature of the curriculum in mathematics education outlined above, as demonstrated by the content of the book *'Alam al-Ḥussāb fi 'Ilm al-ḥisāb* by al-Khatib, a representative of works written in the Malay language in the nineteenth century.

The motivating factors in the teaching of mathematics in the Islamic system of education in the Malay archipelago are tied to the need to comprehend the basic teachings of the religion and efficient implementation of the administrative procedures as outlined by regulations stipulated by Islamic jurisprudence (*fiqh*) that governs everyday activities in the life of a Muslim. This was the dominant factor in the determination of mathematics education in the Islamic school curriculum prior to the introduction of the secular school system brought by the British in the late nineteenth century.

Al-Ḥajjāj

GREGG DE YOUNG

Al-Ḥajjāj ibn Yūsuf ibn Maṭar was one of the earliest translators of Greek mathematical and astronomical texts into Arabic. Few details of his life are known. According to a report of the biobibliographer, Ibn al-Nadīm, he prepared an Arabic version of Euclid's *Elements* under the sponsorship of the ʻAbbāsid caliph, Hārūn al-Rashīd (170–193 AH/AD 786–809). Later, under caliph al-Ma'mūn (198–218 AH/AD 813–833), he prepared a second (and improved) version. There are some hints that the mathematician, Thābit ibn Qurra (died 288 AH/AD 901), may have helped to revise the latter version.

Neither version is extant. Quotations from what purports to be the second version serve as the basis for a commentary by al-Nayrīzī (d. early fifth century AH/AD tenth century). These quotations seem, however, to have been edited by the commentator on the basis of the later translation of Isḥāq ibn Ḥunayn (215–298 AH/AD 830–910). There appear to be other traces of the transmission of al-Ḥajjāj in commentaries by Aḥmed al-Karābīsī and in the epitome of the Euclidean *Elements* in Ibn Sīnā's *Kitāb al-Shifā'* (The Cure [of Ignorance]). Probably this transmission tradition also served as the basis for the Latin translation of Adelard of Bath and the nearly contemporaneous Latin version of Hermann of Carinthia.

Al-Ḥajjāj is also credited with production of an Arabic version of Ptolemy's *Almagest*, perhaps by way of a Syriac intermediary. The relation of this transmission to that of Isḥāq ibn Ḥunayn has not yet been fully established. In this case, both traditions are extant, allowing a more careful scrutiny of philological characteristics and translation techniques. Attempts to apply what we learn from a study of the *Almagest* transmissions to Euclid remain incomplete.

Al-Hamdānī

CHRISTOPHER TOLL

Abū Muḥammad al-Ḥasan ibn Aḥmad ibn Yaʿqūb al-Hamdānī, with the honorific name Lisān al-Yaman ("The Tongue, i.e., the Mouthpiece of the Yaman"), was born into a turbulent time in a turbulent world and was not called to make his time and world less turbulent. He did create not only turbulence, but also a scholarly monument which has remained the pride of his Yamanite compatriots and an enduring contribution to the culture of mankind.

Background and Life

When al-Hamdānī was born, in Ṣanʿāʾ, perhaps on Ṣafar 19th, 280 AH (May 10th, 893 AD), the Muslim expansion had created a wide common market and an equally wide uncommonly cultured world, both without frontiers. The common market and the peace of the caliphate had given rise to huge fortunes which had financed numerous cultural and scholarly activities inspired by the new religion Islam, carried by its versatile language, Arabic, on a foundation laid by Hellenistic culture. Members of different religions, Muslims, Christians, and Jews, with different languages, Arabic, Greek, Aramaic and Persian, had collaborated in transforming the Hellenistic heritage into the Islamic culture of Arabic language. It was possible to travel in search of profit, *faḍl Allāh*, or of knowledge, from the River Indus in the East to Spain in the West without being hindered by frontiers, customs, wars, language difficulties, or different currencies.

Knowledge and profit supported each other. New technology, new industries, new goods and new money were spread; palaces, universities and schools were built. Gardens were made for the study of plants; books were written and manuscripts were collected, copied and translated and libraries founded. Scholars and artists met in the houses of patrons, and in spite of intense discussions there reigned a liberal atmosphere. Never in the Middle Ages had there been such a width and liberty in research and teaching.

Nevertheless, there were sectarian conflicts, e.g. with the Khārijites and Shīʿites, which had dynastic and political aspects, and there were nationalistic conflicts, e.g. with the Shuʿūbīya, a movement of mainly Persians who opposed Arab supremacy. There were nationalistic conflicts also among the Arabs themselves when South and North Arabians brought their rivalry as far as Spain. And there were local conflicts where the control of the central power was weak, as in the Yaman, so that local chiefs were able to oust the representative of the caliph. Al-Hamdānī was one of the most energetic champions of South Arabian nationalism, and yet his nationalism prompted him to scholarly and literary works of high value while it also rendered him open to persecution and maybe, as has been said, brought him a premature death in prison.

As his name shows, al-Hamdānī was a descendant of the powerful tribe Hamdān which had already played an important role in the Yaman to the north of Ṣanʿāʾ in pre-Islamic time. He was born in Ṣanʿāʾ, in the neighbourhood in which his family had lived for four generations. He was surnamed Ibn al-Ḥāʾik, after an ancestor who was a famous poet, and al-Hamdānī was to take up this family tradition.

A few decades before al-Hamdānī's birth the head of a local dynasty from Shibām, Yuʿfir b. ʿAbdarraḥmān al-Ḥiwālī, defeated the governor of the ʿAbbāsid caliphate and later transferred his power to his son Muḥammad who in his turn relinquished it to his son Ibrāhīm. When al-Hamdānī was born, Yuʿfir had recently ordered his grandson Ibrāhīm to murder his father which led to a revolution and the destruction of the silver mine in al-Jawf. In this revolution Ibrāhīmʾs house was plundered and he himself murdered, and the ʿAbbāsid governor reinstated the power of the caliph. But when al-Hamdānī was a small child the governor was called back to Baghdad and his Turkish soldiers were left to ravage Ṣanʿāʾ. The first Zaydī *imām*, al-Hādī ilā l-Ḥaqq, was called in to restore order. The following years witnessed repeated battles between al-Hādī and the Yuʾfirids. When a Fāṭimid *dāʿī* entered the scene, however, the Yuʿfirids under Asʿad b. Ibrāhīm and al-Hādī became allied.

These events did not leave al-Hamdānī unaffected: his own tribe Bakīl of Hamdān won a victory over the Fāṭimid army, and he was imprisoned by Asʿad's nephew, because he was opposed to the foreign element among the followers of the Yuʿfirid's ally. Al-Hamdānī's satirical verses gave rise to a revolt against al-Hādī's son an-Nāṣir, which culminated in the battle of Katafā and the death of an-Nāṣir and his brother Ḥasan. Al-Hamdānī escaped from prison to Hamdān's *sayyid* in Rayda and praised the leaders of the revolt in poems. It is thus doubtful that he died in prison in Ṣanʿāʾ in 334/946 as had been said by Ṣāʿid b. Ṣāʿid al-Andalusī on the authority of the Andalusian caliph al-Mustanṣir; others maintain that he did not die until about 350.

The Geographer

As a scholar, al-Hamdānī had an excellent education and did much travelling. One result of his travels is his geography of Arabia, particularly South Arabia, *Ṣifat jazīrat al-ʿarab*, the only systematic monograph of the Arabian Peninsula from the Middle Ages, which has been preserved in its entirety.

The first part of the work is a general geographical–astronomical introduction which follows Ptolemy. In this introduction al-Hamdānī showed his knowledge of Greek learning (he also quoted Hermes Trismegistos and Dioscorides). He was also familiar with the Indian astronomical work *Sindhind* and its Arabian translator al-Fazārī, as well as Ṣanʿāʾ's own astronomers.

The next part is a work on the physical, political and economical geography of the Arabian Peninsula. Starting with the Yaman, al-Hamdānī describes the different parts of Arabia with their mountains, valleys and wādīs, their vegetation and animal life, their tribes, habitations, villages, towns and castles, the number of inhabitants, the ownership and cultivation and irrigation of land, the pilgrim's roads and the dominions of sultans and governors. One of the themes is meteorology, as has repeatedly been observed, a theme that recurs in al-Hamdānī's medical work *Kitāb al-Quwā* (see below), as he mentions himself in his *Kitāb al-Jawharatayn* (see below).

The geographical description is interspersed with historical, genealogical, ethnographical and psychological notes, and he quotes Islamic and pre-Islamic poetry. In one of the concluding chapters, Hamdānī deals with weather conditions, food, prices, domestic animals and deposits of precious stones.

The Poet

Also as a poet and a collector of poetry al-Hamdānī shows his national and political fervour. His *Qaṣīda aḍ-Ḍāmigha fī faḍl al-Qaḥṭān* is an answer to Kumayt b. Zayd al-Asadī's satirical attack on the South Arabian tribes two hundred years earlier. To this poem – of its 590 verses rhyming *in -i/una* 476 are preserved – al-Hamdānī is said to have written a detailed commentary in a big volume. Another poem, *Qaṣīdat al-Jār*, deals with politics contemporary with the author, blaming the Yu ʻfirid ruler for having put him in prison. *Al-Iklīl* also contains many specimens of South Arabic poetry, including al-Hamdānī's own. His Diwān, with the commentary of Ibn Khālawayh, is said to have comprised six volumes, but has not come down to us.

The Philologist

As a philologist, al-Hamdānī is interested in words for things, e.g., in his *Ṣifa* it is the names of the flowers rather than the flowers themselves which are the object of his interest. In his *K. al-Jawharatayn* he discusses different words for gold and silver and for gold and silver coins and their sides and parts with their etymologies. In this context he explains the South Arabian mīmation and the formation of words of four radicals with *-m* as the fourth radical as originating in the *mā l-ibhāmīya*. In his *Ṣifa* he treats the spoken language of 113 different parts of the Arab peninsula and whether their language is correct or not or even ununderstandable. The best Arabic is spoken by, i.a., the Hamdān and by the nomads in the Ḥijāz and Najd as far as Syria, whereas in ʻAdan the common people not only speak bad but are even stupid, and the Mahra are as foreigners, impossible to understand (actually, the South Arabic Mahrī dialect is also today not understood by those speaking a North Arabic dialect). Al-Hamdānī also illustrates his verdicts by examples, e.g. when he says that the Sarw Ḥimyar say *ya bna m- ʻamm* instead of *ya bna l- ʻamm* and *sima*' instead of *isma* '- also other tribes have a definite article with *-m* instead of *-l*. Some tribes are said to speak Ḥimyarite. Al-Hamdānī gives in *al-Iklīl* some further examples to illustrate the Ḥ imyarite language and even some text samples.

Quotations from book 9 of *al-Iklīl* in a later work (the commentary on Nashwān's Ḥimyaritic *qaṣīda*) show that al-Hamdānī had a certain knowledge of the South Arabic script, which he reproduces in a table in book 8 with the (North) Arabic equivalents, but that he did not understand the inscriptions.

Al-Hamdānī's own language, by the way, does not seem quite to have followed the rules of the classical grammar. Al-Qifṭi tells us that *lamma dakhala l-Ḥusayn b. Khālawayh al-Hamadhānī an-Naḥwī ilā l-Yaman wa' -aqāma bi-hā bi-Dhamār, jama'a diwān shi ʻrihi* (*ya ʻni shi ʻr al-Hamdānī*) *wa- ʻarrabahu wa-a ʻrabahu* ("When Ḥ. b. Kh. al-H. the Grammarian came to Dh., he collected his (sc. al-Hamdānī's) poetry and made it into correct and clear Arabic"). And at least his *Kitāb al-Jawharatayn* shows in fact deviations from the classical norm and traces of the author's spoken language.

The *Faqīh*

Al-Hamdānī was also interested in law. In a work that has not been preserved but has been mentioned by al-Qifṭī, *Kitāb al-Ya ʻsūb*, he is said to have written about the legal rules concerning hunting. The legal chapter in the *Kitāb al-Jawharatayn* has been omitted in the manuscript with the exception of the title, *bāb ḥukūmat al- ʻiyār wa-fiqhihi wa-mā' ashbahahu*. Only short comments on gold and silver in the Hadith, on the prohibition of interest and of two purchases in one or the selling of gold for gold and silver for silver, and on the question of whether it is allowed to change God's creation are found in other chapters of the *Kitāb al-Jawharatayn*. The idea that gold as God's creation should be worked as it is without being refined is refuted by al-Hamdānī who compares it with wheat and sugar-cane which are also of God's creation but are worked and used in different ways.

The Historian

Al-Hamdānī's geography is supplemented by his historical work, *al-Iklīl*. This work was written in 332/944 while its author was living as the guest of Sayyid Hamdān, Abū Jaʿfar ad-Dahhāk, in the castle of Tayfum in Rayda. It consisted of ten books: books 1, 2 and 10 deal with the beginning of genealogy and present genealogies of South Arabian tribes, and book 8 describes the old castles of pre-Islamic South Arabia. These books are extant today. Of those not preserved, book 3 is said to deal with the merits of the South Arabian tribes, books 4–6 with the history of South Arabia before Islam, book 7 contained a critique of false traditions, and book 9 South Arabian inscriptions. Al-Hamdānī's sources were Abū Naṣr Muḥammad b. ʿAbdallāh b. Saʿīd al-Yahar al-Ḥanbaṣī, the learned lord of the castle Ḥanbaṣ, the archives (*sijill*) of the Banū Khawlān in Ṣaʿda and oral popular tradition and written information from different sides, e.g. from the legendary ʿUbayd b. Sharya al-Jurhumī, the collector of legends

Wahb b. Munabbih and the famous genealogist Hishām b. Muḥammad al-Kalbī. *Al-Iklīl* (The Crown) is quoted in al-Bakrī's *Muᶜjam ma staᶜjam*. Another historical work of al-Hamdānī, *Kitāb al-Ayyām*, to which he refers in his *Ṣifa*, has not been recovered. That so many of al-Hamdānī's historical writings were lost is, according to al-Qifṭī, because members of tribes not favourably mentioned had destroyed all the copies they could find.

The Philosopher

The two works, *Ṣifat Jazīrat al-ᶜArab* and *al-Iklīl* have made al-Hamdānī known as a geographer and a historian. But that he was also said to be one of only two famous Arab philosophers – the other was al-Kindī – is difficult to understand. Al-Kindī is well known as a famous philosopher, but why al-Hamdānī? After two other works by al-Hamdānī have become known, however, it is easier to understand the appreciation of the philosopher al-Hamdānī. As a philosopher, al-Hamdānī was interested, in his book on gold and silver, *Kitāb al-Jawharatayn al-ᶜatīqatayn* (see below), in the generation and corruption of matter, in the transmutation of one element into another and in the influence of the heavenly bodies upon the earth. He was a follower of the Greek philosophers, and he quotes the works of Aristotle concerning the generation of heat. But in his astronomical work *Sarāᶜir al-ḥikma* (see below) he opposes Aristotle, maintaining that each part of the celestial sphere is connected with a corresponding part of the earth.

The celestial sphere is divided according to the signs of the Zodiac, and this division also governs that of the seasons. In his *Kitāb al-Jawharatayn* al-Hamdānī gives a survey of the seasons with the qualities (warm, cold, dry and moist), elements (fire, water, earth and air) and cardinal humours (blood, phlegm, black and yellow bile) belonging to each season, and he also tells us which substances are related to which planet or sign of the Zodiac: lead, e.g. belongs to Saturn and to Capricorn. The influence of the planets on their substances varies according to their positions and the season of the year. The influence occurs also according to similarity: fire can influence only what already contains fire.

When al-Hamdānī compares the earth as round and globular and situated in the middle of the likewise round and globular sphere with the centre in the circle, he is repeating a comparison already to be found in a quotation by Archimedes from Aristarchos. Also in his historical work, ancient conceptions of the world as being eternal or created are said to be discussed. Some influence from the theory of atoms seems to be found in expressions such as *ijtimāᶜ* for having a three-dimensional body, properly signifying the fusion of atoms into a body, and the repeated use of the word *ajzāᶜ*, particles, atoms.

The Aristotelian theory of the generation of substances from the four elements under the influence of the heavenly bodies forms the basis of alchemy. The theory is that the different matters consist of a mixture of the four elements. According to their purity and proportions and the influence of the planets the metals arise in the earth. Of the metals, gold is the most pure, containing the elements in ideal proportions. Thus it ought to be possible to imitate the processes of nature by artificial means, removing the impurities and restoring the ideal proportions and thereby to obtain gold.

The alchemists used sulphur, being hot and dry, and mercury, being cold and moist, as representing the elements. It appeared, however, that no mixing of sulphur and mercury results in gold. The alchemists then presumed ideal forms of sulphur and mercury, not existing in the natural world. In order to accelerate the transformation which happens very slowly in nature, they used an elixir, having the same effect as yeast, and to produce this elixir the alchemists used a lot of methods, such as distillation and sublimation, boiling and calcination, amalgamation, etc. by means of crucibles, retorts and distilling-apparatuses, thus laying the foundations of chemistry. Later alchemists made this procedure into a ritual with an allegorical meaning, and a secret art.

The Muslim scholars had different opinions about alchemy. The great physician al-Rāzi (d. 313 or 323 H) tried to transmute metals, and he classified the matters he used according to their natures and properties. The great scientists al-Bīrūnī and Ibn Sīna (both fifth century H) believed in the generation of matter and in the sulphur–mercury theory, but they were opposed to alchemy because they were of the opinion that art was not able to imitate nature.

The Astronomer

In Greek and Islamic tradition you cannot separate the philosopher, the scientist and the doctor, and the views which I have mentioned are closely related to astronomy and astrology, chemistry and medicine, subjects on which al-Hamdānī was also productive.

Al-Hamdānī is also said to have compiled astronomical tables, *az-Zīj* – he mentions *Tanbīh az-Zīj* – and a book on horoscopes and the projection of rays (*Kitāb at-Ṭāliᶜ wal-maṭāriᵓ*. In a medicinal work, *al-Quwā*, which is lost, he showed the influence of the planets upon the temperature of the earth. It is also said that pieces on astronomy and physics are scattered through his historical work.

Of his astronomical work, *Sarā 'ir al-ḥikma fi ‘ilm an-nujūm*, al-Qifṭī says, quoting Ṣā‘id al-Andalusī, that its aim is *at-ta‘rīf bi-jumal hay 'at al-aflāk wa-maqādīr ḥarakāt al-kawākib wa-tabyīn ‘ilm aḥkām an-nujūm wa-stifa' ḍurūbihi* "the definition of the total form of the celestial bodys, the extent of the movements of the stars, the exposition of astronomy, and the exhaustive treatment of its kinds". It is also quoted by Abū Marwānal-Istijī, according to Ṣā 'id one of the best astrologers in al-Andalus. However, only the tenth chapter of this work has been recovered in two manuscripts in al-Yaman. In this work several Greek scholars are cited – Dorotheos of Sidon, Ptolemy, Valens, Hipparchos and the mythical Hermes Trismegistos – as also the Indian astronomical work Sindhind as well as its Arabic translator al-Fazārī and Persian astronomical works but also Islamic scholars, such as Māshā'allāh, Abū Ma 'shar, Abū Muḥammad b. Nawbakht, Sulaymān b. 'Iṣma.

The Economist

We have seen that al-Hamdānī's historical and geographical works were intended to be complementary to each other. In the same way his book on gold and silver, *Kitāb al-Jawharatayn al-ʿatīqatayn min aṣ-ṣafrāʾ wal-bayḍāʾ*, belonged to a trilogy on South Arabic economy, the parts of which were also complementary. Part 1 dealt with agriculture, part 2 with camel breeding and part 3 with gold and silver, i.e. the three kinds of property: landed property, cattle and precious metals. Only the part dealing with gold and silver has been preserved. Here gold and silver are mentioned as a form of investment, and its advantages in this respect are praised, above all that it is easy to take along.

The Metallurgist

In the *Kitāb al-Jawharatayn* the *Qurʾān* and the *Tradition* are quoted but so are popular traditions. An abundance of Persian expressions for substances and tools show that al-Hamdānī also had inherited an Iranian tradition with which he had personal contact. He says that Persian tribes, which had immigrated into al-Yaman already before Islam, were working the mines in South Arabia. They were called *furs al-maʿdin* and enjoyed a good position and property in Ṣanʿāʾ.

Al-Hamdānī also learnt about metallurgy and minting from specialists among his compatriots. The art of forging is very old in al-Yaman. It perhaps has its origin in the connections of al-Yaman with India – the Indian steel and the Indian swords made from it are often mentioned in Arabic poetry and by al-Hamdānī. The art of forging swords and armours is traced back by tradition to the Tubbaʿ, the kings of Ḥimyar, and the swords of al-Yaman are famous in Arabic poetry. Another important source of his knowledge was the master of the mints in Ṣanʿāʾ and Ṣaʿda and his sons, one of whom was to succeed him in the office.

Al-Hamdānī's *Kitāb al-Jawharatayn* is the oldest and most comprehensive of the four Arabic works on gold, silver and minting known to us (the other three are *Kashf al-asrār* by Ibn Baʿra, a manual of the Egyptian mint of the seventh century H, *ad-Dawḥa al-mushtabika fī ḍawābiṭ dār as-sikka* by ʿAlī b. Yūsuf al-Ḥakīm, a manual of the mint in Fās of the eighth century H, and a manual of the mint in Marrākush from the 990s H). It abounds in technical and chemical information which extends from the extraction of ore from the mines to the minting of coins. It also contains valuable information about gold and silver mines in Arabia, Africa and Iran. It also mentions the use of gold and silver for gilding and silvering and for ornaments and of gold leaf for decorating pages of the *Qurʾān*. It describes glass and methods of counterfeiting. Also the use of other metals such as iron and mercury and the sickness caused by some substances and their use are dealt with. The main subject of the book is, however, the fabrication of coins.

The fabrication of coins can be divided into three stages: the fabrication of the dies, the fabrication of the flans and the stamping of the flans. According to al-Hamdānī the die was made from hardened steel, its surface filed and the inscription engraved with an iron stylus. The die was pegged and holed in order to hold its two halves in a fixed position and to achieve a fixed relationship between the coin's obverse and reverse.

The flans were made after the gold and silver had been purified. The impurities in the gold ore were separated from the gold by means of sulphur, and the gold left in the separated impurities was collected by amalgamation with mercury. Silver was also extracted by amalgamation and otherwise purified by heating while supplying air at the same time, so that the lead in the silver ore combined with the oxygen in the air and was separated as lead oxide. Al-Hamdānī describes three methods to fabricate the flans. One was lamination: the cutting of flans from moulded bars. A second method consisted of casting the flans in moulds of clay. The third method consisted of pouring molten silver or gold into water. Thus small round pieces of metal were obtained which were hammered flat and used as flans, in spite of their different size.

The Physician

Al-Qiftī calls al-Hamdānī *aṭ-ṭabīb* (physician), and one of his books, *al-Quwā*, is said to be a medical work, but we do not know its content. That al-Hamdānī was interested in medicine is, however, clear also from *Kitāb al-Jawharatayn*, which contains some medical information. The pain of burns is mitigated by means of gold. Rash is treated with water containing gold. Chips of gold and silver are ingredients in important remedies. The oculists use dross of gold and silver. Silver slag removes the stink of the sweating of the axillae and is used in salves to close wounds. Verdigris, made from copper and wine vinegar, is used in many remedies and in colours. Antimony heals wounds and stops haemorrhage from the cerebral membranes, and mixed with fat it is used for burns. Mercury is used against colic but can also increase colic, causing constipation and death.

There are also some general remarks on the influence of compound drugs on the body and the difference between medicine for internal and external application. Some of the information is borrowed from Dioscorides' materia medica.

Al-Hamdānī also mentions damages caused by different substances. The mercury vapour produced by gilding and amalgamating causes hemiplegia and convulsions. Since mercury is moist and cold the remedy ought to be something warm, such as wine. The fumes of lead, which evaporate when silver is purified, affect the brain, and the vapours of the substances used for purifying the gold dry out the nose and saliva, cause cutaneous fissures and affect the brain. Therefore, a wall is put between the furnace and the workers, or the workers cover their noses – early examples of safety precautions for workers. Fumes from lead and copper injure the teeth, weaken the bladder and cause a pain in the waist. The fume from the manure used when silver amalgam is heated causes headaches, and other fumes from the furnace give rise to jaundice, disturbed vision, attacks of sickness, abdominal pains, and headaches.

The Man

Intellectually, al-Hamdānī was a man of independent thought. We have seen that he did not simply reproduce the learning of others. As a geographer he relied mainly on his own observations, travelling extensively over the country he was going to describe. He had his own opinion about the colour of the skin of the peoples in the tropical countries, which was contrary to that of Ptolemy. He had his own division of the world with more climata than the usual seven. He contrasted the opinion of the Greeks concerning the extension of the inhabited world with that of the Indians and the Chinese and exposed in detail the differences between the Greek, Indians and Arabs concerning latitude and longitude. He also contrasted two theories concerning the seasons, their qualities and the cause of these qualities.

Morally, al-Hamdānī was a man of courage and strong passions. Although a Muslim, he dared to attack the tribe of the Prophet, and his strong stand for the Yaman can also be seen in the absence of descriptions of Makka and al-Madīna from his *Ṣifa*. He was not afraid of taking part in the political turmoil of his days, and prison did not frighten him and did not break him down. Nothing in his writings, however, gives the impression that he was but a pious Muslim, well versed in the *Qurʾān* and the *Hadīth*.

Al-Hāshimī

F. Jamil Ragep

ʿAlī ibn Sulaymān al-Hāshimī flourished some time in the second half of the ninth century, probably somewhere in the central lands of Islam. Virtually nothing is known about him other than the fact that he wrote a rather uncritical work on *zījes* (astronomical handbooks) that nevertheless preserves a great deal of otherwise unknown or little known information. This book, *Kitāb fi ʿilal al-zījāt* (Explanation of Zījes), was written at a time before Ptolemaic astronomy had become the dominant astronomical tradition in Eastern Islam. As such, it contains considerable material about the Indian and Persian astronomical traditions, at least insofar as they were received and preserved during this early period of Islamic science.

Hāshimī mentions some sixteen *zījes*, of which two are Greek (Ptolemy's *Almagest* and Theon's *Canon*, which is based upon it); seven are Indian or derived mainly from Indian sources (the *Arjabhar*, the *Zīj al-Arkand*, the *Zīj al-Jāmiʿ*, the *Zīj al-Hazūr*, the *Zīj al-Sindhind* of al-Fazārī [eighth century] as well as a second *zīj* by him, and the *Zīj* of Yaʿqub ibn Ṭariq [eighth century]); two are Persian but mainly Indian in inspiration (the *Zīj al-Shāh* of Khusro Anūshirwān and the *Zīj al-Shāh* of Yazdigird III); and five are from the ninth century and use material from these three traditions in varying degrees (the *Zīj al-Sindhind* of al-Khwārizmī, the *Zīj al-Mumtaḥan* of Yaḥyā ibn abī Manṣūr, the first Arabic *zīj* that was principally Ptolemaic, two *zījes* of Ḥabash, one mainly Indian, the other mainly Ptolemaic, and the *Zīj al-Hazārāt* of Abū Maʿshar).

Besides its importance as a historical resource, Hāshimī's work provides some valuable clues about the state of Islamic science during this early period. It is clear that the impressive number of astronomical works floating about made a work explaining them desirable, giving evidence for the vitality of science during this period. The influx of "foreign" knowledge had its detractors, though, and Hāshimī felt compelled, in a passing comment, to affirm that the cycles of Indian astronomy were not from their prophets, whatever might be claimed; nor were they for the purpose of "soothsaying", something he knows would be unIslamic. Rather he asserts that they are mathematically derivable and as such safe, an interesting and not atypical way of handling religious opposition to astronomy in Islam.

This makes the subsequent history of Islamic astronomy all the more remarkable. Indian astronomy with its cycles and computational tradition, but lacking a full-blown cosmology would, at first glance, seem to be a much more congenial tradition for Islam, which had its own religious cosmology and metaphysics. In fact Hāshimī implies as much in introducing the *Sindhind*; he also reports that Shāh Anūshirwān (sixth century) preferred Indian to Ptolemaic astronomy. So the subsequent predominance and triumph in Islam of Ptolemaic astronomy, based ultimately on Aristotelian physical principles and cosmology, was a remarkable occurrence indeed.

Al-Idrīsī

Sayyid Maqbul Ahmad

Abū ʿAbd Allāh Muḥammad ibn Muḥammad ibn ʿAbd Allāh ibn Idrīs, known as al-Sharīf al-Idrīsī, was one of the great Arab geographers of medieval Islam. He was born in Ceuta (Morocco) in AH 493/AD 1100 and died there in AH 560/AD 1166. Al-Idrīsī belonged to a ruling family, the Alavī Idrīsīs, who were claimants to the caliphate and had ruled in the region around Ceuta from AD 789 to 985. His ancestors were the nobles of Malaga, Spain who, unable to maintain their authority there, migrated to Ceuta in the eleventh century. Al-Idrīsī was educated in Cordoba and began traveling at a very early age. At the age of 16, he visited Asia Minor and then traveled in southern France, England, Spain, and Morocco.

This was a period of the growing power of the Normans in Europe and the Mediterranean region. It is said that Roger II (1097–1154), the Norman ruler, invited al-Idrīsī to come and stay with him in Palermo (Sicily), saying he would be safe from Muslim kings who were trying to murder him. Al-Idrīsī accepted the king's invitation and went to Palermo sometime in AD 1138 and stayed there until after the death of Roger in AD 1154. Then he returned to Ceuta.

Sicily at this time was an important center, where Arab-Islamic and Western European cultures intermingled. Roger himself was very interested in the promotion of arts and sciences, and we learn from al-Idrīsī that he was also interested in geography and astronomy. Roger gave al-Idrīsī an important task, probably from political motives, which was to construct a world map. Roger was still engaged in expanding his empire in North Africa, and thought al-Idrīsī would be a suitable person for this task. Although he was well traveled in North Africa and Europe, al-Idrīsī was not a geographer in the true sense of the word at this stage. But he began constructing the map under the patronage and supervision of Roger. Finding that the courtiers at his palace did not possess sufficient knowledge of the geography of the world, Roger sent envoys to different regions to collect fresh data. After the information was acquired, al-Idrīsī utilized only such data on which there was unanimity; the rest was discarded. He also used the Arabic geographical works which were available to him, such as the Arabic version of Claudius Ptolemy's (ca. AD 90–186) *Geography* (Arabic *Jughrāfiya*), *Kitāb Ṣūrat al-Arḍ* (Book on Routes and Kingdoms) by Ibn Hawqal, *Al-Masālik wa'l Mamālik* by Ibn Khurdādhbih (AH 232/AD 846), and the lost work of al-Jayhānī entitled *Kitāb al-Masālik wa'l Mamālik*. Thus it seems that al-Idrīsī had a vast amount of geographical material on the known world at his disposal.

He worked on the map for 15 years, basing it primarily on Ptolemy's map, with some modifications. When it was completed, Roger asked him to have it carved on a round silver disc, which al-Idrīsī did with great skill with the help of artisans. The silver map had all the physical features and names of places drawn on it. Roger was so pleased with al-Idrīsī's performance that he asked him to write a book on world geography. He produced the voluminous compendium *Nuzhat al-Muṣṭāq fi ikhtirāq al-ʾAfāq*, the full Arabic text of which has now been published as *Opus Geographicum* under the auspices of the Italian Institute of the Middle and Far East in Rome and the Institute of Oriental Studies at Naples University. Although the silver map has not survived, the original world map has. The *Nuzhat* is supposed to be a description of this world map. Al-Idrīsī divided the known world into seven climes (*iqlīm*) running parallel to the equator up to 64°N latitude and divided each of the climes into ten longitudinal sections. Thus there are 70 odd sectional maps, and the arrangement of the book follows the 70 divisions. In many cases, there is more information in the book than is depicted on the maps. Al-Idrīsī's world map is the most detailed and largest map drawn by any Muslim cartographer. His book is indeed a mine of information on physical, topographical, human, cultural, and political geography. From the world map and the book, one can see that his knowledge of Europe, North Africa, and West and Central Asia was much deeper and more correct and extensive than it was of South Asia or the Far East.

Al-Idrīsī had a mathematical basis for his map, but he did not provide latitudes or longitudes as al-Maghribī did, who followed the pattern of al-Idrīsī. As he tried to include all the information at his disposal, some distortions were bound to take place, especially in the northern and southern regions. For example, the shapes and positions of the islands in the Indian Ocean were distorted. Even with these errors, his book is an encyclopedia of geographical knowledge of medieval times, and was an important geographical textbook for a long time.

Al-Jawharī

Sonja Brentjes

Probably of Iranian origin, al-ʿAbbās Ibn Saʿīd al-Jawharī was one of the court astronomers/astrologers of Caliph al-Maʾmūn (r. 813–833) in charge of the construction of astronomical instruments. He participated in astronomical observations carried out in Baghdad in 829–830 and in Damascus in 832–833. He is said to have composed an astronomical handbook (*Zīj*), which is lost, except for indirect references (Sezgin 1973). In his house in Baghdad, meetings were held at which the participants discussed Ptolemy's *Almagest*, Euclid's *Elements*, and problems derived from the two books. A not yet studied manuscript, *Kalām fī maʿrifat buʿd al-shams ʿan markaz al-arḍ* (Speech about the Knowledge of the Distance between the Sun and the Center of the Earth), might be an extract of his *Zīj* or an independent astronomical treatise. In astrology, he was considered an expert at horoscopes determining an individual's length of life.

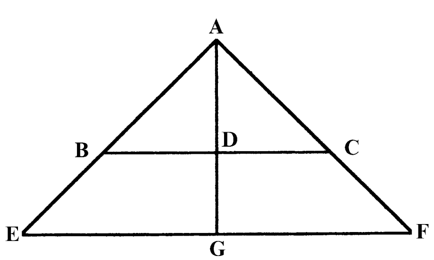
His main achievements in the mathematical sciences are in geometry. He edited or commented on the *Elements*. Extracts of this work are preserved as independent manuscripts containing fragments of his *Ziyādāt fī'l-maqāla al-khāmisa min kitāb Uqlīdis* (Additions to Book V of Euclid's Book) and as quotations of his attempted proof of the parallel postulate (Book I) in Naṣīr al-Dīn al-Ṭūsī's *al-Risāla al-shāfiya ʿān al-shakk fī'l-khuṭūṭ al-mutawāziya* (The Healing Treatise on the Doubt Concerning Parallel Lines). In this treatise, al-Ṭūsī also cites one of al-Jawharī's additions to Book I, namely that the angles contained by three lines drawn from one point in different directions equal four right angles.

Al-Jawharī's attempted proof of the postulate was contained in the same edition of the *Elements* as the aforementioned additional proposition. It evidently was inspired by the proofs of Simplikios (sixth century) and Aghānīs/Aghānyūs (Agapios?, fl. ca. 511), since he used the same variant of the so-called Eudoxos-Archimedes axiom as Aghānīs and at least two propositions attributed by ʿAlam al-Dīn Qayṭar (d. 1251) to Simplikios. Since both proofs were contained in Simplikios' commentary on the definitions, postulates, and axioms, its Arabic translation obviously was made in the first half of the ninth century.

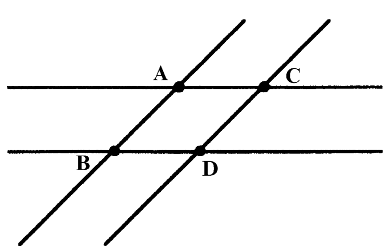
The theorem upon which al-Jawharī's proof is built states principally that if a triangle ABC is divided by a line AD and this line and the two sides AB and AC are extended and cut by a line EF such that $AB = BE$ and $AC = CF$, then $AD = DG$ with G being the point of intersection between line EF and the extension of line AD (see Fig. 1).

The proof of this proposition and consequently the proof of the postulate ultimately depend upon two propositions possibly introduced by al-Jawharī himself. The problem of the whole proof lies in the incomplete proof of the second part of the first of the two theorems, which al-Ṭūsī had already discovered. This second part states principally that the distance between one point of a line and its "corresponding" point on a second, parallel line always equals the distance between a second point on the first line and its "corresponding" point on the second line, $AC = BD$ (Fig. 2). Al-Jawharī's proof of this part not only treats a special case, but also fails to prove the equality of the two joining lines.

The fragment of al-Jawharī's additions to Book V contains three propositions which try to prove Euclid's definitions V, 5 (identity of ratios), V, 7 (one ratio > a second ratio), and the negation of definition V, 5. This illustrates how difficult those definitions were. Usually, a definition is not proven, since it was regarded as an evident assumption or a statement agreed upon between scholars. Al-Jawharī's explanations dressed as



Al-Jawharī. Fig. 1 Jawharī's theorem.



Al-Jawharī. Fig. 2 The distance between one point of a line and its corresponding point on a second, parallel line always equals the distance between a second point on the first line and its corresponding point on the second.

formal proofs do not really clarify those definitions, since all he did was simply to repeat them for special objects, namely, natural numbers.

Al-Jawharī is also credited with the translation from Persian into Arabic of a book about poison of supposed Indian origin, the so-called *Kitāb al-Shānāk* (The Book of Shānāk), for al-Maʾmūn.

Al-Jazarī

Donald R. Hill

Al-Jazarī, Badīʾ al-Zamān Abū'l-'Izz Ismaʿil ibn Al-Razzāz, was an engineer who worked in al-Jazira during the latter part of the twelfth century. His reputation rests upon his book, *Kitāb fī maʿrifat al-ḥiyal alhan-dasiyya* (The Book of Knowledge of Ingenious Mechanical Devices), which he composed in 1206 on the orders of his master Nāsir al-Dīn Maḥmūd, a prince of the Artuqid dynasty of Diyar Bakr. All that we know of his life is what he tells us in the introduction to his book, namely that at the time of writing he had been in the service of the ruling family for 25 years. The book is divided into six categories (*nawʿ*). Each of the first four contains ten chapters (*shakl*), and the last two consist of only five each. The categories are as follows:

1. Water clocks and candle clocks
2. Vessels and pitchers for use in carousals or celebrations
3. Vessels and basins for hand washing and phlebotomy
4. Fountains and musical automata
5. Water lifting machines
6. Miscellaneous

There are many illustrations, both of general arrangements and detailed drawings, and these are of considerable assistance in understanding the text, which contains many technical expressions that have since fallen into disuse. Some 13 manuscript copies, made between the thirteenth and the eighteenth centuries, are extant to bear witness to the widespread appreciation of the book in the Islamic world.

There are, however, no references to al-Jazarī in the standard Arabic biographical works of the Middle Ages, and there is no known translation into a European language before the twentieth century.

Only one of the complete machines, a twin cylinder pump driven by a paddle-wheel, can be said to have direct relevance to the development of mechanical technology. Many of the devices, however, embody techniques and mechanisms that are of great significance, since a number of them entered the general vocabulary of European engineering at various times from the thirteenth century onward. Some of these ideas may have been received directly from al-Jazarī's work, but evidence is lacking. Indeed, it seems probable that a large part of the Islamic mechanical tradition – especially water clocks and their associated mechanisms and automata – had been transmitted to Europe before al-Jazarī's book was composed. Even leaving aside the question of direct transmission, we still have a document of the greatest historical importance. First, it confirms the existence of a tradition of mechanical engineering in the Eastern Mediterranean and the Middle East from Hellenistic times up to the thirteenth century. Al-Jazarī was well aware that he was continuing this tradition and was scrupulous in acknowledging the work of his predecessors, including Apollonius of Byzantium, the Pseudo-Archimedes, the Banū Mūsā (ninth century), Hibat Allah ibn al-Ḥusayn (d. 1139–1140), and a certain Yūnus al-Asṭurlābī.

Other writings and constructions, whose originators were unknown to al-Jazarī, are also mentioned.

Second, his use of and improvement upon the earlier works, together with his meticulous descriptions of the construction and operation of each device, enables us to make an accurate assessment of mechanical technology by the close of the twelfth century.

Al-Jurjānī

E. Ruth Harvey

Abū˒l-Fadā˒il Ismā˓īl ibn al-Ḥusayn al-Jurjānī, Zayn al-Dīn, sometimes called Sayyid Ismā˓īl, was the most eminent Persian physician after Ibn Sīnā (Avicenna), and the author of the first great medical compilation written in Persian. Born at Jurjan, 50-mile east of modern Gurgan, east of the Caspian, he was a pupil of Ibn Abī Ṣādiq (d. 1066–1077), who had himself been a pupil of Ibn Sīnā. In 1110 al-Jurjānī entered the service of the ruler of Khwarizm (modern Khiva), the Khwārizmshāh Quṭb al-Dīn Muhammad (d. 1127) and his son Atsiz; later he moved to Marw (Merv) and served the rival sultan Sanjar. Al-Jurjānī died at Marw in about 1136 (AH 531).

Al-Jurjānī's great work is entitled *Dhakhīra-i-Khwārazmshāhī* (The Thesaurus of the King of Kharazm). Comparable in size and scope to Avicenna's *Canon*, the *Thesaurus* is a compendium of medical knowledge and clinical practice. It rapidly became a classic and established the medical and scientific vocabulary in Persian; its influence was extensive and long-lasting. It was translated into Hebrew, Urdu, and Turkish, and remained in use until the nineteenth century. There are many manuscripts, both complete and fragmentary, but no available modern edition (although Keshavarz records an Indian edition of 1865–1866, and one produced in Tehran in 1965).

In addition to the *Thesaurus*, al-Jurjānī composed other works in Persian which appear to be, in the main, abridgements of it. Chief among these is the condensed version called *Mukhtaṣar-i Khuffī-i ˓Alā˒ī* (Abridgement for the Boots of Alā˒) in two long volumes for Shah Atsiz to carry in his tall riding boots. This work was printed in Agra (1852) and Cawnpore (1891), but neither edition is readily available. There are several manuscripts in Turkey, one in the British Library, and an Arabic translation in Paris and at the University of California.

The *al-Agrāḍ al-ṭibbīya* (Aims of Medicine), composed for the vizier of Atsiz, is partly another abridgement of the *Thesaurus* combined with an account of the symptoms and treatment of local diseases. The *Yadgar i-ṭibb* (or Remembrancer) is largely on pharmacology.

Al-Jurjānī's works have not been much studied, and the relationships between the various texts and translations have not been worked out. A work in Arabic, *Zubdat al-ṭibb* (Essence of Medicine), is frequently assigned to him; this is presumably a translation of one of the Persian treatises mentioned above, but it is not clear which one. Some of the other manuscript works ascribed to al-Jurjānī are probably excerpts from his lengthy books.

Al-Karajī

Jacques Sesiano

Al-Karajī Abū Bakr Muḥammad was a Persian mathematician and engineer. He held (ca. 1010–1015) an official position in Baghdad during which time he wrote his three main works.

1. His *al-Fakhrīfī'l-jabr wa 'l-muqābala* (Glorious on Algebra) contains an exposition of algebra and auxiliary topics (e.g. summing series of integers). The next and larger part is a collection of problems: some are commercial and recreational, but for the

most part they belong to indeterminate algebra. All of the latter sorts are taken from Diophantus or Abū Kāmil.

2. The *Badī*ᶜ *fī'l-ḥisāb* (Wonderful on Calculation) is more original. After restating many of Euclid's theorems, al-Karajī shows how to calculate with square, cubic, and biquadratic roots and with their sums, then how to extract the root of a polynomial in *x* (this is the earliest known mention of the procedure). A second part contains problems on indeterminate algebra. Here, al-Karajī has taken the basic methods used by Diophantus in his problems and classified them, the result being a useful introduction to Diophantus's algebra.
3. The composition of the *Kāfī fī'l-ḥisāb* (Sufficient on Calculation) belongs to the usual duty of a mathematician holding an official position: to write a simple textbook in a way accessible to civil servants and containing the elements of arithmetic with integers and fractions (common and sexagesimal), the extraction of square roots, the determination of areas and volumes, and elementary algebra. All this is illustrated by numerous examples.
4. The ᶜ*Ilal al-jabr wa'l-muqābala* (Grounds of Algebra) is a small compendium on basic algebra (reckoning with roots, solving the basic six forms of the equations of the first two degrees), without resort to any geometrical demonstrations.
5. The *Inbāṭ al-miyāh al-khafīyah* (Locating Hidden Waters) was written after al-Karajī's return to Persia. It is concerned with finding subterranean water, extracting it, and transporting it in accordance with the soil's configuration.

Other, lost works of al-Karajī's are known to have dealt with indeterminate algebra, arithmetic, inheritance algebra, and the construction of buildings. Another contained the first known explanation of the arithmetical (Pascal's) triangle; the passage in question survived through al-Samaʾwal's *Bāhir* (twelfth century), which heavily drew from the *Badī*ᶜ.

Although much of his work was taken from others' writings, there is no doubt that al-Karajī was quite an able and influential mathematician. However, the quality of his writings is uneven, as he seems to have worked hastily sometimes.

Al-Kāshī

Boris Rosenfeld

Al-Kāshī, or al-Kāshānī (Ghiyāth al-Dīn Jamshīd ibn Masᶜūd al-Kāshī (al-Kāshānī)), was a Persian mathematician and astronomer. He was born in Kāshān in northern Iran, and worked at first in Herat (now in Afghanistan) at the court of *khāqān* ("khān of khāns" Shāhrukh, the son of Tīmur). In 1417 he was invited by Ulugh Beg, the son of Shāhrukh, the ruler of Samarqand (now in Uzbekistan) to become the director of his astronomical observatory. His scientific treatises were mostly written in Arabic, and partly in Persian. Al-Kāshī died in Samarqand in about 1430.

Al-Kāshī's main mathematical work is *Miftāḥ al-ḥisāb* (Key of Arithmetic). This work, written in the tradition of Arabic mathematical texts, contains five books (1) Arithmetic of integers, (2) Arithmetic of fractions, (3) Arithmetic of astronomers, (4) Geometry, and (5) Algebra.

In book 1, al-Kāshī considers duplication (multiplication by 2), mediation (division into 2), addition, subtraction, multiplication, and division. As Naṣīr al-Dīn al-Ṭūsī (1201–1274) did in his arithmetic treatise, he also considers extraction of roots of arbitrary integer powers by means of what we now call the Ruffini–Horner method and expresses the approximate value of the root by means of "Newton's binomial formula" for $(a+b)^n$. In book 2, al-Kāshī introduces decimal fractions and calls the digits of these fractions "decimal minutes," "decimal seconds," "decimal thirds," etc. Arithmetic of astronomers considered in book 3 is arithmetic of sexagesimal fractions borrowed by Islamic astronomers from Ptolemy, who in turn had borrowed them from Babylonian astronomers. Islamic astronomers designated figures from 1 to 59 by means of letters, and zero by ō. Like the ancient Babylonians, al-Kāshī extended the sexagesimal system onto integers and called the sexagesimal digits "raised," "twice raised," "three times raised," etc. In book 4, the rules of mensuration of many plane and solid figures, including buildings, cupolas, and stalactite surfaces, are formulated. In book 5, besides explaining the algebraic solution of quadratic equations and equations reducible to them, al-Kāshī discusses the solutions of equations by means of the rule of two errors, actions with roots, algebraic identities, and Thābit ibn Qurra's rule for the determination of amicable numbers. Al-Kāshī claims that he wrote an algebraic treatise with the classification of equations of the fourth degree, and that for every type he proposed the solution by means of the intersection of conics more general than the conics by means of which ʿUmar al-Khayyām solved cubic equations. This algebraic treatise is not extant and since the number of these equations does not coincide with those mentioned by al-Kāshī, this treatise was not finished.

The *al-Risāla al-muḥīṭiyya* (Treatise on Circumference) is devoted to the calculation of the ratio of circumferences of circles to their radii (now this ratio is designated by 2π). Al-Kāshī calculates the perimeters of regular inscribed and circumscribed polygons with 3.2^{28} sides. The number of sides is chosen on the condition that the difference between these polygons for the great circle of the sphere of fixed stars must be less than the "width of a horse hair." The result is expressed in sexagesimal and decimal fractions.

In the *Risāla al-watar wa'l-jayb* (Treatise on Chord and Sine) al-Kāshī calculates the sin 1° according to known sin 3°. This problem was necessary for composition of the tables of sines with five sexagesimal digits in Ulugh Beg's *Zīj-i Ulugh Beg* (Ulugh Beg's Astronomical Tables). This problem was reduced to the cubic equation $4x^3 + q = 3x$ ($x = \sin 1°$, $q = \sin 3°$) and was solved by the method of successive approximations

$$x_1 = \frac{q}{3'},\ x_2 = \left(\frac{q + 4x_1^3}{3}\right), \ldots$$

In the field of astronomy, al-Kāshī was author of *Zīj-i Khāqānī* (Khāqān Astronomical Tables) written in 1413–1414 in Herat. He also composed a treatise on astronomical instruments written in 1416 dedicated to the ruler of Iṣfāḥān Iskandar, who was the nephew of Shāhrukh, and was one of the authors of Ulugh Beg's *Astronomical Tables*. He was also the translator of the last tables from Persian into Arabic. In the treatise *Nuzha al-ḥadāiq* (Delight of Gardens), al-Kāshī describes an instrument for representation of the movements of planets which he invented. He was also the author of numerous other astronomical treatises.

Al-Khalīlī

David A. King

Al-Khalīlī, Shams al-Dīn Abū ʿAbdallāh Muḥammad ibn Muḥammad, lived in Damascus, ca. 1365. He was an astronomer associated with the Umayyad Mosque in the centre of Damascus. A colleague of the astronomer Ibn al-Shāṭir, he was also a *muwaqqit* – that is, an astronomer concerned with ʿ*ilm al-mīqāt*, the science of timekeeping by the sun and stars and regulating the astronomically defined times of Muslim prayer. Al-Khalīlī's major work, which represents the culmination of the medieval Islamic achievement in the mathematical solution of the problems of spherical astronomy, was a set of tables for astronomical timekeeping. Some of these tables were used in Damascus until the nineteenth century, and they were also used in Cairo and Istanbul for several centuries. The main sets of tables survive in numerous manuscripts, but they were not investigated until the 1970s.

Al-Khalīlī's tables can be categorized as follows:

- Tables for reckoning time by the sun, for the latitude of Damascus
- Tables for regulating the times of Muslim prayer, for the latitude of Damascus
- Tables of auxiliary mathematical functions for timekeeping by the sun for all latitudes
- Tables of auxiliary mathematical functions for solving the problems of spherical astronomy for all latitudes

- A table displaying the *qibla*, that is, the direction of Mecca, as a function of terrestrial latitude and longitude
- Tables for converting lunar ecliptic coordinates to equatorial coordinates

The first two sets of tables correspond to those in the large corpus of spherical astronomical tables computed for Cairo that are generally attributed to the tenth-century Egyptian astronomer Ibn Yūnus.

Al-Khalīlī's fourth set of tables was designed to solve all the standard problems of spherical astronomy, and they are particularly useful for those problems that, in modern terms, involve the use of the cosine rule for spherical triangles. Al-Khalīlī tabulated three functions and gave detailed instructions for their application. The functions are as follows:

$$f_\phi(\theta) = \frac{\sin\theta}{\cos\phi} \quad \text{and} \quad g_\phi(\theta) = \sin\theta\tan\phi,$$
$$K(x,y) = \arccos\left(\frac{x}{R\cos y}\right),$$

computed for appropriate domains. The entries in these tables, which number over 13,000, were computed to two sexagesimal digits and are invariably accurate. An example of the use of these functions is the rule outlined by al-Khalīlī for finding the hour-angle t for given solar or stellar altitude h, declination δ, and terrestrial latitude φ. This may be represented as:

$$t(h,\delta,\phi) = K\{(f_\phi(h) - g_\phi(\delta)),\delta\},$$

and it is not difficult to show the equivalence of al-Khalīlī's rule to the modern formula

$$t = \arccos\left(\frac{\sin h - \sin\delta\sin\phi}{\cos\delta\cos\phi}\right).$$

These auxiliary tables were used for several centuries in Damascus, Cairo, and Istanbul, the three main centres of astronomical timekeeping in the Muslim world.

Al-Khalīlī's computational ability is best revealed by his *qibla* table. The determination of the *qibla* for a given locality is one of the most complicated problems of medieval Islamic trigonometry. If (L, φ) and (L_M, φ_M) represent the longitude and latitude of a given locality and of Mecca, respectively, and $\Delta L = |L - L_M|$, then the modern formula for $q(L, \varphi)$, the direction of Mecca for the locality, measured from the south, is

$$q = \arccos\left(\frac{\sin\phi\cos\Delta L - \cos\phi\tan\phi_M}{\sin\Delta L}\right).$$

Al-Khalīlī computed $q(\varphi, L)$ to two sexagesimal digits for the domains φ = 10°, 11°, …, 56° and ΔL = 1°, 2°, …, 60°; the vast majority of the 2,880 entries are either accurately computed or in error by ±1′ or ±2′. Several other *qibla* tables based on approximate formulas are known from the medieval period. Al-Khalīlī's splendid qibla table does not appear to have been widely used by later Muslim astronomers.

Al-Kharaqī

Boris Rosenfeld

Abū Muḥammad ʿAbd al-Jabbār ibn ʿAbd al-Jabbār al-Kharaqī was a Persian astronomer, mathematician and geographer. He was born at Kharaq near Marw and worked at Marw at the court of Saljuq Sultan Sanjar (1118–1157). Al-Kharaqī wrote in Arabic.

His main work was *Muntahā al-idrāk fī taqāsīm al-aflāk* (The Highest Understanding of the Divisions of Celestial Spheres). The work consists of three books: astronomical, geographical, and chronological. It is written in the tradition of Arabic astronomical textbooks initiated by al-Farghānī, continued by Ibn al-Haytham, and widely spread after al-Kharaqī in the form of Arabic and Persian books on the science of cosmography (*ᶜilm al-hayᶜa*). In these books the planets are considered not as supported by imaginary circles according to Ptolemy's *Almagest*, but as supported by massive material spheres in which they move in tubes.

His *Kitāb al-tabṣira fī ᶜilm al-hayᶜa* (Introduction to the Science of Cosmography), written in the same tradition, is the shortened version of the first work, and contains two separate books, "On the Heavens" and "On the Earth."

Al-Kharaqī was also the author of two lost mathematical treatises, *al-Risala al-shāmila* (Comprehensive Treatise), devoted to arithmetic, and *al-Risala al-maghribiyya* (The North African Treatise), on the "calculus of dirham and dinar."

Al-Khāzinī

Julio Samsó

Abū'l-Fatḥ (or Abū Manṣūr) ᶜAbd al-Raḥmān (also called in some sources ᶜAbd al-Raḥmān Manṣūr) was an astronomer and expert in mechanics and scientific instruments. He lived in Marw (Khurāsān) ca. 1115–ca. 1131. A slave (and later a freedman) of Byzantine origin, he was bought by a treasurer (*khāzin*) of the Seljuk court at Marw, called Abū'l-Ḥusayn (or Abū'l-Ḥasan) ᶜAlī ibn Muḥammad al-Khāzin al-Marwāzī, who gave him a good scientific education.

As an astronomer his main work is his *al-Zīj al-Sanjarī*, an astronomical handbook with tables, compiled between ca. 1118 and ca. 1131 and dedicated to the Seljuk Sultan Sanjar ibn Malikshāh (1118–1157). This *zīj* seems to be influenced by the work of Thābit ibn Qurra, al-Battānī and al-Bīrūnī, but parts of it seem to have been checked against a limited number of his own observations (planetary, solar, and lunar in moments of conjunctions and eclipses) made in Marw. He is credited with a careful determination of the obliquity of the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course), but he adopts the Battanian value of 23°35′ and concludes (against al-Battānī and most of the successive Islamic astronomical tradition) that this parameter is a constant. His *zīj* includes a rich chronological section and a lot of materials related to the theory of Indian cycles. It also contains very important developments on the theory of planetary visibility as well as a very elaborate set of eclipse tables. He seems to have been interested by the problem of *qibla* determination (attempting to figure out the direction to Mecca) and the canons of his *zīj* mention a double entry *qibla* table computed for each integer degree of difference in latitude (from 1° to 30°) and in longitude (from 1° to 60°) between Mecca and other localities. This *qibla* table seems to be lost and the one ascribed to al-Khāzinī by the fourteenth century author al-Mustawfi does not seem to have anything to do with our author. Al-Khāzinī's *Zīj* was used in Byzantium by Georges Chrysoccoces (fl. ca. 1335–1346) and Theodore Meliteniotes (fl. ca. 1360–1388).

Among his minor astronomical works we find his treatise on instruments (*Risāla fī-l-ālāt*) which deals with observational instruments as well as with analog computers and simple helps for the naked eye. Furthermore, his short treatise on "the sphere that rotates by itself with a motion equal to the motion of the celestial sphere" (*Maqāla li'l-Khāzinīfiittiḥād kura tadūru bi-dhātihā bi-ḥaraka musāwiya li-ḥarakat al-falak wa maᶜrifat al-ᶜamal bihā sākina wa mutaḥ arrika*) –probably the earliest of all his extant works – shows the link between his interest both in astronomy and in applied mechanics. It describes a solid sphere, marked with the stars and the standard celestial circles and half sunk in a box, the rotation of which is propelled by a weight falling in a leaking reservoir of sand. Similar devices were known and built in Classical Antiquity.

The most important of al-Khāzinī's works is probably his *Kitāb mīzān al-ḥikma* (Book of the Balance of Wisdom), a treatise on the physical principles that underlie the hydrostatic balance as well as the construction and use of the instrument. This work was written in 1121–1122 and dedicated to Sultan Sanjar: the instrument it describes was meant for Sanjar's treasure, for its main application was to discriminate accurately between pure and adulterated metals as well as between real gems and fakes. A similar balance, also called *mīzān al-ḥikma*, had been built by al-Khāzinī's predecessor al-Asfizārī also for Sanjar, but its scales had been destroyed. Al-Khāzini's book is a long work, divided into eight books and 80 chapters, and its quotations bear witness to the Classical sources on pure and applied mechanics that reached the Islamic lands (Aristotle and the pseudo-Aristotelian treatise on mechanical problems, Euclid, Archimedes, Menelaus) as well as to the development of the discipline in Islamic civilization (Muḥammad ibn Zakariyyāʾ al-Rāzī, al-Bīrūnī, Ibn al-Haytham, Abū Sahl al-Qūhī, ʿUmar al-Khayyām). There is nothing specifically new in al-Khāzinī's physical ideas which derive mainly from Aristotle and Archimedes, but his treatise has the obvious interest of its very careful description of a highly precise instrument with which he has been able to calculate tables of the specific gravities of many substances, both metallic, and nonmetallic, attaining, in some cases, results which are correct to within 1%.

Al-Khujandī

Sevim Tekeli

Abū Maḥmūd Ḥāmid ibn al-Khiḍr al Khujandī (ca. 990) was a mathematician and astronomer who lived and worked under the patronage of the Buwayhid ruler, Fakhr al-Dawla (978–997).

In mathematics he worked on equations of the third degree and tried to show, although in an imperfect manner, that the sum of two cubed numbers cannot be another cube $a^3 + b^3 \neq c^3$. His name is included among others such as Abū'l-Wafā al-Buzjanī (940–997), Abū Nasr Manṣūr ibn ʿAlī ibn Irāq (ca. 1000), and Naṣīr al-Dīn al-Ṭūsī (1201–1274) to whom the discovery of the sine law is attributed. The sine law says that if *ABC* is any triangle, then

$$\frac{c}{b} = \frac{\sin\ C}{\sin\ B}.$$

Although we do not have any reliable information on whether al-Khujandī founded an observatory on Jabal Tabrūk, in the vicinity of Rayy, he tells us that he made observations on planets for Fakhr al-Dawla with armillary spheres and other instruments and prepared a *zīj* (astronomical handbook with tables) entitled *al-Fakhrī* based on these observations. According to E. S. Kennedy an incomplete copy of a *zīj* in the Library of the Iranian Parliament (Tehran Ms. 181) may be attributed to al-Khujandī.

His fame depends on an important instrument constructed for the measurement of the obliquity of the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course). This instrument surpassed all previous ones in size. Al-Khujandī praises his instrument and says that it is of his own invention. It is a 60° of meridian arc and is called *al-suds al-Fakhrī*, after Fakhr al-Dawla. Although *suds* means the sixth part of a circle (i.e., to say sextant), in reality it is constructed in place of a mural quadrant. As the distance between the summer solstice and the winter solstice is about 47°, a 60° of meridian arc is enough for observations of the sun. It has a radius of about 20 m, and each degree was subdivided into 360 equal parts. Therefore each 10 s portion was distinguished on the scale, and with it the limit of precision had been pushed to seconds.

This arc was constructed between two walls erected on the meridian. On the arched ceiling there was a hole through which the sun's rays passed and there were projections on the divisions of the arc. Al-Bīrūnī tells us that the aperture sank by about a span, and caused a slight displacement of the center of the arc.

In 384 H (AD 994), al-Khujandī observed the summer solstice in the presence of a group of scientists. They gave their written testimony concerning the observations. Although the cloudy weather prevented his observing the winter solstice, he calculated the position of the sun from the observations made preceding the solstice. The result was 23°32′19″. According to al-Bīrūnī, displacement of the center of the arc also affected the result. By comparing this result to the Indian astronomers' and Ptolemy's he deduced that the obliquity of the ecliptic was decreasing. He also fixed the latitude of Rayy (35°34′39″).

He describes a kind of astrolabe which is called *shāmila* (universal instrument) in his *Risāla fī Aʿmāl al-ʿāmma* (Treatise on the Construction of the Universal Instrument). The astrolabe, which carried a stereographic projection of the heavens on a circular plate, is a portable instrument. As we know from existing specimens, they ranged in size from 2 in. to 2 ft in diameter. They were used to measure the altitudes of the sun and to show the places of the stars in certain latitudes. Khujandī's *shāmila* could be used over a larger territory than former ones. He also provides methods of projection concerning intersections of circles of the azimuth by the equator and *muqanṭarāt*. Abū Naṣr Manṣūr mentions al-Khujandī's two methods on this topic. Al-Birūnī, in his *Tahdīd Nihāyāt al-Amākin* (Limit of Ends of Places), states that al-Khujandī was unique in his age for his constructions of astrolabes and other astronomical instruments.

Al-Khwārizmī

Jacques Sesiano

Al-Khwārizmī, Muḥammad ibn Mūsā, is the earliest Islamic mathematician and astronomer of fame, and his works had considerable influence in the medieval world. His name suggests that he was of Persian origin, but his treatises were written in Baghdād during the caliphat of al-Maʾmūn (813–833).

The *Algebra* (possibly *al-Kitāb al-mukhtaṣar fī ḥisāb al-jabr wa'l muqābala*), al-Khwārizmī's best known work, consists of four parts of very unequal length. The first part explains the fundamentals of algebra: the resolution of the six basic types of equations of first and second degree (with positive coefficients and at least one positive solution), then basic algebraic reckoning (with expressions involving an unknown or square roots); then, six examples of problems each ending with one of the six equations, and lastly various other problems of the same kind. This structure as well as some characteristic features (no symbolism, numbers written in words, illustrations of algebraic rules by geometrical figures) remained customary in early textbooks on algebra. The second part contains a few considerations on the application of the rule of three to commercial transactions. Part 3 covered surfaces and volumes of elementary plane and solid figures, mostly without any use of algebra. The lengthy part 4 is devoted to the application of algebraic methods (or simple arithmetic) to the sharing out of estates in accordance with wills and Islamic legal requirements regarding the parts due to heirs.

Several Latin translations of parts 1 and 2 were made in the Middle Ages.

The *Arithmetic* (possibly *Kitāb al-ḥisāb al-hindī*) exposes the newly introduced Indian positional system of numerals and its use in arithmetical operations and (square) root extraction, for integers and fractions, both common and sexagesimal. This work is lost in Arabic, but has survived in two Latin translations.

The *Zīj al-sindhind* (Astronomical Tables), al-Khwārizmī's best known work in astronomy, is a set of tables based mainly on Indian material. Instructions on the use of the various tables are provided; with their help, one can determine the mean motion of the seven known celestial bodies, also daily motions, sizes, and eclipses of the sun and moon; calendric and trigonometrical tables are included. We do not know the original text, since only a Latin translation of a later reworking has come down to us.

The *Kitāb ṣūrat al-arḍ* (Geography) is a list of longitudes and latitudes of cities, mountains (geographical points along), sea coasts, islands, center points of regions and countries, and detailed courses of rivers. The information is drawn from Ptolemy's *Geography*, but improvements are found, mostly, of course, for the regions under Islamic rule or traveled through by Arabian merchants.

The *Istikhrāj taʾrikh al-yahūd* (Calendar of the Jews) is the oldest extant description of the modern Jewish calendar. After reporting that God inspired it to Moses (its Mesopotamian origin was unknown to al-Khwārizmī), we are told about the year and the intercalation of 7 intercalary months within the 19 year (Metonic) cycle and how to determine on which day *rosh ha-shana* falls. Next we are given the positions of the celestial bodies at the beginning of three eras (Adam, Temple of Jerusalem, and Alexander). Finally, we are taught how to determine the mean positions of the sun and moon for any given date and the time elapsed since their last conjunction.

The *Kitāb al-ʿamal bi'l-asturlāb* (On the Use of the Astrolabe) contains short instructions, but perhaps not in their original form. We are taught how to find altitudes of celestial bodies, and how to determine time or latitudes from celestial observations.

The purpose of another minor work, *Kitāb al-rukhāma* (On the Sundial), is to explain the construction of a plane sundial; the appended tables are given for various latitudes besides that of Baghdād.

A *Kitāb al-ta^c^rīkh* (Chronicle) is known by quotations from other historians; it reported purely historical events and covered at least the years 632–826.

As to lost works, a short treatise *Kitāb ^c^amal al-asṭur-lāb* (On the Construction of the Astrolabe) is attributed by Arabian bibliographers to al-Khwārizmī (it may be extant as an anonymous work). At the end of his *Algebra*, Abū Kāmil explains a short way for calculating the result of the duplication on the chessboard's cells $(1 + 2 + 2^2 + \ldots + 2^{63} = 2^{64} - 1)$, which he attributes to al-Khwārizmī but which appears in no known work of his. Another lost work was concerned with the rule of false position.

Al-Khwārizmī has enjoyed a great reputation, particularly as the first algebraist. Although he seems not to have made a great number of original contributions, he was a learned man of great versatility and didactical ability. His role was primarily that of a disseminator of science in early Islamic times. As some of his works were studied in eleventh century Spain, he played the same role for the Christian world through Latin translations. The latinization of his misread Arabic name as *algorizmus*, later misread as *algoritmus*, later misinterpreted as *algorithmus*, has kept his name if not his fame alive until the present time.

Al-Kindī

George N. Atiyeh

Al-Kindī, Abū Yūsuf Ya^c^qūb ibn Isḥāq, was born ca. 801 in Kūfah and died ca. 866 in Baghdad.

Often called the Philosopher of the Arabs, little is known with certainty about the life of this early Muslim philosopher and scientist. He flourished in Baghdad, then capital of the Abbasid Empire and center of its intellectual life. Greek, Persian, and Indian works were being translated into Arabic and a multitude of religious and other thinkers were developing new and sophisticated schools of thought and literature. The *Mutakallimūn*, Islamic theologians, were actively engaged in controversies over God's attributes and freedom of the will as well as over the methodology of knowledge. During the life of al-Kindī, Baghdad experienced the political ascendancy and fall of the dialectical theological movement of the *Mu^c^tazilah*, a movement that used a rationalistic approach to defend the religious dogmas of Islam. Al-Kindī sympathized with some ideas of this movement such as the uniqueness of God, his justice, and the use of a rational approach in the defense of Islam against its opponents. Also like *al-Mu^c^tazilah*, al-Kindī looked at God as the ultimate source of all being, yet believed his creations were independent in their daily function.

Most of the works of al-Kindī have, unfortunately, disappeared. Ibn al-Nadīm (d. ca. 987), one of the earliest bibliographers of Islam, lists 242 works, mostly essays and epistles, dealing with a wide range of sciences: logic, metaphysics, mathematics, spherics, music, astronomy, geometry, medicine, astrology, theology, psychology, politics, meteorology, prognostics, and alchemy.

The scientific works of al-Kindī are by far the most numerous. In fact there are among the early Arabic authors many who considered him a mere scientist and not a philosopher. Z. al-Bayhaqī (d. 1169), who is often cited, referred to him as an engineer, and Ibn Khaldūn (d. 1406) did not list him among the philosophers. Whatever the case may be, one can find in al-Kindī's presently known works the outline of a philosophical system. Based on his treatise *Fī al-Falsafeh al-ula* (On First Philosophy), al-Kindī defined philosophy as the "knowledge of the realities of things according to human capacity." He stressed the cumulative character of philosophy and the duty to receive the truth gratefully from whatever source it comes. He distinguished between philosophy and theology proper as two different disciplines, both pursuing and reaching the same goal, which is truth. The first pursues it through arduous research and effort, the second through prophetic knowledge which is granted to certain individuals immediately and without any effort. He established the various divisions of philosophy on the basis of the different channels of human knowledge, the sense experience of material entities and that of rational cognition of immaterial ones. First philosophy or metaphysics is concerned with the First Principle, the True One, the Necessary and Uncaused Being who is eternal and infinite. Probably drawing upon the ideas of the pre-Islamic John Philoponus who championed the concept of creation ex nihilo, he opposed the Aristotelian theory of the eternity of the universe. The chief attribute of God, argued al-Kindī, is unity. God is the only real agent or cause in the world. Unlike the Muslim theologians, he did not ignore the role of secondary agents in the process of nature. He established the premise that the causes of generation and corruption are the heavenly bodies, which are superior to the physical bodies and possess intelligence.

The writing of al-Kindī on the soul and the intellect are neither numerous nor comprehensive. Besides his important short treatise *Risālah fī māʿiyat al-ʿaql* (On the Intellect), he wrote *Kalām fī al-nafs mukhtaṣar wajīz* (A Discourse on the Soul Abridged and Concise) where he explains the nature of the union between the soul and the body as different from the union between the elements. Inspired by Aristotelian, Plantonic, and Pythagorean sources, he considered the soul as the principle of life and only accidentally related to the body, being nobler in nature. In his *On the Intellect*, al-Kindī presents a Platonic interpretation of Aristotle's noetics. He defines the intellect as "a simple essence cognizant of things in their true realities." There are four intellects, the first of which is separate and seems to be construed in the image of Aristotle's active intellect. It exists outside the human soul and is the cause of "all intelligible thoughts and secondary intellects." The four intellects – the active, the potential, the habitual, and the manifest or acquired – played an important role in the history of medieval discussions on the nature of the intellect. In his *Risālah fī dafʿ al-aḥzān* (On the Means to Drive Away Sadness), al-Kindī offers practical advice to overcome sorrow based on the principle that true riches are not material by nature. What causes sadness is the loss of externals and the failure to attain what we highly cherish. By despising external things and educating our souls to seek what is spiritual, we avoid the miseries of sorrow.

With many of his scientific works not available, it is difficult to offer a systematic exposition of al-Kindī's scientific works and contributions. They covered almost all fields of the physical sciences and went beyond the mere transmission of Hellenic scientific data by adding to it through observations of his own and some rudimentary experimentation. Al-Kindī took over the Greek scientific heritage which was available in translations or which he had helped to translate, and tried to assimilate, summarize, and at times develop it and experiment with it. In his classification of the sciences, he starts from the idea of a hierarchy of beings according to which the lower sciences deal with sensible beings and higher sciences with the nobler and intelligible beings. There is a close relationship, however, between science and philosophy, especially mathematics, which he considers preparatory and essential to the study of philosophy. He uses mathematical concepts and arguments when discussing infinity and plurality in proving his theory of the unity of God.

Al-Kindī was not satisfied with the role of the transmitter and commentator. In many of his scientific works we feel the surge of an investigative spirit. In works on optics, pharmacology, and music, for example, he provided new data and approaches, thus enhancing our knowledge of these subjects, among many others. At times, he sought to verify some statements through experimentation, as when he shot an arrow in the air to verify Aristotle's statement that substances expand when heated. In his work *Risālah fī ikhtilāf al-manaṣir* (*De Aspectus*), which is based on Euclid and Heron of Alexandria's optics, he rejected the Euclidean theory of the emission of light, and using geometrical arguments, he offered amendments so it conformed with observable data. Furthermore, al-Kindī gave an original interpretation independent from that of Aristotle of the azure blue we see in the sky. He argued that the color we actually see is the reflection of light from vapors and particles of dense bodies carried up into the atmosphere.

Likewise, al-Kindī, in his medical and pharmaceutical works, was a contributor of new ideas trying to improve upon the knowledge of antiquity. In his work on pharmacology *Risālah fī maʿrifat qūwah al-adwīyah al-murakkabah* (translated into Latin as *De medicinarum compositorum grabidus investigandis libellus*), he applied the principles of posology [the study of dosages]. He based the efficacy (*qūwah*) of compound medicine upon geometrical progression. He linked the degree of intensity with the numerical changes in the qualitative forces that produce them. The efficacy corresponds to the proportion of the sensible qualities: warm, cold, dry, and humid. If a compound medicine was to be warm in the first degree, it had to possess double the equable mixture. If it was to be warm in the second degree, it had to possess four times as much, etc.

The same tendency to improve on the ancient sciences is seen in his works on music. For example, he used the letters of the alphabet to designate the notes of the scale. Al-Kindī's musical works in Arabic on the theory of music paved the way for the *Kitāb al-musiqi al-kabir* (Great Book on Music) by al-Fārabī.

Al-Kindī's influence in medieval Europe might not be as great as the other Arabic philosophers such as Ibn Sīnā and Ibn Rushd; he was nevertheless a courageous intellectual and scientist. Whether he was the first philosopher in Islam is still not ascertainable in the absence of many of his philosophical works. There is no doubt, however, that he was the first in Islam to bridge the gap between philosophy and the Islamic dogma, thus establishing the conceptual framework that became characteristic of philosophy in Islam.

Almagest: Its Reception and Transmission in the Islamic World

Paul Kunitzsch

Around AD 150, Ptolemy wrote his great handbook of astronomy called *Mathematike Syntaxis* (The Mathematical Composition) in the original Greek. Because of its importance, it soon received wide attention throughout the Hellenistic world. Its fame seems to have radiated into the Middle East, because there are hints that the work was known, and perhaps even translated partially or completely, into Middle-Persian (Pahlavi) under the Sassanian ruler Shāhpur I (reigned AD 241–272). A second period of intensive contact of the Persians with Greek science was in the middle of the sixth century, after the closing of the Academy in Athens (AD 529), when several Greek scholars sought refuge in Persia. At this point Ptolemy's work may again have been brought to the attention of Persian scholars. However this was, the first knowledge of the Arabs (who conquered the Middle East and established the Islamic empire of the caliphs around the middle of the seventh century) about Ptolemy and his work betrays Persian influence. The Arabs first knew Ptolemy's astronomical handbook under the title *Kitāb al-majasṭī* (The Book Almagest), which evidently derives from a Greek superlative (*Megiste* [scil. *Syntaxis*], The Greatest Composition). Under this title the book was already known in Arabic–Islamic circles before the translations proper. It would seem that the Arabic spelling *al-majasṭī* is derived from a Middle-Persian form rather than from the Greek directly – a Middle-Persian spelling *mgstyk* is documented, and a form like this may have led to the Arabic spelling *al-majasṭī.* Later, in twelfth-century Spain, the Europeans translated Arabic scientific works into Latin and converted the Arabic *al-majasṭī* into Latin *almagesti*, and henceforth Ptolemy's work has been known in the West under this short title, Latinized from an Arabicized Greek word. It may be added that in the direct transmission, in Greek, the title *Megiste Syntaxis* has not yet been found – here we have only the forms *Mathematike Syntaxis* or *Megale Syntaxis* (The Great Composition).

Direct knowledge of the text of the *Almagest* in Arabic–Islamic science developed through a series of translations from Greek into Arabic. Before the Arabic translations, a translation was made into Syriac, the language common among Christian monks and scholars who later played the main role in the translation of Greek scientific works into Arabic. It is not known when and by whom this Syriac translation was made, but it is probable that the first translators of the work into Arabic knew and used the Syriac version. Still, in the twelfth century Ibn al-Ṣalāḥ had the Syriac version to hand. A first Arabic translation of the Almagest was made some time around AD 800 – its text is now lost, but it was often cited by Arabic–Islamic astronomers and bibliographers as "the first" or "the old" or "the ma'mūnian" translation, after the caliph al-Maʾmūn, who patronized translations and scientific work in general. Traces of it are found in the astronomical work of al-Battānī (d. 929) and in Ibn al-Ṣalāḥ. A second translation was made in 827–828 by al-Ḥajjāj ibn Yūsuf ibn Maṭar in cooperation with a Christian, Sergius the son of Elias. Of it two manuscripts have survived until our times, one complete and the other fragmentary. About 50–60 years later, a third translation was made by Isḥāq ibn Ḥunayn (830–910). It was soon afterward revised by Thābit ibn Qurra (836–901) – of this revised version, nine manuscripts are still extant today.

The two versions of al-Ḥajjāj and of Isḥāq revised by Thābit were received in Muslim Spain – they were both used by Gerard of Cremona for his translation of the Almagest into Latin (Toledo, ca. 1150–1180). Gerard's Arabo–Latin version then remained the standard version of the Almagest in Europe until Renaissance times.

In the following centuries Arabic–Islamic astronomers not only studied the *Almagest* as their main source in astronomy, but they also wrote commentaries on the entire book or on problems of detail. Fuat Sezgin lists more than thirty commentaries, several of which were afterward commented upon themselves. Among the numerous commentators two shall be named here. Ibn al-Ṣalāḥ (d. 1154) is important, because he had to hand five versions of the *Almagest* (the Syriac version, the "old" version, the version of al-Ḥajjāj, the original of Isḥāq's version, and Isḥāq's version as revised by Thābit) from all of which he tried – by comparing the texts and by observing the stars – to establish the best values in longitude and latitude for a selected number of stars from the star catalog in the Almagest. Another famous commentator was Naṣīr al-Dīn al-Ṭūsī (1201–1274) who wrote revisions of many translated Greek mathematical and astronomical texts, which included the Almagest – his *Taḥrīr* (based on the version of Isḥāq as revised by Thābit) survives in numerous manuscripts, but is still unedited.

The last Oriental translation of the *Almagest*, from al-Ṭūsī's *Taḥrīr* into Sanskrit, was made in 1732, in Jaipur, India, by order of Maharaja Jai Singh II.

The title *al-majasṭī/Almagest* became so famous that other authors freely used the name for their own works, both in the East and in Europe, e.g., the *Kitāb al-majasṭī* (The Book Almagest) of the mathematician Abu'l-Wafā˒ al-Būzjānī (940–987 or 998); the *Almagestum novum* of the astronomer Giovanni Riccioli (Bologna, 1651), or even the *Almagestum Botanicum* of Leonard Plukenet (1696).

Al-Māhānī

Yvonne Dold-Samplonius

Al-Māhānī, Abū ˓Abd Allāh Muḥammad ibn ˓Īsā, was born in Māhān, Kerman, Iran. He lived in Baghdad, ca. 860 and died ca. 880.

Little is known about al-Māhānī's life, and few of his works are extant. In the *Ḥākimite Tables* Ibn Yūnus cites observations of conjunctions and lunar and solar eclipses made by al-Māhānī between 853 and 866. In the only extant astronomical work, *Maqāla fī Ma'rifat as-samt li-aiy sā'a aradta wa-f ī aiy mauḍi' aradta* (On the Determination of the Azimuth for an Arbitrary Time and an Arbitrary Place), al-Māhānī added arithmetical solutions to two of the graphic ones. His method corresponds to the cosine formula in spherical trigonometry, and is later applied by al-Battānī.

Al-Māhānī worked on the fundamental problems of mathematics of his time and is especially known for his commentaries to Euclid's *Elements*, to Archimedes' *De Sphaera et Cylindro* (On Spheres and Cylinders), and to the *Sphaerica* by Menelaus. In the last treatise, now lost, he inserted explanatory remarks, modernized the language, especially the technical terms, and remodeled or replaced obscure proofs. It was revised and finished by Aḥmad ibn Abī Sa˓īd al-Harawī in the tenth century. Al-Ṭūsī considered al-Māhānī's and al-Harawī's improvements valueless and used the edition by Abū Naṣr Manṣūr ibn ˓Irāq. This redaction, the most widely known Arabic edition, is included in the collection of the *Intermediate Books*. These were the books read between Euclid's *Elements* and Ptolemy's *Almagest*.

Of the commentaries to the *Elements* only those to Book V and to Book X are extant. In the former al-Māhānī compared magnitudes by comparing their expansion in continued fractions, referring to Thābit ibn Qurra. Ratio is defined as “the mutual behavior of two magnitudes when compared with one another by means of the Euclidian process of finding the greatest common measure.” Two pairs of magnitudes were for him proportional when “the two series of quotients appearing in that process are identical.” Essentially the same theory was worked out later by al-Nayrīzī. Neither established a connection with Euclid’s definition, which was first done by Ibn al-Haytham. In the commentary to Book X al-Māhānī examined and classified not only quadratic irrationalities, but also those of the third order. In contrast with Euclid, for whom magnitudes were only lines, he considered integers and fractions alike as rational magnitudes, while regarding square and cube roots as irrational ones. Al-Māhānī then explicated the contents of Book X using rational and irrational numbers instead of geometric magnitudes.

According to al-Khayyāmī, al-Māhānī was the first to attempt an algebraic solution of the Archimedean problem of dividing a sphere by a plane into segments, the volumes of which are in a given ratio (*De Sphaera et Cylindro* II,4). He expressed this problem in a cubic equation of the form $x^3 + a = cx^2$, but he could not proceed further. Al-Khayyāmī relates that the problem was thought unsolvable until al-Khāzin succeeded by using conic sections.

Al-Majrīṭī

Emilia Calvo

Al-Majrīṭī Abū-l āsim Maslama ibn Aḥmad al-Faraḍī was born in Madrid, Spain in the second half of the tenth century and died in Cordoba ca. AD 1007. He settled early in Cordoba where he studied with Abū Ayyūb ibn ʿAbd al-Gāfir ibn Muḥammad and Abū Bakr ibn Abī ʿĪsà. He was engaged in making astronomical observations in about AD 979; he may have served as court astrologer.

He had a number of disciples who made his work known throughout the provinces of Spain. Among them were al-Kirmānī (d. AD 1066); Abū-l-Qāsim Aṣbagh, known as Ibn al-Samḥ (d. AD 1035) who is the author of a treatise on the construction and use of the astrolabe in 130 chapters and of the *Book of the Plates of the Seven Planets*, of which the original Arabic version is lost. [However, it was translated into Spanish and included in the *Libros del Saber de Astronomía*;] Abū-1-Qāsim Aḥmad known as Ibn al-Ṣaffār (d. AD 1034), who is the author of a treatise on the astrolabe attributed in its Latin version to al-Majrīṭī; Ibn al-Khayyāṭ; al-Zahrāwī; and Abū Muslim ibn Khaldūn of Seville.

Maslama’s most important work is the adaptation of al-Khwārizmī’s astronomical tables (*zīj*) which were elaborated ca. 830. This adaptation is not preserved in his original Arabic form but in a Latin translation made by Adelard of Bath (fl. 1116–1142) and revised by Robert of Chester. The work done by Maslama in this adaptation illustrated his high degree of astronomical and mathematical knowledge.

Another work is an Arabic commentary on Ptolemy’s *Planispherium*, entitled *Tasṭīḥ basīṭ al-kura* (Projecting the Sphere onto a Plane), which deals with the stereographic projection on which the conventional astrolabe is based. This adaptation is only preserved in a Latin version by Hermann of Dalmatia (1143) and in a Hebrew abridgement. This work was the point of departure of a long series of Andalusian treatises on this topic. Maslama also knew the *Almagest* as well as al-Battānī’s tables.

Maslama also wrote a treatise on *muʿāmalāt* (commercial arithmetic) which probably dealt with sales, cadastre (an official record of property ownership and value), and taxes using arithmetical, geometrical, and algebraic operations.

Some other works are attributed to him, such as *Rutbat al-ḥakīm* (The Rank of the Sage), composed after AD 1009, and *Ghāyat al-ḥakīm* (The Aim of the Sage), translated into Spanish in AD 1256 by order of Alfonso el Sabio and distributed throughout Europe under the name of *Picatrix*.

Al-Maʾmūn

Paul Kunitzsch

Al-Maʾmūn, Abul'-ʿAbbās ʿAbdallāh ibn Hārūn, was born in 786 in Baghdad, and died in 833 near Tarsus, in a campaign against the Byzantines.

Al-Maʾmūn was not himself a scientist. He was the seventh caliph of the dynasty of the Abbassids, son and second successor of the famous caliph Hārūn al-Rashīd (well known from the tales of the Arabian Nights). He ruled the Islamic empire from 813 to 833, at first from Marw (in the Eastern province of Khurāsān, where he was based before his accession), and from 819 from the capital of Baghdad (founded in 762 by the caliph al-Manṣūr). In the intellectual history of the Islamic world and in the history of science, al-Maʾmūn played an important role as an instigator and patron of many important activities. He was a firm adherent of the Muʿtazila, a rational school of Islamic theology which was strongly influenced by Greek philosophy; in 827 he declared Muʿtazilism the official doctrine for the whole empire. His interest in philosophy and the sciences manifested itself in many ways. He initiated and patronized the translation of scientific works, mostly from Greek, but also from Persian and Syriac, into Arabic. One translation (of several successive versions) of Ptolemy's *Almagest*, and two translations (also of several successive versions) of Euclid's *Elements* were distinctly called, after him, "the Maʾmūnian version(s)." In the *Elements*, the theorem I, 15 was given, after him, the nickname *al-maʾmūnī*, "the Maʾmūnian [theorem]." Later, in the medieval Latin translation, this degenerated into *elnefea*, *id est fuga* and, more contracted, *eleufuga* or *elefuga*. In 832 he founded the Bayt al-Ḥikma (House of Wisdom, in continuation of a similar institution established earlier by his father Hārūn), which was established for collecting scientific texts, translation, and teaching. Further, on his order, astronomers carried out new measurements of many of the astronomical parameters transmitted in Greek texts, such as precession of the equinoxes, inclination of the ecliptic, length of the year, length of a degree of geographical latitude, geographical coordinates, etc. For many of these data, they arrived at remarkably better values. The results of the observations made by al-Maʾmūn's astronomers were laid down in a work called *al-Zīj al-mumtaḥan* (The Revised Tables, dated 829–830; in medieval Latin, *Tabulae probatae*); it is only preserved in a reworked form. These values were afterwards widely quoted and used by other Islamic and also medieval Western astronomers. From quotations in the *Elementa astronomica* of al-Farghānī (ninth century), al-Maʾmūn's name entered the West in the forms Almeon (Johannes Hispalensis's Latin translation of al-Farghānī's *Elementa*) and Maimon (Gerard of Cremona's translation of the same). On Riccioli's map of the moon (1651) a crater was called Almaeon (i.e., the aforementioned Almeon); as Almanon the name survives on modern charts, in permanent memory of this remarkable Eastern ruler.

Al-Māridīnī, Jamāl al-Dīn, and Badr al-Dīn

David A. King

Jamāl al-Dīn al-Māridīnī was a competent astronomer who lived in Damascus or Cairo ca. 1400. He authored numerous short treatises, mainly dealing with instruments. One of the most remarkable of these instruments is a universal quadrant, the only known example of which is from Spain ca. 1580, made by a craftsman in the Louvain tradition (now in the Adler Planetarium, Chicago). His name indicates that he or his family came from Mardin, now in southern Turkey, but biographical information is lacking; indeed it is not even clear where he worked. He is often confused with his grandson, Sibṭ al-Māridīnī.

Badr al-Dīn al-Māridīnī, known as Sibṭ al-Māridīnī, lived in Cairo, ca. 1460. He was a grandson (Arabic *sibṭ*) of Jamāl al-Māridīnī and was one of the leading astronomers in Cairo. He compiled a large number of treatises, including many short works on the standard instruments of his time, the trigonometric and astrolabic quadrant and sundials. These treatises became extremely popular and exist in hundreds of copies. In fact they were studied by everyone in Egypt who was interested in astronomy in the succeeding centuries. As a result of this, more significant works were forgotten and the level of astronomy declined.

Al-Masʿūdī (Abuʾ ʻl Ḥasan ʿAlī Ibn al-Ḥusayn al-Masʿūdī)

Mushtaqur Rahman

In the tenth century AD Muslims were arguably the leaders of world sciences, including geography. Many Muslim geographers, including al-Masʿūdī, established the principles of science and research in geography. Al-Masʿūdī's geographic curiosity took him as far as China and Madagascar. His conceptual orientation, which combined geography and history to explain cultural history, made him an outstanding scholar.

Not much is known about al-Masʿūdī's early life and education, except that he was born in Baghdad in AD 893 and died in Old Cairo, Egypt, in AD 956. His two surviving books, *Murūj al-dhahab wa-Maʿādin al-Jawhar* (Meadows of Gold) and *Kitāb al-tanbīh waʾl Ishraf* (Book of Indication and Revision) provide no biographical information. Presumably, his early education was with historians, philosophers, scientists, *ḥadīth* specialists (those who study the words of the Prophet Muḥammad), grammarians, and literary critics. He began his travels at the age of 23 to seek geographic knowledge and ended them when he was 56 years old. He lived and traveled during a period of Islamic Renaissance in many fields including geography.

In his book, al-Masʿūdī described the shape of the earth, seas and their depths, islands, mountains and rivers, mines, marshes, and lakes. He also provided information on inhabited areas and explained why land and sea changed their forms.

As a historian and geographer, al-Masʿūdī broadened the concept of geography by including all the known branches of geography in his discussions. In doing so he benefited equally from the scholarly works of both Muslims and non-Muslims. He quoted quite extensively from Greek, Persian, and Indian sources. Al-Masʿūdī also studied people within their own habitats. To him, "nature" (*ṭabīʿā*) meant the processes of the external physical world. He related those processes to humans in the universe, the activity of God in history, and the growth and development of societies.

An aspect of the development of Arabic geographic literature of his period was the production of maritime literature and travel accounts. Al-Masʿūdī also made important contributions to the field of oceanography, but his reputation as a scholar and scientist is based on his two surviving books on history and natural history.

Al-Masʿūdī had a universal outlook. He focused on a wide range of topics dealing with Islamic and non-Islamic cultural histories and provided elaborate cultural, historical, geographical, ethnological, climatic, and maritime descriptions of the known world of his time. He was a cultural geographer of the first order, and far ahead of his time.

Al-Muqaddasī

Mushtaqur Rahman

Born at Al-Bayt al-Muqaddas (Jerusalem) in AD 946, al-Muqaddasī (Shams ad-Dīn Abū ʿAbdallāh Muḥammad ibn Aḥmad ibn Abī Bakr al-Bannāʾ), also called al-Maqdisī, made important contributions in regional geography. In his early days he studied Muslim history, especially its political and cultural aspects, civilization, religion, and jurisprudence. To seek knowledge he visited distinguished scholars, met the men of science, and studied in royal libraries at a fairly young age.

Among other Arab geographers of the time, al-Muqaddasī's definition of a region was probably the most original and produced one of the most valuable treatises in Arabic literature, *Kitāb aḥsan-al taqāsim fī maʿrifat al-aqālim* (The Best Divisions for the Classification of Regions). Though al-Muqaddasī belonged to the Balkhī school, he was critical of it and felt that they disregarded real geography. He argued that scientific geography must be based on observation. He critically examined the information presented by Al-Jayhānī, al-Balkhī, Ibn al-Faqīh, al-Jahiz, and others and questioned their methods of acquiring information, their objectives, and their misrepresentations and selectivity of information. Then al-Muqaddasī stated:

> I have endeavored not to repeat anything other writers have written, nor narrated any particulars they narrated, except where it was necessary, in order neither to deny their right nor myself to be guilty of plagiarism, for in any case those alone will be able to appreciate my book who examine the works of those authors or who have travelled through the country, and are men of education and intelligence.

Al-Muqaddasī claimed that no one who had treated geography before him adopted his method or provided the information he did. In order to achieve his objective, he traveled through the Muslim world, with the exception of Spain and Sindh, conversed with scholars, and waited on princes. He discussed matters with judges, studied under doctors of law, frequented the society of men of letters, and associated with people of all classes until he attained what he wanted.

In his book, *Aḥsan al-taqāsim*, al-Muqaddasī divided the Muslim empire into 14 divisions, and treated the Arab world separately from the non-Arab world. Then he described the districts in each division, identifying their capitals and principal cities and giving their towns and villages in due order. Information which did not fit into either the Arab or non-Arab context was treated separately. While treating the regions in their entirety, Al-Muqaddasī provided a regional framework, and can rightly be called the father of regional geography.

Al-Muʾtaman ibn Hūd

Jan P. Hogendijk

Yūsuf Al-Muʾtaman ibn Hūd was the king of the kingdom of Zaragoza in Northern Spain from 1081 until his death in 1085. He lived in the Aljafería palace in Zaragoza, which was built by his father Aḥmad al-Muqtadir ibn Hūd (r. 1041–1081), and which is now the site of the Parliament of Aragon. Al-Muʾtaman was interested in mathematics, optics, and philosophy. He wrote a very long mathematical work, the *Kitāb al-Istikmāl* (Book of Perfection), of which large parts have recently been identified in four anonymous Arabic manuscripts in Copenhagen, Leiden, Cairo, and Damascus. A revised version of the whole *Istikmāl* was recently discovered.

In the *Book of Perfection*, al-Muʾtaman divides most of pure mathematics according to a philosophical classification in five "species" (*anwāʿ*). Species 1 deals with arithmetic and the theory of numbers. Al-Muʾtaman summarizes the arithmetical books of Euclid's *Elements*, and he proves Thābit ibn Qurra's rule for amicable numbers. The remaining species 2–5 deal with geometry. Al-Muʾtaman summarizes the works of Greek authors such as the *Elements* and *Data* of Euclid (300 BCE), *On the Sphere and Cylinder* of Archimedes (250 BCE), and the *Conics* of Apollonius (200 BCE). He does the same for Arabic authors as well, such as the *Quadrature of the Parabola* (*Miṣāḥat al-qaṭʿ al-mukāfī*) by Ibrāhīm ibn Sinān (909–946) and the *Optics* (*Kitāb al-Manāẓir*), *On Analysis and Synthesis* (*Fīʾl-taḥlīl waʾl-tarkīb*), and *On Given Things* (*Fīʾl-maʿlūmāt*) by Ibn al-Haytham (965–ca. 1041). The summaries in the *Book of Perfection* show that al-Muʾtaman really understood these works. Often he was able to shorten and generalize their contents quite drastically.

Al-Muʾtaman does not mention his sources, and he does not tell us what his own contributions are. The *Book of Perfection* probably includes some original contributions, such as a construction of two mean proportionals between two given lines by means of a circle and a parabola. A few geometrical theorems occur in the *Book of Perfection* for the first time in history, such as the theorem of Ceva (hitherto named after Giovanni Ceva, who independently discovered it in 1678), and the general proof of the invariance of crossratios under a perspectivity (a special case was proved by Pappus of Alexandria in late antiquity). It seems that al-Muʾtaman intended to add to the *Book of Perfection* a second part on astronomy and optics, but he probably did not have the time to do so.

Al-Nayrīzī

Sonja Brentjes

Born in Persia, al-Nayrīzī spent most of his life in Baghdad. He was a court astronomer/astrologer of caliph al-Muʿtaḍid (r. 892–902), to whom he dedicated several treatises, among them *Al-Risāla fī aḥdāth al-jaww* (Treatise on Meteorological Phenomena) or *Al-Risāla fī maʿrifat ālāt yuʿlamu bihā abʿād al-ashyāʾ-al-shākhiṣa fī l-hawāʾ wal-latī ʿalā basīṭ al-arḍ wa-aghwār al-audīya wa'l-abār wa-ʿurūḍ al-anhār* (Treatise on the Knowledge of Instruments through which Distances between Distinct Things in the Air or Set up on the Ground and the Depth of Valleys and Wells, and the Widths of Rivers Can be Known). He wrote commentaries on Ptolemy's (fl. ca. 127–167) *Almagest* and his astrological work *Tetrabiblos* and an astronomical handbook (*Zīj*), a longer and a shorter version. And he commented on Euclid's (fl. ca. 300 BCE) *Elements* and his astronomical work *Phainomena* and wrote independent works on the determination of the *qibla*, the direction of Mecca, the spherical astrolabe, methods for solving particular astronomical problems, and astrological subjects.

The longer version of his *Zīj* is said to have been based upon Indian astronomical tradition (*Sindhind*) and used data from the *Zīj* prepared for al-Maʾmūn (r. 813–833). This was criticized by Ibn Yūnus (d. 1009), who pointed out further differences in opinion, especially with respect to the theory of Mercury, the eclipse of the moon, and the parallax. His commentary on the *Almagest*, lost as are his handbooks and his commentary on the *Tetrabiblos*, was quoted by later authors like al-Bīrūnī or Ibn al-Haytham and even occasionally called the best work of this type.

His extant works on the *qibla* and the spherical astrolabe built on the works of earlier scholars are some of the very best summaries on the subject still available. Others of his extant works on astronomy, astrology, geodesy, and meteorology have not yet been seriously studied.

Al-Nayrīzī's commentary on the *Elements* translated by Gerard of Cremona (d. 1187) into Latin includes extracts of the lost Greek commentaries by Heron (second century?) and Simplikios (sixth century) and of Arabic treatises like Thābit Ibn Qurra's alternative proof of the Pythagorean theorem. He omitted Simplikios' own proof of the parallels postulate in favor of that by Aghānīs/Aghānyūs (Agapios?, fl. ca. 511), which is also preserved in his independently transmitted *Al-Risāla al-muṣādara al-mashhūra* (Treatise on the Proof of the Well-Known Postulate).

In Book V, al-Nayrīzī follows a theory of proportion adopted before him by al-Māhānī (d. ca. 880) and, perhaps, Thābit ibn Qurra, a theory based on definitions of ratio and proportion which compared the expansion of magnitudes in continued fractions.

The text of the *Elements* contained in the Arabic manuscripts of al-Nayrīzī's commentary was viewed for a long time as the second version made by al-Ḥajjāj ibn Yūsuf ibn Maṭar. Although it is derived from a text of the Ḥajjāj tradition, al-Nayrīzī evidently edited it using a text of the Isḥāq/Thābit tradition. He changed its language, didactical features, and even letter symbols used for diagrams. He incorporated references to earlier Euclidean theorems, definitions, postulates, or axioms as well as to propositions stated by the Greek commentators. In a similar manner, he edited those texts he added as comments.

Alphabet

Sema'an I. Salem

As far as we know, literacy goes back to about 3500 BCE. The earliest people to have left written symbols are the Sumerians, followed by the Egyptians. The earliest clay tablets unearthed in Mesopotamia are picture writings which have not yet been deciphered, but those written after 3200 BCE are clearly Sumerian and their content is well known. Their subject matter includes groups of words, accounts of deeds of sale, and some fragments of early literature.

The Sumerians wrote primarily on clay tablets, producing wedge-shaped characters, which became known as cuneiform script, from the Latin *cunus* (wedge). It is quite probable that the idea of writing was introduced into Egypt from Mesopotamia. Soon after the Sumerians invented their script, the Egyptians formulated their own system, which consists of picture word-signs, and which they called *m-d-w-n-t-r* (speech of the gods), and which is now known by its Greek name, hieroglyphs (sacred, carved letters). The Egyptians then produced a simplified version, which is known as Hieratic (sacred). When the common Egyptians, not only the priests, learned to write, they used a highly simplified form known by the Greek name demotic (popular). Several scholars consider the demotic script a first step toward alphabetic writing.

By about 2000 BCE other forms of writing began to appear in various parts of the Middle East. The Hittites, who lived in modern-day Turkey, introduced a new form of hieroglyphs, consisting of some 70 signs, each of which stood for a simple syllable, and about 100 word-signs. Similar forms of hieroglyphs, consisting of word-signs and syllable-signs, were also used in Crete, Cyprus, Lebanon, Palestine, and Syria. The early script uncovered in Crete is in the form of pictograms and was probably introduced into Crete from Egypt. Although it has not been completely deciphered, it is known that it contains the names of certain gods such as Zeus, Athena, and Poseidon.

All the word-sign methods of writing are complex and difficult to learn, and only professional scribes were able to read and write. To write a letter, keep an account, check a legal document, or read a will, an ordinary person had to rely on the services of trained scribes.

This monopoly on reading and writing persisted until the advent of the alphabet, whose invention is one of the most important and useful inventions of all time. The transformation from word or syllable writing to an alphabetic script is immense – it simplified the process of reading and writing to a degree that enabled a common person to master the art, thus freeing him from the need for professional scribes. Its value lies in its elegance and its simplicity, and in its ability to express all the vocal sounds needed in any language in about two-dozen symbols.

There has always been speculation as to the origin of the alphabet, beginning with the early Greek and Latin authors, who credited the invention of the alphabet to practically every near-eastern country. Diodorus Sciculus states, “The Syrians are the discoverers of the letters, and the Phoenicians having learned them from the Syrians and then passed them to the Greeks.” Pliny, on the one hand, claims that: “the invention of the letter is a Phoenician feat,” and speaks also of a Mesopotamian origin. Tacitus maintains that the alphabet is of Egyptian origin, and adds, “The Phoenicians took all the credit for what they received before passing it on to others.” The various views of the classical authors are mere speculations that demonstrate their awareness of the problem and their cognizance of the importance of the discovery.

Opinions as to the origin of the alphabet are still voiced. There are those who still believe that the alphabet is of Mesopotamian origin – they base their opinion on the Ugaritic script which dates back to about 1400 and which consists of 30 symbols representing 30 consonant letters written in cuneiform script.

The existence of an alphabet in a cuneiform script does not imply, in any way, that the idea of an alphabet originated in Mesopotamia, where there is no evidence that it ever existed. Of the half a million or so cuneiform tablets and fragments of tablets uncovered in Mesopotamia, there is not one that bears a sign of an alphabet.

By about 2000 BCE the Mesopotamian cuneiform system of writing was used throughout the Near East and particularly in Canaan, where the rulers were using it in their correspondence even with the pharaohs of Egypt. When the Ugaritic scribes were writing their alphabet using the wedge-shaped cuneiform signs, the Mesopotamians were still content with their word-symbols.

There are also contemporary scholars who believe that the alphabet is of Egyptian origin; they base their views on the yet undeciphered Sinaitic inscriptions uncovered in 1906 in the Sinai Desert by Sir William Flinders Petrie and which date back to about 1500 BCE. The discovery was hailed by many as the missing link between the alphabet and the Egyptian demotic writing, and led to the belief that the Canaanites learned their method of writing from their contacts with the Egyptians. A recent discovery in the land of Canaan showed that the so-called Proto-Sinaitic inscriptions were used by Semitic people as early as 1700 BCE, and they are purely a Semitic script. The Canaanites, who were working the Egyptian turquoise mines in south-western Sinai, left symbols scribbled on rocks and stones, and some scholars believe that the Canaanite workers learned their signs from their Egyptian lords. The Sinaitic pseudo-hieroglyphic and proto-Canaanitic scripts may at best be considered a first attempt at the complex process that led to the alphabetic script.

The champions of an Egyptian origin support their claims by the presence of simple symbols in the Egyptian hieroglyphs that goes back to about 2000 BCE. Egyptian scribes, like many others, were introducing symbols, which stood for simple sounds or syllables and to a certain degree resemble the symbols of the alphabet. This pseudo-hieroglyph has so many signs that it is considered more syllabic than alphabetic, and instead of simplifying the Egyptian way of writing, it added to its complexity. The Egyptians priests could not relinquish their complex picture word-signs, and kept using them until about AD 500.

The uncovering of Minoan hieroglyphs and other Minoan pictograms in the beginning of this century suggested to the archeologist Sir Arthur Evans that the Phoenician alphabet was itself derived from Crete. On the basis of Evans’ statement, and in spite of the fact that the excavations on the island revealed no alphabetic signs, Glasgow wrote, “We now know, for instance, that the art of writing came from Crete, Phoenicia being the medium.”

Many of the supporters of non-Phoenician origins point out that some of the sounds assigned to the signs that make up the alphabet do not correspond to the Canaanite names represented by the signs. As a matter of fact a few of the signs, only two, do not correspond to any known objects, but as we shall see, all the rest do. The variations may be attributed to the whim of a scribe or scribes, who forsook fidelity in favor of beauty or simplicity. The alphabet evolved for several centuries before reaching its known Phoenician form.

The most probable origin of the invention of the alphabet is the land of Canaan. It seems that a scribe in Canaan conceived of the idea that a language might be written without the numerous signs used in Babylonian cuneiform or Egyptian hieroglyphs. It took a great deal of effort and insight to realize that complex words may be broken down into simple sounds, and that it does not take many of these simple sounds to write an entire language. This is tantamount to saying that the large number of words that forms a language are made up of various combinations of a relatively small number of simple sounds.

Each one of the simple sounds was represented by the picture of a familiar object, whose Canaanite name corresponds to the sound. Thus *beit* (house) stood for the *b* sound and *daleth* (door) stood for the *d* sound – the pictures stood for the simple sounds only and not for the word-sign. In a similar fashion all the consonants that form the language were represented. For reasons yet unknown, the vowels were not considered important enough to play a role in this scheme. This is why it is rather difficult to read modern-day Arabic and Hebrew scripts, where only the consonants are written.

In addition to the script uncovered in the Sinai desert, there are those unearthed in Byblos (Jbayl) and ascribed to the middle of the second millennium BCE. Other proto-Canaanite inscriptions were found in various parts of the Near East, such as Beit Shamesh, Gezer, Lakish, etc. The Gezer calendar is relatively recent – it dates to ca. 950 BCE. The alphabetic signs found in various localities are different – they do not resemble one another. This leads to the speculation that once the often-competing Canaanite clans knew of the magnificent invention, each group began to formulate its own symbols. Thus began the early stages of the alphabet of which several examples have been recovered, but many aspects of its early development are lost.

Except for the Ugaritic alphabet, which was written on clay tablets, the few early alphabetic signs found in the land of Canaan were scratched on stones or rocks. Toward the middle of the second millennium BCE Canaan was under the influence of Egypt, and the Canaanite scribes were writing on Egyptian papyrus. Unfortunately, in the relatively damp soil of Canaan, papyrus did not prove to be a durable material, and the early development of the alphabet written on it is lost; the real origins may never be known.

The earliest known pure "alphabetic" signs are the proto-Canaanitic scripts, and they may be considered as first attempts in a long process that led to what we call the Phoenician alphabet. However, on the whole, they do not suggest true alphabetic designations as a large number of the Sinaitic signs are syllabic rather than alphabetic. Although there are a few similarities between the Sinaitic and the Phoenician signs, many are very different, indicating that radical changes had taken place.

The Ugaritic alphabet may be considered a new way of writing the Canaanite script. The Ugaritic literature, written on clay tablets, is the earliest, most comprehensive alphabetic script that has survived. Furthermore, the order of the letters of the alphabet, at least the first few signs, support this possibility – the head of the Canaanite pantheon is El, whose epithet is *thor* (bull). It is most appropriate to put the head of the pantheon at the head of the alphabet, hence the first letter, *aleph*, meaning bull or ox. In the Canaanite mythology, the great gods dwell in large houses, and one often reads about the house of god, and the adobe of El is frequently mentioned. Thus the second letter of the alphabet, b, is represented by *beit* (house); and what is a house without a *daleth* (door), thus d is the fourth letter of the alphabet, followed by *hah* (window). There are several other such conjugate pairs in the Phoenician alphabet: *yad* and *kaff* (hand and palm), *mem* and *nahir* (water and river), and *rosh* and *shin* (head and tooth) (Fig. 1).

The earliest proto-Canaanitic symbols found in Phoenicia belong to the fourteenth century, and the first inscriptions of the Phoenician alphabet, which were left on arrowheads in Jbayl, belong to the twelfth century BCE. It is quite probable that the roots of the Phoenician alphabet go back to the Sinaitic proto-Canaanitic scripts. This hypothesis is strengthened by the few similarities between the Sinaitic and the early Phoenician signs and by the fact that they are listed in somewhat corresponding orders. Thus one may deduce that the formulation of the alphabet was a lengthy process culminated by the Phoenicians easy-to-reproduce form, which replaced the Sinaitic almost syllabic and the Ugaritic cumbersome cuneiform, with simple signs. There are indications that the scribes of Ugaritic, in their later writings, wrote from right to left and dropped a few of their consonants symbols. The Phoenicians continued the process of converging sounds to accommodate sound variations in their standard language, reducing the total number from 30 characters to 22.

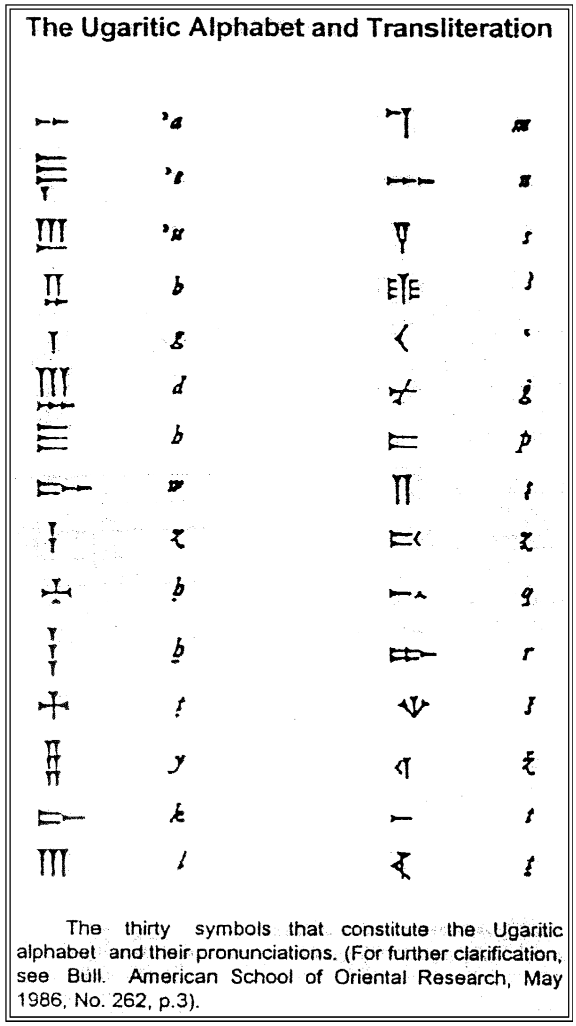
Most recent authors attribute the origin of the alphabet to Phoenicia and more precisely to Jbayl. This is a definite possibility; the invention of the forms of the letters may have taken place in Jbayl. To compare the three scripts, let us reproduce the word "MLK" meaning king and written without vowels:

- Ugaritic ,
- Proto-Canaanitic ,
- Phoenician .

Note the similarity between the Phoenician and the Latin letters. The simplicity of the Phoenician signs rendered them more accessible than all others, and by the end of the second millennium, the Phoenician alphabet became firmly established in the entire land of Canaan.

If doubt persists as to the origin of the invention of the alphabet, it is absolutely clear that the Phoenicians taught the letters to the Greeks and then to the rest of the known world. Some authors recognize the importance of this step and do not speak so much about the invention as about the diffusion of the alphabet. Herodotus is one such author and in one often quoted passage, he wrote, "These Phoenicians who came with Cadmus… among other kinds of learning, brought into Hellas the alphabet, which had hitherto been unknown, as I think, to the Greeks."

The vowels, sometimes erroneously referred to as a Greek contribution, were arrived at either by sheer misunderstanding or because some of the Phoenician consonants were not needed in the Greek language, and the Greeks themselves were having difficulty pronouncing them. Thus the Phoenician aspirate "hah" became a short "e" or *epsilon* in Greek, the aspirate



Alphabet. Fig. 1 The Ugaritic alphabet.

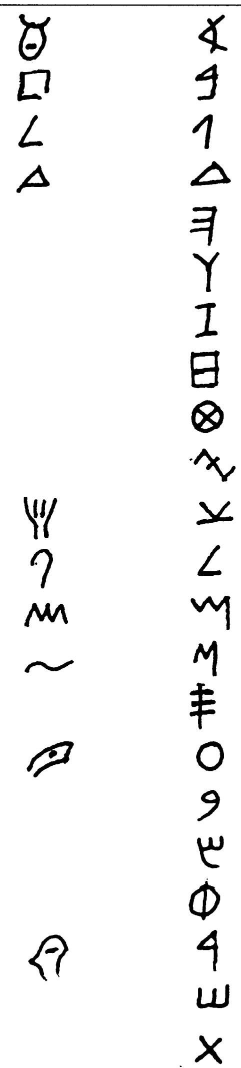
"heth" became a long "e" or *eta*, the semiconsonantal "yad" or "yod" became an "i" or *iota*, and the throaty "ayn" became an "o" or *omicron* (Fig. 2).

The similarities between the old Phoenician and Greek alphabets are apparent; the order to the letters are basically the same and the names assigned to most symbols, which have no significance in Greek, are taken from Phoenician words. In the fifth century BCE the Greek scribes altered the shape of their letters by changing them into their mirror images. In general, minor changes took place whenever the alphabet was adapted to a new language.

The early Greeks expressed their gratitude to their benefactors by referring to their letters as *phoinikeia* (Phoenician objects). An inscription unearthed in Crete contains the verb *poiniazen* (to write) and the title *poinikastas* (scribe).

This alphabet soon spread into the Mediterranean region, or wherever Phoenician and later Greek trading posts were established. This helped in keeping records of commercial transactions and simplified the work of the Phoenicians, the sea traders of the ancient world. While the Phoenicians carried their alphabet with their goods and deposited both all over the Mediterranean world, Western Europe, and Northwest Africa, their cousins, the Arameans, moved with it eastward, where it displaced most of the cuneiform script down the Euphrates and into Persia, then penetrated the western frontiers of India, furnishing the Indians with their Sanskrit alphabet.

The diffusion of the Phoenician alphabet, first into the Greek, then into the Roman cultures, provided the proper tool that fueled one of the greatest cultural explosions the world has ever known.



Caananitic (ca. 1500 BC)	Phoenician (ca. 1200 BC)	Picture represents	Meaning	Greek character	Greek name
		aleph	ox	α	alpha
		beit	house	β	beta
		gamma‘	sickle	γ	gamma
		daleth	door	δ	delta
		hah	window	ϵ	epsilon
		waw	hook	ζ	zeta
		Zayn	–	η	eta
		ḥeth	–	θ	theta
		ṭeh	–	ι	iota
		yad	hand	κ	kappa
		kaff	palm	λ	lambda
		lamed	staff	μ	mu
		myi *or* mem	water	ν	nu
		nahir	river	ξ	xi
		samkeh	fish	o	omicron
		‘ayn	eye	π	pi
		feh or peh	–	ρ	rho
		ṣad	–	σ	sigma
		quof	–	τ	tau
		rosh	head	υ	upsilon
		shin	tooth	ϕ	phi
		tā	cross	χ	chi
				ψ	psi
				ω	omega

Al-Qalaṣādī

Ahmed Djebbar

In the Islamic world of the fifteenth century there was a general halt in research and a lowering of the level of instruction. In mathematics this tendency resulted in a repetitive scientific production made up of poems or commentaries directed at an increasingly narrow public: teachers, *muwaqqits* (astronomers) charged with determining the hours of daily prayers, judicial functionaries, government bookkeepers, etc.

It is in light of this tendency that we can appreciate both the intellectual journey and the scientific contribution of al-Qalaṣādī, one of the last scholars of Andalusian origin who dedicated a large part of his life to disseminating – to the central Maghreb, to Ifriqiya, and to Egypt – what he knew of the Arab mathematical tradition of the preceding centuries.

ʿAlī ibn Muḥammad al-Qalaṣādī was born around 1412 in the Andalusian village of Basta. This small village, which is in the northeastern part of Grenada, was already prosperous in the time of the geographer al-Idrīsī (d. 1153) and continued to be so for two centuries.

We know nothing of al-Qalaṣadī's childhood except that he grew up in his birthplace where he learned the *Quʾrān* from his teacher Ibn ʿAzīz and where he received his first lessons in Arabic and probably also in mathematics. In the course of his adolescence he continued these studies and was taught grammar and mathematics from the arithmetic texts of Ibn al-Bannāʾ (d. 1321), as well as law, the science of inheritance, and calculation.

In 1436, at the age of 24, al-Qalaṣadī left his native village and began his first educational voyage, heading to Tlemcen, the first stop of a long journey to scientific centers in the Maghreb, al-Andalus, and Egypt. The educational voyage (*riḥla* in Arabic) was a medieval tradition, one of whose goals was to allow students to complete their education in various places, taking classes from famous professors.

Al-Qalaṣādī's stay in Tlemcan lasted eight years. His most serious study of mathematics was with az-Zaydūrī (d. 1441). He himself says that az-Zaydūrī taught him the contents of two important texts of Ibn al-Bannāʾ: the *Kitāb al-Uṣūl wa l-muqaddimāt fi l-jabr wa' l-muqābala* (Book on the Foundations and Preliminaries in Algebra and Restauration) and the *Rafʿ al-ḥijāb ʿan wujūh aʿmāl al-hiṣab* (Lifting of Veil on the Science of Calculus Operations).

It also appears that the first scientific works of al-Qalaṣādī were written in Tlemcen, between 1436 and 1444. There were three commentaries on writings on the science of inheritance and a mathematics book entitled *al-Tabṣira* (The Book which Makes Things Intelligible).

In 1444, al-Qalaṣādī left Tlemcen for Tunis, which was at that time one of the most dynamic intellectual centers in the Maghreb. In the *madrasas* (colleges) where he studied, al-Qalaṣādī took courses in Malikite law, the Arabic language, grammar, and the rational sciences. At the same time, he devoted time to his own writing. He published three books on calculation: the *Kashf al-jilbāb ʿan ʿilm al-ḥisāb* (Unfolding the Secrets of the Science of Calculation) in 1445, the *Qānūn fi al-ḥisāb* (Canon of Mathematics), and his commentary entitled *Inkishāf al-jilbāb ʿan qānūn al-ḥisāb* (Explaining the Canon of Mathematics). He also published two works on traditional sciences, *al-Kulliyyāt fi al farā'iḍ* (Collection on Successional Division), and a commentary on it. At the end of his stay in Tunis, in 1447, it appears that he wrote his epistle on irrational numbers entitled *Risāla fi dhawāt al-asmāʾ wa 'l-munfaṣilāt* (Epistle on Binomials and Apothems).

On 30 May 1447, al-Qalaṣādī left Tunis and headed to Cairo and then to Mecca, where he wrote a commentary on the *Farā'iḍ* (Book on Successional Division) of Ibn al-Ḥājib on traditional science. Returning from the pilgrimage, he again stayed in Cairo, teaching and taking classes from several professors, notably Shams al-Dīn al-Samarqandī in rational sciences.

In April 1449, al-Qalaṣādī left Cairo and returned to al-Andalus. In 1451 he returned to his native village of Basta, and then went to Grenada, where he stayed for 30 years. There he studied with eminent professors like the astronomer Ibrāhīm Ibn Futūḥ, who specialized in the study of astrolabes.

A deterioration of the political climate of the interior of the kingdom of Grenada and increasingly worrisome menaces from outside forced al-Qalaṣadī to leave the Andalus once and for all in 1483. He settled finally in Béja in Ifriqiya where he died in 1486, just 6 years before the fall of Grenada.

Mathematical Works of al-Qalaṣadī

Like some of his contemporaries in al-Andalus and the Maghreb, al-Qalaṣādī wrote on many different subjects. In almost all disciplines he also, again like many of his contemporaries, published numerous commentaries on classical texts. But he is, to my knowledge, the only scholar of his era to have written so many works on mathematics.

The mathematical development of al Qalaṣādī seems to have been centered basically on the science of calculation, on the processes of arithmetic and algebraic calculation and their application in the solving of abstract exercises and practical problems – e.g., problems of commercial transaction, monetary conversions, or the division of inheritances.

In algebra, he wrote chapters included in the arithmetical works already noted. In these chapters he treats algebraic operations and the resolution of the canonical equations of al-Khwārizmī. To that we must add his commentary on the algebraic poem of Ibn al-Yāsamīn.

In these texts one finds a peculiarity of the Maghrebian mathematical tradition, the utilization of a certain symbolism to express objects or algebraic concepts such as an unknown, different powers, or equality in equations. For a long time the invention of this symbolism was attributed to al-Qalaṣādī. But the results of recent research now permit us to affirm that this same algebraic symbolism was already in existence in this twelfth century, particularly in the work of Ibn al-Yāsamīn entitled *Talqīḥ al-afkār* (Fertilization of Thoughts), and that it was widely in use in the fourteenth century, in particular by Ibn Qunfudh (d. 1407). The work of al-Qalaṣādī bears witness to the persistence of these symbols and of their widespread use throughout the Maghreb.

In arithmetic, his writings deal essentially with the four arithmetic operations (applied to whole numbers, fractions, and irrational quadratics), with the extraction of the exact or approximate square root of a number, with the rule of three, with the method of false positives, and with other arithmetical procedures such as the breakdown of a number into prime factors and the calculation of the sums of series of natural numbers from their squares and cubes. Again, it is important to note that the techniques used by al-Qalaṣādī in these books are related to techniques already used in the works of al-Ḥaṣṣār (twelfth century) and of Ibn al-Bannāʾ.

The fact that these themes are present in the works of al-Qalaṣādī and his method of treating them leads to the conclusion that in the fifteenth century, the mathematical traditions of al-Andalus and of the Maghreb were unified by being based upon each other. Moreover, if one compares the work of al-Qalaṣādī with that of Ibn al-Bannāʾ, one notices a certain continuity both in form and content. Because of this, one can argue that al-Qalaṣādī is more Maghrebian than Andalusian. This stamp of the Maghreb on the education and work of a scholar from al-Andalus of the importance of al-Qalaṣādī offers proof, moreover, of the decline of scientific activity in al-Andalus in the fourteenth and fifteenth centuries.

On the other hand, when one compares his different works in mathematics, one does not see a noticeable evolution from one book to another, but rather different formulations of classic themes and techniques. Al-Qalaṣādī himself claimed that some of his books were only developments or summaries of previously published works. It is important to note that this process, which was not unique to al-Qalaṣādī and which was already in evidence at the end of the fourteenth century both in the Maghreb and in Egypt, only reflects the continuation in the fifteenth century of the slow decline of scientific activity in the Islamic city. In this difficult context the scientific aptitude of al-Qalaṣādī was not really able to flourish fully, and it is greatly to his credit that he contributed to maintaining the level of scientific activity of that of the fourteenth century in the Andalus and the Maghreb.

Al-Qūhī (or Al-Kūhī)

Yvonne Dold-Samplonius

Abū Sahl Wayjan ibn Rustam al-Qūhī (or al-Kūhī) probably originated from the village of Quh in the Iranian province of Tabaristan. He worked in Baghdad under the Buwayhid Caliphs ʿAḍud al-Dawla and his son and successor Sharaf al-Dawla. In 969/970 al-Qūhī assisted at the observations of the solstices in Shiraz. These observations, ordered by ʿAḍud al-Dawla, were directed by Abū'l-Ḥusayn ʿAbd al-Raḥmān ibn ʿUmar al-Ṣūfī. In 988 al-Qūhī supervised astronomical observations in the garden of the palace of Sharaf al-Dawla in Baghdad in the company of several magistrates and respected scientists.

Some of al-Qūhī's contemporaries considered him to be the best geometer of his time; al-Khayyāmī held him in high esteem. In the geometrical writings known to us he mainly solved problems that would have led to equations of higher than the second degree. A note by al-Qūhī is added to Naṣīr al-Dīn al-Ṭūsī's redaction of Archimedes' *Sphere and Cylinder* in the Leiden manuscript, on how to construct a sphere segment equal in volume to a given sphere segment, and equal in surface area to a second sphere segment. This problem is similar to but more difficult than the constructions solved by Archimedes in *Sphere and Cylinder* II,6 and II,7. Al-Qūhī constructed the two unknowns, i.e., the radius of the sphere and the height of the segment, by intersecting an equilateral hyperbola with a parabola and rigorously discussed the conditions under which the problem is solvable.

Conic sections provided the tools for several problems, as in the classical problem of trisecting an angle. In the small treatise *Risāla fī qismat al-zāwiya* (On the Trisection of the Angle) al-Qūhī gave a purely Islamic solution by means of an orthogonal hyperbola. This solution was taken over by al-Sijzī. In *Risāla fī istikhrāj ḍil'al-musabba'al-mutasāwi'l-aḍlā*ʾ (On the Construction of the Regular Heptagon) the precise construction is more complete than the one attributed to Archimedes. Al-Qūhī's solution is based on finding a triangle with an angle ratio of 1:2:4. He constructed the ratio of the sides by intersecting a parabola and a hyperbola, with all parameters equal. Al-Sijzī, who claimed to follow the method of his contemporary Abū Sa'ied al-ʿAlā ibn Sahl, used the same principle. A second, different solution by al-Qūhī also exists. One of the most interesting examples of late tenth-century solutions is al-Qūhī's construction of an equilateral pentagon in a given square in *Risāla fī ʿamal mukhammas mutasāwi l-aḍlāʿ fī murabbaʿ maʿlūm* (On the Construction of an Equilateral Pentagon in a Known Square). This solution is based on Books I–VI of Euclid's *Elements*, Euclid's *Data*, and parts of Books I–III of Apollonius' *Conics*. The construction is remarkable, because it contains a proof of the focus–directrix property of a hyperbola with eccentricity $\varepsilon = 2$. It is reasonable to assume that al-Qūhī independently discovered and proved this property, thus going a step further than Apollonius.

In *Risāla fī istikhrāj misāḥat al-mujassam al-mukāfī* (On Measuring the Parabolic Body) al-Qūhī gave a somewhat simpler and clearer solution than Archimedes had done. He said that he knew only Thābit ibn Qurra's treatise on this subject, and in three propositions showed a shorter and more elegant method. Neither computed the paraboloids originating from the rotation of the parabola around an ordinate. That was first done by Ibn al-Haytham, who was inspired by Thābit's and al-Qūhī's writings. Although he found al-Qūhī's treatment incomplete, Ibn al-Haytham was nevertheless influenced by his thinking. Maybe the two met in Basra, where al-Qūhī wrote his correspondence to Abū Isḥaq al-Ṣābī and four books on centers of gravity. Analyzing the equation $x^3 + a = cx^2$, al-Qūhī concluded that it had a (positive) root if $a \leq 4c^3/27$. This result, already known to Archimedes, was not known to al-Khayyāmī, whose analysis is less accurate.

Al-Qūhī was the first to describe the so-called perfect compass, a compass with one leg of variable length for drawing conic sections. In this clear and rather general work, *Risāla fī'l birkar al-tāmm* (On the Perfect Compass), he first described the method of constructing straight lines, circles, and conic sections with this compass and then treated the theory. He concluded that one could now easily construct astrolabes, sundials, and similar instruments. In his *Kitāb ṣan'at al-aṣṭurlāb* (On the Manufacture of the Astrolabe) al-Qūhī used an original method for drawing azimuth circles, based on an analemma, a procedure for reducing problems in three dimensions to two dimensions. A commentary on this work was written by Abū Sa'd al-ʿAlā ibn Sahl. Al-Qūhī's proofs for this construction were reproduced in an inferior form by Abū Naṣr Manṣūr ibn ʿIrāq, who highly esteemed al-Qūhī, in *Risāla fī dawā' ir as-sumūt fī al-aṣṭurlāb* (Azimuth Circles on the Astrolabe).

The correspondence between al-Qūhī and Abū Isḥaq al-Ṣābī contains discussions of the possibility of curvilinear figures being equal to rectilinear figures, the meaning of "known ratio," and whether one can square a parabolic segment by exhausting it with triangles. The first letter especially gives impressive evidence for al-Qūhī's creativity in two theorems on centers of gravity of circular sectors and arcs. In the same correspondence he deducted a value of 28/9 for the ratio of the circumference of a circle to its diameter (π). This result was attacked by Abū Isḥaq and then, almost 150 years later, by Abū'l-Futūḥ Aḥmad ibn Muḥammad ibn al-Sarī. The latter thought that al-Qūhī got swept away by enthusiasm about his result. Also the 27 propositions in *Hādhā mā wujida min ziyādat Abī Sahl ʿalā al-maqālah al-thāniiyah min kitāb Uqlīdis fī al-uṣūl* (Abū Sahl's Additions to Book II of Euclid's Elements) are rather weak and not very clearly stated. Probably, however, those additions, if they were even written by al-Qūhī, were originally only marginal notes in his copy of Euclid's *Elements*.

Al-Rāzī

Albert Z. Iskandar

Abū Bakr Muḥammad Ibn Zakariyyā al Rāzī (Rhazes), the most original physician philosopher of his time, was born in al-Rayy (hence the name, al-Rāzī), now ruins near modern Teheran. Medieval historians wrote more on his copious bibliography than on his life.

Al-Bīrūnī (d. AD 1048 or 1050) writes in his *Risāla fī Fihrist Kutub Muḥammad Ibn Zakariyyā al-Rāzī* (Missive on the Index of Books of Muḥammad Ibn Zakariyyā al-Rāzī) that he was asked by a learned man to compile a bibliography of al-Rāzī. To accomplish this task, he examined many manuscripts, and recorded only those works in which he found al-Rāzī's name mentioned as author in the text. Al-Bīrūnī's method of research undoubtedly resulted in his failure to record some of al-Rāzī's genuine works.

Al-Rāzī advised doctors to practice in densely populated cities, where they could benefit from the experience of many skillful physicians and have the chance to examine many patients. He himself moved from al-Rayy to Baghdad where, in his youth, he studied and practiced the art of healing at its hospital (*bīmāristān*). Later, he returned to al-Rayy, at the invitation of its ruler, Manṣūr ibn Isḥāq, to assume responsibility as Hospital Director. To this ruler, al-Rāzī dedicated two books, *al-Almnṣūrī fī'l Ṭibb* (al-Manṣūrī on Medicine) and *al-Ṭibb al-Rūḥānī* (The Spiritual Physic). These were intended to unite the study of diseases of the body with those of the soul.

Having achieved fame in al-Rayy, al-Rāzī returned to Baghdad to become Head of its newly founded hospital, named after its founder the Abbasid caliph al-Muʿtaḍid (d. AD 902). The last years of his life were spent in al-Rayy, where he suffered from glaucoma (*al-māʾ al-azraq*), and died in AD 932 or 925.

Al-Rāzī's book *Fi'l Shukūk ʿalā Jālīnūs* (Doubts about Galen), so far unpublished, is devoted to the criticism of 28 of Galen's books, beginning with the *al-Burhān* (Demonstration) and ending with *Fi'l Nabḍ* (On the Pulse).

Before embarking on the criticism of Galen, he writes an apology in which he acknowledges his debt to his master, but says that "the art of physic is a philosophy which does not tolerate submission to any authority, nor does it accept any views, or yield to any dogmas without proper investigation." He says Galen himself supported this view. In the closing passage of his introduction, al-Rāzī affirms the validity of his book, saying that none of Galen's predecessors had escaped Galen's own scathing criticism.

To al-Rāzī, progress in scientific knowledge is inevitable. In his treatise *Fī Miḥnat al-Ṭabīb wa Taʿyīnih*, he says "He who studies the works of the Ancients gains the experience of their labour as if he himself had lived thousands of years spent on investigation."

Al-Rāzī also mentions *al-Jāmiʿ al-Kabīr* four times in his book *al-Murshid aw al-Fuṣūl* (The Guide or Aphorisms), which was written to serve as an introduction to medicine. *Al-Jāmiʿ al-Kabī* consists of 12 sections (*aqsām*), of which only two have been recently discovered in manuscripts: *Ṣaydalat al Ṭibb* (Pharmacology in Medicine) and *Fī Istinbāṭ al-Asmāʾ wa'l-Awzān wa'l-Makāyīl* (On Finding the Meaning of Unfamiliar Terms, Weights, and Measures).

His medical prescriptions took into account the patients' social status. For the rich, princes, and rulers, the effective drugs had to be mixed with sweet vehicles, as explained in *al-Ṭibb al-Mulūkī* (The Royal Medicine). For the poor, he wrote a book of recipes entitled *Man lā Yaḥḍuruh al-Ṭabīb* (Who has no Physician to Attend Him) also known by the title *Ṭibb al-Fuqarāʾ* (Medicine for the Poor).

Al-Rāzī argued that the medicinal properties attributed to various parts of animals, vegetables, and minerals should be recorded in books, which he did in his *Khawāṣṣ al-Ashyāʾ* (The Properties of Things). Such properties should neither be accepted nor discarded, unless experience (*al-tajriba*) proves them to be true or false. Physicians should not accept any property as authentic, unless it has been examined and tried.

In theory, al-Rāzī followed Galen, yet he found it necessary to correct him, and in practice, he revived the Hippocratic art of clinical observation. Having read the Hippocratic book *Abīdhīmyā* (Epidemics), he decided to write his own case histories, where he carefully recorded the name, age, sex, and profession of each patient. He also gave an early example of a clinical trial, when he divided his patients suffering from meningitis (*al-sirsām*) into two groups. He treated one group with bloodletting and intentionally, as a control, refrained from applying venesection to the other group.

All these detailed case histories are extant in his private notes which became known after al-Rāzī's death as the *al-Ḥāwī fi'l Ṭibb* (Continens on Medicine). It should be considered a private library of a well read and highly educated physician–philosopher, not a book meant for publication. It is interesting to remark that illnesses which affected al-Rāzī himself are recorded in *al-Ḥāwī fi'l Ṭibb*. In a note, preceded with "*Lī* (mine)," he mentions how he cured an inflammation of his own uvula by gargling with strong vinegar; in another, he jots down the fact that he recovered from a swelling in the right testicle by taking emetics (*muqayyiʾāt*) for a long time.

Al-Rāzī's medical works had great influence on medical education in the Latin West. *Al-Ḥāwī fi'l Ṭibb* was rendered into Latin (*Liber Continens*) by a Sicilian Jew, Faraj Ibn Sālim (Farrajut) in AD 1279. It was printed five times between AD 1488 and 1542. His *Liber ad almansorem*, consisting of ten books, and his *Liber Regius* were very popular among medieval European practitioners. The seventh book of *Liber ad Almansorem* (On Surgery) and the ninth entitled *Nonus Almansoris* (A General Book on Therapy) constituted a part of the medical curriculum in Western universities.

Al-Rāzī established an accurate differential diagnosis, based on clinical observations, between smallpox (*al-jadarī*) and measles (*al-ḥaṣba*). His book *Smallpox and Measles* was translated into Latin (*De variolis et morbillis*), and into other occidental languages and was printed about 40 times between AD 1498 and 1866.

The subject matter in this book is quite original. First, al-Rāzī asserts that Galen knew of smallpox, yet failed to indicate its etiology and to prescribe any satisfactory therapy. Secondly, he lays down his own differential diagnosis by his vivid description of the pustules of smallpox and the rash of measles. In his prognosis of the course of smallpox, he recommends close attention to the heart, the pulse, respiration, and excreta. He outlines his own method of protecting the patient's eyes and elaborates on how to avoid deep facial scarring.

Al-Ṣāghānī

Boris Rosenfeld

Abū Ḥāmid Aḥmad ibn Muḥammad al-Ṣāghānī al-Asṭurlābī was an Arabic astronomer and mathematician. He was born in Chagaian (Central Asia) and worked in Baghdad.

His main work was the *Kitāb fī'l-tasṭīh al-tāmm* (Book of the Perfect Projection on to a Plane) which is extant in two manuscripts. The treatise is devoted to a generalization of the stereographic projection of a sphere on to a plane, usually used in the making of astrolabes. This concerns the projection from a pole of the sphere on to the equatorial plane or a plane parallel to it. Under this projection, circles on the sphere are imaged on to the plane as circles or straight lines. The "perfect projection" invented by al-Ṣāghānī is the projection of the sphere from any point of its axis on to a plane orthogonal to the axis. Under this projection, circles on the sphere are imaged on the plane as conic sections (ellipses, hyperbolas, and parabolas) or straight lines. These descriptions of methods for conics construction are important for geometry. In the treatise, al-Ṣāghānī considers the construction methods for images of different circles of the celestial sphere, such as the celestial equator and its parallels, the horizon and its almacantars, verticals, and one ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course). The contents of the treatise are explained in detail by al-Bīrūnī (973–1048) in his *Astrolabes*.

Al-Ṣāghānī was also the author of two mathematical treatises, on the construction of a regular heptagon inscribed in a circle, and on the trisection of an angle. He also wrote three astronomical treatises. *Kitāb qawānīn ʿilm al-hay'a* (Book on Rules of the Science of Astronomy) is not extant, but al-Bīrūnī in his *Geodesy* mentioned measuring the value of the angle between the ecliptic and the celestial equator found by al-Ṣāghānī in Baghdad. The second, *Maqāla fī'l abʿād wa'l-ajrām* (Article on Distances and Volumes), dealt with the distances and volumes of planets and stars. The third work was *Fī'l sāʿāt al-maʿmūla ʿalā ṣafāʾiḥ al-asṭurlāb* (On Horary Lines Produced on the Tympanums of Astrolabes).

Al-Samarqandī

Gregg De Young

Shams al-Dīn al-Samarqandī, as his name implies, was from Samarqand, in what is now Uzbekistan. We know few of his biographical details with any certainty. He is believed to have been active during the second half of the seventh AH/AD thirteenth century, since he composed a star calendar for 675 AH/AD 1276-7 to accompany his *Al-Tadhkira fī'l-Hay'a* (Synopsis of Mathematical Cosmography or Hay'a). Although Naṣīr al-Dīn al-Ṭūsī had gathered many leading intellectuals together at the Marāgha observatory, al-Samarqandī is never mentioned among their number.

Al-Samarqandī's earliest contributions were in the field of logic, but he is best known to historians of science for his brief tract, *Kitāb Ashkāl al-Ta'sīs* (*Book of Fundamental Theorems*), a collection of 35 propositions from Euclid's *Elements* (mostly from Books I and II, although VI, 1 is also included), with abbreviated demonstrations. The treatise is very concise, and is historically better known through the commentary composed by Qāḍīzāde al-Rūmī (died 840 AH/AD 1436). Of special interest has been the "proof" of Euclid's parallels postulate (the fifth postulate of book I) which al-Samarqandī included. Once this "proof" was thought to be the work of al-Samarqandī himself, but now it is frequently ascribed to Athīr al-Dīn al-Abharī (died 663 AH/AD 1265).

Al-Shīrāzī

John Walbridge

Quṭb al-Dīn Maḥmūd ibn Masʿūd al-Shīrāzī (1236–1311) was a Persian scientist and philosopher. He was born into a medical family in Shiraz in central Iran. His father was a staff physician and ophthalmologist at the newly established Muẓaffarī hospital. As a child he was the apprentice of his father, who died when Shīrāzī was 14. Having assumed his father's position at the hospital, he continued his studies with several other local teachers of medicine and the rational and religious sciences. At this time he began the study of the first book, *al-Kullīyāt* (On General Principles) of Ibn Sīnā's *Qānūn fī 'l-Ṭibb* (Canon of Medicine), the leading medical textbook of the Middle Ages. His father had also initiated him into the Suhrawardī order of Sufis (Islamic mystics).

By the time he reached adulthood, he was in need of advanced medical instruction that could not be provided by the teachers of a provincial city like Shiraz. It would have been normal for him to have gone off earlier to one of the major Islamic cities for advanced studies, but in 1253 the Mongols had invaded the Islamic lands of Central and Southwestern Asia, sacking Baghdad in 1258, so Shīrāzī was confined to his home city until peace was reestablished.

In 1259 Hulegu, the Mongol ruler of Iran, gave a large grant to the famous scientist Naṣīr al-Dīn al-Ṭūsī (1201–1274) to pay for the preparation of a new set of astronomical tables (*zīj*) for use in astrological calculations. Ṭūsī established an observatory in the town of Marāgha, at that time the Mongol capital, and brought together a brilliant team of scientists and scholars. Shīrāzī came to the observatory as a student soon after it was founded. While he was disappointed by Ṭūsī's lack of knowledge about medical theory, he learned a great deal of mathematics, astronomy, and philosophy from him and his faculty, and he soon became the most important student at the observatory. Ṭūsī took him along on his travels and introduced him at court. Shīrāzī also apparently spent some time studying in Qazvīn, Khorasan, and Baghdad with various teachers.

Around 1270 he left the observatory and went to Konya in Anatolia, where he met the famous Sufi poet Rūmī and studied *ḥadīth* (the sayings of Muḥammad) with Ṣadr al-Dīn Qūnawī, the leading disciple of the mystical philosopher Ibn ʿArabī. Soon after he was appointed *qāḍī* (religious judge) of the Anatolian cities of Sivas and Malatya. This was evidently a sinecure to allow him to pursue his scientific work, for his first major work, *Nihāyat al-Idrāk fī Dirāyat al-Aflāk* (The Highest Attainment in the Knowledge of the Spheres), a technical work on mathematical astronomy, was published in Sivas in 1281 and was dedicated to the vizier of the Mongol ruler. Other works on astronomy and mathematics soon followed.

In 1282 he was appointed to a diplomatic mission to Egypt. Though the mission failed in its political objectives, Shīrāzī found three complete commentaries on the first book of Ibn Sīnā's *Qānūn*, along with glosses and other sources. With this new material in hand, he was finally able to achieve his youthful goal of mastering the intricacies of this work. Shortly after his return to Anatolia he published a large commentary on the *Qānūn*. He published second and third editions in 1294 and in 1310, a few months before his death.

Of his personality we are told that he had a sharp wit, and indeed he was a stock character in a certain genre of joke for several centuries thereafter. He was expert in chess and prestidigitation and was a lively conversationalist and lecturer. He was an authority on musical theory, which in the Middle Ages was considered a branch of mathematics, and was a fine player of the *ribāb*, a forerunner of the violin. He seems to have grown more concerned with religious matters as he grew older, although he was a Sufi all his life.

He eventually settled – interrupted by several exiles – in Tabriz, at that time the capital of Mongol Iran. He was an intimate of the court. The funds that supported his scientific work came from a series of viziers and petty rulers. In addition to his works on astronomy and medicine, he wrote on mathematics, philosophy, and the Islamic religious sciences. In his last years he spent less time on the rational sciences and more on religious subjects. He died in relative poverty, having given almost everything he had to charity and to his students and not yet having received the large payment promised for the third edition of his commentary on Ibn Sīnā's *Qānūn*. He was given a lavish funeral by a wealthy student.

Shīrāzī was typical in most respects of Islamic scientists. He was a polymath, interested not only in the corpus of science inherited from the Greeks but also in the religious sciences of Islam. Of the rational sciences it was astronomy and medicine that found the most ready market – astronomy as the handmaid of astrology or for timekeeping in the mosques. The other rational sciences, particularly mathematics, and philosophy, were supported by their more practical subordinate sciences. Sophisticated practitioners of the rational sciences generally drifted to the royal courts, the only reliable sources of funding for such subjects, and became involved in the life and politics of the court – and in its perils.

Al-Sijzī

Yvonne Dold-Samplonius

Al-Sijzī, Abū Sa'īd Aḥmad ibn Muḥammad ibn ʿAbd al-Jalīl, was born in Persia, ca. 945 and died ca. 1020. The name al-Sijzī indicates that he was a native of Sijistān in southeastern Iran and southwestern Afghanistan. This is confirmed, for example, when al-Sijzī refers in his *al-Mudkhal ilā ʿilm al-handasa* (Introduction to Geometry) to a planetarium which he had constructed in Sijistān. Al-Sijzī was already active in 963, when he copied a manuscript of Pappus' *Introduction to Mechanics* (Book VIII of the Collection), and still active in 998, when he completed a treatise on the proof of the plane transversal theorem.

Al-Sijzī's father, Abū'l-Ḥusayn Muḥammad ibn Abd al-Jalīl, was also interested in geometry and astronomy, and al-Sijzī addressed some of his works to him, e.g., *Risālat fī Khawāṣṣ al-qubba az-zā'ida wa-l-mukāfiya* (On Parabolic and Hyperbolic Cupolas), completed in 972. Around 969 al-Sijzī spent some time at the Buwayhid court in Shirāz and assisted in 969/970 at the observations of the solstices conducted by Abd al-Raḥmān ibn ʿUmar al-ṣūfī. There he met a number of important geometers and astronomers, including Abū'l Wafāʾ, Abū Sahl al-Qūhī, and Naẓif ibn Yumn (d. ca. 990).

Al-Sijzī was active in astrology and had a vast knowledge of the literature. He usually compiled and tabulated, adding his own critical commentary, as with three works by Abū Maʿshar and the second of the five books ascribed to Zoroaster. He used Sassanid material and sources from the time of Hārūn al-Rashīd and from the late Umayyad period for a book on general astrology and its history. In his work on horoscopes he gives tables based on Hermes, Ptolemy, Dorotheus, and "the Moderns." Al-Sijzī's tables, together with those of Ptolemy, are quoted by Iḥtiyāzu' l-Dīn Muḥammad in his *Judicial Astrology*. The treatise *Kitāb fī Qawānīn mizājāt al-asṭurlāb al-shimālī maʿa l-janūbī* (On the Astrolabe) deals with the different kinds of astrolabe retes (a circular plate with many holes used on the astrolabe to indicate the positions of the principal fixed stars) with which al-Sijzī was familiar. This treatise is used by al-Bīrūnī in his *Istīʿab al-wujūh al-mumkina fī ṣan 'at al-asṭurlāb* (Book on the Possible Methods for Constructing the Astrolabe).

Al-Sijzī wrote at least 45 geometrical treatises, of which some 35 are extant, and about 14 astronomical treatises. He was well-read and had many contacts with his contemporaries. A number of his works are therefore of unusual historical interest. In *Risālat fī Qismat az-zāwiya al-mustaqīmat al-khaṭṭain bi-ṭalāṭat aqsām mutasāwiya* (On the Division of the Angle into Three Equal Parts) al-Sijzī describes a number of problems, to which various other writers had reduced the problem of the trisection of the angle. The method of "the Ancients" by means of a neusis was not considered a legitimate construction by al-Sijzī. His own construction, by intersecting a circle and a hyperbola, is a variation of the solution by al-Qūhī. The treatise ends with five problems of al-Bīrūnī. Regarding al-Sijzī's construction of the heptagon, this is, according to Jan Hogendijk, to a great extent the history of a dispute between two young geometers, al-Sijzī and Abū'l-Jūd, who were both engaged in plagiarism. In the meantime al-Qūhī solved the problem in an elegant manner.

For the *Geometrical Annotations* (*Kitāb fi l-masā'ili l-mukhṭārati llatī jarat baynahu wa-bayna muhandisī Shīrāz wa-Khurāsān wa-taʿlīqātihi*, Book on the Selected Problems Which Were Currently Being Discussed by Him and the Geometers of Shirāz and Khorāsān, and His (Own) Annotations) al-Sijzī had the example of Ibrāhīm ibn Sinān's *al-Masā'il al-mukhṭāra* (Selected Problems) in mind. A number of the problems and solutions are clearly influenced by or adapted from the *Selected Problems*, but al-Sijzī's treatise is on the whole on a lower level.

The *Misāḥat al-ukar bi-l-ukar* (Book of the Measurement of Spheres by Spheres) is about a surrounding sphere which contains in its interior up to three mutually tangent spheres. Al-Sijzī determines the volume of the solid which results when one deletes from the surrounding sphere all points that belong to the spheres in its interior. He expresses this volume as the volume of a new sphere, and he determines the radius of this new sphere in terms of the radii of the spheres used in the definition of the solid. Al-Sijzī's proofs are trivial consequences of identities for line segments, proved geometrically. The treatise contains 12 propositions, of which proposition 11 and its proof are false for (three-dimensional) spheres. The proposition holds in dimension 4. Perhaps al-Sijzī had four-dimensional spheres in mind, although he does not use them elsewhere in the treatise; perhaps he made a mistake.

His small treatise *Risālat fī Kaifīyat taṣauwur al-khaṭṭain alladhain yaqrubān wa-lā yaltaqiyān* (On the Asymptote, or How to Conceive Two Lines Which Approach Each Other But Do Not Meet, If One Extends Them All the Way to Infinity) is devoted to Apollonius II,14. Some cases, he says, can be solved as explained in his *Kitāb fī tashīl as-subul li-stikhrāj al-ashkāl al-handasīya* (On Facilitating the Roads to the Geometrical Propositions); for others a philosophical method is needed, as Proclus has shown in the definitions of his *Elements of Physics*. The treatise ends with the case where the two asymptotes are two hyperbolas. In *Risālat fī anna 'l-ashkāl kullahā min al-dā 'ira* (On [the Fact] that All Figures Are Derived from the Circle), a treatise until recently attributed to

Naṣir ibn ʿAbdallāh, al-Sijzī describes one of the few instruments that finds the *qibla* (the direction of Mecca) geometrically. He also wrote an original treatise on the construction of a conic compass.

In the introduction to *Risālat fī'l-shakl al-qaṭṭāʿ* (The Transversal Figure), written before 969, al-Sijzī says that he wrote the work having seen neither Thābit ibn Qurra's *Kitāb fī'l-shakl al-mulaqqab bi-l-qaṭṭāʿ* (Book of the Transversal) nor any other work on the topic, except Ptolemy's *Almagest*. The treatise begins with enunciations and proofs of two lemmas, which also appear, in different terms, in the *Almagest*. Following the two lemmas al-Sijzī enunciates and proves his 12 propositions. Aware of the astronomical applications of the theorem he evidently saw the need to provide a complete mathematical basis for these uses. The details of the proofs of all 12 theorems are carried out according to a uniform procedure. This makes the treatise a step toward recognizing the mathematical discipline of trigonometry.

Al-Ṣūfī

Paul Kunitzsch

Al-Ṣūfī, Abu'l-Ḥusayn ʿAbd al-Raḥmān ibn ʿUmar, was born in 903 in Rayy, near modern Tehran, and died in 986.

Al-Ṣūfī was an astronomer in the Arabic–Islamic area. He was of Persian origin, but wrote in Arabic, the language of all science in that time. He was best renowned, and became most influential, through his *Kitāb ṣuwar al-kawākib al-thābita* (Book on the Constellations), written around 964. Knowledge of the fixed stars in Greek-based Arabic–Islamic astronomy was mainly derived from Ptolemy's catalog of 1,025 stars arranged in 48 constellations contained in his *Almagest* (ca. AD 150). Al-Ṣūfī reexamined Ptolemy's values of the star coordinates and magnitudes. In his book, he described all the stars catalogued by Ptolemy, adding his criticism in each individual case. However, in the tables added to his book he nevertheless faithfully rendered Ptolemy's traditional values, adding a constant of 12°42′, for precession, to Ptolemy's longitudes. Only the magnitudes were given according to al-Ṣūfī's own observation. For each constellation he added two drawings, one showing the figure as seen in the sky, the other as seen on the celestial globe. His book and his drawings served as models for work on the fixed stars in the Arabic–Islamic world for many centuries, and became known even in medieval Europe, where his constellation drawings were imitated in a series of Latin astronomical manuscripts (though no veritable Latin translation of his book was made). Apart from this book, al-Ṣūfī left treatises on the use of the astrolabe and the celestial globe, an introduction to astrology, and a short geometrical treatise. His name lives on, Latinized as Azophi, as a name for a crater on the Moon.

A

Al-Suyūṭī

Anton M. Heinen

Al-Suyūṭī (1445–1505) wrote on just about every discipline that had been recognized, in his time, as having its own method and subject matter. What is most noteworthy is that *hay'a* (cosmology, cosmography, but also astronomy) was among them. The author was in his own estimation an authority in the traditional Arabic and Islamic sciences (*al-ᶜulūm al-ᶜnaqliyyah*, transmitted sciences), especially in grammar, jurisprudence, and in tradition (*ḥadīth*, the Sayings of the Prophet), but in no way in those "Sciences of the Ancients" (*al-ᶜulūm al-ᶜaqliyyah*), which had entered the libraries of Islamic culture through numerous translations from Greek, Syriac, Middle Persian, etc. He even expressed his special hatred for philosophy and logic. The title of his treatise, *al-Hayʾa al-sanīya fī l-hayʾa al-sunnīya*, already reveals the challenge he had in mind: his was to be *the* Islamic cosmology, based on authentic Islamic traditions, the *Sunna*, which so conveniently rhymed with *sanīya* (brilliant, magnificent, glorious). The choice of the technical term *al-hay'a* in the title implies that the author is offering an alternative to those cosmologies based on the principles and methods of pre-Islamic astronomers. As such it is a parallel of his book *al-Ṭibb al-nabawī* (Prophetic Medicine). As the author says himself, it was his goal "that those with intelligence might rejoice, and those with eyes take heed." Actually, the great number of extant manuscripts in our libraries proves that as-Suyūṭī's *Hay'a* attracted more attention than most other contemporary books on the cosmos.

This work is a collection of fragmentary descriptions and explanations of such natural phenomena as the sun, moon, and stars in their celestial spheres, lands and seas, winds and clouds, etc. The distinctive feature is, however, that all these fragments are authenticated in the traditional manner with chains of trustworthy authorities which connect them with Quranic revelation or Prophetic wisdom. As a result, some of the earliest theories about cosmological entities and natural phenomena have been preserved that may elucidate the world-views prevalent among the young Muslim community before they were developed under the impact of the translations from pre-Islamic cultures. It remains doubtful whether even in the Middle Ages a mythical theory about the winds, because of the traditional authorities, would have been accepted with the same truth claim as a modern one. But the fact that the authorities were already interested in the phenomena of nature and cosmos may have opened rather than closed the eyes of the student.

Al-Ṭabarī

Sami K. Hamarneh

Abū'l-Ḥasan ᶜAlī ibn Sahl Rabbān al-Ṭabarī was born in the environs of the city of Marw, in the province of Khurasān in Persia (presently Mary, in Turkmenistan), about AD 783, before the reign of the Abbasid Caliph Hārūn al-Rashīd (786–809). His father Sahl was a prominent citizen of great learning and a highly placed state official. As a religious leader in the Syriac-speaking community, he was reverently called *Rabbān* (from the Aramaic for teacher), and had far-reaching knowledge in theology, philosophy, and medicine.

Sahl took a special interest in his son's upbringing, providing him with the best available educational opportunities. ᶜAli read the best Syriac books and excelled in learning. When he was 14, he turned to medicine. He concentrated there, because he realized he could help the sick and the needy.

From the Marw region, he moved to Tabaristān (Māzandarān, south of the Caspian Sea). Thus he became known as al-Ṭabarī. He was appointed counselor-secretary-scribe to the Prince-Sultan Māzyār ibn Qārin. When the latter rebelled against the Abbasid's authority in open revolt, Caliph al-Muᶜtaṣim sent a powerful army that crushed the mutiny and killed Māzyār in AD 839.

Al-Ṭabarī spoke of it later on as "a tragic episode" which left deep scars that remained until late in his life. Meanwhile, he was summoned to the Caliph's court at the new capital, Sāmarrāʾ. Under the Caliph's influence, al-Ṭabarī renounced his Christian faith and embraced Islam. He continued as a physician during the remaining part of al-Muᶜtāsim's life, and remained there under his successor, his brother al-Wāthiq (843–847).

His good fortune came with the rise of Caliph al-Mutawakkil (AD 847–861). He was promoted to the position of physician-in-ordinary, and also became the Caliph's counselor and trusted companion (*nadīm*). In appreciation, al-Ṭabarī dedicated his best and largest medical compendium, *Firdaws al-Ḥikmah* (Paradise of

Wisdom) to his patron in AD 850. This was the first and most comprehensive medical encyclopedia of its kind in Islam. It took him 20 years to complete. In the introduction, the author stated that the work was to be useful to his medical students as well as to practitioners. He listed five points concerning the importance of the art of medicine:

1. It brings relief and healing to the sick, and consolation to the weary.
2. It successfully diagnoses and skillfully treats ailments, even unseen diseases not easy to discover or observe.
3. It is needed by all, regardless of age, gender, or wealth.
4. It is among the noblest of all callings.
5. The words *ṭibb*, *ṭibābah*, *mu'āssāh*, and *usāt* all relate to medicine and its healing processes.

Al-Ṭabarī then mentioned four virtues that all physicians had to possess in order to be successful and esteemed: *al-rifq* (leniency and kindness), *raḥmah* (mercy and compassion), *qanāᶜah* (contentedness and gratification), and *ᶜafāf* (chastity with simplicity).

Firdaws was divided into seven sections in 30 treatises, composed of 360 chapters in all. They ranged from cosmogony, the nature of man, embryology, and anatomy, to materia medica, psychotherapy, pathology, and surgery. Other topics included theoretical and practical medicine in the Greek and Indian traditions, and rules of conduct with insistence on strict adherence to the highest ethical standards.

Another noteworthy literary contribution was his book *al-Dīn wā'l-Dawlah* (Religion and the State). It represents a defense as well as an exposition of the religion of Islam, the Holy Qurʾān, and the Holy Prophet Muḥammad. It seems temperate, rational, and objective in style and tone, and appears free from misgivings or barren argumentation. It also abounds with quotations from the Bible (in the Syriac version).

In these two works, al-Ṭabarī shed much light on the development and progress of the religious, philosophical, and medical advancements during the first two quarters of the ninth century AD. He died in Sāmarrā ca. 858.

The Kitāb al-Dīn was soon eclipsed during the Islamic Middle Ages, because of a lack of interest in such studies as comparative religion. Only in the twentieth century was the book edited more than once. *Firdaws*, however, has continued to enjoy a good reputation, with a wide circulation throughout the Islamic world. Both works can now be considered classical literary works.

Al-Uqlīdisī

Jacques Sesiano

Al-Uqlīdisī, Abū'l-Ḥasan Aḥmad ibn Ibrāhīm, wrote an Arithmetic (*Kitāb al-Fuṣūl fi'l-ḥisāb al-hindī*) in Damascus in 952–953. This is a sizable compendium and remarkable as the earliest arithmetic extant in Arabic.

The first part explains the place-value system, the four arithmetical operations (addition, subtraction, multiplication, division), and the extraction of square roots for integers and fractions, both common and sexagesimal. Numerous examples are given. This part is supposed to be accessible to a large audience. The second part develops the earlier topics and adds curiosities or different methods. The third part would seem to be the result of the author's experience in teaching; it consists of explanations and questions with their answers concerning some difficulties the reader might have met in the first two parts. The fourth part contains some digressions about the changes Indian arithmetic undergoes when one uses ink and paper (since Indian computations were made on the dust abacus). In this part al-Uqlīdisī also explains (according to him, better than his predecessors) how to extract cube roots.

Al-Uqlīdisī was concerned with the applicability of arithmetic. How original his work was we do not know. He often claims originality or at least superiority of his teaching, but so do his contemporaries. He does not claim originality, however, for the most important feature of his *Arithmetic*, the first occurrence of decimal fractions (besides the usual common and sexagesimal ones). He uses a mark placed over the last integral unit in order to indicate the separation from the subsequent, decimal part.

Al-ʿUrḍī

Boris A. Rosenfeld

Muʾayyad al-Dīn ibn Barmak al-ʿUrḍī al-Dimashqī (thirteenth century) was an astronomer, architect, and engineer. He as born in Damascus and first worked in Syria. He did some hydraulic engineering in Damascus and constructed an astronomical instrument for the ruler of Hims (Emessa), al-Manṣūr Ibrāhīm (1239–1245). He also taught *handasa* (architecture or geometry).

In or soon after 1259 he was in Maragha, the capital of the Mongol conqueror Hulagu Khan, the grandson of Genghis Khan. He was one of four astronomers who worked with Naṣīr al-Dīn al-Ṭūsi, the founder of the Maragha observatory. He participated in the organization, building, and construction of the instruments of this observatory, and in the building of a mosque and a palace in Maragha.

The best known al-ʿUrdī's works is *Risāla fī kayfiyya al-arṣād wa mā yukhtāj ilā ʿilmihi wa ʿamalihi min al-ṭuruq al-muwaddiya ilā maʿrifa ʿawdāt al-kawākib* (Modes of Astronomical Observations and the Theoretical and Practical Knowledge Needed to Make Them, and the Methods Leading to Understanding the Regularities of the Stars). Manuscripts of this treatise are extant in Istanbul, Paris, and Teheran. The treatise contains the description of 11 of the most important astronomical instruments of the Maragha observatory which he himself mainly constructed (1) mural quadrant, (2) armillary sphere, (3) solstitial armilla, (4) equinoctial armilla, (5) Hipparchus' diopter (alidade), (6) instrument with two quadrants, (7) instrument with two limbs, (8) instruments to determine sines and azimuths, (9) instruments to determine sines and versed sines, (10) "the perfect instrument" built by him in Syria, and (11) parallactic ruler (after Ptolemy).

Al-ʿUrḍī was also the author of three astronomical treatises: *Kitāb al-hayaposa* (Book on Astronomy) on the motion of planets; *Risāla fī ʿamal al-kura al-kāmila* (Treatise on Construction of the Perfect Sphere); and *Risāla fī'l-taʿrīf al-buʿd bayna markaz al-shams wa'l-awj* (Treatise on the Determination of the Distance between the Center of the Sun and the Apogee).

Al-ʿUrḍī's sons Shams al-Dīn and Muḥammad also worked in the Maragha observatory. Muḥammad (ca. 1280) constructed a celestial globe 150 mm in diameter, which is extant in the Mathematical Salon in Dresden.

Anatomy in Ancient India

Lakshmi Rajgopal

"In India I found a race of mortals living upon the earth but not adhering to it; inhabiting cities but not being fixed to them; possessing everything yet possessed by nothing. Apollonius Tyanaeus (Greek thinker and traveller, first century AD)".

The history of India is both fascinating and daunting. The geographical terrain of Bharat (Hindustan), as India was known then, extended far beyond the boundaries of India as they exist now. It is this region that cradled a civilisation in the Indus valley about 5,000 years ago, evidence of which is amply found in Harappa, Mohenjo-daro, Lothal (Gujarat) and other places. There is evidence that ancient Hindus practiced science, especially medical science; they were adept in practical anatomy and knew how to apply anatomical knowledge to the practice of surgery.

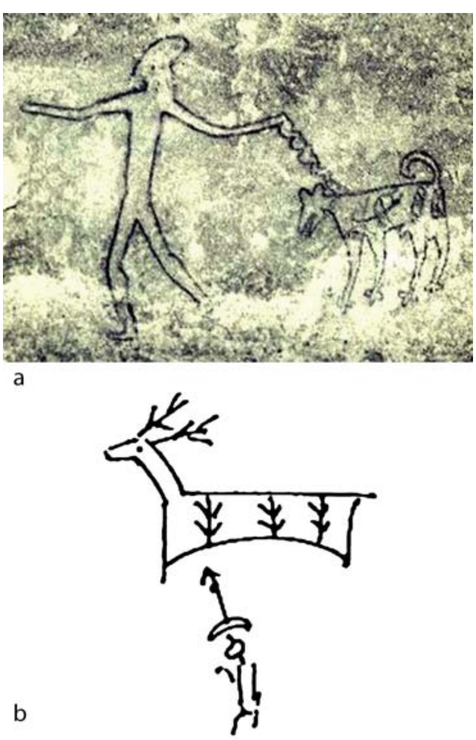
Prehistoric Period

The history of medicine in India can be divided into two broad periods. The prehistoric period ranges from the Stone Age to the beginning of written history. This period can again be subdivided into the early prehistoric period (40000–2500 BCE) and the protohistoric period (2500–1500 BCE). Prehistoric people were wanderers, hunters and worshippers of supernatural phenomena (Subba Reddy 1971). Any anatomical knowledge these men might have possessed was only to use it for hunting and not as a basis for diagnosis and surgical treatment of diseases. There is evidence, in the form of cave paintings (Fig. 1a, b) discovered in Bhimbetaka, near Bhopal in Central India, that superficial anatomical knowledge was used to hunt animals.

These are similar to the Pindal elephant pierced by arrows near its heart and the Niaux bison portrayed with weapons directed at its vital centres; they show that prehistoric man had some knowledge of gross anatomy (Gordon 1949).

Protohistoric Period

The Protohistoric period is the time when the Indus Valley civilisation flourished in northwest India. The people of this civilisation were architects and built planned cities. They were also public health experts, as is evidenced by the wells and bathrooms in the houses and a closed system of drains that have been excavated in Harappa, Mohenjo-daro and other sites. They were also healers, although the practice of healing was more magico-religious, based on rites and rituals (Kutumbiah 1962).



Anatomy in Ancient India. Fig. 1 a, b Cave paintings at Bhimbetaka (reproduced from K. L. Kamath. Prehistoric Paintings, URL: ►http://www.kamat.com/kalranga/rockpain/betaka.htm accessed on 23 Sept. 05).

Historic Period

The historic period of ancient Hindu medicine started with the invasion of the Indus valley by Indo-European tribes such as the Aryans around 1500 BCE. The Vedic period extended from 1500 to 800 BCE. This was followed by the Brahmanic period or the Buddhic period, from 800 BCE to 1000 AD. This was followed by the Mongol period or the Moghul period from 1000 AD onwards (Major 1954).

Vedic Period

The word "Veda" means knowledge – *Ṛgveda* is knowledge of hymns of praise; *Yajurveda* is knowledge of sacrificial formulae; *Sāmaveda* is knowledge of melodies and *Atharvaveda* is knowledge of magic formulae (Major 1954). The Vedas speak about the structure of the body. In the *Ṛgvedic* hymns mention is made of the lungs, the heart, the stomach, the intestines, the kidneys and other viscera (Kutumbiah 1962). Atharvavedic medicine is an amalgam of magico-religious elements consisting of chants and charms and empirico-rational elements which used drugs to cure disease. The *Atharvaveda* gives an impression of the coarser anatomy of the body. There is a hymn in the tenth book which mentions the creation of man describing the articulation of bones (Lanman 1905). *Atharvaveda* also refers to the heart as a "lotus with nine gates". The comparison of the heart with a lotus is very common in Sanskrit literature. When we compare it with present day knowledge, we see that there are indeed three venous openings in the right atrium, four pulmonary veins opening in the left atrium and the pulmonary artery and the aorta leaving the right and the left ventricles, making nine openings in all. The heart, if held upside down, does resemble a lotus bud (Rajgopal et al. 2002). *Atharvaveda* also describes childbirth in some detail.

Brahmanic Period

Vedic books such as *saṃhitās* contained hymns. It was difficult for common people to follow them. So the post-Vedic period saw a lot of literary work which described the Vedic work in simpler language. Thus were born the *Brāhmaṇas* which described and explained the Vedic rites and stories. These were followed by *Aranyakas* which were the continuation of the *Brāhmaṇas* but were meant for people who have entered the third ashram of *Vanaprasta* in life. *Aranyaka* is derived from *arni* meaning wooden sticks, the rubbing of which results in the production of the sacrificial fire. The fire thus produced was used by the Vanaprastis for their day-to-day living (Bodas 1908). Aranyakas were followed by *Upaniṣads*. In fact *Upaniṣads* are part of Aranyakas which treat the higher doctrine of the soul (Upaniṣad = secret knowledge/esoteric lore). Upanishadic knowledge is obtained by the disciples by sitting around a teacher and listening to him in the 'Guru-Shishya' tradition (Udwadia 2000).

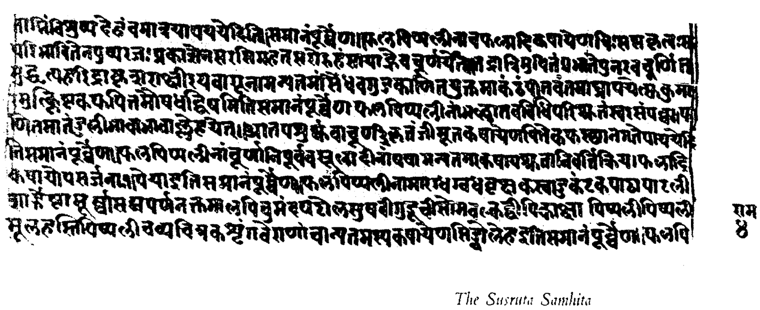
Hindu scriptures had a peculiar way of comparing the structure of human body with things that are metaphysical. In *Satapatha Brāhmaṇa*, Yajnavalkya, who flourished in the court of King Janaka, mentions that the total number of bones in the body is 360 and compares it to 360 days of the year (Hoernle 1907). It is during this period that the science of "Āyurveda" came into being, roughly between 800 and 600 BCE. Āyurveda, or the science of life, was expounded by Brahma and given to the Ashwinikumars; they then taught Indra, who transmitted his knowledge to other priests (Jaggi 1972). This period was the "Golden Period" in the history of Indian medicine.

The Golden Period

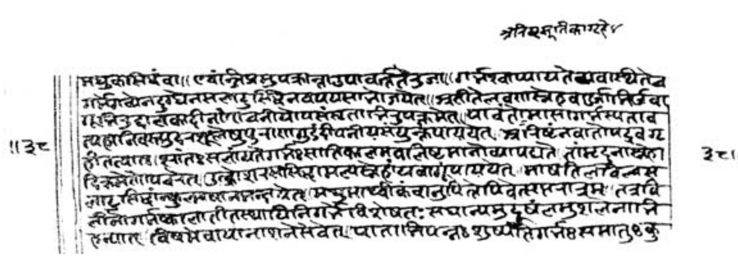
According to the Indian medical tradition, the knowledge of medicine had two origins. On the one hand, it was delivered by the God Indra to the sage Bharadwaja and the latter then handed it over to Punarvasu Ātreya. On the other hand, it descended from Indra to Dhanvantri (also called Divodasa or Kasiraja) and from him to Suśruta. This tradition gives medicine a mythical origin and when traced further leads to historical facts. In the age of Buddha, two great universities existed in India where all forms of science including medical science were taught. They were Benares or Kasi in the East and Takshila or Taxila in the West on the river Jhelum (Hoernle 1907). The leading professor of Medicine in Takshila was Ātreya and the famous teacher of surgery at Benares was Suśruta. They were two stalwarts of Āyurveda and their teachings were compiled in the form of texts. Suśruta's teachings were compiled as *Suśrutasaṃhitā* (Fig. 2).

Ātreya had Agniveśa as one of his disciples, and Caraka was in turn his student. Caraka revised *Agniveśatantra* and it came to be known as *Carakasaṃhitā*. Caraka was the court physician of the celebrated Indo-Scythian king Kanishka and that puts the period of Caraka as 125–150 AD (Bhandarkar 1906) (Fig. 3).

Suśrutasaṃhitā is a great storehouse of Aryan surgery. Though Garrison claims that Indian medicine was weak in anatomy which he attributes to fanciful enumerations (Garrison 1924), it is a fact that to practise the art of surgical healing, one must have sound knowledge of anatomy. Suśruta could not have achieved such mastery over surgery without a thorough knowledge of anatomy. It is precisely for this reason Suśruta insisted that his disciples practice dissection, even though their religion prohibited it. Suśruta had devised his own method of overcoming religious



Anatomy in Ancient India. Fig. 2 A leaf from *Suśrutasaṃhitā* (reproduced from Indian System of Medicine by O. P. Jaggi. New Delhi: Atmaram & Sons).



Anatomy in Ancient India. Fig. 3 A leaf from *Carakasaṃhitā* (reproduced from Indian System of Medicine by O. P. Jaggi. New Delhi: Atmaram & Sons).

cutting open the dead body prohibition by placing the dead body in a cage covered with hemp and then keeping it in a secluded spot in the riverbed which would allow the body to decompose slowly in water. Later the observer gently scraped off the layers of the skin using *kusa* grass and could see both the external and internal aspects (Kutumbiah 1962; Jaggi 1972; Dampier 1942; Clendening 1942) (Fig. 4).

Both Suśruta and Caraka devoted an entire chapter to anatomy, *Sarira Sthana*, in their *Saṃhitās*. Osteology (the study of bones), myology (the study of muscles) and splanchnology (study of the viscera and its organs) are some divisions of anatomy in which these ancient authors excelled. Suśruta noted 300 bones and 210 joints in the body. He also classified joints into eight different types, e.g. *kora* (hinge joint) at the ankles and elbows, and *samudga* or *ulukhala* (ball and socket joint) as in the hip and shoulder. Caraka's anatomy is mainly that of external observation. Caraka described 360 bones and 200 joints. The reason for the discrepancy is that many cartilages, nails and protuberances were counted as separate bones. Suśruta gave the total number of muscles as 500 and specified their distribution as 400 in four extremities, 66 in the trunk and 34 in the head and neck regions. Caraka's description of muscles is quite rudimentary. Besides muscles, both Suśruta and Caraka described 900 *snayus* (ligaments; Kutumbiah 1962).

Suśruta had more thorough and critical knowledge of the internal viscera as is evidenced by his description of the heart and the vessels. He referred to the heart as a lotus bud hanging with its apex downward and also noted 24 *dhamanis*, 700 *siras* and 22 *srotas*. Dhamanis are thick-walled tubes and siras are thin-walled tubes equivalent to present-day arteries and veins. Srotas probably referred to lymphatics. Suśruta observed that all the dhamanis and siras arose from the umbilicus and there were 40 important ducts in the body. Caraka said that the heart was the root of ten dhamanis which run to different parts of the body. Nerves were also classified as ducts and included in the count of vessels.

Suśruta does not state anything of importance concerning the brain but considers the head as the centre of all senses. Both Suśruta and Caraka mention various viscera in the abdomen. The stomach is referred to as *amasaya*; the intestine is called *pakvasaya* and the rectum *gudam*. The uterus is known as *garbhasaya* and the gallbladder as *pitthasaya* (Kutumbiah 1962).

According to Suśruta, apart from dissecting, a student of anatomy should learn the subject and obtain mastery over it by preparing clay models (Fig. 5). Suśruta implored his students of surgery to be careful about 107 vital spots or *marmas* in the body. Marmas are the meeting place of any two or more of the five elements of the body: vessels, muscles, ligaments, bones and joints. The marmas are then classified into five groups (1) *Mamsa* marmas (fleshy); (2) *Sira* marmas (of the vessels); (3) *Snayu* marmas (of the ligaments); (4) *Asthi* marmas (of the bones) and (5) *Sandhi* marmas (of the joints). According to Suśruta, some of them when injured will result in instantaneous death and some others when injured will cause pain and paralysis (Jaggi 1972; Dampier 1942; Clendening 1942; Bhishagratna 1991) (Figs. 6 and 7).

Apart from gross anatomical findings, embryology, the study of the development of the foetus, also achieved a high level in ancient India. Structures such as amniotic membranes are mentioned in the *Bhagavad Gītā* (Needham 1934). Indian anatomists were of the opinion that union of the blood of the mother, called

sonita and the semen of the father, called *sukra* was responsible for the production of the foetus. They were aware that the mechanism of sex determination took place at the time of fertilisation (Kutumbiah 1962). Moore and Persaud (1999) quote *Garbhoniṣad* (sixth century BCE) which describes the stages of development of the foetus. A 1-day-old embryo is jelly-like and called *kalala*. After seven nights, it becomes vesicular (*Budbuda*) which indeed is the case, as we know now. We call this a blastocyst. After a month it becomes a firm mass and the head is formed after 2 months.

In the third month legs and arms appear distinctively. In the sixth month hair, nail, bones and veins develop. In the eighth month there is drawing of the vital force (*ojas*) from the mother. Indian anatomists believed that the growth of the embryo occurs by a process of layering where at least seven strata are superimposed one upon the other. The seven layers are *avabhasini*, *lohita*, *sveta*, *tamra*, *vedini*, *rohini* and *mamsadhara* (Kutumbiah 1962). They also believed that softer parts of the foetus, such as skin, blood, flesh, fat, navel, heart, lungs, liver and marrow, are derived from the mother and the harder parts, such as the head, nails, teeth, bones and nerves, are derived from the father (Jaggi 1972; Zimmer 1948). The formation of the embryo is also compared with the formation of creamy layers of milk; this similar comparison to the clotting of milk to form cheese has also been used by Aristotle (Needham 1934).

It is possible that Indian thought influenced the schools of Asia Minor and through them those of Greece (Dampier 1942). There is evidence that Indian medical practices spread all over Asia including Indonesia, Tibet and Japan. The translation of Ayurvedic literature into Arabic and Persian in the eighth to eleventh century AD led to its further spread (Lyon and Petrucelli 1987). *Carakasaṃhitā* was translated from Sanskrit into Arabic in the eighth century AD and *Sharaka indianus* appears in the Latin translation of Avicenna, Rhazes and Serapion. *Suśrutasaṃhitā* was translated into Arabic before the end of the eighth century AD as 'Kitab-i-shawshoon–Al-Hindì' and also mentioned as 'Kitab-i-Susrud' by Ibn Abillsaibal. Rhazes often quotes 'Sarad' as an authority in Surgery (Mukhopadhyaya 1913).

The ancient Indian medical doctors can be credited with the inquisitiveness to learn about the structure of the human body and a systematic study of the same. They practised human dissection despite religious restrictions. They also had an appreciation of the relation of anatomy to the practice of medicine. Even if the enumerative method of various parts of the body may minimise their significance, what cannot be denied is that they used their knowledge of anatomy to master surgery and practised medicine in a more scientific way.

Ancient Egypt

J. Worth Estes

Humanity was concerned with sickness and death long before the Egyptians appeared along the banks of the Nile. But only from the beginning of pharaonic civilization, about 2900 BCE, do we have evidence of how sickness and trauma were treated in the ancient world. It comes primarily from several monographs, or collations of sections of earlier monographs, written on papyrus. The major medical papyri are, in their probable chronological order:

Veterinary Papyrus of Kahun, ca. 1900 BCE, on the treatment of animals

Gynecological Papyrus of Kahun, ca. 1900 BCE, a fragment of a monograph on the diseases of women

Papyrus Edwin Smith, ca. 1550 BCE, part of a monograph on wounds that also includes a fragment of a work on the heart and vessels called the *Secret Book of the Physician* that was probably composed ca. 3000 BCE

Papyrus Ebers, ca. 1550 BCE, a collection of remedies for several kinds of ailments that contains a longer version of the *Secret Book*

Papyrus Hearst, ca. 1550 BCE, a less systematically organized collection of remedies that duplicates many of those in the Ebers Papyrus

Papyrus Berlin 3038, ca. 1350–1200 BCE, another collection of drug recipes, with another version of the *Secret Book*

Papyrus Chester Beatty, ca. 1250–1150 BCE, a fragment of an earlier monograph on diseases of the anus

Magical Papyrus of London and Leiden, ca. third century AD, containing many examples of spells used in healing rites

From the beginning, magic dominated Egyptian concepts of illness and its treatment. Empiric observations eventually entered therapeutic thinking, but magic was seldom far removed from it. The Egyptians attributed healing powers to a number of their local gods, while Thoth, scribe of the major gods and inventor of the arts and sciences, became a part-time god of medicine. Not until he was deified sometime after 525 BCE did Imhotep, who had been the chief minister of the pharaoh Zoser (reigned 2630–2611 BCE), and the inventor of the pyramid, assume the role of chief god of Egyptian medicine.

Throughout most of the three millennia of pharaonic history, three kinds of healers treated the sick. Two of them, magicians and priests, relied chiefly on magical or religious rituals. The third group, the lay physicians called *swnw* (pronounced something like "sounou"), relied chiefly on surgery and drugs, techniques that were also used by healing priests. How they learned their professional skills is not known, but most probably they learned from their fathers, and all were literate. Interestingly, not all were men: an inscription from the Old Kingdom period (2575–2134 BCE) describes a woman named Peseshet as the Lady Director of the Lady Physicians.

*Swnw*s usually accompanied armies into the field, and were employed at public works sites such as temples, pyramids, and quarries. The oldest known doctor's bill lists payments to a *swnw* who worked at the village of the workmen who built the tombs and temples of Thebes, in about 1165 BCE. Although physicians were paid only about a third as much as construction workers, *swnw*s sometimes achieved very high rank at court, and were rewarded accordingly.

The average age at marriage was 12–13 for women, and 15–20 for men. The fertility rate, at east among the few queens for whom we have data, was lower than might have been expected, about 3.5 births per woman, in part because children were not weaned until they were 3-years old. The average life expectancy at birth was probably about 30 years in the early Old Kingdom, and might have increased to as much as 36 years over the next 2,500 years. Evidence of very old age is scarce among mummies simply because most Egyptians died in their 30s, before the diseases that are typical of old age could have developed. A few kings and priests lived into their 90s, but fewer than 10% of Egyptians lived longer than 40 years. By contrast, about 94% of modern Americans die after age 40, and their life expectancy is about 76. As in most preindustrial cultures, both the population and the average life expectancy rose (and the death rate fell) when the food supply increased, as farmers increased their ability to exploit the Nile with improved irrigation systems.

Egyptians well understood the biological relationships among the testes, penis, semen, and pregnancy. However, because much of their anatomical knowledge came from cattle, they thought that semen was produced in the bone marrow, even if they also knew that removing the testes – castration – prevented any possibility of fatherhood. On the other hand, they knew nothing about the ovaries, and thought that women's role in reproduction was simply to nourish the fully formed seed that the father planted in the fertile uterus. Although the *swnw* did not attend births, he did treat women's medical problems. He attributed menstrual abnormalities to malpositions of the uterus, which meant that many "gynecological" treatments were designed to restore it to its proper position.

It has been difficult to learn much about the actual causes of death in ancient Egypt, despite the hundreds of mummies in the world's museums. Several have been studied nondestructively, using X-rays and CAT scans. Such noninvasive techniques can easily reveal diagnoses such as fractures, dislocations, calcified arteries, and gall stones, but such conditions need not be fatal per se. X-rays of 26 royal mummies from the New Kingdom (1550–1070 BCE) period have revealed more about their age at death, their teeth, and about mummification techniques, than about their illnesses, and even less about the causes of their deaths. The few mummies that have been dissected have provided surprisingly little specific pathological information, partly because most Egyptians probably died of infections that left few anatomical traces, and partly because mummification usually destroyed potentially diagnostic tissues. On the other hand, Egyptians may have been so thinly scattered along the river that many infectious diseases could not easily have propagated themselves. Nevertheless, in some places at least, the population may have finally become sufficiently dense over the centuries to facilitate the spread of such diseases.

Not all evidence of illness in ancient Egypt has come from human remains. A few statuettes show spinal distortions characteristic of tuberculosis of the spine, as do several mummies. Similarly, both a funeral monument and a mummified leg show the dropped foot deformity typical of poliomyelitis (although it could also have been a club foot). Identifiable illnesses are not found in the detailed pictures of everyday life that adorn tombs, since sickness had no useful role in the next life.

In addition to tuberculosis, Egyptians had many of the diseases we have, although in different proportions of the population, plus several protozoal and worm infestations that are still found along the banks of the Nile, such as trachoma and schistosomiasis. Most of the nontraumatic illnesses that occurred in ancient Egypt have not been identified in modern terms, but the Ebers Papyrus shows that the *swnw* classified them by their anatomic location, such as the skin, hair, abdomen, limbs, genitalia, and so on.

The Edwin Smith Surgical Papyrus contains several "firsts" in the history of medicine, including the first written descriptions of any surgical procedures, and the earliest examples of inductive scientific reasoning. The 48 cases described in the monograph are organized anatomically, from the top of the head down through the neck to the upper arm and chest; the scribe stopped transcribing the text when he reached the section on the upper spine. Because many injuries described in the Smith Papyrus were probably battle wounds, its prognostic predictions can also be taken as early examples of systematic battlefield triage.

The original author of this surgical text classified injuries by their extent and severity, and by their localization in bone or flesh, and established a systematic procedure for dealing with each kind of problem. Each chapter is devoted to a different injury, beginning with clinically important phenomena that could be seen or palpated, followed by a diagnosis based on facts elicited during the examination, and concluding with a prognosis. The prognoses are in three standard forms: injuries that are treatable, those of uncertain outcome that the *swnw* will try to treat anyway, and those that are unlikely to respond to any treatment, such as depressed skull fractures and compound fractures. The latter prognosis usually leads to the recommendation that nature be allowed to take its course.

Ancient Egyptian surgery provided simple, practical solutions to a number of self-evident problems. Today, most of it would be called "minor surgery," such as incising and draining abscesses, removing superficial wens, tumors, and so on. Circumcision was practiced on adolescent boys, but by priests, not physicians. The *swnw* did not perform major operations such as amputations, although he did try to reduce simple fractures and dislocations. Penetrating wounds were drained and cleaned. The *swnw* used adhesive plasters, not sutures, to hold wound edges together.

He differentiated between "diseased," or infected, wounds, and "nondiseased" wounds, which we would call "clean." The Smith Papyrus recommends daily inspections so that dressings can be changed when necessary. Many wound ointments were made with honey or the green copper ore malachite. Recent experiments have shown that both substances could have been effective against the kinds of bacteria most often found in contaminated wounds, permitting them to begin healing of their own accord.

When it came to what we now call internal medicine, magicians and healing priests relied largely on spells and incantations to cure their patients, and on amulets, written spells, and repulsive materials like animal feces to drive away or prevent illness. Sometimes they relied on healing statues standing in sacred ponds, so that patients who bathed in the same water would be cured by the god to whom the statue was dedicated. Late in pharaonic history, a patient might be instructed to sleep in a temple, expecting that its god would send him a dream that would reveal his cure, a procedure called "incubation."

The *swnw* might not have understood the underlying pathology of nonsurgical illness, but he had a logical, even if speculative, theory of disease. According to the medical historian Henry Sigerist, "Physiology began when man tried to correlate the action of food, air, and blood." The Egyptians saw the heart as the focal point of that correlation. It was the body's most important organ, and the seat of intelligence and emotion.

The *swnw*, who knew that air is vital to life, thought that it passed through the trachea to both the heart and the lungs. From the heart it traveled, in blood and along with other fluids, to other organs in primary afferent ducts called *metu*. From those organs a series of secondary *metu*, or efferent ducts, led to the surface of the body. The body's secretions and excretions, including phlegm, tears, semen, urine, and even a little blood, escaped through that second set of *metu*. This concept permitted the *swnw* to exploit a fairly plausible theory of disease. He could accept the *metu* as fact chiefly because Egyptians could not differentiate arteries, veins, nerves, and tendons anatomically. They thought that all of them were hollow *metu* that transported disease, in the form of a foul substance called *ukhedu*, to various organs, depending on how many *metu*, and which ones, were involved.

Because decay and foul odor characterize both normal feces and death, the potentially fatal *ukhedu* was thought to originate in the feces as the residue of incompletely digested food. Indeed, postmortem putrefaction is most noticeable in the intestines. Thus, if any *ukhedu* were allowed to accumulate to overflowing within the intestines, the excess would overflow up into the *metu* that normally carry blood from the heart to the intestines, so that the excess traveled backward to the heart. From there it could then enter other primary or secondary *metu* and be carried to other organs. Once it had entered a given *metu*, the *ukhedu* in that vessel could destroy the blood in it, producing pus. When it reached other organs, the pus would settle in and produce disease in them. Thus, the appearance of pus on the surface of a wound was a favorable prognostic sign, inasmuch as it signified that it was escaping and not accumulating within the body. Many treatments were designed to help *ukhedu* escape from the body. For instance, because boils were obviously filled with pus, they were opened so that the dangerous *ukhedu* could escape. Similarly, the standard wound ointments made with malachite or honey would counteract *ukhedu* that surfaced in a wound.

Egyptian drugs included many animal parts. Almost no clinical selectivity was associated with any of them, although ostrich eggs were used somewhat selectively in diarrhea remedies. Most of the animal products used in drugs, such as fat and grease, were used principally as emollients in wound ointments. In addition, the blood of several species was thought to be modestly selective for hair problems and eye trauma. But most animal parts used in drugs were included chiefly because of their magical associations. For instance, since ravens are black, their blood was used to treat the Egyptians' black hair; stallion semen was used to restore sexual drive; and fish skulls appear in headache remedies.

By contrast, the majority of drugs recommended in the Ebers Papyrus was aimed at disorders of the gastrointestinal tract, followed by remedies for the eyes, limbs, and skin. The *swnw* classified accumulations of *ukhedu* in the *metu*-ducts as gastrointestinal disorders, because the *ukhedu* originated in the alimentary canal. Thus, cathartics were usually prescribed to help flush *ukhedu* out of the rectum before it could accumulate to dangerous levels. Although some remedies for disturbances within the *metu* or the intestines do promote bowel movements, many laxative or cathartic drugs were used to treat nonintestinal symptoms. For instance, the mild laxative aloe was sometimes prescribed for eye disease, and the strong laxative colocynth for respiratory ailments. Thus, it seems likely that the *swnw* thought that all cathartics were at least somewhat selective for removing *ukhedu* from both the rectum and the *metu* which distributed it in the body.

Constipation implied that accumulated *ukhedu* could not escape by its usual route through the anus. Indeed, an Egyptian might take strong laxatives 3 days a month just to prevent *ukhedu* from filling up, and overflowing from, his rectum into his *metu*, whence it might reach his heart. Although diarrhea was a frequent complaint, sometimes it was not treated at all, because plentiful stools implied that the bowels were being adequately emptied of the dangerous *ukhedu*.

Honey, the most popular of all drug ingredients mentioned in the papyri, was used not only in wound ointments, but also in both laxatives and antidiarrheals, and in many other remedies. Since it was not used for any one kind of clinical problem more often than another, we can infer that honey was not used very selectively for symptoms associated with any particular organ system. Honey was probably regarded as selective for the *ukhedu*, especially when it appeared in wounds as pus.

The next most frequently used drug was called *djaret*. The word has not yet been convincingly translated, but it was clearly a plant product. Because it appears in about half of all prescriptions for diarrhea, *djaret* was probably thought to have some selectivity for that problem. In addition, it was included in a third of the prescriptions for eye diseases, and may have been thought to be at least modestly selective for them. However, whatever it was, *djaret* was also prescribed for many other disorders, so it must have been regarded as a multipurpose drug, even if as not as a panacea. Frankincense, too, was often prescribed for many illnesses, but it was aimed most selectively at pains of the head and limbs, and less often at intestinal problems. Like the mysterious *djaret*, an antimony ore was applied to eye problems.

The next most frequently used ingredients were applied fairly nonselectively, although some were often used in both laxative and antidiarrheal mixtures. The pulp of the colocynth gourd is a very powerful cathartic that was also used for the latter purpose. Figs were used for abdominal pains and urinary disorders. Malachite was aimed at eye problems; it could not be taken internally because copper salts cause vomiting. It probably first entered medical usage as a topical ointment after long usage as an eye cosmetic. The author of the Ebers Papyrus knew about the laxative property of castor oil, but he included it in only a very few recipes for cathartics; he thought it was better suited for making women's hair grow. Like many other Egyptian remedies, it, too, survived in Western medical usage until well into this century, but as a cathartic, not as a hair restorer. However, most of the 328 different drug ingredients mentioned in the Ebers Papyrus were used for almost any illness.

Although Egyptian physicians prescribed a wide variety of remedies, they appear merely to have dispensed predetermined remedies to patients with similar ailments; the *swnw* seems not to have treated each patient as an individual. That concept would not be introduced until Greek medicine began to flourish in the fifth century BCE. There is no evidence that any of the *swnw*'s remedies, save for malachite and honey, when applied topically, had any truly beneficial effect on the outcome of ancient patients' illnesses, nor is there any modern reason to think so. Although they may not have known it, ancient physicians were able to rely on their drugs, and even on their magical spells, because of the body's impressive ability to use mechanisms such as the immune and inflammatory responses to heal itself of most ordinary ailments. By contrast, Egyptian surgery probably did provide reasonably effective treatments for many traumatic injuries.

Animal Domestication

Christine M. Rodrigue

Animal domestication is the process by which humans exert direct or indirect, conscious or unconscious influence over the reproduction and evolution of animals that they own or otherwise manage (Rodrigue 1987: 1). There is quite an extensive continuum between wild species utilized as resources by humans and fully domesticated species (Russell 2002; Terrell et al. 2003). The question of "origins" depends on a choice of where to draw the line between "wild" and "domesticated" along this continuum, and that choice is often the basis of arguments about the "earliest domestication" of many species.

A fully domesticated animal exhibits significant genotypic and phenotypic differences from its nearest wild relatives due to its evolution under conditions dominated by humans. The domestication of animals and plants is one of the most important impacts that humans have had on their natural environments, ultimately the root of the contemporary global economic system and its marvels and tragedies. For most of human existence, people did not tend crops and care for animals, living instead as seasonally migratory gatherers, hunters, and fishers of wild food sources.

The Geography of Domestication

The archaeological record of settlements, bones, pollen, and artifacts indicates that settled societies based on plant and/or animal domestication go back roughly 10,000–11,000 years in certain areas of the world. Archaeological research into the earliest domestications has tended to focus largely on the Near East. For example, suggestions of goat (*Capra hircus*) domestication reach back about 10,000 years in western Iran (Zreda and Hesse 2000), sheep (*Ovis aries*) domestication some 10,500 years in northernmost Iraq (Perkins 1964), and pig (*Sus scrofa*) domestication possibly as early as 11,000 years ago in southeastern Turkey (Pringle 1998a; Rosenberg et al. 1998). The early domestication of barley (*Hordeum vulgare*) is evidenced in the Levant some 10,000 years ago, while einkorn (*Triticum monococcum*) and emmer (*T. turgidum*) wheats trace back to southeastern Turkey and northern Syria nearly 11,000 years ago (Lev-Yadun et al. 2000; Özkan et al. 2002). The cultivation and domestication of rye (*Secale cereale*) may well go back 13,000 years (Pringle 1998b). Within roughly a millennium, plant and animal domesticates were joined together in agriculture and husbandry complexes, which quickly spread throughout the ancient Near East and beyond.

Other parts of the world, however, saw similar, apparently independent domestications and assemblages of crop and animal complexes. Some of these include New Guinea with taro (*Colocasia esculenta*), going back 10,000 years, and banana (*Musa* spp.), going back nearly 7,000 years (Denham et al. 2003); eastern China, with rice (*Oryza sativa*) cultivation going back at least 11,000 years (Mannion 1999) and chicken (*Gallus gallus*) domestication nearly 8,000 years (West and Zhou 1988); Southeast Asia, with still controversial signs of cultivated cucumbers (*Cucurbita* spp.), water chestnuts (*Trapa natans*), peppers (*Piper* spp.), almonds (*Prunus dulcis*), and betel nuts (*Piper betel*) dating back 11,000–9,000 years and possible chicken domestication before 8,000 years ago (Gorman 1969; Fumihito et al. 1996; Yen 1977); Africa having domesticated cattle (*Bos taurus*), donkeys (*Equus asinus*), African rice (*Oryza glaberrima*), pearl (*Pennisetum glaucum*) and finger millets (*Eleusine coracana*), sorghum (*Sorghum bicolor*), teff cereal (*Eragrostis tef*), yam (*Dioscorea* spp.), cowpea (*Vigna unguiculata*), okra (*Abelmoschus esculentus*), oil palm (*Elaeis guineensis*), cola (*Cola* spp.), and coffee (*Coffea canaphora*) variously going back 10,000 BP (cattle) to 2,000 BP, with several distinct centers of domestication: northeast Africa, west Africa, and the Ethiopian highlands (Hanotte et al. 2002; Harlan 1971).

In the New World, northwestern South America and highland Mexico began the domestication of gourds and squashes (*Cucurbita* spp.) 10,000–12,000 years ago (Piperno and Stothert 2003), while maize (*Zea mays*) domestication has been traced over 6,000 years before the present (BP) in Mexico (Piperno and Flannery 2001). Potatoes (*Solanum tuberosum*) go back about 8,000 years ago near Lake Titicaca in the Andes (Roach 2002). Other crops domesticated in the New World include tomato (*Lycopersicon esculentum*), peppers (*Capsicum* spp.), tobacco (*Nicotiana tobaccum*), and cacao (*Theobroma cacao*) (Sauer 1969). The New World domesticated few animals, however. Alpaca (*Lama pacos*) and llama (*L. glama*) domestication goes back 6,000–7,000 BP in Peru (Wheeler 2003), as does guinea pig (*Cavia porcellus*) domestication there (Sandweiss and Wing 1997). Turkey (*Meleagris gallopavo*) may go back 500–2,000 years ago in the Pueblo cultures of the American Southwest (Pinkley 1965).

Sequencing of Animal Species Entering Domestication

In terms of the sequence of animals entering domestication, the dog (*Canis lupus familaris*) is widely considered the first domesticate. The oldest tentative identification of domestic dog remains through traditional archaeological methods goes back about 14,000 years in Germany (Benecke 1987). Dog remains are also found dating from 12,000 years ago in Israel (Tchernov and Valla 1997).

DNA analysis has begun to transform the archaeology of domestication, most dramatically in its recent application to a large sample of living dogs of a variety of breeds, in order to determine how far back the domesticated breeds began to diverge from their common ancestor (Vilà et al. 1997). This approach has yielded the startling and still contested figure of 135,000 BP, while analysis of patterns of variation in mitochondrial DNA suggests a concentration of genetic diversity (indicative of an ancestral population) in East Asia with divergence from wolf populations there roughly 15,000 BP (Savolainen et al. 2002). All dogs are now known to be domesticated wolves (hence the Latin species name change from *Canis familiaris* to *C. lupus*), most being descendants of smaller subtropical subspecies. The earliest dogs may have been pets, self-domesticating scavengers, and convenient sources of meat.

Several species entered domestication in a second, nearly simultaneous development from 11,000 to 8,000 years ago: the sheep, the pig, and the goat, as discussed above, and possibly cattle, chickens, and cats (*Felis sylvestris catus*) as well. Domesticated cattle are evidenced in south central Turkey some 8,400 years ago (Grigson 1989; Perkins 1969), but there is recent DNA evidence that a line of cattle was domesticated even earlier in northeast Africa about 10,000 BP (Hanotte et al. 2002). Domesticated chickens appear in northern China around 8,000 years ago (West and Zhou 1988), and mtDNA studies imply they were domesticated sometime before that in Thailand and neighboring areas (Akishinonomiya et al. 1996). Cats may have been domesticated as early as 9,500 years ago, judging from recent finds in Cyprus (Vigne et al. 2004).

A third wave of animal domestications occurred roughly 7,000–5,000 years ago, this time involving the New World, too. The species involved included South American camels – llama and alpaca – in Peru approximately 6,000–7,000 years ago (Wheeler 2003); the pigeon (*Columba livia*) in Mesopotamia and Assyria 6,000–7,000 years ago (von Hünerbein and Rüter 2000: 20); the horse (*Equus caballus*) in the Ukraine, southernmost Russia, and westernmost Kazakhstan, about 6,000 years ago (Vilà et al. 2001); the donkey in northeast Africa and possibly also in Somalia about 5,000 years ago (Beja-Pereira et al. 2004); the Bactrian camel (*Camellus bactrianus*) perhaps 5,000–6,000 years ago in Northwest China and perhaps 4,000–5,000 year ago in Turkmenia and eastern Iran (Wild Camel Protection Foundation n.d.); dromedary (*C. dromedarius*) in the Arabian Peninsula about 5,000 years ago (Larson and Ho 2003); water buffalo (*Bubalus bubalis*) in India and southern Iraq about 5,000–6,000 years ago (National Research Council 1984); yak (*Bos grunniens*) in Tibet around

5,000 years ago (Li et al. 2003); and the silkworm (*Bombyx mori*) in China about 5,000 years ago (Yamauchi et al. 2000: 17).

A number of minor domestications have taken place from that time to this, such as the rabbit (*Orytrolagus cuniculus*), ferret (*Mustela putorius*), cormorant (*Phalacrocorax carbo*), turkey, carp and koi (*Cyprinus carpio*), and goldfish (*Carrasius auratus*). Domestications continue at the present, including parakeets (*Melopsittacus undulatus*), canaries (*Serinus canaria*), diamond doves (*Geopelia cuneata*), mink (*Mustela vison*), laboratory rats (*Rattus norvegicus*), foxes (*Vulpes fulvus*), aquarium fish, and ongoing experimental domestications of livestock, such as eland (*Taurotragus oryx*) and fallow deer (*Dama dama*) (National Research Council Board on Science and Technology for International Development 1991).

Why Domesticate Animals?

Why did people give up the hunting of animals for the work entailed in domesticating them? The factors involved differ by species and human circumstance. The simple human tendency to pet keeping no doubt played a role.

Nomadic hunters–gatherers could have domesticated certain herd animals (Ingold 1980). Such peoples as the reindeer-herding Saami of northernmost Europe sometimes follow the migratory herd species (*Rangifer tarandus*) all year and influence the direction and spatial cohesion of the animals through driving and herding. They selectively cull the animals, which amounts to the evolutionary pressure associated with domestication. The reindeer nomads may have been exploiting reindeer for as long as 20,000 years (NRC Board on Science and Technology for International Development 1991: 285). It is not clear, however, whether migratory herding hunters in the past actually undertook independent domestications of the animals they hunted or adopted the idea later from nearby agriculturalists and associated pastoral nomads.

Settled cultivators may have had a variety of reasons to undertake the control and maintenance of animal populations. Their crops, food stores, and even their salty latrine areas attracted animals, inviting reciprocal exploitation (Zeuner 1963). The small southern wolves would steal scraps of food and may have been tolerated as a garbage disposal system. Fields, grain stores, and latrine areas would attract bovine species. The granivorous and cliff-nesting pigeons would descend on early cereal fields and roost in nearby buildings (Woldow 1972). The opportunities for coevolutionary interactions between people and animals increased once people settled and especially once they took up crop cultivation (Rindos 1984).

Certain scholars have argued that settled cultivators had no particular economic or ecological need for animals, and animal management does entail work and can prove dangerous. They feel that the earliest animal domestications provided sacrifices for sacred rituals or amusement for gamblers (e.g., Isaac 1970). This argument has not done well in archaeological testing (Rodrigue 1992), but the data may not yet be complete enough to dismiss the argument entirely (Akishinonomiya et al. 1996: 6795). Other scholars have worked out coevolutionary ecological contexts for animal domestications (Rindos 1984) and economic arguments relating to relative time costs and resource yields of hunting and husbandry in different contexts (Alvard and Kuznar 2001; Layton et al. 1991).

In some cases, people may have at least partially domesticated an animal species and later abandoned it. Gazelles (*Gazella gazella*), for example, may have been in the process of domestication in the ancient Levant around 11,000 years ago, later being replaced by goats and sheep (Bar-Oz et al. 2004; Legge 1972; Moore et al. 2000). These latter may have had some sort of advantage over indigenous domesticates. Military displacement and conquest of one culture by another could have replaced one constellation of animal domesticates with another. Religious taboos have caused species to be dropped from husbandry in given areas (e.g., pigs in areas of Jewish or Muslim religion).

To resolve these different issues and disputes over their interpretation will take considerable work. Much of the world has never had adequate coverage of its archaeological heritage. Archaeological funding has been biased toward those areas regarded rightly or wrongly by Westerners as somehow connected with their own culture histories, such as the Biblical Levant and Mesopotamia, Egypt, ancient Greece and Rome, Europe, and even Mesoamerica and Peru (due to Mormon religious interest in the region). There are many tantalizing indications that archaeological work in other areas in the non-Western world, applying the many new techniques and technologies available, will transform our present perceptions of the origins of domestication.

Animal Mummies

SALIMA IKRAM

Although it is commonly known that the ancient Egyptians mummified humans, it is a less well-known fact that they also mummified animals. Animals were mummified for the same reason as humans: to preserve their bodies so that they could live forever. This suggests that a belief in animal souls was a part of Egyptian religion.

Mummification is the preservation of a body through artificial means. In terms of animal mummies it varied somewhat depending on the time period and the type of mummy that was being created. The basic principle, however, remained the same: to desiccate the body using natron (a naturally occurring compound of salt and soda found in the Wadi Natron in Egypt) or even salt. Once the corpse was desiccated, it was anointed with oils and resins and wrapped in linen bandages. There are four types of animal mummies: food offerings, pets, sacred animals, and votive offerings. Pets and sacred animals seem to be the most carefully mummified, while votive offerings are the most carelessly prepared. The preparation of food offerings varies.

Food or victual mummies consist of mummified foods for humans, such as beef ribs, steaks, joints of meat, ducks, and geese that were placed in tombs so the tomb owner could feast for eternity. The meat and poultry was prepared for consumption, so joints are cut, and the poultry is cleaned, ready for roasting. This mummy type was especially common in the New Kingdom (1549–1060 BCE) and the 21st Dynasty (1060–940 BCE).

Pet mummies were of animals beloved of their owners and therefore preserved so that they and their owners could enjoy eternity together. These appear throughout Egyptian history, though the better-known examples come from the New Kingdom and the 21st Dynasty, with the gazelle of Queen Isetemkheb D being an example from the latter period.

Sacred animals were animals that were worshipped during their lifetime as the spirit or *ba* of the god entered them, and upon their deaths mummified as were kings, and buried in sarcophagi which were interred in single or catacomb-like sepulchers. Whilst alive these animals would provide oracular advice. The Apis Bull, a manifestation of Ptah, and the Ram of Elephantine, the manifestation of Khnum are particularly well-known animal incarnations. Although the Apis is known from Dynasty I, the Serapeum at Saqqara where the mummies of these animals were kept dates to the 18th Dynasty (1549–1298 BCE) and later.

Votive offerings consisted of mummified animals that were dedicated to specific deities. Gods had specific animals that were their totems or symbols: cats were sacred to the goddess Bastet, goddess of pleasure, ibises and baboons to the god Thoth, god of learning, etc. These mummified animals were purchased and offered by pilgrims at shrines dedicated to these gods, and finally buried in deep catacombs. The mummified animals would present the prayers of the pilgrim to the god throughout eternity, much in the way votive candles are purchased and burned in churches. This type of mummy was common from the seventh century BCE until the fourth century AD (Fig. 1).

Not all mummy packages contain animals. A group of "fake" mummies, generally found amongst the votive offerings, have come to light during scholarly investigations. These consist of packages that are wrapped to look like real creatures, but either contain fragments of real animals, or rags and bits of mud or wood. In the case of the former the idea is that a part signifies the whole, while in the latter case, one might suggest that the appearance of the package and the identification of the bundle as a certain creature turns it

Animal Mummies. Fig. 1 A mummified cat in a sycamore wood coffin, CG 29783 from the Egyptian Museum, Cairo (photo by Anna-Marie Kellen).

Animal Mummies. Fig. 2 CG 51098 food mummy from the Egyptian Museum, Cairo (photo by Anna-Marie Kellen).

into that animal. Thus, when there was a paucity of actual animals to mummify the embalmers made these substitutions. On a more cynical note, these could be ways of defrauding unsuspecting pilgrims.

In the early days of archaeology most animal mummies were ignored and often discarded, or else taken away as casual souvenirs that illustrated the oddity of the Egyptians; they were never seriously considered as artefacts that could elucidate any relevant aspect of ancient Egypt. However, in more modern times scholars have realized that a study of these mummies can provide information about the fauna of the country and, indirectly, its climate, as well as animal domestication, veterinary practices, human nutrition, mummification itself, and the religious practices of the ancient Egyptians. Examining their wrappings can also inform us about chronological and geographical variations in production practices.

These mummies are currently studied in a variety of ways, all of which tend to be non-destructive. Visual examinations and radiography are most common. Sometimes CT-scans are employed. Destructive studies include tests on the wrappings and the flesh itself in order to determine the types of resins and other embalming materials used.

All sorts of animals were mummified, including: dogs, cats, ibises, raptors, shrews, crocodiles, snakes, cattle, rams, fish, and even scarab beetles. The practice of animal mummification reached is heyday in the Late and Graeco-Roman periods (700 BCE–AD 395), when sacred and votive animal mummies became increasingly popular. The many millions of ibis, cat, and dog mummies that have been found all date to these periods. The majority of animal mummies created in earlier periods belonged to the pet, food, and to some extent, sacred animal genres. Animal mummification ceased in the fourth century AD with the advent of Christianity (Fig. 2).

Approximation Formulae in Chinese Mathematics

Jean-Claude Martzloff

Approximation formulae may be used for various reasons. In some cases, certain computations (such as for example, the extraction of roots digit by digit) are by nature inexact. It may also be that exact solutions of certain problems are unknown or else that such solutions are theoretically known but deemed too complex, so that users prefer elaborating alternative solutions more or less accurate with respect to a certain context of utilization. The history of Chinese mathematics illustrates well these two aspects of the question.

Remarkably, many Chinese approximation formulae are also attested in Babylonian, Greek, Roman, Indian, and Mediaeval European mathematics. For example, the so-called "Hero's iteration formula" for the approximation of square roots converges quadratically to x is also found in the *Jiuzhang suanshu* (Computational Prescriptions in Nine Chapters, also translated as Nine Chapters on the Mathematical Arts) from the Han dynasty (206 BCE–AD 220).

Hero's iteration formula:
Let $x = \sqrt{n}$. Then, the sequence

$$x_k = x_k = \frac{1}{2}\left(x_{k-1} + \frac{n}{x_{k-1}}\right)$$

The approximation formula for the computation of the area of a quadrilateral by taking the product of the half sum of its opposite sides appears not only in the *Wucao suanjing* (Computational Canon of the Five Administrative Services), and the *Xiahou Yang suanjing* (Xiahou Yang's Computational Canon) (fourth century AD) but also in the Babylonian mathematical corpus,[1] in the writings of the Roman agrimensors (surveyors),[2] in Alcuin's *Propositiones ad acuendos juvenes* (Propositions to Sharpen the Minds of the Youth)[3] and numerous other places. The same remark also applies to the *false* formula for the computation of the area of a segment of a circle:

$$A = \frac{h(b+h)}{2}.$$

In the *Jiuzhang suanshu*. Such examples are much more numerous than historians of mathematics formerly imagined.

This striking phenomenon is an indicator of the strong unity of ancient mathematics. Recent research unceasingly confirms that ancient mathematics were not so much "Chinese" than "written in Chinese," "Indian" than "written in Sanskrit" and so on, even though, by any standard, the cultural imprint they bear is certainly very strong in each case. Nevertheless, this unavoidable conclusion has opened the way to controversial issues, especially when the famous mathematician and historian of mathematics van der Waerden deduced from this that all ancient mathematics have a common Indo-European origin. (Waerden 1983). This new theory has gained little acceptance and it is a fact that it surpasses by far the data on which it is based.

However, Chinese mathematics also contains examples of approximation formulae apparently not attested anywhere else. These all occur in Chinese astronomy and concern astronomical problems such as that of the determination of gnomon shadows or questions of conversions between the ecliptic (the band of the zodiac through which the Sun apparently moves in its yearly course) and equatorial coordinates.

1 More precisely in YBC 4675 (Neugebauer and Sachs 1945: 44–47).
2 References are given in Martzloff 1997: 325.
3 The *Propositiones* have been translated into German by M. Folkerts and H. Gericke, "Die Alkuin Zugeschriben Propositiones ad Acuendos Iuvenes (Aufgaben für Schärfung des Geistes der Jugend)." *Science in Western and Eastern Civilization in Carolingian Times*. Eds. L. Butzer and D. Lohrman. Bale: Birkhaüser Verlag, 1993. 288.

The monograph on mathematical astronomy of the Song Dynasty, the *Songshi* (Song History), an official text compiled between 1343 and 1345, for example, reports that between AD 1102 and 1106, Chinese imperial astronomers devised a new theoretical algorithm for the determination of the length of the shadow of the sun cast by a standard gnomon 8 *chi* (feet) long, each day, at noon, during a whole year. If t = the number of days elapsed since the last winter solstice and

$$s_1(t) = 12.83 - \frac{20,000t^2}{100\left(100,617 + 100t + \frac{10,000t^2}{725}\right)},$$

$$s_2(t) = 1.56 + \frac{4t^2}{7,923 + 9t},$$

$$s_3(t) = 1.56 + \frac{7,700t^2}{13,584,271.78 + 44,718t - 100t^2},$$

at Kaifeng, the Song imperial capital whose latitude is 34°48′45″, the length of the shadow of the gnomon is computed as follows (the original text is formulated in words, with no symbols, but its interpretation is straightforward):

if $t < 662.2$	$l(t) = s_1(t)$
if $< 62.2 < t < 91.31$	$l(t) = s_3(182.62 - t)$
if $< 91.31 < 182.62$	$l(t) = s_2(182.62 - t)$
if $< 182.62 < t < 273.93$	$l(t) = s_2(t - 182.62)$
if $< 273.93 < t < 303.04$	$l(t) = s_3(t - 182.62)$
if $< 303.04 < t < 365.24$	$l(t) = s_1(365.24 - t)$

The various numerical coefficients appearing in these formulae all depend on the lengths of the seasons.)

Chen Meidong, a contemporary historian of Chinese astronomy from the Academia Sinica in Beijing, has compared the results provided by these approximate formulae and those of actual observations (simulated for the years 1102–1106 by using the modern astronomical theory of the sun backward). He has concluded that the error never exceeds 0.02 *chi*, that is much less than a centimeter! Yet Song astronomers were still not satisfied with their approximation and sought new formulae; some of these have reached us. Incidentally, these formulae are vaguely reminiscent of the Indian approximation formula for the sine, cosine, and other trigonometric functions cited in (Gupta 1972). In both cases the approximations use rational fractions.

Another interesting approximation formula occurs in the *Yuanshi* (Yuan History), an official compilation written about AD 1370 but reporting on Guo Shoujing's astronomical reform undertaken one century earlier. (Guo Shoujing (1231–1316) was a specialist on canal draining and astronomy.) Without going into too much detail, we note that Guo's technique was devised to compute certain segments corresponding to given arcs of circles similar to those which arise when converting ecliptic coordinates into equatorial coordinates. For us the question is solved in a relatively simple way by means of spherical trigonometry. But plane and spherical trigonometry were both unknown in China at the time, so that the mathematical techniques of Chinese astronomy had necessarily to rely on approximation formulae. In particular, Guo's technique relied on the three following formulae:

$$(1)\quad p = \sqrt{r^2 - q^2} = \sqrt{(2r - v)v},$$

$$(2)\quad x = p + \frac{v^2}{2r},$$

$$(3)\quad v^4 + (4r^2 - 4rx)\,v^2 - 8r^3v + 4r^2x^2 = 0,$$

where r represents the radius of the "trigonometric" circle, and p, q, and v the sine, cosine, and versed sine of the arc x, respectively.

Formula (1) is exact; (2) and (3) are approximate. The polynomial of the fourth degree in v, (3), is the consequence of the elimination of the half chord p between the second part of (1) and (2); (3) serves to compute v given the arc x by finding a root (in fact the smallest positive one) of (3) by means of a technique similar to that which is usually known as "Horner's method" (from a method attributed to the British mathematician William George Horner (1786–1837) who lived five centuries after Guo Shoujing). Lastly we also observe that Guo Shoujing divides the length of the circumference into as many degrees as there are days in a year (365.25°) and computes the radius of the corresponding circle by dividing the circumference by 3 (i.e., by taking $\pi = 3$). A priori, the reliance on such a value of π would indicate a severe mathematical deficiency. However, when Guo Shoujing devised his techniques, better values of π, such as Zu Chongzhi's (429–500) celebrated approximation $\pi = 355/113$, were currently available in China. In fact, according to Toshio Sugimoto, a mathematical analysis of the above formulae shows that when (1), (2), and (3) are computed using approximations of π better than 3, worse results are obtained! The recourse to approximations disturbs the impeccable logic which would hold if exact representations were used.

These various examples show that approximation formulae are well represented everywhere but that some of them are attested only in China. As recent works by historians of Chinese astronomy indicate, the recourse to such formulae seems typical of Chinese astronomy (see the articles in the journal *Ziran Kexue shi yanjiu*, 1982–1994). Are Chinese approximation formulae really original or are they also found elsewhere? Further historical researches not limited to Chinese mathematics will perhaps shed some light on a question which has never really been studied in depth.

Archaeoastronomy of North Africa

César Esteban

In this article, I review data on orientations of pre-Islamic funerary and religious monuments in North Africa, including Sahara and the Maghreb and excluding Egypt, which has been extensively discussed elsewhere. The time span of the monuments discussed is extremely wide, from the Neolithic up to the Arabic invasion. The main conclusion is that there were enduring patterns in the orientations, very likely related to the ritual or symbolic importance of the rising sun. The overwhelming evidence confirms the strong solar aspects of the North African religion that the ancient writers indicated.

The prehistoric dry stone funerary monuments of the Sahara are called *idebnan* (in plural) and *idebni* (in singular) by the present-day Tuareg. There are several different architectural types and they are distributed in a very extended geographical area. Early European visitors realised that a large proportion of these monuments tend to be orientated with their main distinctive elements towards the east. The earliest type of *idebnan* is called "keyhole monument". Paris (1996) has obtained radiocarbon dates for some of these monuments in Niger (Emi Lulu) finding that they date from 3600–220 BCE. This kind of monument is found even more densely at Tassili (Algeria). Savary (1966) obtained that the orientations of 158 keyhole monuments in Fadnoun (Algeria) lie in the azimuth range where the sunrise (or moonrise) takes place, and can be described as a clear case of sun-rising (SR) custom following Michael Hoskin's definitions (Hoskin 2001: 19–20). Paris (1996) obtained a similar result for the orientations of the corridors of 17 keyhole monuments at Emi Lulu.

Another relevant type of Saharan dry stone prehistoric burial is the so-called V-shape monument which consists of a tumulus and two lines or arms of stones – also called antennae – that could be about some tens of meters or even up to 200 m long (see Fig. 1). These monuments are more concentrated in the Messak Settafet in the Fezzan region of Libya. The earliest monuments of this kind are dated about 3200–2900 BCE (Cremaschi and Di Lernia 1998). Hachid (2000) has compiled data for many *idebnan* in Tassili indicating that the antennae of most of the V-shape monuments of this zone are oriented to the east. Some of them are located in the middle of wonderful landscapes, facing the borders of the impressive mountain ranges of Tassili. Recent statistical studies of the orientations of 49 and 31 V-shape monuments of the Messak plateau (Fezzan, Libya) and Immidir mountains (Algeria) by Gauthier and Gauthier (1999, 2003; see Fig. 1) show that the bisectors of the antennae show a narrow range of orientations also consistent with a SR custom. Other kinds of dry stone monuments as the "platforms cairns with an arm" (Gauthier and Gauthier 1999) and "L shape monuments" (Gauthier

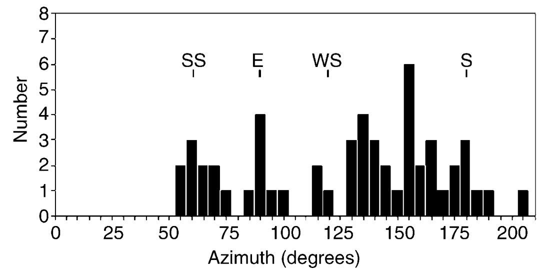
Archaeoastronomy of North Africa. Fig. 2 Number histogram of orientations of 132 V-shape monuments, "goulets" and "platform cairns with an arm running eastwards" of Immidir (Algeria) and Fezzan (Libya). Data are binned in 2° intervals. SS and WS indicate the azimuths of the rising sun at summer and winter solstices, respectively. Diagram adapted from Gauthier and Gauthier (2003). This is an example of a sun-rising (SR) custom of orientations.



Archaeoastronomy of North Africa. Fig. 3 Number histogram of orientations of 53 dolmens at Elles (Tunisia). Data are binned in 5° intervals. SS and WS indicate the azimuths of the rising sun at summer and winter solstices, respectively; E and S indicate east and south, respectively. Data taken from Belmonte et al. (1998). This is an example of a sun-rising/sun-climbing (SR/SC) custom of orientations.

and Gauthier 2001–2002) of Fezzan, as well as the "goulets" (narrow parts) of Immidir (Gauthier and Gauthier 2003) show exactly the same orientation pattern (Fig. 2).

Later types of Saharan stone burials such as "crater tumulus" and "monuments with an alignment", which are dated from 1900 BCE down to the start of Islamic culture locally, also have their structural elements as well as the head or faces of their skeletons oriented to the east (Hachid 2000). Other Saharan stone monuments – not necessarily related to tombs – as the so-called "horseshoe" structures with a straight line of little towers or altars are usually also oriented to the east, although with a much wider azimuthal distribution (Gauthier and Gauthier 2002). These monuments are also known as "tents of Fatima" and are supposedly rural shrines. However, some kinds of monuments such as the single or triple crescents of the Messak Settafet, some crescents of south Algeria, and the bazina/tumulus with small auxiliary towers of Morocco and Algeria do not follow the typical Saharan orientation customs (Gauthier and Gauthier 2002, 2003, 2005). In fact, the orientations of the last group of monuments could be oriented towards the rising or setting Moon (Gauthier and Gauthier 2005). It would be interesting to reassess the orientation data of Saharan monuments considering the correction due to the real (non-flat) horizon where the monuments are actually facing, a kind of analysis that has not yet been carried out in the area.

Earlier possible evidence of astronomical observances by the Neolithic Saharan people has been found at Nabta Playa in Egypt, on the border of the Libyan Desert (McKim Malville et al. 1998). Here a group of megalithic circles and stone rows dating from some time earlier than 4500 BCE are oriented to the summer solstice or zenith passage of the sun.

Burial monuments of coastal and pre-desert zones of North Africa from the first millennium BCE up to the Islamic conquest are extremely diverse. One can find simple and monumental dolmens, tumuli of very different typology, rock-cut tombs (*hawanat*), hypogaea (the subterraneous portions of a building or subterranean galleries, such as the catacombs), and the later great mausolea. In his magnificent book about protohistoric funerary monuments of North Africa, Camps (1961) admits that the orientation of the main entrances, façades and corridors of those burial monuments is in most cases consistent with a general east–west arrangement. This fact makes one wonder if the protohistoric orientation pattern is related to the ancient Neolithic Saharan traditions discussed above.

Savary (1969) analysed the precise orientations of 13 North African dolmens at Beni Messous (Algeria). He found that the orientation pattern could be classified as a sun-rising/sun-climbing (SR/SC) custom following Hoskin's scheme (Hoskin 2001: 19–20); this definition covers a range of azimuths from about 60° to due south or thereabouts. This range includes the sunrise and the position of the Sun while it is climbing in the sky or around culmination. Belmonte et al. (1998) have measured dolmens in different necropolises of Northern Tunisia. These authors find a clear SR/SC pattern for the orientations of megalithic monuments of the necropolis of Elles (see Fig. 3). A SC and a SR/SC orientation pattern seems applicable to the dolmenic necropolis of Thugga and the complex megalithic tombs of Mactar (see Fig. 4), respectively. On the other hand, the very rough and simple dolmens of Bulla Regia show a highly unusual westerly orientation. Hoskin and Foderà Serio (private communication) and Hoskin (2001) consider that the reason for the orientation of the dolmens in the Tunisian necropolises of Elles, Henchir Midad and some others around the town of Mactar, is simply topographical: they are facing downhill. However, the orientations of Henchir Midad have been further discussed by Belmonte et al. (2003) stressing their astronomical significance. They

Archaeoastronomy of North Africa. Fig. 4 Complex megalithic tomb of Mactar (Tunisia) with six chambers.

Archaeoastronomy of North Africa. Fig. 5 Group of rock-carved tombs (*hawanat*) at Chauach (Tunisia).

Archaeoastronomy of North Africa. Fig. 6 East-facing chapel tumulus of Taouz (Morocco). Photograph reproduced from Belmonte et al. (2002).

have studied the several groups of Numidian dolmens of Northern Tunisia, finding a general SR/SC orientation pattern. Finally, it is remarkable that the orientations of several groups of rock-cut tombs (*hawanat*) of Northern Tunisia analysed by Belmonte et al. (1998, 2003) also show orientations following the typical SR/SC scheme (see Fig. 5).

It is mostly accepted that the North African dolmens were earlier than the Roman conquest, perhaps prior to the Phoenician expansion, and clearly after the Neolithic (Camps 1961: 146–148). The distribution of the North African dolmens along the Maghreb suggests that their origin is not autochthonous and should be the Iberian Peninsula for the monuments of the north of Morocco and Sardinia, Corsica, Italy and/or Malta for the Algerian–Tunisian group (Camps 1961: 149–152, 1995a: 2508–2509). In this context, Camps remarks on the important role that Sardinia could play in this transmission. He notes that Diodorus Siculus (Diodorus V, 8) and later Pausanias affirmed the Libyan origin of the Sards. In fact, Hoskin (2001: 175–192) has found that the 97.7% of around 200 Sardinian dolmens, *corridoi dolmenici* and *tombe di giganti*, show the same orientation custom as the North African dolmenic and *hawanat* necropolises. Therefore, taking into account the differences with respect to the most common ancient Saharan pattern of orientations – which is clearly SR – the data are consistent with an alien origin of the North African dolmens and *hawanat*.

Information about the orientations of the most common protohistoric North African burial monuments – stone and earth tumulus and *bazinas* (classified as autochthonous by Camps 1961: 60–62) – is rather scarce, mostly because of the impossibility of defining an axis of symmetry in most of them. However, we have information about some groups of stone monuments: chapel-tumuli, niche monuments and the great Algerian mausolea. In the case of the chapel tumuli, there are detailed studies of two necropolises of the Tafilatl: the chapel-tumuli of Taouz (see Fig. 6) show an apparent SR custom in their orientation (Belmonte et al. 1999; Castellani 1995), while the monuments at Hassi Beraber seem to be oriented somewhat more southerly, consistent with a SC custom (Castellani 1995). Camps (1961: 180–184 and references therein) reviews data for the chapel-tumuli of the necropolises of Bouia (Tafilatl) and Negrine, pointing out that all the monuments are oriented with their entrances facing east. From published plans of the chapel-tumuli of Djorf Torba, Belmonte et al. (1999) find two predominant orientations, to nearly due east and to southeast. Southeast and east seem also to be the orientation of a sample of circular niche monuments at d'El-Esnam and Kef Sidi Attalah, respectively (see Camps: 1961: 177–178 and references therein). Belmonte et al. (1999) also study 34 skylight-tumuli in the necropolis of Foum al Rjam in the Saharan Morocco, finding a clear SR/SC custom in their orientation.

The most evolved and impressive pre-Islamic burial monuments of North Africa – the Algerian great mausolea (Medracen, Blad el-Guitoun, Tombeau de la Chrétienne, Djedar), which show clear Punic architectural and stylistic influences – have their ceremonial corridors and external platforms oriented towards the east (Camps 1961: 199–205). In particular, the Djedar of north Algeria are especially interesting because of their late chronology, which is as late as the fifth and sixth century AD, just before the Arabic conquest (Camps 1995b: 2419–2422). They represent the end-point of the genuine pre-Islamic North African funerary traditions.

Elements of the proto-Berber culture survived in the Canary Islands until its conquest by the Castilians in the fifteenth century. Belmonte et al. (1997) obtain orientation diagrams of the burial chambers of several important tumular necropolises in the islands of Gran Canaria and Fuerteventura, finding a SR (or sunsetting) custom in the necropolis at Tirba mountain (Fuerteventura) and for the dry stone tumuli of Maipez (Gran Canaria). Perhaps as a reflection of the mixed trends found in the continent, a SC custom is found for the tumuli of Arteara (Gran Canaria).

In the land of the Garamantes (Fezzan, Lybia), one finds burials of very different typology perhaps associated with the different cultural contacts experienced by this warrior people. The extensive excavations carried out by Daniels (1989) point out that the Garamantian tombs are mainly dated from Roman times. Belmonte et al. (2002) have studied the orientation of funerary monuments in some of the most representative Garamantian necropolises as the pyramidal tombs of Charaig and El Hatir (see Fig. 7), the mud-brick tombs of Saniat ben Howedi, and the mastaba-like royal tombs at Germa. The pyramidal tombs are arranged with their four sides oriented approximately to the cardinal points. Many of the tombs of Saniat ben Howedi have stone offering-tables and are facing near due east or due west. The most clear orientation pattern is shown by the mastaba-like and circular tumulus (with a stele showing the relevant direction) of the royal necropolis of Germa; all the tombs measured are oriented to the east, following a clear SR custom. Although the formal similarity to the Egyptian monuments is evident and even the presence of obelisks

Archaeoastronomy of North Africa. Fig. 7 Field of Garamantian pyramidal tombs at El Hatir (Fezzan, Libya).

or stelae in their proximity could suggest a direct Nilotic influence, this is not entirely clear. Camps (1961: 165–166) indicates that the Garamantian monuments are not very different to the pre-Islamic rectangular *bazinas* of late chronology that can be found elsewhere in North Africa, whose geographic distribution cannot be explained by a gradual diffusion from Egypt. Moreover, their orientation pattern is also consistent with the typical customs of the rest of the contemporary North African funerary monuments and especially with the much older and autochthonous *idebnan* of the Fezzan.

It is generally accepted that the impact of the Punic culture was profound and enduring on the Libyan or proto-Berber culture and especially on their religion (Picard 1954; Bénabou 1975: 377–380). There are interesting facts about the orientations of Punic funerary monuments. Belmonte et al. (1998) find a clear SR custom in the early Punic necropolis of Utica and a doubled-peaked distribution centred on the sunrise at the equinoxes and the winter solstice in Menzel Temine and the early Phoenician necropolis of Villaricos in the southern Mediterranean coast of the Iberian Peninsula (Belmonte 1999; his Fig. 5.5). A general east–west orientation is also found for the Punic necropolises of Tipasa in Algeria (Baradez 1969) and of Aïn Dalia Lekbira in north Morocco (Alaoni 2000). González García et al. (2006) have measured a large number of tombs in the Punic necropolises of Sardinia and Ibiza, finding a general tendency of orientations towards the solstices and equinoxes. However, there is not a regular orientation in all Phoenician/Punic necropolises studied. In Byrsa (Carthage), Belmonte et al. (1998) have found a rather unusual south–west distribution. In Dermech (Carthage) the orientations show an azimuth preference between 120° and 160°. Finally, the Maltese shaft tombs and burial chambers studied by Ventura (2000) show a clear preference for the approximate north–south direction. It is also interesting to remark that the general planning of the Punic sacred areas or tofets in Sicily and Sardinia is usually arranged along the cardinal axes (Ribichini and Xella 1994). Finally, an additional interesting archaeological indication was obtained by Carton, who found that in an open sacred area in Thuburnica (Sidi-Ali-Bel-Kassem, Tunisia), all Neo-Punic stelae were orientated to the east (see Leglay 1961: 276). In summary, there is not a regular pattern in the orientations of the Punic tombs, although many necropolises and funerary areas show an east–west custom. This has also been observed in the Phoenician-Punic necropolises of south Spain, where the archaic tombs (eighth–seventh centuries BCE) tend to be oriented to the east and the later ones do not follow that rule so strictly (Ramos Sainz 1986: 32–33).

The Roman custom of building mausolea or monumental tombs was also common in North Africa, especially from western Algeria to Tripolitania.

Belmonte et al. (2002) compiled data on some different monuments of Roman epoch and most of them were oriented following an SR custom. However, the largest concentration of mausolea from the late Roman epoch is in the settlement of Ghirza, in the Libyan pre-desert. The plans published by Brogan and Smith (1984) show that the doorways or the ornamental false doors of the tombs of the northern group show a clear SR custom, whilst the tombs of the northern complex are oriented towards the north (Esteban 2003).

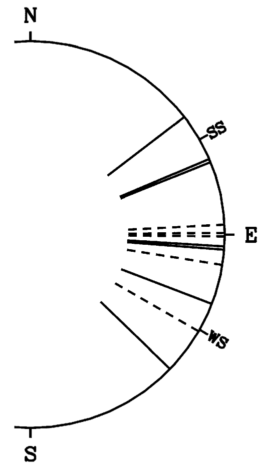
Perhaps the earliest known constructions that can be considered sanctuaries or temples in North Africa to the east of the Nile Valley are of Punic origin. The importance of the orientation in the Punic ritual is documented in a stone inscription found in the zone of Salammbo in Carthage. This stone was an offering placed in a sanctuary dedicated to Baal Hammon. The text indicates explicitly that the stone was orientated with its front side to the sunset and its back side to the sunrise (Xella 1991: 48).

Esteban (2002a) reports that the *decumanus maximus* of Roman Carthage – as well as the layout of the Roman and the Punic city and acropolis – is oriented towards the winter solstice sunrise. This author also compiled the orientations of five Punic and Neo-Punic temples and sanctuaries from published plans and measurements, finding that the temples were orientated towards a fairly narrow zone of the horizon, from 90° to 127°. It is remarkable that three of them are also oriented to or near the winter solstice sunrise.

Esteban et al. (2001) have carried out an extensive survey of the orientations of a large number of Roman and pre-Roman temples of Morocco, Tunisia and Libya. They found that the complete sample of temples built in Roman times show a definite random distribution of orientations. Moreover, there is no correlation between the dedication of the temples and their orientation, except for those dedicated to Saturn. Most of the religious buildings dedicated to this deity are oriented following an SR custom (see Fig. 8).

Saturn was the most important deity worshipped in Northwest Africa in Roman times (Picard 1954: 100–129; Leglay 1966; Bénabou 1975: 370–375) from ancient Numidia to Mauretania (present-day Tunisia to Morocco). Its cult had strong pre-Roman roots and was the inheritor of the ancient cult of the Punic Baal Hammon, who was the most important god of both the rural and Punicised Libyan population, probably because of the strong similarities of the Cartaghinian deity with a former ancient supreme Libyan god (Leglay 1966: 417–447).

The cult to Saturn is almost completely absent in the deeply Punicised Tripolitania (Leglay 1966: 267–268, Brouquier-Reddé 1992: 255–265). In this region Jupiter Hammon was an adaptation of the great god of the Eastern Libyans, the ram-headed Ammon (see Bénabou 1975: 335–338; Mattingly 1994: 167–168). The spread of the cult of Ammon is demonstrated by the many rural (mostly indigenous) temples or *ammonia* for which we have evidence in Tripolitania and among the Garamantes and the Libyan desert oases of Siwa and Augila (Mattingly 1994: 36, 168). Esteban (2003) has collected published data for rural shrines built in Roman times in Tripolitania (Esteban et al. 2001; Brouquier-Reddé 1992, and references therein) and for the Garamantian ashlar masonry temple at Germa (Esteban et al. 2001). It is remarkable that the range of orientations of many of the rural sanctuaries of Tripolitania show an orientation similar to those dedicated to Saturn in the rest of the Maghreb, a fact that could be related to the common pre-Roman substrate in the popular religion in both territories.



Archaeoastronomy of North Africa. Fig. 8 Orientations of temples dedicated to Saturn from Roman North Africa (Esteban 2003). Continuous lines: direct measurements by Esteban et al. (2001); *dashed lines*: orientations obtained from published plans. SS and WS indicate the azimuths of the rising sun at summer and winter solstices, respectively.

Among the Tripolitanian rural shrines, the one of Ghirza (Brogan and Smith 1984: 80–92) is especially interesting due to its strong Punic elements; these make it an unique monument in Tripolitania. Brogan and Smith (1984: 88) suggest that the building was perhaps devoted to the cult of Baal–Saturn in his role of earthly fecundity, but Brouquier-Reddé (1992: 146) proposes that the sanctuary was dedicated to the Libyan bull-headed god Gurzil, son of Ammon. From the plans published by Brogan and Smith (1984: their Figs. 25 and 26), Esteban (2003) finds that the orientation of the building is towards the east, very similar to that of Germa (Esteban et al. 2001) and also consistent with the SR range.

Finally, Esteban at al. (2001) have also measured the orientation of some temples built in the epoch of the Numidian and Mauretanian kingdoms, prior to the Roman annexation of all North African provinces.

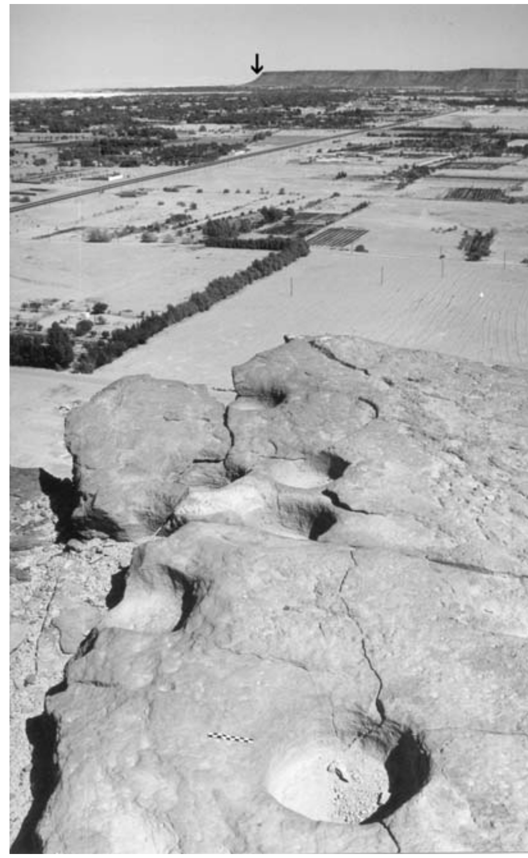
These kingdoms were autochthonous but deeply Punicised in their culture, especially in religion (Camps 1979). All these monuments show orientations consistent with the patterns found for the temples of Saturn and the rural temples of Tripolitania.

The possible astronomical motivation of the orientation patterns of the North African funerary and religious monuments discussed above has further support in some remarkable astronomical markers that have been found in important archaeological sites of the area, from Libya to Morocco.

Belmonte et al. (2002) report the discovery of an impressive solstitial marker over a distant foresight from the east edge of the top of Zinchecra, the capital city of the Garamates of the Fezzan (Libya) and inhabited since the ninth century BCE. The sun at summer solstice rises just on the most conspicuous distant topographical element of the skyline: the intersection of the flat escarpments of the Messak and the southern border of the sand sea of Ubari (see Fig. 9). The discovery of a striking astronomical marker in the first known political centre of the Garamantes gives further support to the importance and continuity of the astral elements of the genuine Libyan funerary and religious world, just before the contacts with the Phoenicians and Greeks.

Esteban et al. (2001) found another possible pre-Roman solstitial marker at the Numidian city of Simithus (Tunisia). From the Roman forum, which is located above the preceding Numidian tombs dated from the fourth to the first centuries BCE, it is possible to see the Numidian sanctuary (dedicated to Saturn in Roman times) just on the top of the Sacred Hill of Simithus. Esteban et al. find that the line-of-sight of the sanctuary as seen from the Numidian tombs at the forum coincides with the summer solstice sunrise. Moreover, a large Numidian monumental tomb is oriented precisely to the hill summit.

The group above found another spectacular astronomical marker in the temple of Apollo of Mactar (Tunisia). The Numidian-Punic traditions were very strong in this city and survived for several centuries after the Roman conquest (M'Charek 1982: 12). The temple is located outside the city; it is oriented east–west and built over a previous Punic or Libyan sanctuary (Picard 1984). The temple faces a small natural cut in a mountain which is exactly where the sunrise takes place at the equinoxes (see Fig. 10). Although the Punic Baal Hammon was conflated with Saturn in most of the Roman province of Africa, there is some controversy that this could be not the case in the region of Mactar (see the discussion by M'Charek 1991 and references therein). Bisi (1978) suggests that in Mactar, the ancient cult of Baal Hammon was assimilated to Apollo, the sun god of the Romans. If this hypothesis is true, the presence of an equinoctial marker at the temple of Apollo would provide proof of the transmission of the solar elements from the ancient Punic-Libyan religion to the Romanised local cults.



Archaeoastronomy of North Africa. Fig. 9 Carved cupmarks at the eastern border of the cliff of Zinchecra, the hilltop fortified capital of the ancient Garamantes of the Fezzan (Libya).The *arrow* indicates the place where the Sun rises at the summer solstice, just on the intersection of the escarpment of the black plateau of the Messak and the sand sea of Ubari.

Another possible relation with the equinoxes has been found at the temple B of Volubilis (Morocco) that shows all the characteristics of the temples of Saturn but lacks a direct confirmation of its dedication. It has a very precise orientation towards the sunrise at the equinoxes (Morestin 1980: 56–57; Esteban et al. 2001) that takes place over the nearby mountain Zerhoun, the most famous holy mountain of Muslim Morocco (see Morestin 1980: 135). The actual Roman building was built over a previous *tofet*, the westernmost Punic funerary sacred area known in Africa.

A last possible equinoctial marker could be at the temple of Saturn at Thugga (Tunisia). As in the case of the temple B of Volubilis, the Roman temple was built over a previous Punic *tofet*. The temple is oriented inside the range of the sunrises but not related to the

Archaeoastronomy of North Africa. Fig. 10 Remains of the Temple of Apollon in Mactar and its eastern horizon. The *arrow* indicates the place where the sunrise takes place at the equinoxes. The *upper left box* shows an enlargement of the horizon, the *white circle* indicates the size of the solar disk (figure reproduced from Esteban et al. 2001 and Esteban 2003).

solstices or equinoxes (Esteban et al. 2001). Esteban (2003) found that the peak of Zaghouan (the highest peak of Tunisia and the most important water source of ancient Carthage) is located very near the point of the horizon where the sunrise takes place at the equinoxes.

As we can see, there are possible equinoctial markers in three sacred areas or *tofets* of important cities of Libyan-Punic origin (Mactar, Volubilis and Thugga). In the three cases, the sanctuaries were re-utilised in Roman times and were dedicated to Saturn (the great North African deity) or to the Roman sun god Apollo. It is interesting to note that several equinoctial markers (analogous to the one found at Mactar) have been found in sanctuaries belonging to the Iberian culture in the southeast of Spain (Esteban 2002b) which was also influenced by the Punic civilisation in many aspects, and especially in its religion. Finally, the discovery of striking equinoctial markers in important pre-Hispanic sanctuaries of the Canary Islands also suggests that this element was important in the ritual of the proto-Berber peoples of the archipelago (see Esteban 2000 and references therein). In the light of the results gathered, it seems very probable that the ancient settlers from the continent imported this astronomical tradition. Very probably, this original population was culturally Punicised to some degree.

A

Architectural Decoration in Islam: History and Techniques

Ruba Kana'an

Architectural decoration has been one of the most resilient of the Islamic arts. The partial and more often overall decoration of buildings has been a characteristic feature of Islamic architecture from the eighth century onwards. Religious monuments as well as secular complexes have been decorated with an array of styles and techniques that reflected the multiplicity of Muslim societies and their cultural expressions. The importance given to decorating one's built environment has also been applied to temporary settlements such as tented encampments.

Up until the eleventh century, most decorative techniques such as the use of decorative brickwork or moulded stucco in the Muslim east, and mosaics, *ablaq* and carved stone in the central Muslim world were inherited from pre-Islamic cultures and societies. Muslim artisans transferred these skills into their respective contexts and adapted them to their architectural needs. It was only in the eleventh to thirteenth centuries that the use of repetitive patterns and intricate designs of geometric, calligraphic, and abstract vegetal

motifs became the dominant decorative repertoire (Jones 1978). These elements permeated architectural decoration throughout the Muslim world resulting in a new and distinct decorative language (Fig. 1).

Decorative elements such as the use of arabesque, geometric interlace (*girih*) and *muqarnas* or stalactite vaults became widely spread. Common among these decorative elements are notions of modularity, geometry and rhythm. Arguably, these forms are manifestations of a geometric pattern that is based on the subdivision of space, form or surface and the infinite repetition of the structural modules and motifs. Division and repetition, for example, applied to abstract forms of vegetation that are subjected to the rules of geometry and then extended indefinitely in all directions, formed the arabesque. Geometric interlace patterns (*girih*) also follow the same structural principle; these decorative compositions are based on the folding and repetition of regular shapes using circles, triangles and squares. The resulting patterns are purely mathematical and their artistic value lies in the choice of what aspect of the geometric pattern to highlight and which colours to use. (See "The nature of Islamic art", MET timeline ►http://www.metmuseum.org/toah/hd/orna/hd_orna.htm).

Subtle mixtures of geometry and rhythm also characterized the *muqarnas* or stalactite vault which is distinctive to Islamic architecture and decoration. The *muqarnas* is both a structural element filling zones of transition between walls and domes and a decorative element that follows the same structural composition (Fig. 2). *Muqarnas* domes, vaults, niches and decorative friezes are found in different construction materials including brick, stone, wood and stucco all over the Muslim world. (See a good survey of *muqarnas* types and their geographical distribution ►http://www.tamabi.ac.jp/idd/shiro/muqarnas/). In its simplest form the *muqarnas* can be described as layers of superimposed

Architectural Decoration in Islam: History and Techniques. Fig. 2 Mihrab of the mausoleum of Haseki Hürrem wife of Süleyman the Magnificent, Istanbul, Turkey. 1550–1557.

niches that link or decorate two surfaces. The earliest surviving mathematical treatise on *muqarnas* was written during the fifteenth century by the mathematician Ghiyāth al-Dīn Masʿūd al-Kāshī (d. 1429). The treatise was used to inform the simulation of a model of a *muqarnas* in Necipoğlu's book on a Timurid period scroll found in the Topkapi Saray Museum in Istanbul (Asad 1995). The earliest surviving drawing of a *muqarnas*, however, was found in the Takht-i Sulaiman excavations in the northwest of Iran. The plaster panel of (50 × 50 cm) inscribed with a design of a *muqarnas* dating to ca. 1270 currently housed in the archaeological museum of Berlin was drawn into an exact plan (Harb 1978) and later studied and analysed by a numerical geometry group at the University of Heidelberg in Germany. (See the numerical geometry study group ►http://www.iwr.uni-heidelberg.de/groups/ngg/Muqarnas/ and the Takht-I Sulaiman muqarnas drawing ►http://www2.iwr.uni-heidelberg.de/groups/ngg/Muqarnas/Img/suleyman_plate.jpg).

The use of calligraphy in architectural decoration pre-dates Islam. However, after the birth of Islam words and calligraphic compositions became a primary component of a collective aesthetic. Notably, decorative inscriptions were not often applied in isolation as calligraphy was most commonly used as part of an overall composition that at times overlapped with other decorative techniques such as arabesque. Like other decorative forms, calligraphic compositions are based on a modular principle where letters, words, or full

Architectural Decoration in Islam: History and Techniques. Fig. 3 Mihrab of the mausoleum of Gur-i Emir, Samarqand, Uzbekistan. 1404. Decorated with painted and gilded arabesque designs and square Kufic inscriptions.

sentences are subject to geometric rendition and repetition. The purpose, form, content and location of inscriptions on buildings varied according to time and place (Blair 1998). A large percentage of surviving inscriptions are Qur'anic or religious in nature but inscriptions with historical information providing the name of the building's patron, its date of construction and at times the name of a builder are also common (Fig. 3). Whereas Arabic served as the main language for monumental inscriptions, Persian, Ottoman Turkish and in a few cases Pahlavi and Swahili were also used. The location of calligraphy on a building followed stylistic developments and regional variations. Most commonly, calligraphic friezes tend to delineate structural zones in a building such as between walls and zones of transition, the bases of domes, entrances and on the voussoirs (wedge-shaped stone building blocks used in constructing an arch or vault) or tympana (the triangular area in a pediment) of arches. Calligraphy was also used as a form of overall decoration such as the large buff and turquoise brick inscriptions in the *hazārbāf* technique (see below) that adorned walls and minarets of monuments during the Timurid period. (See the Islamic Art and Architecture Organization ►http://www.islamicart.com/main/calligraphy/index.html).

The application of different decorative elements on a building was wide-spread in Muslim architecture. Nevertheless, the form of decoration and its location followed regional preferences and local traditions. For example while monuments of Fatimid and Mamluk Egypt were decorated with carved inscriptions, *ablaq* stonework, and architectonic features, the facades of monuments in Khurasan and Transoxiana were decorated with overall brick patterning, blind arches, glazed and moulded tiles, terracotta inlays, stucco and ornamental inscriptions. Even in buildings where the exteriors were left almost totally unadorned such as the Ilkhanid period mosques of Iran and Iraq (1256–1353), interiors and particularly the mihrab niche was the focus of sumptuous stucco decoration (Fig. 4). So too is the case in fourteenth century North Africa and Spain as for example in the courtyard arcades of the Nasirid palace in Granada or the complex decoration of the Marinid ʿAṭṭārīn Madrasa in Fez built between 1323–1325.

Architectural Decoration in Islam: History and Techniques. Fig. 4 The mihrab of the Shrine of Pir-i Bakran in Linjan, Iran. 1299–1312.

Decorative elements applied to architecture were used singularly or in combinations. Of particular significance was the use of overlapping patterns in two or more dimensions. An example is the tile mosaic design on the dome of the Shah Mosque in Isfahan, Iran (1611–1638), with its ochre lattice screen pattern and white and blue arabesque. Another example with a similar overlapping composition yet a different effect is the stone dome of the Sultan Qaytbay mausoleum in Cairo (1472–1474) with its geometric interlace design and flowering arabesque (Fig. 5). Whereas the former is two-dimensional, the Cairo example has a sculptural effect as both elements are carved in a precise bas-relief. The use of complex and overlapping decorative patterns was also subject to stylistic changes. The pre-Mongol arabesque based on twining vine tendrils and acanthus or palm leaves gave way from the turn of the fourteenth century to lotus scrolls with peony sprays and serrated leaves (*hatāʾī*). This aesthetic became popular in Iran and was later adopted in the early sixteenth century Iznik ceramic tiles produced by the Ottomans.

Architectural Decoration in Islam: History and Techniques. Fig. 6 Muqarnas dome of the Mausoleum of Nūr al-Dīn in the al-Nūriyya Madrasa, Damascus, Syria. 1168.

The Meaning, Purpose and Transmission of Architectural Decoration: Problems of Interpretation

Because of the perennial emphasis on geometric patterns and abstract vegetal motifs, the decorative language of Islamic architecture is commonly perceived to reflect a Muslim ethos that is aniconic[1] and unchanging. This perception is at the heart of a number of debates in the study of Islamic art and culture including: was the use of geometry and arabesque patterns a reflection of Islam's antipathy to images? Was it a reflection of the special status of mathematics and geometry in Muslim cosmology? Or was it, perhaps, a reflection of a cultural process with its social, political and religious ramifications? These debates represent the two main current schools of thought on the meaning and purpose of architectural ornament: the "iconological" and the "cosmological".

In the iconological approach all works of art, including architectural decoration, are interpreted as visual signifiers of the cultural context which they embody. As such, a work of art has a meaning that is culturally constructed and related to a specific time, place and context of production. It is read and considered as evidence or representation of its context on par with other historical, political, social or literary documents. Such an approach is at the heart of Tabbaa's analysis of the transformation of architectural decoration in the central Muslim lands between the middle of the eleventh and the middle of the thirteenth centuries (2001). He argues that the evolution of an artistic language which is characterized by the use of arabesque, geometric interlace, *muqarnas* vaulting, and monumental calligraphy was largely brought on by a Sunni revival that strived to standardize religious norms in a period of political and sectarian upheaval (Tabbaa 2001: 6). The evolution of the gravity-defying and ever changing effect of the *muqarnas* domes, for example, is interpreted in his study as an embodiment (or abstraction) of the Ash'arite Sunni theology which is based on an occasionalistic cosmology (133). As such, the evolution of the *muqarnas* dome, as well as the other decorative techniques, is explained within a precise political and religious context within which it would have had a symbolic meaning (Fig. 6).

For the proponents of the cosmological approach, geometric and decorative patterns are interpreted as manifestations of underlying principles of faith that are regarded as both universal and timeless. This approach attributes a functional role to ornament that is first and foremost a reminder of the principle of Tawḥīd: the Oneness and Transcendence of the Divine (al-Faruqi and al-Faruqi 1986: 163–169). Islamic art and geometric patterns used in architectural decoration are thus seen as means to reconcile multiplicity with Unity. They depict a physical mathematical pattern which reflects a sacred cosmology. Islamic art is thus regarded as an aniconic art where the spiritual world is reflected through geometry, rhythm, arabesque and calligraphy.

[1] When referring to a deity image, aniconic denotes a symbol which does not attempt an anthropomorphic (humanlike) or representational likeness.

For example, the circle is read as symbol for the origin and the end, an archetypal form from which the three primary shapes (triangle, hexagon and square) emerge (Critchlow 1976). The same ideas are expressed by Burckhardt (1976: 63) who sees geometric interlace as a direct expression of the idea of Divine Unity. Thus unlike the iconological approach, the cosmological approach does not take into account the socio-political context of a decorative programme or the vicissitudes of artistic influences.

These two approaches often regard each other as incompatible. The iconological school sees the attempt to interpret style through faith too speculative and at best normative. Whereas for those who consider Islamic art as an expression of Muslim faith and Divine Unity in particular, the temporal contextual analysis of decorative patterns misses the point. What the two approaches agree on, however, is the need for intermediaries to translate these complex mathematical and philosophical ideas into patterns that could be understood and applied by craftsmen. For example, Nasr explains geometric patterns as being the "results of the vision of the archetypal world by seers and contemplatives who then taught craftsmen to draw them upon the surfaces of tiles or alabaster" (1987: 49). Tabbaa (2001: 100) and Necipoğlu (1995: 123), on the other hand, propose that one of the reasons for the development of these complex and geometrically based decorative techniques is that geometric treatises were increasingly available for artisans. This presumed relationship between the artisan and the mathematician in medieval Islam, however, was dismissed by George Saliba, Professor of Arabic and Islamic science at Columbia University. Saliba argued that based on the available evidence from the few surviving mathematical treatises the assumption is hard to entertain, let alone prove (1999: 641). He also provides textual evidence for the difference in the technical language used by mathematicians and artisans, and the need therefore to avoid the assumption that the presence of mathematical treatises means that they are used or understood by artisans. Theoretical mathematicians, according to Saliba, "rarely taught artisans directly, and seldom wrote for them specifically" (643).

Another important issue that arises in debates about architectural decoration is the manner in which architectural or decorative designs were transmitted. Jonathan Bloom (1993: 25) argues that the form and general characteristics of early mosques were transmitted mostly by example. That is, the general features of one building were copied by another in the same region. Bloom also argues that such buildings could have been described orally or in geographical works, and thus what was transmitted was a notional idea of a building or a decorative detail. These suggestions remain to be fully proven. It is worth noting that there are also a few historical accounts which mention the involvement of patrons in drawing designs of a desired monument, but no material evidence survives before the fourteenth century (O'Kane 1987: 34). In this connection, the presence of a notational convention used by craftsmen based on drawings and models is only attested to from the thirteenth century with the 1270s stucco panel with a *muqarnas* plan (discussed above) as the earliest surviving example. Early drawings on paper survive from the sixteenth and seventeenth century in Tashkent, and the fifteenth and sixteenth century in Istanbul (Necipoğlu 1995). Finally, one of the important ways of transmitting knowledge about decorative techniques and practices was through the movement of craftsmen who brought with them new traditions and technical know-how.

Architectural Decoration by Media

Studies on the building crafts in Muslim societies are sparse and mostly regional or media specific. The best example is Hans Wulff's book on Iran (1966) which provides an invaluable detailed study of building and decorative traditions concentrating on local practices and techniques. Iran's craft industry during the nineteenth and the early twentieth centuries and its encounter with Western technical development are also documented (Floor 2003). For Syria and Egypt dictionaries of traditional crafts (al-Qasimi 1988) and architectural terms (Amin and Ibrahim 1990) provide glimpses into local technical practices. IRCICA, the Research Centre for Islamic History, Art and Culture based in Istanbul has had since 1990 a programme for the study and development of crafts in Muslim societies. The programme hosted conferences and seminars in different regions and recently published some of their proceedings (see ►www.ircica.org). What follows is a summary of the history and techniques of stone, brick, tile and stucco decoration.

Stone

Stone was used as a decorative medium in Syria, Anatolia, Egypt after the eleventh century, Spain, and India (Fig. 7). North Syria, especially the area around Aleppo during the period between the twelfth and fifteenth centuries, seems to have been a source of technical innovation for stereotomic[2] stone techniques that are based on the precise cutting and assemblage of stone blocks (Clévenot and Degeorge 2000: 68). The decorative use of stone exploited the natural variety of stone colours to produce polychrome compositions for the interior and exterior of buildings. Some techniques

[2] Stereotomy is the science or art of cutting solids into certain figures or sections, as arches; the art of stonecutting.

Architectural Decoration in Islam: History and Techniques. Fig. 7 Portal of the Ayyubid palace. Aleppo Citadel, Syria. ca. 1210.

Architectural Decoration in Islam: History and Techniques. Fig. 8 The Fatḥiyyah Madrasa, Damascus, Syria. 1743.

such as alternating the colours of stone courses (*ablaq*) or interlocking the stones of arches (joggled voussoirs) were used in pre-Islamic monuments but became more sophisticated and more widely used after the spread of Muslim culture. Stone mosaic designs of *opus sectile* (pavement or wall decoration made of shaped tiles of coloured marble) and its stone paste derivatives were used only for decorative purposes (Fig. 8). In most cases, however, structural and decorative techniques overlapped. The most common decorative stonework techniques were:

Stone Mosaic

This is a technique that was inherited from the Byzantines in Syria and Palestine. It was used for land covering and paving during the Umayyad periods in Syria and Spain.

Ablaq

This is a simple technique of alternating different colours of stone courses in order to achieve a colouristic impact. The most commonly used colours were light sand or limestone alternating with dark basalt and in some cases a third layer of reddish stone. This technique spread from Syria to Egypt under the Mamluks and Turkey under the Rum Saljuqs and the Ottomans.

Joggled or Interlocking Stones

This is a technique in which stone blocks with precisely cut scallops, zigzags and complex carved profiles were fitted together without the use of mortar. Single or multiple coloured stones were used to create a beautiful effect. Interlocking stones, however, were technically challenging as the desired shape was cut into a regular block that was bonded into the masonry. They decorated horizontal decorative bands on facades or had a structural function in lintels and arch voussoirs.

Muqarnas Vaulting Over Portals

These vaults consist of three or more tiers of staggered *muqarnas* cells usually surmounted by a scalloped or centrifugal half-dome. Muqarnas became the main decorative feature of monumental portals between the thirteenth and the fifteenth century. It seems to have developed in Aleppo in Northern Syria and spread from there south to the rest of Syria and Egypt and north to Anatolia and Turkey.

Monochrome and Polychrome Geometric Interlace

Stone geometric interlace was introduced during the twelfth century and used mostly in the spandrels above arched gates and prayer niches (mihrabs). Technically, the geometric interlaces are different from surface cladding as each component of the geometric interlace is cut on the face of a regular block that is built within the structure of the arch spandrel, and as such, fully bonded to the masonry (Tabbaa 2001: 156).

Stone Cladding and Inlay

This technique included the decorative use of marble panelling which was common in Syria, Palestine and Egypt. Stone inlay in *opus sectile* and marble intarsia reached its apogee under the Mughals of India (Fig. 9). Inlay in hard stones and semi-precious stones (*pietra dura*) where lapis, onyx, jasper, topaz, cornelian and agate were inlaid in marble made its first major appearance in the Tomb of Iltimād al-Dawla in Agra (1622–1668).

Architectural Decoration in Islam: History and Techniques. Fig. 9 Tomb of Akbar. Sikandra, India. 1614.

Stone Sculpture

The most common form of stone sculpture was relief carved inscriptions and decorative patterns. Dense patterns created through carving out or hollowing the stone surface is also demonstrable in the façade of the Mushatta palace in Jordan (ca. 740) currently in the museum of Islamic Art in Berlin. The surface is carved in the form of triangles housing rosettes that are surrounded by dense foliage at times inhabited by birds and mythical creatures. An exceptional example of a more plastic modelling in stone sculpture comes from the portals of the Great Mosque of Devriği in Anatolia built in 1228–1229 (Fig. 10).

Bricks

Decorative brickwork was used to articulate the structural walls of monuments built over a vast area including Iraq, Iran, Afghanistan and central Asia. Brick was readily used as a medium of structure and decoration as it was cheap to make and fast to build. The alluvial plains of the various rivers in the region provided rich sources of clay that were used for manufacturing rammed-earth (*pisé*), mud brick, baked brick and terra cotta in addition to clay pipes and tiling roofs (Wulff 1966: 108–113). Although the size of the brick differed from one region to the other, the overall visual effect of plainly built brick walls was similar. The indigenous builder was able to develop various decorative uses for brick construction based on simple alternate layering of bricks in horizontal and vertical rows creating patterns in the otherwise plain facades. Bricklayers also used half-bricks, quarter-bricks, and moulded bricks along with the full size bricks to create more dynamic decorative patterns (Fig. 11). The ability to design a small composition based on a simple brick pattern and multiply the design vertically and horizontally meant that the bricklayers were able to maximize the effect of the pattern and minimize the human effort.

Architectural Decoration in Islam: History and Techniques. Fig. 11 Mausoleum of the Samanids. Bukhara, Uzbekistan. 914/43.

Hazārbāf and Bannā'ī

In addition to the basic technique of forming decorative patterns in brick walls through varying the orientation of bricks, builders used the contrast between light and shadow that resulted from alternating flush and protruding bricks to create intricate decorative patterns. The most widely spread technique of ornamental brickwork is known as *hazārbāf*, from Persian, meaning a thousand twisting or a 1,000 weaving, accentuating the structural similarities between creating continuous brick patterns and weaving a textile. This technique is also known as the *bannā'ī* or the 'builder's art', as the decorative patterns are part of the structure of the building and not an afterthought or a later cladding. Carved brick plugs and carved and moulded plaster joints were developed to enhance the overall effect.

The earliest surviving example of decorative brickwork comes from Abbasid Iraq and dates to the eighth century in (the city gate in Raqqa ca. 772). In the Ukhaydir Palace south of Baghdad (possibly begun around 762) the south wall of the courtyard has an *iwān*[3] with *hazārbāf* decorative patterns using 1/3, 2/3, and full size bricks. Early examples from Iran and Central Asia are later than those in Iraq but more complex. The decorative use of bricks in the tomb of the Samanid ruler Ismāʿīl in Bukhara, Uzbekistan (913–943), for example, created a weaving effect by highlighting the contrast between recessed and protruding bricks in an overall decorative design. This play between shadow and light in brick construction continued to be a dominant decorative medium for building exteriors such as the twelfth century Gunbad-i 'Alawiyān in Hamadan (Iran) where bricks were used to create a 'key' and 'swastika' patterns (Shani 1996: 61) or the minaret of Masʿūd of Ghazna in Afghanistan where the builder used brick layering, brick mosaic, sculpted bricks and brick inscriptions in a sumptuous decorative composition.

Architectural Decoration in Islam: History and Techniques. Fig. 12 Minaret of the Kalayan Mosque. Bukhara, Uzbekistan. 1127.

Glazed Bricks

Glazed bricks were also a pre-Islamic tradition inherited from Babylonian and Achaemenid times. The earliest examples in the eastern Muslim provinces date back to the early twelfth century when moulded tiles or 'end plugs' were used as a contrast to the natural buff colour of bricks. During the twelfth century glazed tiles were used in inscription bands such as the Tower of Jam, Afghanistan (late twelfth century), or the minaret of the Kalayān mosque in Bukhara (1127) (Fig. 12). One might argue that colour was introduced in brick architecture to render the complex decorative and inscription friezes more legible from the distance. Under the Ilkhans (1256–1353) the use of glazed bricks became a prominent feature of monumental architecture as domes and large surfaces were covered in decorative compositions of glazed bricks and tiles. The Timurid opulence of Tamerlane's mausoleum in Samarqand, the Gur-i Emir, (ca. 1400–1404), or the royal necropolis of Shah-i Zand demonstrate the skilful combinations of plain bricks, glazed bricks and glazed tiles that were used to maximize the decorative effect (Fig. 13).

Architectural Decoration in Islam: History and Techniques. Fig. 13 Façade of the Shir Dor Madrasa. Samarqand, Uzbekistan. 1619–1636.

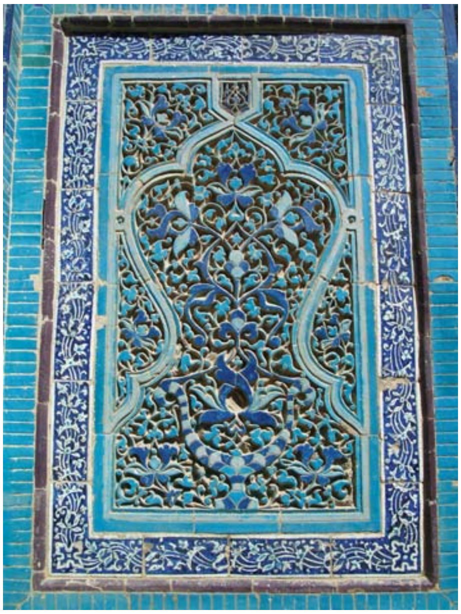
To create glazed bricks, brickmakers used glazes or filmy glass layers that were fired and fused over the porous clay body of the brick for functional and aesthetic reasons. Glazes were added to the brick in a powder format that coated the body and melted in the kiln. The colour and opacity of the glazes were determined by their chemical composition. The most commonly used colours in Iran and the Muslim east were turquoise and blue. These colours were achieved by using an alkaline fluxing agent composed of powdered pebbles and potash for copper oxide and cobalt, respectively (al-Hassan and Hill 1986).

[3] An *iwān* is a large, vaulted chamber with a monumental arched opening on one side.

Glazed Tiles

Decorative tiles comprise glazed slabs made out of clay or frit (stone paste) that were used in a variety of forms and shapes to create impervious surfaces with stunning visual impacts. The surface of the tile can be left plain before glazing but it can also be carved, incised or moulded for additional effect. Glazed tiles were used to cover different parts of a building including walls, domes and zones of transition. The technical know-how and desired final decorative effect dictated the development of the glazed tiles tradition in different regions of the Muslim world. A good, yet incomplete, starting point for the study of Islamic ceramics including glazed tiles is the teaching website developed by the Ashmolean museum in Oxford, UK (see ►http://islamicceramics.ashmol.ox.ac.uk/). Tiles are covered with a layer of glaze and fired in a kiln in the same manner as glazed brick (Fig. 14).

Many decorative techniques were used with glazed tiles including painting in the glaze, under the glaze and over the glaze. Glazes are either transparent or opaque depending on their chemical compositions. They are found in different colours and at times colour combinations. The most commonly used metals by Muslim potters were cobalt for blue, manganese for purple, iron for green, and copper for turquoise. Changing the chemical agent used for fluxing the glaze produced different colours. Copper, for example, turned into green if fluxed with a lead glaze, and turquoise-blue if fluxed with an alkaline glaze. Cobalt turned sapphire-blue in an alkaline glaze, and turquoise in lead glaze (al-Hassan and Hill 1986).



Architectural Decoration in Islam: History and Techniques. Fig. 14 Details of carved and glazed tiles from the Shah-i Zinda necropolis. Samarqand, Uzbekistan. End of fourteenth or beginning of the fifteenth century.

Lustre Tiles

The best-documented tradition of lustre tile production is the city of Kashan in Iran where there is evidence of continuous production between the twelfth and the early fourteenth centuries. Lustre production (for vessels and tiles) requires special materials, double firing and a special kiln. The metal oxides added to the tile after the first firing form a metallic deposit upon firing in a reducing kiln at a much lower temperature. The recipe and the process of making lustre vessels and tiles were described in a 1301 treatise [►http://islamicceramics.ashmol.ox.ac.uk/Glossary/abulqasim.htm] (Allan 1973). Abu al-Qāsim's treatise suggests that that vessels and tiles were covered with an alkaline glaze and fired for 12 h. They would then have six and a half days of cooling in the kiln before the lustre design was applied. The recipe for lustre glaze comprised a mixture of red and yellow arsenic, gold and silver marcasite, yellow vitriol, copper, and silver ground with sulphur dissolved in grape juice or vinegar. The second firing takes place in a low-temperature reducing kiln which allows the metal oxides to fuse with the alkaline glaze and create the lustrous sheen. Star-and-Cross tile patterns with figural and vegetal motifs, at times moulded in bas relief, as well as moulded and painted inscription friezes were the most common patterns of decoration. The buff-and-blue aesthetic that characterises the early use of glazed bricks on the exterior of buildings was also predominant in the decoration of interiors with lustre tiles. Cobalt blue was used to highlight relief-moulded inscriptions on lustre tiles as is clear from the *mihrab* tile now in the Los Angeles County Museum of Art (see ►http://www.lacma.org/islamic_art/figures/fig_a31.htm).

The earliest surviving lustre tiles known to have decorated Muslim monuments are the tiles that adorned the *qibla* wall of the Great mosque of Qayrawan in Tunisia (ca. 862). According to the historian Ibn Nājī (d. 1433), who cites al-Tujībī (d. 1031), some of those tiles were sent from Baghdad but an Iraqi craftsman who knew the lustre technique manufactured some locally. There is also evidence for the use of lustre in Egypt and Syria before the technical know-how was transmitted to the potteries of Kashan in Iran.

Cut Tiles or Tile Mosaic

The earliest examples surviving in this technique are from twelfth century Iran and thirteenth century Anatolia. Technically, tiles are glazed and fired separately and then cut according to the desired design or pattern. They are placed face down and a layer of plaster is applied to the back of the pattern which, once

Architectural Decoration in Islam: History and Techniques. Fig. 15 Detail of a floral tile mosaic from the Gur-i Emir Mausoleum. Samarqand, Uzbekistan. 1404.

dried, turns into a panel that can be easily fitted onto a wall. The same technique is used for the application of tile mosaics on concave or convex curved surfaces. The heyday of the tile-mosaic technique was under the Timurids when designs became increasingly complex with overlapping layers of arabesque and geometric patterns on flat or curved surfaces (Fig. 15). See also the fourteenth century mihrab from Isfahan, Iran currently in the Metropolitan Museum of Art, New York. ►http://www.metmuseum.org/Works_Of_Art/viewOne.asp?dep=14&viewmode=0&item=39.20.

Cut tile mosaic has the advantage of maintaining the brilliance of the colour of each tile. The different coloured tiles are fired separately according to the specific temperature needed by the chemical component that gives the colour of the glaze. (Wulff 1986: 120) In North Africa, there was a phase of experimentation in cutting the *zillīj* components from a clay panel after the first firing and then glazing each piece separately. The result, however, was less precise patterns (shrinkage), and less smooth surfaces, as the glaze would bulge around the sides (Hedgecoe and Damluji 1992). This technique, however, is still practiced in some workshops in Titwan in Morocco.

Tile mosaic technique was the predominant form of tile decoration in North Africa. Known as *zillīj*, the ceramic cut tiles are put together in a complex geometric design. Each component of the *zillīj* is monochromic but the final design is a polychrome matrix. Glazed tiles first appear in North Africa in the archaeological context of tenth century Qal'at Banū Ḥammād, possibly inspired by the Aghlabids, who in turn were copying Abbasid models. During the twelfth and thirteenth centuries glazed tiles were nailed to or embedded in minarets and towers. The *zillīj* tradition in North Africa, however, reached a stunning maturity under the Marinids who ruled from Fez between 1244 and 1465. In Spain *zillīj* became common only during the late thirteenth and early fourteenth centuries. There are some differences in the colour palette between Spain and North Africa as Spanish tiles made more use of various shades of blue using cobalt as a colouring agent. The colour palette also used ochre yellow, copper for green and manganese for purple, brown and black.

The Cuerda Seca (Dry Thread) Tiles

This is a method of painting with different colour glazes on a single tile in order to achieve the overall colouring effect that cut tile techniques provide in a less expensive and less time consuming manner. Tiles were painted with different colours of glazes that were separated by a greasy or wax material that leaves a black matt line between the different glazes when fired. The waxy material stops the colours from running into each other in the kiln and acts as a pencil line or drawing line that defines the different components of a pattern. The tiles, however, were fired at a preset temperature and as a result, the glazes were not fired to their ultimate brilliance (as in the case of separate firings for the different colours). The colours achieved were less brilliant but the method was much faster and cheaper than tile mosaic. This technique started to replace tile mosaic in popularity during the reign of Shah Abbas in Isfahan.

The colour palette of this technique is necessarily limited to the chemicals that melted or fluxed at reasonably close temperatures. The predominant colours used in the *cuerda seca* technique are known as the *haftrang* or seven colours. This range of colours was used in Iran and central Asia from the late eleventh century and reached its apogee in the late fourteenth and early fifteenth centuries. To create overall patterns for large areas square tiles are put side by side and the overall design is transferred on to them. The colour glazes were then added and each tile fired separately (Fig. 16).

Underglaze Painting: Ottoman Tiles and the Iznik Tradition

Blue-and-white underglaze painted tiles evolved in Central Asia and Anatolia during the thirteenth and fourteenth centuries. Their popularity under the Ottomans is linked to a group of Iranian craftsmen known as the 'Masters of Tabriz' who are responsible for the decoration of the Yeşil Mosque in Bursa (1419–1424). The full repertoire of their work included *cuerda seca*

Architectural Decoration in Islam: History and Techniques. Fig. 16 Detail of *cuerda seca* tiles currently embedded in a re-constructed wall in the Topkapi Palace. Istanbul, Turkey. Late fifteenth century.

Architectural Decoration in Islam: History and Techniques. Fig. 17 Underglaze painted tile, Circumcision Room, Topkapi Palace. Istanbul, Turkey. ca. 1520.

tiles, monochrome glazed tiles, and underglaze painted blue-and-white tiles. Tile production in Ottoman Turkey went through various phases of development that became linked to the court workshops from the early sixteenth century (1525–1550 blue and white from the Freer Gallery ►http://www.asia.si.edu/collections/singleObject.cfm?ObjectId=25488). One of the most stunning examples of early Ottoman underglaze painted tiles is a group of large tiles dated to the 1520s now decorating the exterior of the Circumcision Room in the Topkapi Saray (Fig. 17). The tiles are painted in the *sāz* style featuring serrated leaves, lotus blossoms and rosettes inhabited with birds and mythical creatures in a blue and turquoise palette on a white background. This painting style is associated with Shahkulu who served as the court designer between 1526 and 1556. This period of experimentation led to the development of a more natural floral repertoire that featured tulips, carnations, roses and hyacinth, the hallmarks of the exuberant floral style that distinguishes Ottoman decorative language.

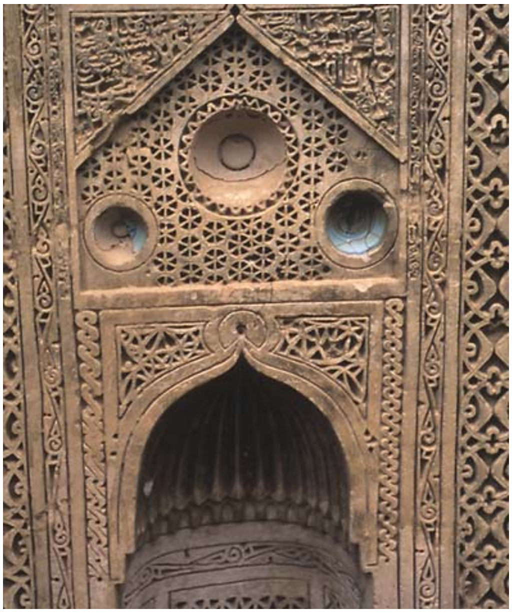
The colour palette of the underglaze painted tiles also went through changes in the early part of the sixteenth century. In addition to blue, turquoise and green, purple was introduced in the late 1540s. It was only in the 1550s when the well known architect Sinan became in charge of the royal workshops of Iznik producing ceramics and tiles that tile sizes became standardized allowing for vast pictorial compositions and monumental calligraphy. It was also under Sinan in 1557 that the colour red was introduced into the palette of Iznik tiles (Fig. 2 above) (1575 typical Iznik with red Freer ►http://www.asia.si.edu/collections/singleObject.cfm?ObjectId=37077).

Stucco

Stucco is a plaster-based decorative medium that was used throughout the Muslim world as a decorative finish as it was cheap and created a considerable effect in a relatively short time. It was perhaps the most common form of decorating building interiors until some of its role was taken over by tile revetments from the thirteenth century. Stucco can be applied to all sorts of surfaces rendering the basic rammed-earth structures (*pisé*) into buildings with sumptuous decoration (Milwright 2001).

Stucco is commonly made out of gypsum, but lime stucco is also used especially for exterior decoration and for rendering exteriors and special features impervious. A watertight variety of stucco made out of lime and wood ashes bonded with goat hair is used for water channels and for decorating buildings in Oman (known as *ṣārūj*) and in Yemen (known as *Qudād*) (al-Radi 1994). In some regions certain substances are rubbed onto the surface of the final pattern to provide a shiny patina. Colour or gold leaf could then be added to the surface.

Stucco is prepared by the calcinations of gypsum or lime through mixing the sifted powder with water while continuously stirring in order to slow down the process of crystallization (Clévenot and Degeorge 2000: 84). It is usually applied in several layers then smoothened. A pattern is then traced either through the use of dry point, ruler and compass or stencil paper which is blotted with charcoal powder. The pattern can be cut out or carved and some of the components further



Architectural Decoration in Islam: History and Techniques. Fig. 18 Evidence of the use of stencils to copy stucco patterns, the mihrab of the Mosque of al-'Uwaynah. Wādī Banī Khālid, Oman. ca. 1540.

Architectural Decoration in Islam: History and Techniques. Fig. 19 Detail of the mihrab of Oljeitu, Friday mosque of Isfahan. Iran. 1310.

articulated through hatching, perforating and quilting (Fig. 18). Decorative patterns could also be moulded onto the wet stucco by pressing a pre-carved mould (probably hardwood) into the last layer of gypsum – each being allowed to set separately providing a faster way of achieving decorative patterns. For stucco grills which were common all over the Muslim world designs were knife cut in semi-set gypsum boards.

The different techniques for cutting and shaping stucco followed regional and historical patterns. In Samarra, the Abbasid capital of the ninth century, three styles of stucco were excavated. Stucco styles developed from hollowed out background creating patterns of vine leaves and grapes to one where the design is abstract and cut in a bevelled style. Stucco panels with the bevelled style were excavated in a house in Nishapur (Iran) and are now in the Metropolitan Museum of art in NY (▶http://www.metmuseum.org/toah/hd/nish/ho_gallery_view.htm). The major change to the stucco tradition, however, took place under the Ilkhans (1256–1353) who decorated the *mihrabs* of their mosques with stucco compositions of arabesque, calligraphy and geometric interlace modelled in plastic compositions in tiers and on different planes. One of the most famous examples is the mihrab built in the winter prayer hall of the Friday mosque of Isfahan during the reign of Oljeitu in 1310 (Fig. 19).

Architecture in Africa, with Special Reference to Indigenous Akan Building Construction

Tarikhu Farrar

> The hall itself was the chief object that attracted my attention. It was at least a 100 ft in length, 40 ft high, and 50 broad. It had been quite recently completed, and the fresh bright look of the materials gave it an enlivening aspect, the natural brown polish of the wood-work looking as though it were gleaming with the lustre of new varnish. Close by was a second and more spacious hall, which in height was only surpassed by the loftiest of the surrounding oil palms; but this, although it had only been erected 5 years previously, had already begun to show symptoms of decay... Considering the part of Africa in which these halls were found, one might truly be justified in calling them wonders of the world; I hardly know with all our building resources what material we could have employed, except it were whalebone, of sufficient lightness and durability to erect structures like these royal halls of Munza, capable of withstanding the tropical storms and hurricanes. The bold arch of the vaulted roof was supported on three long rows of pillars formed from perfectly straight tree stems; the countless spars and rafters as well as the other parts of the building being composed entirely of the leaf-stalks of the wine-palm (Raphia vinifera). The floor was covered with a dark red clay plaster, as firm and smooth as asphalt. The sides were enclosed by a low breastwork, and the space between this and the arching roof, which at the sides sloped nearly to the ground, allowed light and air to pass into the building. (Schweinfurth 1874, Vol. II: 42–3.)

Famed 19th century botanist, Dr. Georg Schweinfurth, here writes of one of tropical Africa's most remarkable achievements in indigenous architecture and building technology, what he calls the "royal halls" of the Mangbetu kingdom. In the last years of the 1860s, Schweinfurth, traveling with Sudanese merchants, made his way southward along the Nile corridor toward the African interior. Ultimately, he reached the northeast quadrant of central Africa.

Schweinfurth would go on to write voluminously about this central African world. He also produced illustrations in quantity and of considerable quality. From his writings and illustrations we can gain some appreciation of the technological prowess of this region's cultures in the late precolonial era. The grandeur and elegance of the "royal halls" certainly captured Schweinfurth's imagination. So too did the considerable building skills embodied in their construction.

The "royal halls" were merely the grandest expression of the architectural and building skills of the peoples of this part of Africa. Of the more ordinary buildings, dwellings, storage structures, etc., we can also learn something from Schweinfurth's writings and illustrations. He was encountering traditions of architecture and building technology that were indigenous to tropical Africa. Nor should we imagine that the Mangbetu, in this instance, represent some sort of unusual or atypical culture.

The building materials identified by Schweinfurth are familiar from elsewhere in tropical/sub-Saharan Africa. These include types of clay, particularly those deriving from forest and savanna ochrosols and oxysols, and tropical black earths. Also included are various hardwood tree species. Of great importance is the raphia palm. Virtually every part of this useful tree was employed in the building process. The trunk provided posts; the fronds, laths and rafters; and the leaves, roofing or thatch. Rope and twine for binding purposes (binding laths to posts, for example) were also made from the woven fibers of the leaves. These materials were readily available, abundant, and admirably suited to the task of building. As elsewhere in tropical Africa, the peoples of this region mastered their use. This is evident in the way that the materials were processed, in the techniques of building developed in conjunction with their use, and in the final product of the building process. Here, as elsewhere in tropical/sub-Saharan Africa, people constructed houses that were durable, comfortable, and, in today's jargon, "ecologically sound."

The study of African architecture, at least in an academic setting, did not truly develop until the second half of the 20th century. A small, but determined and dedicated body of scholars, not a few of them from Africa, had taken up the challenge to the orthodoxy. Africa (i.e., sub-Saharan/tropical, or Black Africa), they insisted, was indeed a part of the *historical* world and worthy of study as such. Within this group was body of architects, folklorists, a few historians, and others who began to pay serious attention to indigenous African architecture, or what was termed "African traditional architecture." (See, for example, Denyer 1978; Dmochowski 1988 [1958–1965]; Gardi 1973; Gluck 1973 (1956); Hull 1976; Oliver 1971; Prussin 1969.)

Their work, in conjunction with the written accounts of earlier travelers to Africa like Schweinfurth, provides us with a solid foundation on which to continue to piece together something of a coherent picture of the technologies of building developed by the peoples of tropical Africa at earlier periods in their histories. Also useful are recent ethnoarchaeological/material culture studies of "traditional" building where and to the degree that it continues to be practiced. The writer conducted this type of research in southern Ghana, primarily in the Akan region, in the mid-1980s. The information yielded by this research is useful in developing a broader understanding of indigenous building technologies in tropical Africa based on the use of clay, wood, and other plant materials.

The Akan peoples inhabit roughly the southern half of the modern country of Ghana, and spill over into the eastern borderlands of Cote d'Ivoire. They constitute almost half of the population of Ghana, and in terms of history and culture are among the better known of West Africa's peoples. While the so-called "traditional" architecture of the Asante has been studied and is reasonably well known, that of other Akan groups has not received comparable attention, in some cases none at all. The study of Asante architecture has, in general, focused on the products of the building process rather then the raw materials and the building process itself. Considerable attention has been paid to the esthetics of architectural forms, and the uses and meanings that the various forms of enclosed space (e.g., shrine houses, palaces, etc.) were and continue to be imbued with. The focus here is different. Consideration will be given to the materials used in building construction.

In the mid-20th century, the Akan peoples were practicing a number of different building technologies, as were Ghanaians generally. Of these, only two can be described as being "indigenous." The two are *timber frame construction* and *coursed clay construction*. Both types, by the way, were observed by Schweinfurth in the Upper Nile region and northern central Africa, and are widespread throughout tropical Africa. The Akan and other Ghanaian peoples recognize these building technologies as being of considerable antiquity, long predating the colonial era. They have an existence in local oral history, as the writer was to discover to his surprise. Moreover, historical documents (i.e., written documents from the period of early European contact, or ca. 1500–1750) and archaeological evidence firmly support the idea of great antiquity.

Coursed clay construction is related technologically to the building methods known in other parts of the world as pise, tapia, rammed earth, and tauf. The product of this method is a structure with freestanding, solid clay walls. *Timber frame construction* is historically the more widely practiced of the two by the Akan peoples. It starts with a timber framework, which may then be closed in with a panelling of palm-fronds (this is the case with the Mangbetu "royal halls") or bamboo, or with a structure of clay and wood. The two techniques and resulting built forms are distinguished in local terminology. Timber frame construction finished with clay and wood is often referred to by the archaic "wattle and daub" by English speakers, although some more accurately call it "frame and plaster." In southern Africa it is known as "pole and daga."

Of the range of building materials employed in indigenous building construction, plant materials constitute the most varied group. These include a staggering number of hard and soft wood species, including several species of palm, and other woody plants, notably shrubs and lianes. Many of the tree species, especially the palms, provide not only useful timber, but leaves and bark. The leaves are used for thatch and in the manufacture of binding material. Sometimes, fibers, also used in the manufacture of binding material, are derived from the bark. Also included in this group are various species of grass, particularly bamboo and elephant grass.

Earthen materials consist primarily of clays. Most of the soil types of southern Ghana are characterized by strata classified as light to medium clays. These strata lie immediately beneath a layer of sandy to silty topsoil at depths of 20 cm to 2 m (Brammer 1962: 101–20). Light to medium clays are locally described as being "soft." What this means is that they are easily workable. With little difficulty, they can be trodden or mixed with a hoe into the proper consistency for building. The only thing required is the addition of water.

By contrast, those clays that are described as being "hard" are the types that are more suitable for pottery manufacture. Unlike some of the neighboring peoples, notably the Anlo Ewe and the Se (Shai) Dangme who occasionally use such clays for wall construction, the Akan have never used them for this purpose. Kaolin, *hyire* in the Akan language, is a "hard" clay that was used extensively by the Akan, but for the manufacture of white, yellow, or gray wall finish or plaster. At the time of the earliest European contact (the late 15th century), such plasters were a nearly universal feature of buildings in Akan towns.

As mentioned above, the earthen material used in wall construction is found nearly everywhere in the region inhabited by the Akan, lying just beneath the topsoil. The predominant soil types in southern Ghana are savanna and forest ochrosols, and to a lesser extent, oxysols. Tropical black earths are found, but are of limited distribution. From the point of view of agricultural potential, these differences in soil type have significance. In terms of use as building material, they do not. All contain light to medium clay strata.

Color is the primary characteristic by which the Akan distinguish soil types, but always in combination with other characteristics, for example, viscosity. *Notia/dotia*, or *netia/detia* is the generic term for soil. The different soil types are *notia tumtum*, *notia koko*, and *ntwuma*. Ntwuma is a sub-type of notia koko. Notia tumtum, literally, "black soil," refers to two different types of soil, both black in color. No terminological distinction between the two is made, although people are quite clear on the differences in terms of physical properties in general, and specifically with reference to use for building purposes.

One type of notia tumtum derives from the predominant soil type, notia koko (savanna/forest ochrosols). This type results from the decomposition of organic matter, in particular "kitchen" refuse, into the upper strata of notia koko. Thus, it is typical of the soil found under and around middens and other places of refuse deposit, and is also found near habitations. This type of soil is not at all suitable for building purposes, although excellent for kitchen gardens.

The principal type of notia tumtum is a tropical black earth. It is characterized by light to medium clay strata immediately below the topsoil and is thus appropriate for any type of construction. It has never been widely used by the Akan simply because its distribution in those parts of Ghana where they live is limited. In Ghana, tropical black earths are found principally in the coastal savanna (Brammer 1962: 116–7). They do constitute a good part of the soils of the Accra Plains where they are known as *Akuse clays*. There, they are extensively used for building by the Ga and Se Dangme peoples.

Notia koko, literally, "red soil," is the predominant soil type and the most widely used earthen building material. It is used in both timber and clay (wooden frame with clay plaster) construction, and in coursed clay (free-standing, solid clay wall) construction. It is used for walls, floors, courtyards, and hearths.

Ntwuma is described as a distinct type of notia koko. "Ntwuma" has been translated as "hematite" because it is used as a source of red ochre. The quality that makes ntwuma the building material par excellence for construction of solid, free-standing clay walls is its near ideal balance between clay, sand, and silt. It is widely distributed and is often found beneath the more ubiquitous notia koko by digging down to a depth of about a meter where the red earth matrix begins to reveal traces of yellow clay. The type of ntwuma used for plastering floors, courtyards, hearths, and wall bases, on the other hand, is of more limited distribution. It is quarried from special sites. It is distinguished by its deeper red color, presumably reflective of a higher iron content.

As mentioned above, the number of different species of plants that constitute building materials is extensive. F. R. Irvine (1962), in his *Woody Plants of Ghana*, lists 124 species of trees, shrubs, and lianes used throughout Ghana for building purposes, and this is not likely to be a complete listing.

Through several interviews conducted in the Brong-Ahafo region of Ghana, in the settlements of the Nkoransa Traditional Area and in the town of Nkoransa itself during the dry season of 1986–1987, the writer was able to compile a list of nearly 50 plant species used in building construction. Some 35 of these are species of trees and shrubs used to provide timber. An additional 13 species of trees, shrubs, and vines are used in the manufacture of binding material (rope, twine, etc.), plaster, and thatch. The trees that were identified as the main sources for the timber framework were mostly hardwood species. Some softwoods can be used for elements of the framework that do not come into contact with the ground, for example, thatch poles and rafters. But posts and studs require decay and insect resistant hardwoods (For a complete listing of plant species used in building construction along with their scientific names, see Appendix.).

Each tree, shrub, vine, and cane was thoroughly described in terms of its physical properties and its uses. Trees, for example, had the color and texture of their bark, sapwood, and heartwood described, whether or not the wood was soft, medium, or hard, and how resistant to insect attack and to decay. Discussions always went beyond uses in building construction to include information about uses in woodworking, of medicinal properties of bark, roots, fruits, etc., and uses for food, if any. Some species were said to have specific useful "spiritual" (for lack of a more accurate term) properties, and these, too, were described (For a detailed description of the collection and processing of building materials see Farrar 1996: 95–154.).

This vast range of building materials, earthen and plant, is the stuff of indigenous Akan building. In the past, the materials constituted the universe of Akan building materials and were used in the construction of two timber frame architectural forms and one of coursed clay. Of the two timber frame building types, one, the *mpapa-dan* structure, is built entirely of plant materials. The other, the *tare-dan* structure, consists of a timber framework with an infilling and final plastering of clay. The former is normally a type of temporary dwelling, while the latter is designed to have much greater longevity, or at least was so in the past.

The considerable skill that once characterized indigenous building construction was the product of centuries of technological growth. This process involved the acquisition of a profound knowledge of the environment and the multitude of resources therein, and the result was the evolution of architectural forms that were attractive, comfortable, and reasonably durable. The materials used in this type of building construction were widely available and easily accessible to most people. The tools used in their collection and processing were widely possessed. The skills associated with indigenous building were virtually universal, although some builders attained a level of building skill that earned them the status of "masters" in a way that separated them from others. And finally, the pressures placed on precious resources were minimal. These architectural/building traditions of tropical Africa thus represent an intelligent, rational, and efficient use of the local environment. They are yet another reminder of a largely ignored indigenous African technological ingenuity.

Appendix: Timber Used in Building Construction

Unless otherwise stated, the below-listed trees were described by Akan builders as having hard wood. Finer distinctions between hardwoods were made with respect to degree of hardness, resistance to insects and decay, etc., but are not indicated below because of limited space. Some of the characterizations of the hardness of the wood of various species are at variance with those of F. R. Irvine. The writer, in those cases, has stuck with the descriptions given by builders.

Abisiwa – Vitex Doniana.

Adobe – Raphia spp. The part of the tree that is used in the framework is the midrib of the frond. The leaves are used for thatch and in the making of a strong but soft fiber.

Asesea – Trema Guineensis. A fiber is also produced from the bark.

Atoaa – Spondias Monbin. A softwood timber that is not resistant to insects or decay. It is nevertheless occasionally used in the Bono region by "a lazy man who cannot find a hardwood tree," in the words of one Bono builder.

Babadua – Thalia Geniculata.

Dodowa – Sterculia Tragacantha.

Dwini – Baphia Nitida.

Fihankra – Tetrorchidium Didymostemon. F. R. Irvine claims that the wood is "soft and perishable," but Bono and Asante builders maintain that the wood is hard and insect resistant.

Kane – Anogeissus Leiocarpus.

Kokoaa – Identification uncertain. Possibly *Parinari Robusta*.

Kokobata – Pileostigma Thonningii.

Kranku – Butyrospermum Parkii. This is the well-known Shea butter tree.

Krayie – Pterocarpus Erinaceus.

Kwabedua – Dacryodes Klaineana.

Kyiribente – Lophira Alata.

Mmaa Kube – Borassus Aethiopum. Borassus palm.

Moto – Neuropeltis Acuminata.

Mpampuro/mkanpuro – Oxythenantera Abyssinica. Savanna bamboo. Although technically a grass, bamboo is used like timber in the construction of a house framework.

Mpapa – Elaeis Guineensis. Mpapa are the oil palm-frond midribs. The tree is called Abe.

Ngo ne nkyene – Cleistopholis Patens.

Nwoo – Identification uncertain. Possibly *Terminalia Glaucescens*.

Nyame Dua – Alstonia Congensis.

Odum – Chlorophora Excelsa. The leaves are also used for sandpaper.

Odwuma – Musanga Cercopiodes. A softwood timber used only for rafters.

Ofram – Terminalia Superba. A timber of moderate hardness, but not resistant to insects or decay. Used extensively for building purposes in the areas of dense forest.

Opesiakwa – Morinda Lucida.

Pam – Trichilia Heudelotii.

Pampani – Albizia Adianthifolia.

Pepaa/mpepea – Antidesma venosum.

Pinimu – Unable to identify.

Potorodom – Sterculia Rhinopetala.

Prekese – Tetrapleura Tetrapleura; also, *Prosopis Africana*.

Sisi – Identification uncertain. Possibly *Erythrophleum Africanum*.

Wama/awama – *Vitex Mesozygia.*

Fiber/Rope/Cordage Sources

Asense – *Urera* spp. A vine. Fiber is derived from the fibrous, woody interior.

Batatwene – Unable to identify. A vine. Cut and used as is.

Firaye – Unable to identify. A shrub. An extremely soft fiber is derived from the leaves.

Mfun/mfo – *Triumfetta Cordifolia*. A shrub. Fiber is derived from the stems.

Muto – *Neostachyanthus Occidentalis*. A vine. Cut and used as is.

Nem – *Ancistrophyllum Opacum* and *Calumas Deeratus*. The rattan palms. Fiber is derived from the split stems.

Notuo – *Hippocratea Africana*. A vine. Fiber is derived from the fibrous, woody interior.

Ntwea – *Hippocratea Rowlandii*. A vine. Cut and used as is.

Sibre – *Corchorus Aestuans*. A grass. Fiber is derived from the outer skin of the cane.

Sofo – *Christiana Africana*. A tree. Fiber is derived from the bark.

Toa-ntini – *Paullinia Pinnata*. A vine. Cut and used as is.

Sources of Thatch, Plaster, etc.

Asakoo – *Cissus Populnea*. A liane. The root–bark and stems are used in the manufacture of plaster.

Awuromo – Unable to identify. A shrub. The leaves are used for thatch.

Etoo – *Pennisetum Purpureum*. Elephant grass. The blades are used as thatch. The stalks, "hyiridie" (the Akan term), resemble small bamboo stalks and are used to build doors, gates, fences, "bamboo curtains," etc.

Sapotoro – *Grewa Mollis*. A tree. The bark is used in the manufacture of plaster.

Identifications were made with the aid of F. R. Irvine's Woody Plants of Ghana.

Architecture in Java

Gunawan Tjahjono

This article focuses mainly on the architectural objects of the Javanese people whose worldviews are closely related to the court society of Central Java, Jogjakarta and Surakarta. As architecture concerns ideas of making meaningful space, this article will discuss the spread of ideas represented by various building types.

Throughout their cultural history, the Javanese interacted with five major religions and cultures: Hinduism, Buddhism, and Islam, China and the West (Europe). The most significant influences are from Hinduism and Buddhism, followed by Islam. Chinese carpentry affected East Java and some parts of Central Java. Western culture introduced modern town planning and new building types.

The Javanese House: An Architectural Type

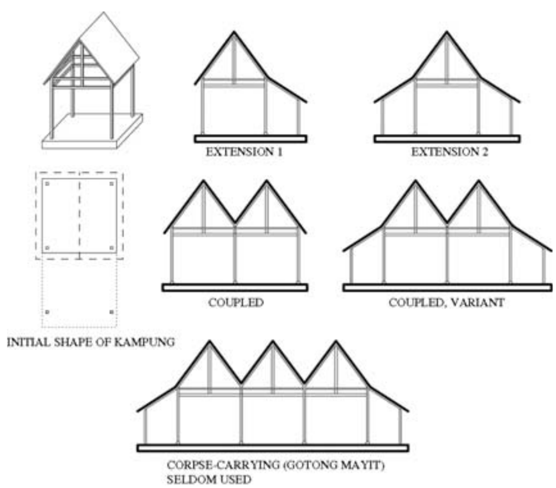
The house is perhaps the first structure human beings constructed to seek shelter. The inherent ideas in a house can thus serve as the architectural basis for other building types, such as temples, cemeteries, and cities. Although there are no remains of ancient houses, as they were constructed with perishable materials, one can trace the tradition of building houses from such remains as palaces and well maintained houses in two Javanese cultural cores around Jogjakarta and Surakarta; and also from the bas-reliefs of temples.

The temples' bas-reliefs illustrate the probable built environment of the Javanese past when stone and wood were the major building materials. Stone appeared in sacred structures, while wood appeared in residential structures. Buildings depicted there are on stilts. Tall pile structures as shown on the bas-reliefs of Central Java's temples can seldom be found in Java now. Low pile structures, as shown on the bas-reliefs of East Java's temples, can still be found in Bali. Thus people in Java probably lived on stilts.

Javanese houses differ in roof shapes but agree in plans. Roof shapes were connected to the social and economic status of the owners. There are three major roof shapes for houses; *Kampung*, *Limasan*, and *Joglo*.

- *Kampung*, also known as *Serotong*, is the simplest shape and is used by the common people. It consists of four main posts braced by a double ring of beams. Two upper posts stand at the middle of one pairs of beams, usually those parallel to the north–south direction, to support the roof ridge beam. Two roof sheets meet at this line and fall away on either side of the beam. The roof can extend in one or two directions at different angles (Figs. 1, 2).
- *Limasan* is a more elaborate *kampung*. It requires more materials and effort to build and is associated with a higher socioeconomic status. It contains eight posts to support its trapezoidal roof. Two transitional posts rise at the middle of the beams that span the interior space between the middle posts. The main roof extends evenly to four sides (Figs. 3, 4).
- *Joglo* looks like a more developed *limasan*. It is more difficult to construct and was the most favorable shape for the nobility. It embodies several distinct features. These include a steeper main roof which resembles a pyramid that comes to two points and four main posts hold layers of wooden blocks which step back in several directions. The outer layer of these blocks holds the roof, while the inner, *Tumpang Sari*, the "essential piling up," divides the ceiling into two inverted pyramids (Figs. 5, 6).

A house consists of at least a basic unit containing essential spatial patterns that all social strata share. All houses have a sanctuary and two storerooms, a clear boundary between the inner and outer domain, and are patterned according to the hierarchy of sacredness of place. The house plan is independent of the roof shape,



Architecture in Java. Fig. 1 The Kampung (Schematic drawing. Illustrator: Paulus).

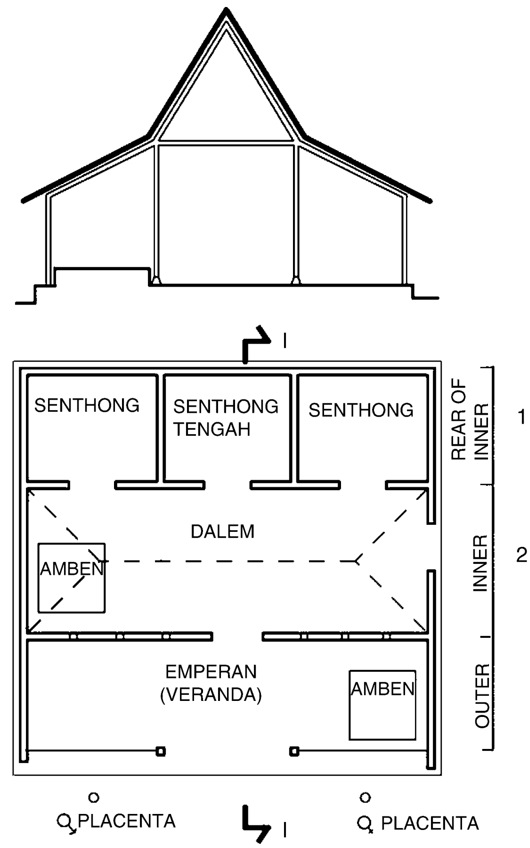
Architecture in Java. Fig. 6 Photo image of Jogo (author's collection).

especially for *kampung* and *limasan*, and to some extent, for *joglo* which has a more elaborate spatial division.

The basic unit of a house is *omah,* which employs a rectangular plan emphasized by a raised floor. It encompasses an inner and an outer domain defined by wall panels. The outer, *emperan* or porch, is about 2 m wide to accommodate the family's more public activities. There is a wide bamboo bench for sitting, lying or sleeping. A wide door at the middle of the front wall connects this domain to the inner part.

The inner, *dalem*, is an enclosed structure which is subdivided into either two: front-rear, or three: front-middle-rear sections along a north–south axis. Each section suggests three spatial domains along the east–west axis. A two-section *dalem* applies usually to a *kampung* or a *limasan* roof, while a three-section one is for a *joglo*.

The middle section, if any, which is defined by four main posts at its center, has no exact usage. The central part was where the incense was burned once a week in honor of the rice goddess Sri, who occupied a permanent place in the house at the center of the rear section.



Architecture in Java. Fig. 7 Plan of a two section Omah (Illustrator: Paulus).

The rear section encompasses three enclosed rooms called *senthong*. The west senthong stored agricultural products. The east one stored other equipment or was sometimes empty. The middle senthong was the most lavishly decorated but the least used part of the house. It was the sanctuary of the rice goddess Sri and thus took the form of a fully equipped bed. The function of this room would be fully revealed during the most celebrated ritual, the wedding ceremony. In this ritual the bride and bridegroom sit at the front of the *senthong tengah*, underneath the house ridge. Now many Central Javanese have transformed the once sacred *senthong tengah* for prayer. Many new houses now do not follow concepts from the recent past but from examples of new models in the big cities (Fig. 7).

An ideal house should have at least two, and if possible, three main structures: an *omah*, a *pendapa,* and a *peringgitan*. Pendapa is a roofed open hall located at the front yard of an omah. Its shape, size and position of posts are often akin to those of the omah. It displays a different spatial quality from that of an omah. It is open, accessible and lighted, while omah is opaque, forbidden and dark. Pendapa is the public domain of a house, a place for gathering and ritual performance and informal entertainment. Peringgitan, which employs a *kampung* or a *limasan* shape, connects pendapa to omah. It is a place for the performance of the shadow puppet play *wayang*, the ritual in Javanese culture that predicted life cycles, harvest, and higher rank career promotions.

The kitchen stays outside an omah, separately built near the well. A well should be the first to be dug out prior to the construction of any erected structure. The well also serves a later developed lavatory which has its own structure at the left and the back of a house compound. As the number of families and income grew, new structures expanded first to the east or to the north, then to the south for pendapa, and next, as needed, to the west to complete the symmetry. In an expanded house, the family lived in the wings and the omah became a real sanctuary.

Most houses in Central Java whose entries were facing south have front, sides, or back yards within a clear boundary marked by a brick wall or low fence. The enclosed wall often has a roofed or unroofed gate, which connects the inner world of family to the outer universe of community. After selecting and purifying a site and after digging out a well, the next step is to determine the location of the omah, as it should always be built first. After setting the omah's position, the team of community volunteers led by a carpenter starts the construction. The basic house plan is a matter of measurement and house shape of affordability. The carpenter will adjust the dimensions derived from the dweller's body to determine the size of the house.

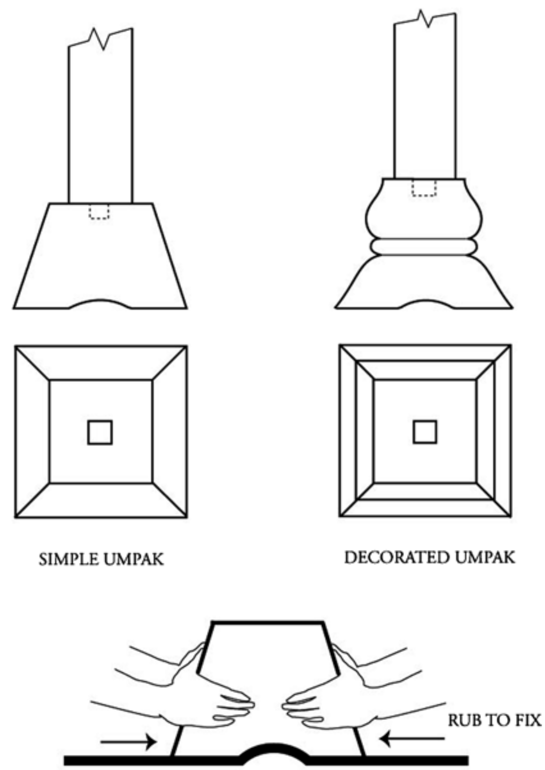
The construction follows this sequence:

1. Dig the well
2. Erect the omah
3. Build the east *gandok* or kitchen
4. Construct the pendapa
5. Finally set up the west gandok
6. Fencing is the last, if needed, to be done

Construction proceeds by leveling the site and improving the strength of the soil by piling bamboo or stones around the edge of the main building. Its floor is often elevated to help drainage. The main posts are usually on *umpaks*, the three dimensional trapezoidal stones which act as transitions between the posts and foundations. The size of the umpak varies, from 20×20 cm^2 to more than a square meter, dependent upon the dimension of the post, which commonly ranges between 12×12 and 40×40 cm^2. Umpak is a structural device which reduces horizontal forces caused by earthquakes. It prevents the posts from the infiltration of ground water. The wooden posts always stand according to the direction of tree growth (Fig. 8).

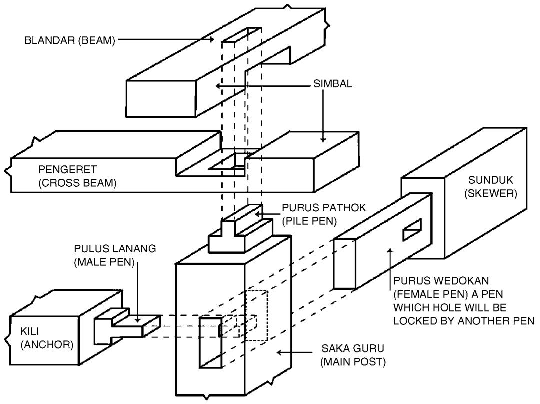
Two or three parallel beams join the post at its top. The posts may directly support roof trusses or roof beams. In the case of joglo, the main posts are usually topped by two sets of inward stepped wooden piles, *tumpang sari,* and outward stepped piles, *elar*. The number of tumpang sari steps reveals the status of the owner. The roof sheet is framed by wood blocks or bamboo sticks (split in half); the smaller blocks or sticks are laid parallel in a horizontal position with some distance between each other. All blocks are in a horizontal position rather than upright which, as seen individually, is more appropriate to the law of force of material (Fig. 9).

The post has pens at both ends; the lower fixes the umpak and the upper plugs in the hole of the main beam, which represents females. At the upper position



Architecture in Java. Fig. 8

Architecture in Java. Fig. 9 Tumpang Sari (Author's collection).



Architecture in Java. Fig. 10 Construction join (Illustrator: Paulus).

of the main post, a hole is cut out to be filled by the pen of a secondary beam which acts as a stabilizer, as opposed to the beam above it. The basic structure is stable upon the completion of all plug-in procedures. The term for pen is *purus* meaning the male sex organ. (Fig. 10).

Modular Coordination and Mobility

The Javanese book of carpenter Kawruh Kalang mentions the basic measurement unit *dim* which is determined by either the length of a foot or the width of a fist. The length of beams and the interval between posts apply the formula $5 \times n \times \text{dim} + m$. The m should be within one to three because four or five dim is considered an inauspicious number for the initial structure, and n is any number defined by a special event such as a wedding. In it a fourfold modular grid based on serving devices is applied. Under such a practice, the interval between the main posts averages 2.5 m, being approximately the width of two floor mats. Plug-in construction join and the application of modular coordination have the flexibility to mobilize the house. A house can be moved after it has been torn down into construction parts and refabricated at other preferable places.

Although there is no concrete proof about the origin of Javanese houses, they can be traced back to agricultural tradition. Buildings for worship or commemoration altered as religion changed. However, the ideas that generate a house remain the source for the spatial arrangement of other buildings.

Buildings for Worship: The Hindu–Buddhist Legacy in Javanese Architecture

Hinduism and Buddhism, whose imprints in Java can be traced back to the fifth century, affected most forms of cultural expression, such as religion, art, (a certain degree of) social organization, technology, language, and statecraft. The intensive ceremonial life filled the interior Javanese landscape with *candis* (temples). Remains of habitats in the forms of foundation stones that spread around various candi complexes indicate that social organization was centered on religious ceremony at the state and, to some extent, the village level.

In prehistoric Java, mountains were the places where the ancestral spirit could be contacted for protection and prevented from their wrath by offerings. *Lingga*, an upright stone and *yoni*, a flat stone plate, were possibly the first erected effigies to consecrate the center of the universe symbolizing creation and fertility. Later on, Hindu Javanese candis were designed to replicate mountains at the high places where spirits of the gods could be induced to go down into a lingga in a cave-like hall. Candis were enclosed by walls to divide the sacred inner from the profane outer. In the inner zone the priests presented offerings, performed prayers, and contacted the gods when they descended to earth. Thus temples were not for holding large numbers of peoples.

As religious buildings, candis were built to last in stone or brick. Archaeologist Jacque Dumarçay observed that the Central Javanese stone candis developed the techniques of interlocking stones articulated with perspective effect to cast expected results. They cut the stones into several modular blocks and created stone courses by joining stones placing one on top of the other without mortar.

The early eighth century Hindu Javanese candi compound is located at the Dieng Plateau. The four major candis known as Arjuna group face west. Candi Arjuna comprises a square room constructed over a pit containing a foundation deposit for ritual. The stone blocks interlocked through tongue-and-groove connections by having cut a section out of each stone in horizontal and vertical directions. The eighth century Buddhist temple compound Candi Sewu's stone wedges were driven between the stone blocks, pushing adjacent sides outward toward the corner of building, strengthening the course and reducing the gap between joints. The ninth century's Candi Loro Jonggrang of central Java exemplifies the greater stone technology achievement in Hindu Javanese candis. Here, according to Dumarçay, the technique of double-leaf walls was adopted by establishing a pair of parallel walls, then filling the gap between them with rubble or unshaped stones by using mud or lime.

The Buddhist legacy Borobudur of the ninth century exemplified such techniques with an adjusted ten-layer *mandala*[1] plan. The 113 m side long square plan base tells the story of a worldly sinful life through carved

[1] Mandalas are geometric designs intended to symbolize the universe.

bas-relief. Ascending from the base are three layers of stepped enclosed roofless corridors with each wall relief describing the world of daily life. Up another three layers one finds on one side a slightly opened corridor which depicts the world of form as the intermediate experience of the last three layers. The last three layers represent the formless world without enclosure so one can also look out against the blank wall. At the top layer, whose center is a *stupa*, you could watch your surroundings as if the whole universe were under your eyes. To experience Borobudur, one ascends nine peripheries of adjusted squares whose size decreases gradually to the top. It brings visitors through a spiral labyrinth route to find nirvana.

Candi Loro Jonggrang exemplified the highest achievement of the Central Javanese Hindu legacy. Consecrated in 856, it was a complex dedicated to Siva and was possibly related to a town of the same size. It consists of three walled courtyards on ascending terraces. The inner two courtyards are concentric and facing east, while the outermost is aligned another way. The terraces are made of heaped-up earth. Eight major sanctuaries fill the upper terrace. Three cruciform plan structures are devoted to the trinity of Hinduism, Siva, Vishnu, and Brahma. Facing each is a smaller structure for vehicles or mounts of the god. Two accompanying candis stand at the south and north entrances of the complex. Two hundred and twenty-four smaller structures fill the four lower terraces of the middle courtyard; those at the corners have two doors and the rest have one door. Such an arrangement recalls the image of mandala (Fig. 11).

Architecture in Java. Fig. 11 Lorojonggrang of Prambanan (author's collection).

Dumarçay concluded from his research on the stone construction of temples in Southeast Asia that Borobudur and Loro Jonggrang applied a perspective principle to create special visual effects in their construction, so that visitors could experience the glory of their existence from various angles. For Borobudur it is at its base that this effect was applied so that its upper terraces would be visible. In Loro Jonggrang it is through the manipulation of the form which enhances the feeling of height.

Buildings for Worship: The Islamic Legacy in Javanese Architecture

Islam spread gradually from the twelfth century on. It began with trade around the ports and then infiltrated the interior of Java. The earlier Islamic buildings retained references from Hindu architectural elements such as ceremonial gateways, split portals and multilayered roofs.

The concept of early mosques in the interior cultural core of Central Java around the sixteenth century resembled that of a house. Dutch scholar de Graaf identified seven distinctive features of these mosques as (1) a square plan, (2) a raised solid floor, (3) a multilevel roof that peaks to one point, (4) a roofed veranda called *serambi* at the front, (5) a *mihrab* – an annex or niche on its western or northwestern edge to indicate the direction of Mecca, (6) encircling by water, which in turn is surrounded by open spaces, and (7) a wall that encloses the whole complex. In addition to those features, the door of early Javanese mosques faced east, with the prayer direction oriented toward the west rather than Mecca.

Of these features, the square plan, raised floor, and walled enclosure can be found in the structure of the remaining Hindu Javanese temples, while the one-point multilevel roof is a common element of the Balinese Meru that existed in East Java before the domination of Islamic culture. The niche, *mihrab*, is a common element in mosques elsewhere in the world; perhaps each regional culture incorporates it differently. The encircling water is an adaptation of a moat appropriated to Javanese cosmology which can be found in old Javanese palaces. *Serambi* is a typical Javanese creation. Separating the sacred domain from other domains is parallel to the division of activity zones in a house. An ideal complete house exemplified such an idea by separating other daily activities from omah, especially the senthong tengah. The spatial quality of a sacred domain, which was usually governed by darkness, as in the main mosque and in the dalem, appeared to dominate Javanese thought (Fig. 12).

The great mosque of Demak of Central Java exemplified all the principles and became the model for

Architecture in Java. Fig. 12 The Great Mosque of Jogjakarta (author's collection).

the subsequent mosque around coastal Java. Its influence continues, as can be seen by the reproduction of its basic shape in the mosques built around Indonesia sponsored by former President Suharto. The four main posts that support the upper roof were originally made by tying pieces of timbers with iron strips.

The additional element in many recently built mosques is the crown, which is now in the shape of a small dome, a result of native adaptation of an outside idea. The onion shaped dome has been associated with Islamic architecture in many parts of the world. However, such a dome has seldom become the main body of the roof in the Javanese mosques. A dome reduced in size is employed as a crown to top the roof. It is interesting to note that any new mosque, whose construction is funded by a special presidential grant, must follow the traditional Javanese two-layer *tajug* roof shape.

The House Extended: Settlement, Palace and City

Settlement patterns in the cultural center of central Java follow the north–south axis. Almost all traditional houses located in this district face south. Some coastal settlements are linearly aligned facing east for the north coast of East Java. The linear arrangement appears in many coastal zones. This is the most practical arrangement considering coastal conditions. Rural houses seldom have pendapa. Housing in the Cilacap, southern Central Java coastal area, has a common hall as a collective pendapa. This instance raises questions as to when the pendapa became the exclusive property of the urban elite.

A concentric settlement called *mager sari*, or fencing the essence, applies in urban Central Java. In it the houses of the wealthy were enclosed by the servants' houses. It is a reflection of a feudal society which illustrates the master–servant relation. The master is the center and the servants are represented by the fence. The palace or *kraton* compound exemplifies these relations.

Kraton refers to the seat of a ruler at a level of king or prince. The term is widely used in many Indonesian Islands such as Sumatra, Java, Kalimantan, Sumbawa, Sulawesi, and Maluku; it is applied not only to an Islamic kingdom, but also a pre-Islamic one. Kraton was a dynasty's center of power, and usually generated an urban environment around it. In Java, e.g., it was the kraton, rather than the territory that identified a kingdom's geographical image.

Most kratons are located on a plain served by a river and its tributaries. In Java, the seat of a kraton was usually backed by a single coned sacred mountain. The Javanese kratons manifest these relations even stronger through axial positioning of the building complex toward the sacred mountain. A kraton comprises several buildings within a clear boundary. Descriptions of such boundaries of older kratons have not been supported by archaeological findings; possibly the materials for the palisades could not survive the tropical climate. The fence can be easily found in more recent kratons. Large kratons, such as those at Banten in West Java, Cirebon in Central Java, Jogjakarta, and Surakarta, had stone-walled boundaries. The wall was a defense device as well as a representation of hierarchical segregation based on status or sacredness.

As an ideal center, the alignment of a kraton reflects the ruler's views on the universe. The kratons of both Jogjakarta and Surakarta expose these images through a series of courtyards and gates lined up on a north–south axis. The axis replicates the directions of the mountain and sea and of cardinal points in Hindu cosmology. The Sultan's residence contains the royal pleasure garden which is located on the outskirts of the inner wall. The main pendapa, where the Sultan held audience, is the only building that faces east. This pendapa created a new east–west axis.

The main pendapa exemplified the most refined construction of a joglo. Timber blocks and rafts frame its roof sheet. The rafts are laid parallel in a horizontal position with some distance between each one. They are tied onto the layers of larger blocks and are arranged in a sun ray or centrally organized pattern. All the blocks are horizontal rather than upright. Dutch architect Maclaine Pont suggested that the Javanese

Architecture in Java. Fig. 13 The Great Pendopo of Jogjakarta Kraton (author's collection).

treated their roof as an entity rather than the sum of individual elements (Fig. 13).

The *alun–alun* or town square is related to the seat of power. Two banyan trees stand at the alun–alun's center to symbolize harmony. The alun–alun was the meeting place of the Sultan and his people. It held major state rituals, festivals, games, and in the past was a place for punishment. The north alun–alun of Jogjakarta still hosts major cultural events today. It is encircled by several important buildings – the state mosque at its west, the main market and a prison at its north, with some other buildings around. The mosque was usually followed by a compound of the *kaum* – the religious experts who initiated religious rites and ceremonies – called the *Kauman*.

The kraton determined the conceptual layout of the city associated with it. From the toponyms one can trace this order in such old towns as Kuta Gede near Jogjakarta and Banten. According to sociologist Selo Soemardjan, the city of Jogjakarta exemplifies the social strata through several rings, which started with the Sultan at the center, with his family around him, and other nobility within the walled compound. Around the wall is the ring of town community surrounded by the rural community. The town community comprises those who have frequent contact with the ruler such as the smiths, the slaughterers, the carpenters, the kaum, and the merchants. The rural community is in charge of cultivating agricultural land.

The layout of both Jogjakarta and Surakarta suggests a Javadvipa, the central continent of the whole cosmos which consists of seven rings of continents separated by seven rings of ocean. Javadvipa contains seven mountains and six plains along a north–south axis, and four mountains and plains along the east–west axis. At the center is the *Mahameru*, the sacred mountain. Both kratons have six courtyards and seven gates with the seat of the sultan at the center to represent this inner cosmos.

This pattern, to some extent, can also be found in a coastal Javanese kraton and its cities. Since the coastal areas had many foreign traders, the ruler also provided a special zone for foreigners which served the same function as a kampung.

Kraton, square, state mosque, and market are the basic features for most Javanese towns. Their appearance set guidelines for building shapes around them. The other governmental centers followed such patterns during the period of Dutch control. The square accommodates recreational activity for the citizen. The mosque also serves as a religious court. The markets have peak activity once a week. There are coastal markets, littoral markets and agrarian town markets. Their location defines the character of the town economy. Such patterns also appeared in other towns, with the office of the ruler at the center and a town square which connected the mosque, marketplace and prison.

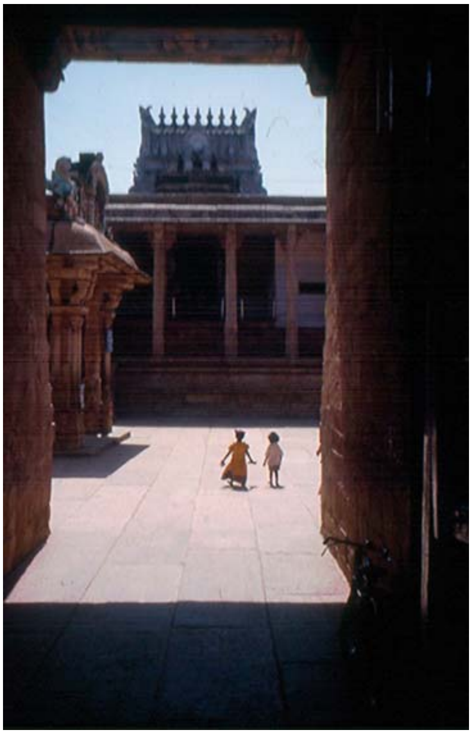
Architecture and Landscape in India

Alexandra Mack

Architecture and landscape are connected on many levels in India. The meanings imbued in the architectural forms create diverse conceptual landscapes overlain on the same geographical area. Architecture defines the landscape, and the presence of different architectural traditions helps create these multiple landscapes. Architecture is used to highlight the landscape's association with the cosmos, with mythological events, with historical and current events, and is also the frame for where people live and work (Mack 2004). This essay will focus primarily, though not exclusively, on architecture built in the Hindu tradition.

The connection between the earthly landscape and the celestial landscape has been apparent in India for thousands of years. There is evidence at Dholavira and other Harappan sites that the cities were planned with axial orientations, apparently following the placement of sky based features (Bisht 2000). Celestial orientations become more apparent in cities and towns built based on the sixth century architectural manuals known as the *vāstuśāstras*, which mandate a grid plan based on the maṇḍala form (Deva 2000). The maṇḍala can take many forms but is essentially a series of concentric geometric figures which represent the structure of the universe. The figures of circle, square, and triangle can be interpreted as representing the elements of light, water, and wind, respectively. They can also represent the four directions, the nine planets, and the three mythic realms (Singh 2000). Maṇḍala-inspired architectural arrangements reflect the cosmological structure in the earthbound landscape, thus connecting the two.

The maṇḍala is frequently represented in Hindu temple complexes and the surrounding towns. This structure is most apparent at sacred sites which serve as pilgrimage centers. The maṇḍala is first reflected at the level of the individual structure of the temple. The geography of the temple is ideally situated on a north-south axis, with enclosure walls and circumambulatory paths creating a series of concentric squares. The *vāstuśāstras* even dictate a formal ritual for measuring and laying out the shrine. Temple towns are frequently laid out to continue the maṇḍala plan, with the temple complex at the center of the town, and streets running around the walls and leading out from the gateways in the cardinal directions (Michell 1993). At Srirangam, the temple is enclosed by seven sets of walls, creating a clear maṇḍala form radiating outward and encompassing part of the town (Fig. 1). Likewise, Madurai and Chidambaram have multiple enclosures around the central temple, with main streets running parallel and perpendicular to the complexes. Some temple towns, such as Kanchipuram and Kumbukonam, house multiple temples, and the spatial arrangement in the town reflects this. Each temple is the center of its own district, and each district has a distinct geometric form. Roadways in these towns tend to link these distinct neighborhoods, forming a unifying whole in that way.



Architecture and Landscape in India. Fig. 1 A view from a gateway into one of the interior courtyards of the Ranganatha Temple at Srirangam shows how the complex is a series of embedded rectangles.

The geometry of the built environment spreads out into the landscape, thus imposing a structure on the landscape through architecture.

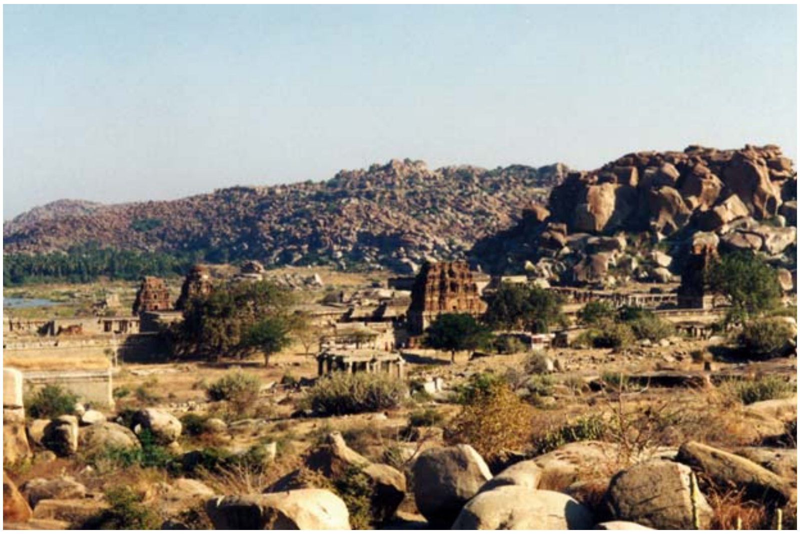
While the built environment can structure the landscape, the physical features of the landscape determine the placement of architecture and influence the nature of the geometric forms of the towns. Vijayanagara is set in a landscape of bouldery granite outcrops, leaving the valleys between as prime construction areas (Fig. 2). Nonetheless, while the landscape strongly influenced the placement of structures, the city nonetheless shows an axial layout and cosmological affinities (Malville 1994).

Circumambulation reinforces the connection of the natural and built environment, and draws connections to the celestial world, since circulatory paths in India are often represented by the maṇḍala. Physically moving though the geometric pattern symbolizes a cosmic journey. The *panchakroshi* route at Varnasi moves pilgrims through 108 shrines spaced in a mathematical pattern which embeds the geography of the site into the psyche of the pilgrim. The 108 shrines also represent a cosmic circuit based on 12 zodiac signs and the nine planets of Hindu mythology (Singh and Fukunaga forthcoming).

While the maṇḍala is an ideal form, influencing architectural constructions, the landscape itself is a key determinant in the location of these structures. Landscape features have sacred qualities, but the built environment is fundamental to imbuing the land with meaning. Landscape and architecture thus are intertwined physically and conceptually. The *vāstuśāstras* prescribe the placement of settlements near water sources, such as river confluences. Rivers represent confluences of sacred and profane and provide homes for deities. Therefore rivers become magnets for settlements and sacred sites, though a nearby water source is essential for sustaining a population, irrespective of the holiness of the site. Most of the ancient towns in India are found of the banks of sacred rivers, such as the Ganga and Yamuna. The seven cities (*Saptāpurī*) of Varanasi, Mathura, Ayodhya, Ujjain, Dvarka, Kanchipuram, and Hardvar are all located on peninsulas, surrounded on three sides by water.

Hills and mountains are also an important landscape element in the Hindu tradition, and like water these features provide domiciles for gods (Fig. 3). The mountain of Tirumula is the home of the god Sri Venkateswara, and the temple there draws the largest number of pilgrims of any Hindu temple. The town of Tirupati at the base of the mountain developed in support of this holy site (Nag and Reddy 1994). The hill at Tiruvannamalai symbolizes the column of fire from which Shiva emerged, and serves as the basis for the conceptual spatial organization for the town. Patterns of movement also serve to connect buildings with the natural landscape. Circumambulatory routes and ritual paths extend far beyond the temple complex, connecting multiple shrines, in cases such as Varnasi, or encompassing the landscape itself, such as the circumambulation of the sacred mountain at Tiruvannamalai, which also includes a journey through the town itself (L'Hernault 1993). These routes blur the line between the built and natural environments.

Beyond the water and hills, entire landscapes are often imbued with symbolic and mythological meaning. Landscapes associated with the Ramayana legend are key examples of this phenomenon, as seen at sites such as Ayodhya, Chirtrakut, and Vijayanagara



Architecture and Landscape in India. Fig. 2 The Vithala temple complex at Vijayanagara is set in a valley below granite outcrops, near the Tungabhadra River.

Architecture and Landscape in India. Fig. 3 A shrine on the top of Malyavanta Hill at Vijayanagara blends with the rocks.

Architecture and Landscape in India. Fig. 4 Humayun's tomb in Delhi sits in man made landscape, where the tanks, gardens, and walkways follow a grid pattern.

(Sinha forthcoming). The pilgrimage circuit at Ayodhya, the site of Rama's birth, takes worshippers to shrines along the banks of the Saryu River, which encircles the town. The river, ghats, and shrines combine to form the total landscape. At Chitrakut, the physical landscape is dominated by the Mandakini and Payasvini rivers, and enhanced by the specific sites associated with Rama and Sita. The area around Vijayanagara is associated with Kishkinda, the monkey kingdom. The Tungabhadra River cuts through the landscape, though the hills form the most significant natural features, and many are associated with the Ramayana—Hanuman is said to have been born on Anjenadri Hill, and Rama and Lakshmana waited out the monsoon on Malyavanta Hill. These hills have been adorned with temples commemorating these events, intertwining the man-made and the natural.

Architectural associations with important events and personages are seen at a variety of sites in India. Stupas, which themselves represent the body of the Buddha, house relics, though in these cases the relics have been brought to the site, and were not necessarily an inherent part of the landscape before construction of the stupa. Elaborate tombs built by Muslim rulers include tanks, gardens, and well-defined paths, creating their own landscape (Fig. 4). Muslim dargahs often attract pilgrims who honor the holy men entombed within, and mark the importance of a specific place on the landscape. Religious claims on the landscape are not necessarily exclusive; multiple religious shrines from different traditions share the landscape at sites such as Ellora and Mathura (Ray 2004).

This historic and mythological significance of the landscape and the associated religious architecture was

Architecture and Landscape in India. Fig. 5 Children playing and grinding food on a side street near the Banashankari temple, occupying the "quotidian landscape."

also used by rulers to lend credence to their claims to power. Basu has argued that the Buddhist Kushan rulers at Mathura built structures specifically to associate themselves with the site's existing sacred geography (forthcoming). Early in the development of the Garhat states of Orissa, forts and settlements were placed on the landscape with defense and supply from nearby villages in mind—forts were protected by hills and jungles. However, rulers maintained their link with the villages by associations with local deities, who were worshipped within the walls (Kulke 1993). This legitimation through the ritual landscape grew in scale as the towns grew. The Ramachandra temple at Vijayanagara was used by the kings to enhance their legitimacy, by associating themselves with the god-king who spent time in the surrounding area. They used the architecture and specifically the placement of the buildings, to build those associations. The temple was built in the heart of the Royal Center, amid palaces and the kings' seat of power. Fritz has argued that the city was planned such that the Ramachandra temple lay at the center of routes of circumambulation and was on an important north-south axis in the city, such that the overall structure of the city was planned to draw associations between the rulers and Rama (Fritz 1986). In this case, the mythic associations of the site were manipulated by Vijayanagara rulers to enhance their own power and to legitimate their rule in the eyes of local chiefs and other high-ranking citizens. However, the sheer act of construction was also used for legitimation, with or without mythic associations. Medieval temples with towering gateways were, and in many cases still are, the most dominant landscape features, and were directly associated with rulers whose funds aided their construction.

While research into the importance of cosmology, mythology, and legitimation have dominated landscape studies in India, the most common usage of the landscape has been for day to day residential and subsistence activities. Most importantly, these activities occur in the midst of all the other happenings. For instance, while axial layouts and cosmological orientations are applied to temples and surrounding towns in order to maintain a ritual integrity, these neighborhoods are also the centers of everyday life. At Srirangam, which was mentioned earlier as an archetypal maṇḍala shape, boys play cricket in the streets on the outer circuits of the walls. A few steps from the primary circumambulatory routes in any temple town leads to residential areas, local shops, and mundane activities—a quotidian landscape (Fig. 5). This overlay of secular and religious use of the same landscape is seen throughout India, at sites sacred to all religious traditions.

Architecture of the Maori People

Michael Linzey

The most striking fact about Maori architecture is that it is a living presence in the traditional heart of the community. When a New Zealand Maori orator stands to speak in front of a meetinghouse, he (or sometimes soon it may be she) addresses the house directly and in the same breath also addresses the assembled people. This fundamental understanding that the *wharenui* (meetinghouse) is a living presence is richer than any mere simile, it is beyond the idea of a metaphor or a representation in the European sense (Mead 1984). The house is not *like* an ancestor, it *is* the ancestor. Maori people conceive of cosmogenesis as an evolution in three parts: *te kore* is a nothingness condition of endless possibility, *te po* is a long night that is rich in potentiality, and *te ao marama* is the world of light which is to say the actuality of the real world. These three fundamental states of existence are represented on the door lintels of traditional architecture (Simmons 1985. 43–47). This traditional understanding resembles the triadic cosmogony of Peirce (Peirce 1992, v. 1: 285–297); it may not be entirely surprising therefore that the idea of an interconnected life-force, *mauri*, pervades the physical world of the Maori, and that architecture is included in this universal embrace.

I am not talking here about the precontact condition of Maori architecture [about which anyway very little is known (Phillipps 1952.rpar;]. What is more significant is that the Maori comportment toward architecture has survived within a predominantly European ambience of New Zealand life, perhaps indeed it developed more pronouncedly within the clash of cultures that was the introduction of colonialism and the rise of nationalism during the nineteenth and twentieth centuries. Modern Maori are not isolated from the majority culture, just as in New Zealand nothing European can claim to be isolated from the Maori presence. But whereas we sometimes lament the loss of meaning within European architecture, and some even go so far as to say that architecture is dead, the architecture of the Maori by contrast is radically alive. It is a living example of the scientific condition that Peirce called "objective idealism," in which the material world itself is understood to be fundamentally alive.

In the confines of this short article three aspects of the living meaning of Maori architecture are addressed. They are its *faciality*, its *ornament*, and an aspect of its *space*. Relevant terms in the Maori language are *mataihi*, *whakairo*, and *kauhanga*. These are not general terms; they have meanings that are quite specific to architecture. In particular the *wharenui* is often also called (and addressed as) *whare whakairo*, meaning a house that is adorned with pattern. *Mataihi* specifically means the gable-end (the front) face of the *wharenui*, and *kauhanga* or *kauwhanga* is the interior space down the middle of the *wharenui* specifically when it is in a *tapu* or highly potent state. Necessarily these three aspects of architecture have to be addressed separately in this article, but they are not separate, not even interrelated concepts. Rather they are three valences that together go to make up the single meaning of addressing the *mauri* or life force in Maori architecture. If I may follow Peirce for a little bit longer, this triadic situation can be compared to an ordinary street sign. A street sign also *faces* us, *points* out a direction in the world, and *tells* us something about what is happening in that direction. The three valences *together* make up the whole meaning of the sign. A reader may be advised to take in what follows here, necessarily in the sequential order of the text, and then to think about it again in a few days time. Perhaps then some small appreciation may be gained about the liveliness of Maori architecture as a whole triadic sign.

Faciality, *Mataihi*

In Maori, as in most of the Austronesian languages, *mata* is a word that signified the leading part or the growing tip of something. It does not indicate a direction, but a frontal *sense* of direction. As well as meaning a person's face, *mata* can also be a prominent geographical point, like a headland, or a rock which marks the leading boundary between fishing grounds.

The prefix *mata-* is used in words that mean a first appearance, for example *mataika* is the first person slain in a battle. *Mataaho* is the window of a house, metaphorically perhaps we could think of it as the "eye" of the house. *Mataihi* is the gable-end "face" of the meetinghouse. In the *Williams Dictionary of the Maori Language*, the word *mataaho* was recorded as early as the first Edition (1844). *Mataihi* appeared for the first time only in the fifth edition (1917). This is not to say that *mataihi* was not a traditional word, but its architectural meaning was perhaps less obvious to early lexographers than *mataaho* was.

Internationally, the ornamental *mataihi* of the *wharenui* is the best-known icon of Maori architecture, comparable to the full *moko* tattooing of the chiefly face. As often as not it is the stately face of Te Tokanganui-a-noho that has carried this image of Maori architecture to the wider world. Te Tokanganui-a-noho is one of the oldest extant meetinghouses. It was built and reconstructed and relocated over a period of years from 1873 to 1882 under the supervision of a visionary leader of the time, who was also the founder of the Ringatu Church, named Te Kooti Arikirangi Te Turuki (Binney 1995. 272–281). The design of this house not only reaffirmed traditional values in a time at which Maori were experiencing all sorts of upheavals, it was also without doubt the most innovative house of this period and it started many trends that were taken up in later meetinghouses. In particular Roger Neich (1993: 175–185) notes that most of the carvings on the gable-end face of this meetinghouse (with the notable exception of the carved door lintel and doorposts) were brilliantly delineated with polychrome paint; naturalistic flowers and religious symbols were painted on the vertical boards inside the porch, and naturalistic portraits of historic personages were on the door panels.

Almost all modern (postrenaissance) meetinghouses in New Zealand now adopt the traditional gable-end form. However the rectangular plan of the *wharenui* and the characteristic gable-end porch is not the only form in which Maori architecture has ever been expressed. A very traditional *whare wananga* or house of learning named Miringa Te Kakara was first built probably in the 1860s and destroyed by fire in the 1980s. This beautiful work had a distinctive cross-shaped plan and four *mataihi* facing the directions of four mountain ranges. Another memorable image is that of the circular "beehive" shaped assembly house named Hiona which was built early in the twentieth century by Rua Kenena (Binney 1996). An awkward-seeming scaffold, platform and staircase were constructed to one side of Hiona which may have been a necessary substitution for faciality in the form of this work. Many Maori churches too do not display the traditional *mataihi* form. In the case of one early church, Rangiatea, completed in 1851 by the famous chief Te Rauparaha, it is recorded that the Reverend Samuel Williams played an important role in its design when after a dispute and in the middle of the night he cut a 10 foot length off the ridge pole. It is interesting to speculate that the dispute may have been related to a perceived conflict between the more traditional Maori expression of faciality, which would have required the extended ridge pole (*tahu*) to support a gable-end porch, and the shorter inward-looking Christian church form that was eventually adopted.

In the case of the pan-tribal meetinghouse Te Hono-ki-Hawaiki which was recently incorporated in the Museum of New Zealand Te Papa Tongarewa in Wellington, the meetinghouse almost seems to be reduced to a pure expression of *mataihi* or face (►http://www.tepapa.govt.nz/virtualhighlight/Marae_english.html). The designer Cliff Whiting comments that this was partly a result of compromises that were necessary to develop a pantribal *kawa* (protocol). The Maui family group was adopted to embrace the widest possible sector of the population including Maori and Pacific Island people. Te Ati Awa and Ngati Toa, as *tangata whenua*, the local hosts, were made responsible for figures on the *amo*, the two side posts of the meetinghouse, while many other figures on the gable-end have yet to be named at all. Whiting remarks that *iwi* (tribal groups) from all other parts of the country can opt to "come into it" or not as they wish. In this sense the *kawa* of Te Hono-ki-Hawaiki is in a state of incompleteness, like the incomplete, yet to be negotiated political *kawa* of biculturalism in New Zealand. Its *mataihi* signifies a dynamic temporal sense of "facing the future" and of going forward with political intent. It has often been remarked that the classical Maori body "faced" the past and had its back to the future, and the front of a meetinghouse more often represents a region of timeless myth and legend (Neich 1993. 232). This modern version of *mataihi* at Te Papa in effect employs the myth of Maui in a bicultural context in order to "face" an unformed future.

Ornament, *Whakairo*

Whakairo means to adorn with a pattern, to give direction, to form and inform aspects of any artistic construction whatsoever. The word was recorded in the first Edition (1844) of the *Williams Dictionary* but with only the limited meaning of "carved, carving, to carve." The prefix *whaka-*, meaning "toward, in the direction of," first appeared in the third Edition (1871). A 1915 version (which was not a separate Edition) of the *Dictionary* extended the meaning of *whakairo* to include "carve, adorn with carving." Two years later this was replaced with the fuller meaning, "ornament with a pattern, used of carving, tattooing, painting, weaving." Today the meaning of *whakairo* has been further extended to also embrace such activities as sculpture, printmaking and spatial design. Thus a *whare whakairo* may not necessarily be a *carved* meetinghouse at all. The decorative scheme of Rongopai, for example, a beautiful 1887 meetinghouse, comprises "a magnificent statement of tribal identity and joyous optimism" (Neich 1993. 192) that is expressed predominantly through painted figures and patterns rather than through woodcarving.

The architectural meaning of *whakairo* "giving direction" and constructing an orientation for people in the world is expressed in every meetinghouse through the orientation of the *tahu*, the long imposing horizontal ridge pole which is sometimes also called *tahuhu*. The *tahu* or *tahuhu* is normally painted with distinctive *kowhaiwhai* patterns in the interior and carved where it joins with the exterior scheme of the *mataihi* under the roof of the porch. What is however a more fundamental aspect of *whakairo* of the *tahu* is its horizontal *orientation*, its direction in the world.

We might say that Te Kooti was the principal architect not only of the Ringatu Church but also of the meetinghouse in its modern form. Te Kooti adopted the meetinghouse form as a way to subvert the intention of the Christian mission church, or to transform the Christian message according to Maori protocols. In place of the tall closed box and the spire pointing upward to heaven, which was a form of church architecture already familiar in Maori villages throughout New Zealand, Te Kooti emphatically reasserted the authority of the *wharenui* form, and in particular the horizontal *tahu* that points to a real horizon.

Roger Neich (1993: 229–234) describes how the *tahu* not only marks the place of the *marae* (the village and its formal gathering place) as a specific location in the world but also describes a direction within and across this place. Referring specifically to a Ringatu meetinghouse named Tutamure at Omarumutu *marae* near Whakatane, Neich identifies multiple layers of interconnected narratives through which the *tahu* points out and constructs a meaningful direction in the world. Firstly Neich writes it points to the openness of the *marae* forecourt in front of the *wharenui*, and to closure at the rear. Then it points to the ocean and the land, the sea and the forest (pointing out that the technoeconomic resources of the local people are found in front of and behind the house, respectively). The ridgepole of the meetinghouse also points to Hawaiki and New Zealand (as directions in front and behind in cosmological space), and to the canoe immigrants (in this case the Mataatua and Nukutere canoes) and the Tino-o-Toi aborigines (directions of arrival, confrontation and retreat in the sociological space of tribal history).

Almost every *marae* has stories similar to this associated with the horizontal pointing form of the *tahu* of the *wharenui*. The "point" of the meetinghouse is this fundamental *whakairo* gesture. It is interesting to note that the Anglican Holy Trinity Cathedral in Auckland recently extended the nave with a strong *wharenui*-like horizontal gesture, but that the church authorities did not see fit to build a vertical campanile (contrary to the advice of the architect).

A

Space, Kauhanga

Kauhanga is a term that means the interior space of the meetinghouse specifically when it is *tapu*. There are other words also that refer to interior space, for example *tara iti* is the space on the inside left of the *wharenui* and *tara nui* is that on the right (as one enters the house from the front.) Literally *tara* refers to the side walls of the house as well as meaning the inside spaces. Whenever a new *wharenui* is constructed a great deal of negotiation takes place to decide which ancestors and stories should be represented and the most appropriate spatial relationships. Naturally, as with any architectural design, the interior space becomes charged with potential meanings far in excess of what is actually built. The highly potent *tapu* condition of a new meetinghouse is dissipated in ritual processes called *whakanoa*.

The *tapu* space is often implicated in what might be called prophetic lore or *kupu whakaari* that is associated with the opening of meetinghouses. One famous example is a prediction or warning that Te Kooti is said to have made when he attended the reopening of Te Tokanganui-a-noho in 1883. It is recorded that Te Kooti said "The day will come when the God of the Pakeha will whistle in these places,… entering right into the porch of the house and coming straight through the back of it…." (Binney 1995. 278). Te Kooti also said of another meetinghouse, Ruataupare, that "… one wall is arguing against the other, and the door against the back wall." (Binney 1995. 328). This is not the place to enter into the interpretation of these prophetic sayings. What is significant is the fact that the *kauhanga* space of the meetinghouse is implicated in them.

Since Maori architecture is alive and its meaning is alive, therefore it is appropriate to speak to the *wharenui*, and also on occasion to speak as it were *through* the *wharenui*, to allow the architecture of the house to structure and guide what is said. Even on some occasions of *whaikorero* or formal talking it is appropriate that the *wharenui* itself speaks. As Hohepa Kereopa succinctly expressed it, "The whaikorero is based on the idea of how a whare is built" (Moon 2003. 113).

Architecture in Mesoamerica

Phil C. Weigand

The Mesoamerican world system was composed of a number of closely connected and related but distinct civilizations. The peripheries of the system extended from the southwestern United States of America, in the north, to the borders of Nicaragua, in the south. Each of these component civilizations, while sharing with the larger whole series of cosmological and iconographic concerns, had an unambiguously regional architectural style. The distinct civilizations usually considered, from south to north, are the highland Mayan area (Guatemala), the lowland Maya (the Petén of Guatemala and the Mexican states of Yucatán, Quintana Roo, and Campeche), the Gulf Coast lowlands (Veracrúz and Tabasco), southern Pacific coast (Chiapas and Guerrero), Oaxaca, Central Mexico (the states of Puebla, Tlaxcala, México, and Hidalgo), the Huaxteca (northern Veracrúz and southern Tamaulipas), western Mexico (Jalisco, Michoacán, Nayarit, Colima, and Sinaloa), and northern Mexico (Zacatecas, Durango, Chihuahua, and Sonora, with extensions into New Mexico and Arizona). The architectural styles represented within each region were original and innovative traditions which in some cases lasted for centuries with only cosmetic changes. To speak simply of the existence of pyramids in Mesoamerica is to miss the point: while pyramids of one type or another indeed were pan-Mesoamerican, accompanying them was a remarkable diversity of other building forms, representing styles that still remain difficult to classify. Some areas, such as western Mexico, had a number of radically different architectural traditions through time, while other zones, such as Central Mexico, displayed much more conservatism. Of course, anything approaching a comprehensive survey is not possible in this summary. Important sites, even regions, have been omitted.

Reference and Bibliographical Considerations

There have been many descriptive architectural studies within Mesoamerica. Over the last century of research this orientation has produced a wealth of detail that has never been completely synthesized. The study by Marquina (1951) is a classic of the descriptive school, though there are major area omissions in his text and very little in terms of comparative or integrative commentary. Never-the-less, his text remains the most useful and encyclopedic source available in the Spanish language. In English, other overviews, though also limited in area coverage, have been published by Kubler (1975) and Gendrop and Heyden (1993). Useful general summaries concerning architecture within specific regions of Mesoamerica are in the *Handbook of Middle American Indians* (Wauchope, various dates). In the *Handbook*, surveys on regional architectural traditions include Smith (1965) on the Guatemalan highlands, Acosta (1965) on Oaxaca, and Margain (1971) on Central Mexico.

One of the best sources for specific site details is the journal, *Cuadernos de Arquitectura Mesoamericana*, published by the Facultad de Arquitectura of the Universidad Nacional Autónoma de México. Early numbers of the journal basically followed the Marquina descriptive tradition, though in recent years interest has broadened to include spatial relationships, cultural symbolism, and astronomical considerations. Excellent and more specialized books and monographs on those topics also exist. As examples, for spatial relationships: Mangino Tazar (1990); for cultural symbolism: Kowalski (1999); and for ancient astronomy as viewed through architecture: Aveni (1977). A useful dictionary for architectural terms and terminology pertaining to Mesoamerica has been compiled by Gendrop (1997).

A number of site studies, emphasizing spatial relationships, describe architectural specifics in addition to the character of community settlements patterns. Three representative studies are Millon (1973) on Teotihuacan in Central Mexico, Blanton (1978) on Monte Albán in Oaxaca, and Folan et al. (1983) on Cobá in the lowland Mayan area. Researchers in the lowland Mayan area have produced some of the most detailed descriptive studies. This is no doubt due to the spectacular nature of the soft limestone building tradition in that region, wherein architectural ornamentation and elaboration, often baroque in character, reached a peak of development unequaled in any other area of Mesoamerica. An example is the study of the Río Bec, Chenes and Puuc styles, by Gendrop et al. (1998). In western Mexico, due to the highly geometric character of the early monumental architecture (Weigand 1996), the approach of Chippindale (1986) and Stiny

(1976) has been utilized to determine the rules of formal design employed there.

Architectural Types

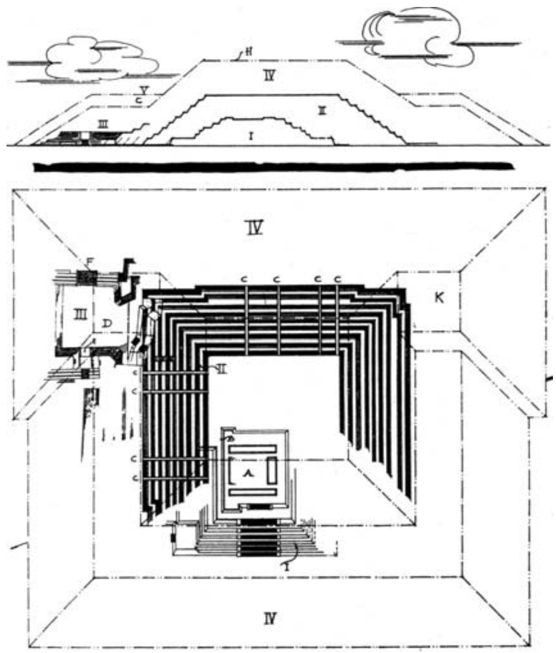
The typology employed *infra* is far from complete, but represents a sampling of building types found throughout pre-Hispanic Mesoamerica.

Pyramids

Urban precincts, as spaces, and the buildings within, are almost universally well organized and formal. Within them are found the most monumental buildings in Mesoamerica, usually pyramids which are often of considerable size.

Among the earliest monumental pyramids is the structure found at La Venta, Tabasco. Located in a tropical rain forest and made from earth, it is badly eroded. Hence, its original shape has generated controversy. Its original shape may have been like a fluted cone, with ten alternating ridges and valleys at regular intervals around the oval base (Heizer 1968). Its original height cannot be determined, but it towered over the flat flood plain that surrounds the site. Apparently, there existed no access ramp or stairway. This structure dates to around 900–400 BCE.

For the Classic period (AD 150–700), while the Pyramid of the Sun at Teotihuacan is the best known, it is not the largest. That distinction belongs to great pyramid at Cholula (Puebla), considered by some to be the largest single structure (by volume) in the Americas. While the pyramid is the greatest single building of the Mesoamerica architectural tradition, it is poorly preserved and understood. This structure eventually covered over 16 ha of surface, and was 55 m high. Some of the 16 ha represent poorly preserved platforms attached to the main body of the pyramid. The basic form is shared with the monumental pyramids at Teotihuacan: square to rectangular and terraced, culminating in a flat surface atop of which was placed a rather small temple (Marquina 1951: 115–125; Fig. 1). The pyramid at Cholula was constructed over a very long period of time, apparently in constant use from around AD 100 to the Spanish conquest in the early sixteenth century. As such, it represents one of the monumental buildings in longest continuous use within the overall area. The material used in construction varied from well-prepared adobe brick to rock and clay fill. The decorative finish, usually described as variations on the *talud–tablero* technique, was painted and highly sophisticated. The *talud–tablero* technique is usually ascribed to influence from Teotihuacan, but in most cases throughout Mesoamerica, including Cholula, this is doubtful. This architectural decorative technique was pan-Mesoamerican, though, very prominent at Teotihuacan.



Architecture in Mesoamerica. Fig. 1 Map of the Cholula pyramid, Puebla, showing plan and profile (taken from Marquina 1951: 119).

The pyramids at Teotihuacan, dating from the Classic period (AD 100–850), as well as adjoining and neighboring structures, have been extensively studied for over a century. The site, while huge (22.5 km^2 – Millon 1973), is still the focus of intensive research. George Cowgill's ongoing project at the Pyramid of the Moon has shown an extremely complex construction history, including prestige burials with sacrifices for this structure, thus supplying documentation equivalent at Teotihuacan for Cholula. The Pyramid of the Sun covered just under 5 ha of surface, and is 61 m high. The restoration of this structure, begun over a century ago, is controversial (Fig. 2). A natural, but improved, cave underneath this pyramid may represent the famed *chicomostoc*, or emergence tunnel through which people of this world originated. A tunnel dug through the Pyramid shows what may be a much earlier structure, perhaps representing a tomb (Millon and Drewitt 1961).

Perhaps one of the best examples of baroque architecture in Mesoamerica is the Pyramid of the Niches at Tajín, Veracrúz. While the substructure as such is comparable to pyramids elsewhere, it is the decorative elements that set it aside (García Payón 1957). Its fine decorative masonry is unique in the non-Mayan regions of Mesoamerica. The niches, 365 in number, set into the ornamental *talud–tablero* facing, probably housed figurines (Fig. 3).

The double pyramid at Tenochitlan, destroyed by the Spanish after they conquered the city in 1521, is the

Architecture in Mesoamerica. Fig. 2 The Pyramid of the Sun, Teotihuacan, State of México (taken from Millon 1973: Plate 24a).

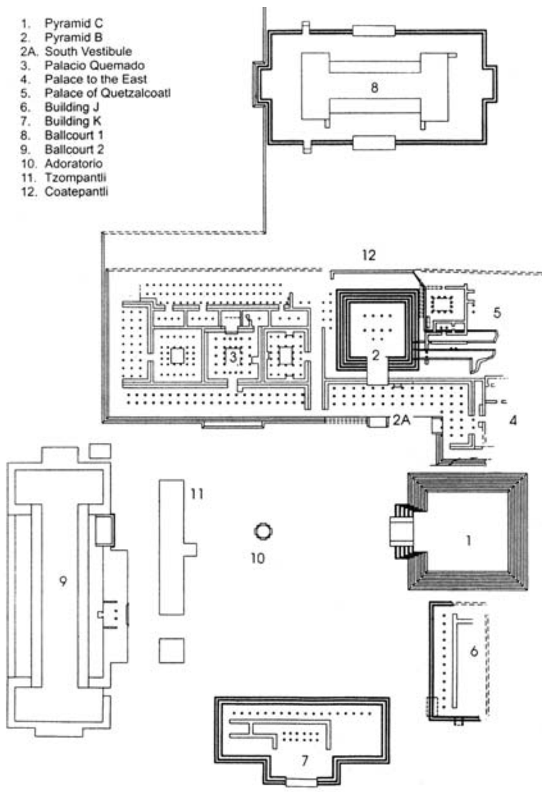
Architecture in Mesoamerica. Fig. 3 Pyramid of the Niches, Tajín, Veracrúz (taken from Porter-Weaver 1981: 244).

most famous of this architectural type. The building has been extensively excavated and restored, and its history and utilization is fairly well understood (Matos Moctezuma 2003). The pyramid was associated with a multiplicity of rooms and adjoining shrines, containing painted murals, rich offerings, and statuary. The "double" term refers to the peak of the pyramid. There, twin temples, each reached by a separate stairway, sat atop a common base. In architectural models and illustrations, this structure is often portrayed as being far more monumental than it actually is. This is apparently due to the centrality given to the Aztecs in the official histories of the Republic.

The small pyramid complex at Tula, Hidalgo, while not impressive if viewed as isolated structures, had extremely complex sculpture and appended buildings. The "atlantean" statues, originally placed atop one of the main pyramids, and the Halls of Columns adjoining that same structure, are unique in Central Mexico (Mastache et al. 2002; Fig. 4).

Pyramids in the Mayan area are unusual for their steepness and height in relation to their bases. The Temple of the Giant Jaguar (also called Temple #1) at Tikal, in the Petén district of Guatemala, is one of the best examples. It had nine terraces, and three rooms at the summit. The rooms' vaults were supported by beams from the sapodilla tree. A large vaulted tomb was excavated in the plaza before this pyramid was finished. On the upper terrace of the pyramid is a limestone temple which has a two-level roof comb. This comb, while adding a decorative element to the building, also increased significantly its overall height. This structure was finished around AD 700 (Coe 1967). Other pyramidal buildings of note are found at Piedras Negras (Houston et al. 2000); Palenque, and its great subpyramid tomb of King Pacál (Ruz Lhuillier 1963); Chichén Itzá (Ruppert 1952); as well as those mentioned in Gendrop et al. (1998). Aside from the decorative sculptures and friezes, some Mayan buildings had elaborate wall murals. The best preserved of these are at the Temple of the Paintings at Bonampác, Chiapas (Ruppert et al. 1955).

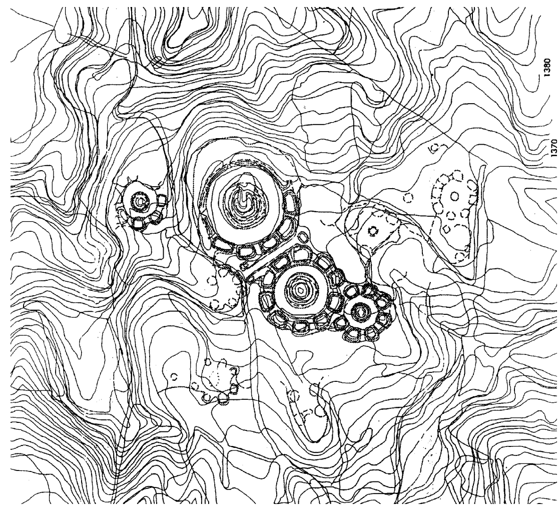
In western Mexico, three sites deserve special note. The Guachimontón precinct, at Teuchitlán, Jalisco, has



Architecture in Mesoamerica. Fig. 4 Plan of the Halls of Columns, and associated buildings, Tula, Hidalgo (taken from Mastache et al. 2002: 92).

ten concentric circular structures, each having central circular pyramids, surrounded by elevated circular patios, which in turn are surrounded by circular banquettes. While some 400 of these precincts have been located to date, this type of architecture morphology is unique in the world repertoire. The largest circle is 128 m in diameter, and 405 m in circumference. The precinct covers 19 ha. The pyramids in these complexes are only attributes of the overall structure. The highest one is 20 m. The outer banquette served as the base for between 8 and 16 platforms, atop of which were large temples. Beneath the platforms are the shaft-tombs, which are full of the figurines that have given the region its fame in the antiquities market. The deepest shaft-tombs are 14–20 m, with between three and five large rooms. These structures date from the late Formative and early Classic period (350 BCE–AD 450; Weigand 1996, 2005; Fig. 5).

Ihuatzio and Tzintzuntzan, Michoacán, are both sites associated with the Tarascan empire of the late post-Classic period (1300-Spanish conquest). Ihuatzio is the earlier site. It has a large double pyramid complex which is partially surrounded by huge walls that clearly limited access to them. The *yácata* style building is also present. *Yácatas* are another unique building form found only in western Mesoamerica. They are large



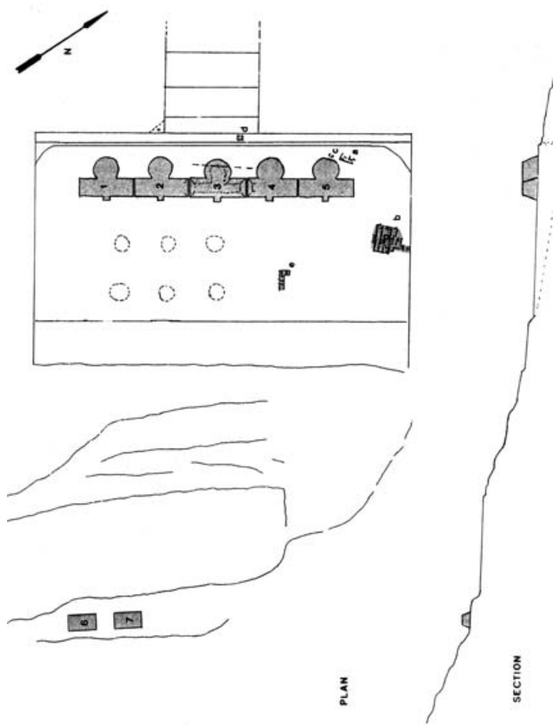
Architecture in Mesoamerica. Fig. 5 The Guachimontón precinct at Teuchitlán, Jalisco (taken from Weigand 1996: 95).

circular altars appended to rectangular platforms. Stairways are at the rear of the structures. The site with the most impressive array of *yácatas* is Tzintzuntzan. Five *yácatas* are lined up atop a huge rectangular platform (Cabrera Castro 1987; Pollard 1993; Fig. 6). Clearly, the *yácatas* and their base platform form a single structure, one of the most monumental of Mesoamerica.

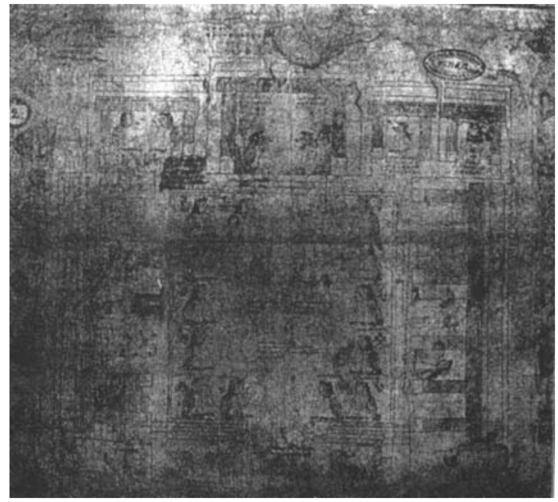
Palaces

These structures, commonly called *tecpan*, abound within the complex sites of Mesoamerica. Although the identification is not certain, the Ciudadela at Teotihuacan is often identified as a *tecpan* (Millon 1973). It is a huge, square structure measuring 400 m to a side. Its interior plaza is a large open space facing a small pyramid complex with complex serpent and rain god heads protruding from its surface (Drucker 1974). It was probably completed around AD 300, if not earlier. Also at Teotihuacan, many sunken patio structures aligning the Street of the Dead have been identified as palaces, or at least as residences of the elite elements that ran the urban complex. Many of these buildings were elaborately decorated with murals and low relief carvings. The Quetzalpapalotl Palace is one of the best examples of this type of building (Acosta 1964). It is a stunning example of a highly complex structure which apparently combined public administrative functions with residential quarters. A magnificent courtyard is bordered by porches. This type of structure is commonly called a *patio hundido*, or a sunken plazuela complex. The palace apparently dates to around AD 500.

The studies by Evans (1998, 2001) constitute the most comprehensive comparative research concerning palace structures in Central Mexico. Since so many of the late palaces in Central Mexico are covered by



Architecture in Mesoamerica. Fig. 6 Map of the *yácatas* at Tzintzuntzan, Michoacan (taken from Pollard 1993: 48).



Architecture in Mesoamerica. Fig. 7 The *tecpan* represented in the Codice of Quinatzín (taken from Weigand and García 1996: 183).

Colonial and contemporary buildings, including that of the last Aztec emperor, Moctezuma II, in Tenochitlan, she has made ample use of ethnohistorical descriptions. In general, the Central Mexican *tecpan* is defined as an open court surrounded by a high banquette on at least three sides and open on one side to community plazas. The Codice of Quinatzín, portraying a Texcoco palace (State of México) clearly shows this type of structure (Fig. 7). Moctezuma's palace is said to have been 200 m to a side, though this structure, buried beneath Mexico City, is no longer visible. The average, however, is considerably smaller: between 60 and 80 m to a side.

Several structures at Monte Albán have been identified as possible palaces (Winter 1974). These structures face the large, rectangular plaza that forms the central feature of the citadel. While they somewhat resemble palace structures at Teotihuacan, and date to approximately the same period, they are much more compact, and with fewer decorative elements. The plazuelas are quite small. Tombs, most probably lineage crypts, are often associated with these structures, and open directly onto the plaza.

At Yagúl, in Oaxaca, a different type of palace structure has been identified. Apparently, six side-by-side structures existed, built during the post-Classic period. Each is characterized by a series of fairly small rectangular patios surrounded by long, narrow rooms. The overall effect is cramped and crowded. The core of these buildings was rough stone and earth, but the exterior decorations were careful and sophisticated, usually plaster or cut stone. Facades and door frames were decorated with small cut stones formed into geometric mosaic patterns (Bernal 1965). This decorative appliqué is similar to that found at Mitla, though the functions of the structures there have not been identified with certainty.

Buildings identified as palaces abound in the Mayan area. Perhaps the best known of these is the Tower Palace at Palenque. This square, four story structure was constructed from finely cut limestone blocks. The floors were supported by wooden beams, instead of corbelled arches so often employed in other palaces and temples throughout the zone. While attached to a palace-like structure, the tower is unusual for its height. A variety of functions have been suggested for the tower per se (Carlson 1976).

From the post-Classic period, the largest visible *tecpan* is found within the village of Oconahua, Jalisco. At 125 m to a side, it conforms rather exactly to the arrangement set out in the aforementioned Codice of Quinatzín. An internal plazuela is surrounded by high platforms, the northern one of which is out-sized at 125 × 50 m. Outside this building is an external plaza measuring 180 × 55 m. Within this plaza were small platforms which served as bases for large stelae. The core of the structure is clay and earth, with some rock. It was finished with cut stone slabs, almost all of which have been looted (Weigand et al. 2005).

Market Places

These spaces were frequent features within Mesoamerican urban spaces. Often, they are hard to identify, and frequently are labeled as just plazas. One of the largest and earliest such spaces has been identified at Teotihuacan (Millon 1973). Across the Street of the Dead from the aforementioned Ciudadela, this open space measures approximately 125 × 250 m. It is surrounded by streets and buildings, some of which are directly associated with the market. Stalls, some of which dealt in obsidian artifacts, were arranged within the plaza of the market. Unfortunately, this space was chosen to house the site museum and a restaurant, and is therefore difficult to appreciate today.

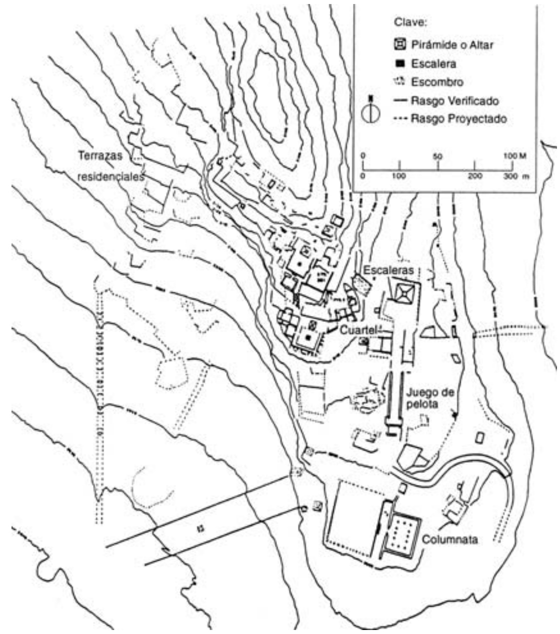
Places identified as markets have been located in the Oaxaca valley, as well, such as at Xaachila. The best information, though, comes from the Spanish sources from the conquest period. These attest to great markets at Cholula and Tlatelolco, in addition to other sites.

Ball-courts

Fortunately, for this type of structure, excellent comparative studies are available. The studies by Taladoire (1981, 1998) are unparalleled in detail, classification, and chronological considerations. A few more recent studies from western Mexico have added detail to his overview (Weigand and García 2005). Taladoire associates the architecture of ball-courts in different areas quite logically with the types of games performed there. Basically, two types of games dominated the Mesoamerican ball-court traditions. One type was the game played off the forearm (*antebrazo*), which required a court that had a hoop and a tall banquette. This is the type of game played at the monumental court at Chichén Itzá, for example. At 135 m in overall length, this court is one of the largest within all of Mesoamerica. The site of Tajín has perhaps the largest quantity of ball-courts, and the decorative elaboration of several is unsurpassed anywhere else. Elsewhere, the game played is called the *cadera*, or hip game. No hoop is required and thus the lateral banquettes are lower than in the *antebrazo* variety. The earliest monumental ball-courts of this type are found in Jalisco, where five buildings have been located and studied. The one at Santa Quitería is 135 m long, and the other four average 110–115 m in total length. The court at the Guachimontones has been restored, and dates to 150 BCE–AD 150 (Weigand and García 2005).

Fortifications

Fortified or defendable sites abound within Mesoamerica. Three strongly fortified sites stand out as excellent examples of military architecture: Tepexi el Viejo in Puebla (Gorenstein 1973), Oztuma in Guerrero (Armillas 1944), and La Quemada in Zacatecas (Armillas 1948; Fig. 8). All three forts share several basic features: located on high, difficult terrain, they are terraced with walls and *revetments*? to make access almost impossible. All have specialized buildings and apparent gateway areas. Ceremonial architecture, while present, is modest and rather inconspicuous. La Quemada is the earliest of these three examples, dating to the AD 600–1100 period, while the other two belong to the Aztec polity. Smaller, but still impressive and earlier forts, can be found at the Peñol de Santa Rosalía, Jalisco (Weigand 1996). Some areas, such as the Caxcan zone of southern Zacatecas, have fortified sites literally on every hill top.



Architecture in Mesoamerica. Fig. 8 The fortified citadel at La Quemada, Zacatecas (taken from Weigand and García 1996: 170).

Architectural diversity characterizes the many traditions of ancient Mesoamerica. This diversity is both temporal and spatial in nature. Some types have not been considered in this survey: specialized shrine sites, such as Malinalco in the State of México; mining complexes, such as those at the Sierra de Navajas in Hidalgo, and Chalchihuites in Zacatecas; ports of trade, such as Xicalanco, between Tabasco and Campeche; elegant burial chambers, such as the monumental shaft-tombs of Jalisco; and the great agricultural field systems such as the chinampas of Jalisco and Central Mexico.

Architecture in Palestine

Shadi Sami Ghadban

When talking about traditional architecture in this area of the Middle East, it is more correct to identify this architecture by the term "Palestinian Architecture" rather than by "Architecture in Palestine." The second term refers to all architectural styles found in Palestine throughout the different historical periods, from Hellenic, Roman, Byzantine, Umayyad, Abbasid, Fatimid, Crusades, Mamluk, Ottoman, and the British Mandate until today. These architectural styles were mainly popular in major cities like Jerusalem, Jaffa, Acre, and Nablus. In addition, these styles were commonly related to the architecture of the economic and political elite and the urban notables.

On the other hand, the first term "Palestinian Architecture" reflects what is known as "architecture without architects," which has flourished for several centuries in urban and rural areas. It maintained its characteristics until World War I because of the social, economic, and religious factors that reflected the needs and living habits of a particular time, and it directly reflects the interaction between human beings and their environment (Fig. 1).

Prior to the year 1839 (when Ottoman land reforms were applied), land in Palestine was the main source of livelihood and status, with very limited transactions with the regional or world market. The Palestinian community retained a system of agricultural subsistence, employing simple agricultural technology. The community as a whole was considered the unit of taxation by the state, and there were patriarchal households, where the extended family acted as the main unit of production and consumption, and labor was divided along clear gender lines.

The year of 1832 marked a critical turning point in the history of the region, when Mohammad ʻAli, the Governor of Egypt from 1805 to 1848, occupied Great Syria, including the Palestinian territories, and implemented several land, administrative and economic reforms (Manna' 1999: 161). He gained the support of the European superpowers for his military campaign when he said that he would take into consideration their vital interests in the area, treat the non-Moslem minorities in a better way than the Ottoman Authorities had, and even try to give them equal rights with the Moslems (Scholch 1988: 130–145). This Occupation brought about several developments accompanied by the implementation of several administrative and economic reforms, but they were obstructed by different uprisings and disobediences that occurred in the area (Manna' 1999: 137–138). The Egyptian policy in the Palestinian territories led to increasing European influence in these territories, mainly in Jerusalem. The activities of different missionary groups concentrated on constructing new churches and providing educational, social, and health services to the local population. The first European British Consulate in Jerusalem was inaugurated in this period, which was followed by other consulates during the period 1841–1858 (Spyridon 1938).

In 1839, the Ottoman Sultan Abdul-Majeed came back to power in Great Syria, and this included the Palestinian territories. He was supported by the European coalition established by Great Britain, Russia, Austria, and Prussia (Scholch 1988: 458–475). In his decree, known as *Khat Golkhanah*, issued in November 1839, he expressed his readiness to apply new reforms that were known later as *Tanzimat Khairiah* (Davidson 1973). In addition, the increasing European influence led to an economic amalgamation of the Palestinian territories with the world capital market, and produced an active involvement of the Palestinian local leadership in the continuously changing political circumstances. All these factors shaped the new socioeconomical interactions within Palestinian society.

By the end of the nineteenth century a new eclectic architecture with mixed styles witnessed the western influence that came through the activities of different missionary groups. This development was accelerated during the last three decades of the nineteenth century and continued intensely during the first two decades of the British Mandate (1920s and 1930s) when a rapid construction growth sprawled in both rural and urban areas (Fig. 2). Therefore, by the end of the 1930s, a new architectural fabric began to emerge which greatly affected Palestinian society since the middle of the nineteenth century.

The Tanzimat period represented one historical period of the Ottoman Empire, but for Palestine and other Arabic areas in the eastern coast of the Mediterranean, this period consisted of three major stages:

- *First stage (1840–1856 AC)*. The Crimean war ended and a decree called *Khat Sharif Hamaion* was issued on 18th February 1856. This decree contained several reforms that Sultan Abdul-Majeed addressed to get the support of the European countries for his war against Russia. In this stage the Ottoman Authorities performed reforms similar to those applied by the Egyptian Government (1832–1840). However, the local leadership, mainly in the countryside, rejected them, arguing that they were contradicting with their interests (Abu Izz-Elddine 1928: 95–96).
- *Second stage (1858–1878 AC)*. The Ottoman land reforms (Tanzimat) started in 1858, which aimed to change the communal ownership of land to private ownership. This period, mainly in 1878, evidenced the first parliamentarian experience during Sultan

Abdul-Hameed the Second's rule. New fundamental changes affected not only the relations between the state and the Palestinian local leadership, but also had an extensive effect on the socioeconomical, cultural, and living conditions of the Palestinian local society.

- *Third stage (1878–1919 AC)*. During this stage the integration of the local economy into the world trade market and acceleration of the European influence in the area continued. However, there was a growing trend toward improving the infrastructure, mainly in the fields of transportation, communication, education, and governmental administration. It was also around this time that Palestinian immigration to both Americas increased and the immigrants started sending back money to their families in Palestine to build their future houses. In addition, this period included the expansion of Jewish emigration and construction of new settlements with imported architectural styles.

Partial view of the old city of Nablus, surrounded by the new modern urban structure

Architecture in Palestine. Fig. 2 Images demonstrating the rapid construction growth outside and within the historical fabrics in Urban Areas. Photos by the author.

The 1840s was a decade rich with events assumed by several historians as indicators for the beginning of a new history in the Palestinian territories. As a result, new architectural systems, i.e., new building styles and forms, use of new materials and methods of construction were imported and implemented, but within the framework of the local knowledge in the area (Fig. 3).

Factors Influencing Palestinian Traditional Architecture

Several factors bear upon the development of Palestinian traditional architecture.

Geography

A distinguishing part of Palestine is its geographical location along the eastern Mediterranean coast. It has a key location between Asia and Africa, and has a specific character as a Holy Place for Judaism, Christianity, and Islam. Altitudes, which range from 394 m below sea level to 1,400 m on the mountainous chain parallel to the coast, allow the existence of a diverse landscape. The mountains shape the nature of the Palestinian territories and control climate and rainfall.

Many influences affected the Palestinian land, and large-scale architectural activities took place during the rule of foreign powers such as the Romans, Crusaders, Mamluks, or Ottomans. Despite the fact that these activities reveal strong local characteristics, they are of foreign origin. Therefore, independent Palestinian architecture was limited to housing structures and modest religious and public buildings. The influence of geography can be observed in the adoption of certain types of construction, architectural forms, orientation, and the arrangement of buildings. The articulation of plan, elevations, simplicity of masses, and the habit of one or two-story constructions are largely caused by the predominant conditions in the three main geographical zones of the country: the coastal area, the highlands and the Jordan valley (Fig. 4).

Natural Building Materials

Palestinian territories have an unusual geology because of their location between Great Syria and the Sinai Peninsula, where different geological formations produced a unique topography, diverse both in form and structure.

The mountainous area consists of hills, valleys, and gorges, where the geological strata are easily accessible. These strata usually consist of sandstone between limestone, and are cut up by various clefts, mainly in the Hebron, Bethlehem, and Nablus areas.

The abundance of stone in the country offers the opportunity for good masonry construction. The continuous use of stone has produced stonemason's families who passed on their accumulated skills from generation to generation, evolving a mastery and tradition of design in stone that is largely responsible for the homogeneous character of Palestinian architecture (Figs. 1 and 3).

Mud is limited to the Jordan valley and some coastal areas, mainly Gaza, because of their geological conditions. The fairly dry climate in these areas allows the application of mud brick (adobe) structures.

For many centuries, the use of wood for construction was limited to some kinds available in the area, such as one-palm trees and olive trees and rarely poplar, willow, walnut, and maple. Wood is mainly used for doors, windows, some furniture, and for roof construction.

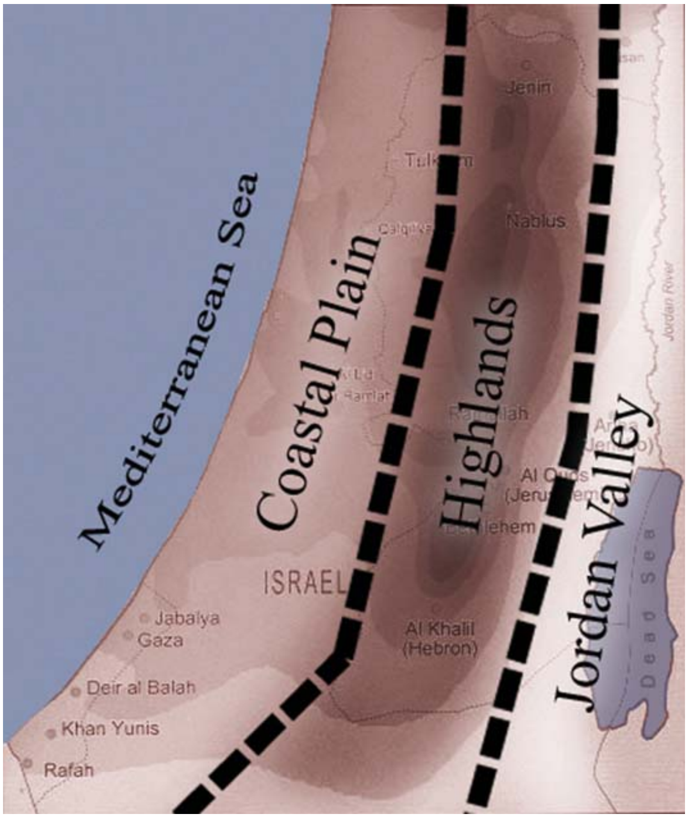
The Climate

There are four climatic zones in the Palestinian area: the coast area, the western slopes of the mountainous area, the eastern slopes and the Jordan valley and the desert. The annual climatic cycle of the country consists of

Architecture in Palestine. Fig. 3 Houses and buildings with new architectural types, forms, new materials and methods of construction. Photos are student works from the course "Local Architecture in Palestine", Birzeit University, August 2000.

four hot dry summer months, a mild autumn with little rainfall, a rainy winter with snow down to 700 m and an early spring with the last rainfall in April.

The architecture of Palestine is a synthesis between local environmental conditions and the formulas of the philosophy of life, art and design prevailing in the entire Mediterranean region. The massive construction in stone or mud-brick in terms of a wall's thickness, height, texture, and verticality, satisfies to a large extent the exigencies of the climate. The roof structure, either flat surfaced from mud, wood, and straw or vaulted mainly from stone, guarantees appropriate temperature insulation and reduces the heat transfer process. Crossventilation is facilitated by openings placed high in the single-spaced structures or by internal windows between rooms and the central space, which is assumed to be the coolest space during the hot daytime (Fig. 5). The open ends of the central space are turned either to



Architecture in Palestine. Fig. 4 An illustration demonstrating the three geographical zones in historical Palestine. Adapted by the author, using as a base a map distributed by Applied Research Institute (ARIJ), ►http://www.arij.org.

the north or to the south in order to avoid deep penetration of the sun's rays. Fortunately, the placement of the house parallel to the contour lines of the slope toward the valley makes its face toward the prevailing wind direction and ensures the desired ventilation.

Socioeconomic Factors

Palestinian traditional architecture has been the result of an experience between human beings and their environment. This dialog has two forms: action and reaction. The action of the human being always produces a reaction in the environment, and vice versa. In both cases, the reaction has two levels: an unconscious reaction and a conscious reaction that needs to be reinforced and enhanced.

Palestinian traditional architecture has been very resonant in functional, constructional, and artistic approaches during the last 120 years. When the changeable living conditions of the Ottoman Reforms and the English Mandate caused some elements of traditions and values to loose their initial meaning, they had to be replaced by new ones with a function closer to the new requirements that still responded to certain sociohistorical conditions.

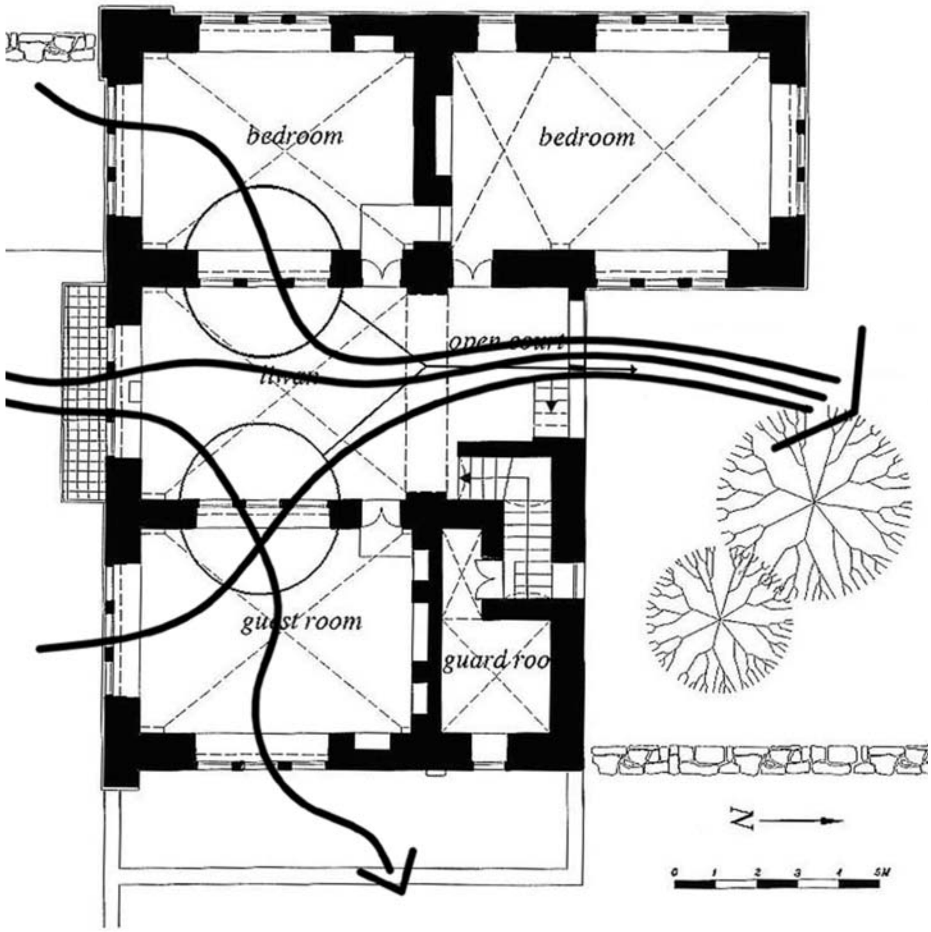
In this regard, there is a substantial importance to specific Palestinian local forms of production, religious customs, beliefs, traditions, mental adaptation, self-confidence, and spirit of people, because all of them are determined by local physical, geographical, and climatic conditions.

The religious affiliation of the Palestinian family did not affect the distribution of house types in Palestine. The conditions of living either in the mountains, valley, or in the coast areas were essentially the same for all religious communities, and all families adhered to a strong paternalistic structure. Great class discrepancies were unknown and the social structure was egalitarian.

On the other hand, the Islamic influence has been very strong in artistic and architectural forms and details, but there is very little Islamic influence in the planning of the houses. They were simple and straightforward, and that includes the lack of specialized spaces as well as a lack of privacy for the individual.

The House

Prior to the Ottoman Reforms (Tanzimat), land in Palestinian Territories was the main source of livelihood and status, and the Palestinian community



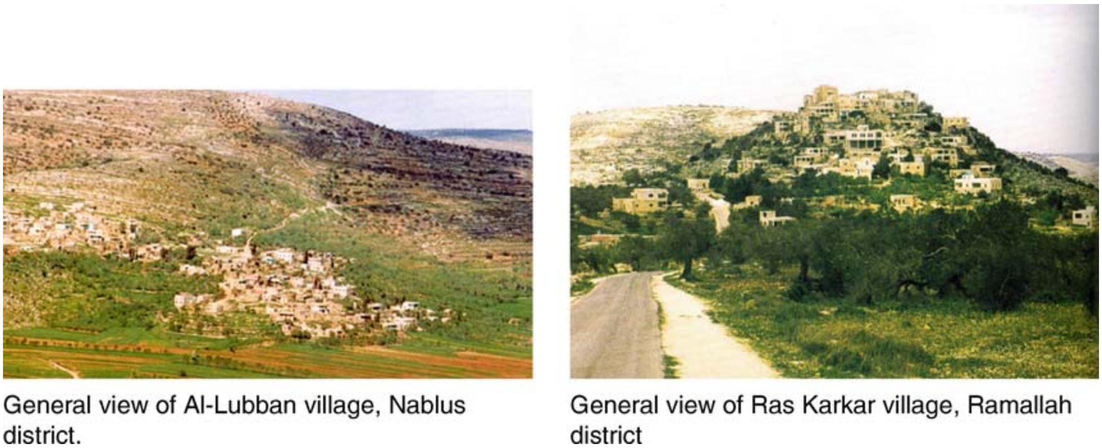
Architecture in Palestine. Fig. 5 A house plan showing the crossventilation system imposed by the central hall system used for functional organization of the internal spaces. A student work from the course "Local Architecture in Palestine", Birzeit University (1998–2001).

employed simple agricultural technology. A system of agricultural subsistence was retained, with very limited transactions with the regional or world market. The village as a whole and not the individual was considered the unit of taxation by the state. The community had patriarchal households, the extended family acting as the main unit of production and consumption, and labor was divided along clear gender lines (A'miry and Tamari 1989: 11–15).

The Palestinian village has had an outstanding harmonic panoramic form and a dimensional connection with the existing environment where the built up area grew together with the land, but revealed its own main image (Fig. 6). This local rural process could be described as a classical expression of organizing the habitation process by spontaneity, intuition, and a connection with site topography. The socioeconomic organization of the built environment before 1832 evoked the implementation of one of two main systems:

- The single-storey freestanding structure, which consists of a square or rectangular space (*bayt*) with a low entrance (*bab*), ventilation opening below the roof (*taqat*), and one or a pair of two small windows (*mijwiz*) (Fig. 7).
- The clustered and concentric patterns of spatial organization, where houses and other structures have formed the traditional clustered fabric. The pattern was produced by repetition of the single-storey structure, as each house unit was adjacent to other house units at least from two sides, as the back of the structures formed a part of the periphery protecting the inner courtyard (Fig. 8).

Both systems were built either from natural stone and roofed by traditional crossvaults or with mud mixed with straw and roofed by a wooden flat structure. The free grounds between the structures mainly were used for agriculture, livestock, and/or for future expansion.



Architecture in Palestine. Fig. 6 Images demonstrating the panoramic form and dimensional connection with the existing environment in rural areas. Photos by the author.

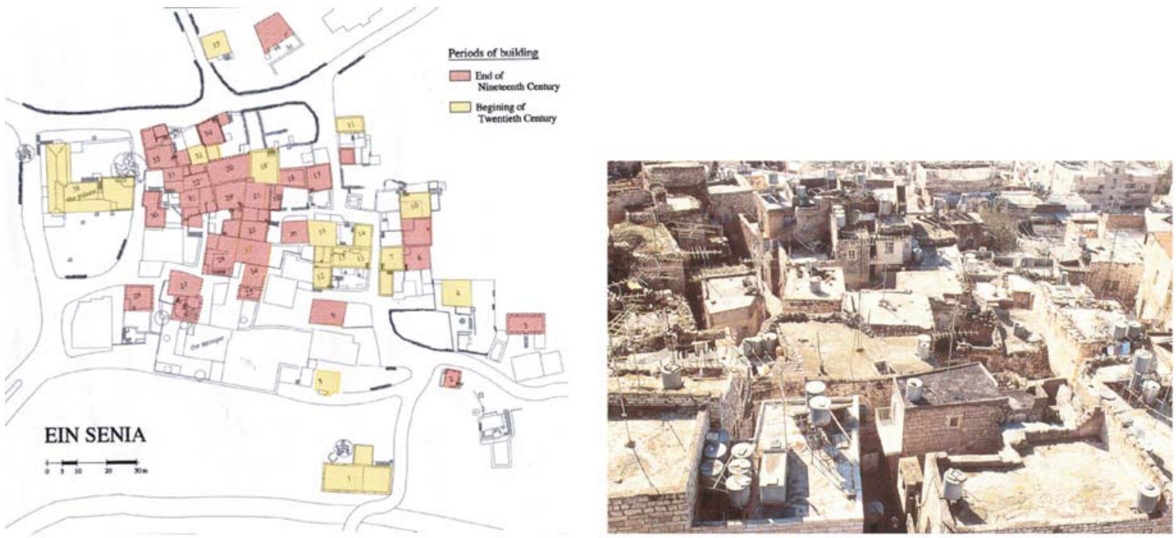
Initial Forms of the Traditional House

Today, there are still some examples that demonstrate the initial forms of the Palestinian vernacular house before 1850, but most of them have been extensively restored that they can no longer belong to any specific period. Three original forms of this architecture are still used as spaces for living, agricultural, and stock-breeding activities. Mostly, they are located in the hilly areas, villages or within the large historical cities. The general characteristics of these forms are as follows:

- *Caves*: they are considered the first habitation structure used by Palestinians for living purposes. Mostly, they are located at the eastern slopes of the Jordan Valley (winter pastures) and at the western mountains of the Palestinian territories (summer pastures). These caves are either natural, or have been rehabilitated to meet new living requirements (Fig. 9a). Each cave consists of one open space articulated into different zones by means of harmony between the various social, functional and aesthetic



Master Plan of the Old Quarter In the Top View of the Old Quarter In the City Village of Ein-Senia, Ramallah of Bethlehem, Bethlehem District.

Architecture in Palestine. Fig. 8 Two images showing the Clustered and Concentric Pattern of the Spatial Organization at the Urban and Rural Palestinian Areas. Student Works within the Course "Local Architecture in Palestine", Birzeit University, 1999–2000.

elements. Furthermore, some of these caves continue to host several living activities as a major element in the further extension of the living environment.

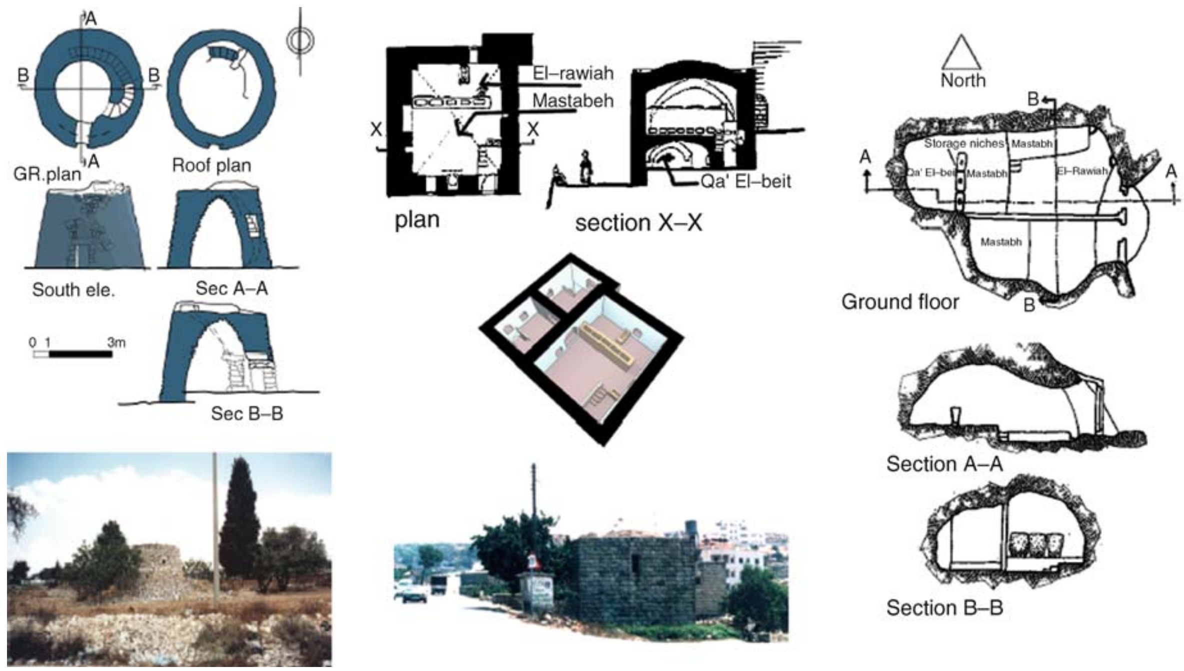
- *Watching Towers (Mantarah)*: a freestanding stone structure that imitates tectonically the vernacular typical house, but with different function and details. Usually, they are located outside the rural or urban fabrics, on the top of hills between fig and olive trees and pastures. These structures had multifunctional purposes as places for watching and cultivating land, summer vacations, storage places and bases for winter agricultural activities. Each watching tower is divided vertically into two or three levels. It consists of a ground floor for livestock and storage, a first floor for living and a second floor in the form of an open terrace used for multipurpose activities. This structure exists in both rectangular and circular plans (Fig. 9b) and all levels are accessible by an internal staircase.
- *Shepherd's House*: this model represents the most popular form of the Palestinian vernacular house with a simple single-storey square structure, built from the limestone rock abundant in the surrounding areas, and has only one low arched entrance (Fig. 9c). Walls are massive, sometimes 1 m thick, in order to support the heavy stone crossvault of the roof. The elevations are free of any window openings apart from small ventilation holes. The three-dimensional development of the shepherd's house produced three well-defined and integrated domains (A'miry and Tamari 1989; Hamdan 1996): (a) the multipurpose space for living (*Mastabeh*), (b) the animals' space (*Qa' El-beit*), and (c) the food storage space (*El-rawieh*).

These three domains were available at all three forms, with certain discrepancies according with physical and environmental needs.

New Forms of Palestinian Traditional Architecture

Palestinian traditional architecture is a product of the cultural development of the East Coast of the Mediterranean basin. Historical events caused a great dislocation of ethnic groups and populations with different public systems, specific customs, and intertwined cultural traditions. Appropriate conditions for mutual influence were established during the formation, development and enrichment of traditions and values. Several new forms of the Palestinian traditional house were created. They reflect the sociopolitical changes, which took place after the Tanzimat (reforms) period in 1842 and brought about essential transformations in the traditional structural of the Palestinian society:

- Creation of modern state institutions, mainly in the large cities, that led to immigration toward the new urban centers. This phenomenon led to major growth in the population inside the boundaries of the Old City. As a result, the existing structure became incapable of assimilating the augmenting needs of the population, and people started moving outside the Old City, creating new urban centers that were in the beginning juxtaposed to the frontiers of the Old City.
- Decline in the power of the village sheikh (Ruler).



Architecture in Palestine. Fig. 9 Original initial forms of the Palestinian vernacular house. Photos and drawings by the author.

- Changes in land tenure due to the Ottoman land reforms (Tanzimat), and privatizations of the main means of production: the land. The new ownership policies allowed foreign citizens to buy and register lands in their names. Foreign religious missions, relief agencies and consulates started their activities and gradually built up their religious, educational, health, and residential compounds.
- Growing integration of the local economy in the world trade market. This had an effect over all agricultural, trade and investment structures in Palestinian society.
- Formation and dissemination of a new culture in addition to the prevailing Islamic one.
- Changes in the occupational structure of the local population.
- Aggravation of social contradictions.
- Active emigration among the young Palestinian generation toward the American continent and Europe, in order to avoid the obligatory military service forced by the Ottoman authorities. Most of the immigrants started sending back their savings to invest them in Palestine by building mansions that reflected the new lifestyle of an affluent social class that was in formation in most Palestinian urban sites around that time.

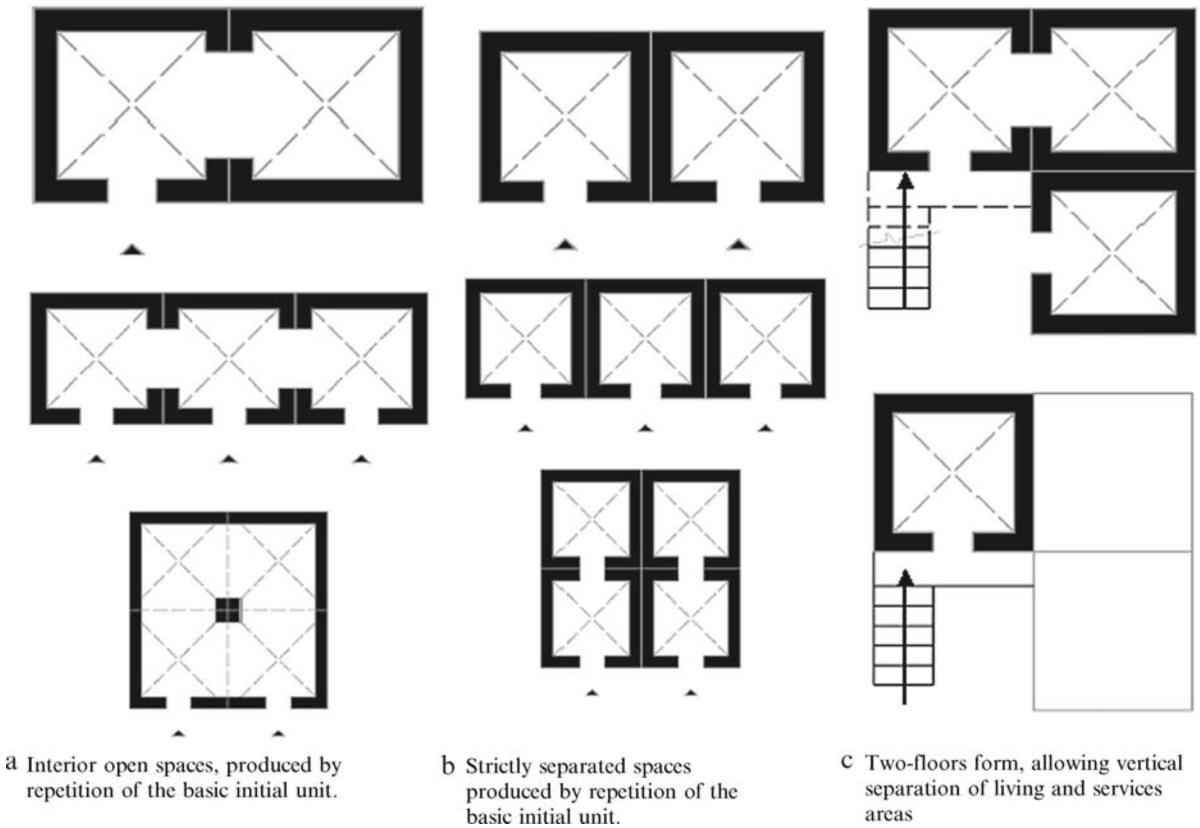
Rectangular House with Repetitive Initial Units

The term "Repetitive Initial Units" is used here to express the way this type of traditional house was produced. It consists of a repetitive arrangement of the rectangular or square initial model in a horizontal or vertical direction producing a composite structure (Fig. 10). Further development of this system initiated other more advanced forms of this architecture:

- Enlarging the space by means of one or more interior supports producing large open spaces with an internal system of pillars or vaulted roofs and enclosed by bearing walls (Fig. 10a). Mud and stone were both used.
- Strict separated spaces with sharp rectangular corners and increased rigidity of forms. In this way the organic unity of the interior space is reduced (Fig. 10b). Roofing was implemented by barrel vault or cross-vault structure, and both invited the addition of an upper floor. This form was mainly produced by stone material.
- Adaptation of a two-floor form of stone construction, which was very significant since it allowed the vertical separation of the living and service areas. This system ended the cohabitation of people and animals, symbolizing their emancipation from unremitting toil (Fig. 10c). The connection between floors was always external.

The Court House

The court denotes an open space delimited by wings and connected to the surroundings or the main alley by a main door or gate. This schema was



Architecture in Palestine. Fig. 10 Basic schemas of the rectangular traditional house. For existing examples refer to Figs. 7 and 9. Drawings by the author.

predominantly applied in the main villages and towns, because of the clustered character of the construction fabric (Fig. 11). In this case building units are arranged in an L or U shape and rarely in a closed square or rectangular shape.

The house built around a courtyard is fairly extensive and contains well-oriented wings that offer privacy and safety and form a reception space and daily activities area for the family. The courtyard was enriched by the addition of a covered terrace on one side called *Liwan*, which served as an extension toward a significant orientation like a valley, seashore or another nice view.

The Gallery House

The gallery (*Riwaq*) indicates a covered space, which opens to the outside through a series of supports such as colonnades or arcades. In the Mediterranean two forms of the gallery are popular. The first is a gallery that exists as an addition of a covered open space, mainly produced by ornamental plants or grapevines and therefore called a passive gallery. The second one is the active version of the gallery and is designed as an open corridor that functions as a traffic or transitional area linking different components of the building (Fig. 12). As a rule the gallery is greater in length than in depth. In general the gallery is reached either directly from the surroundings, if the terrain slope allows that, or by a courtyard in front. In contrast with the closed rectangular type the gallery building expresses three major trends (Ragette 1974: 44): (a) appreciation of the gentle climate and the natural beauty of the region; (b) a feeling of confidence to the inhabitants, and (c) an increasing emphasis on life within the family.

In the majority of cases the gallery building has two floors, the lower of which is vaulted and the upper is flat-roofed or with tiled pitched roofs (imported from Europe in the nineteenth century). In its formal expression the gallery building presents the greatest possible contrast to the closed rectangular type. The continuous arcade or colonnade provides the feeling of openness and expresses the superior social standing of the building's owners.

The Central Hall House

Although this type appears in Palestine at a later date than the other mentioned types, it became the most popular form of traditional house by the second half of the nineteenth century (Fig. 13). It has one, two, or three floors, and one or more entrances. In addition the central hall has a full depth, subdivided or surrounded

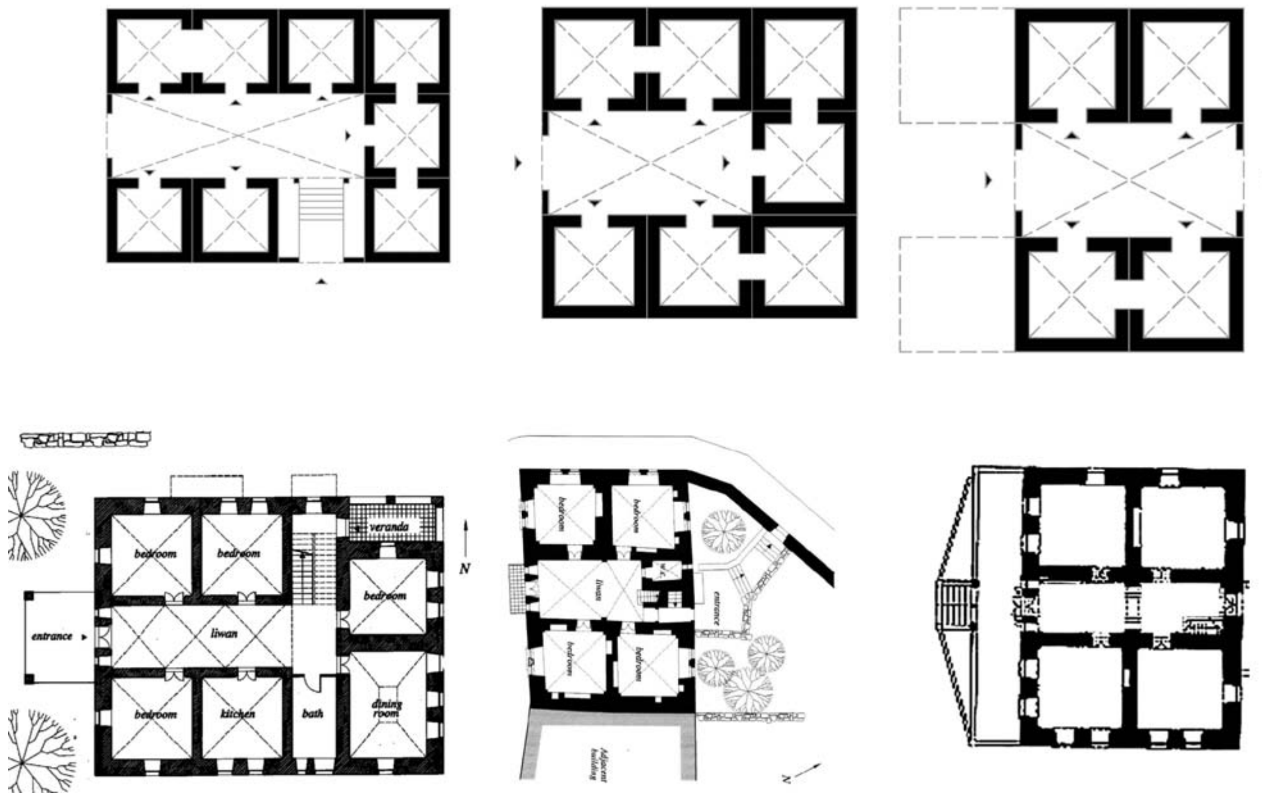
by rooms from three sides. A symmetrical composition prevails when the entrance leads directly to the central hall, while the corridor to the central hall disturbs the symmetry when the entrance is lateral.

By the end of the nineteenth century, due to western influence, the central hall system was adopted widely and the design became increasingly formal. The houses turned into veritable villas that majestically dominated their surroundings outside the Old City walls. Often, the central hall house was built of stone. The lower floor was vaulted and the upper either vaulted, roofed with steel beams or timbered with red tiles.

This descriptive analysis of Palestinian traditional architecture shows that transformations in the structure of Palestinian society reflect not only the achievements of Palestinian ethnic groups, but also those realized by interaction with western identities. In this way both traditional creativity and "formal architecture" have been rationalized:

1. This architecture is a product of a simple and frugal society creating its habitat with elementary means, but also with an understanding of the functional requirements and the potential of the materials available.
2. The artistic quality of the buildings created in the second half of the nineteenth century was not totally dependent upon imported models. The stylistic self-sufficiency of the country's architecture has continued to be expressed through numerous variations of locally rooted traditions, as well as mastery of a craft.
   a. The color and texture of the natural stone contribute to the homogeneous and organic character of Palestinian architecture. The stone finishing reveals an intimate knowledge of the material acquired by generations of stonemasons. The use of color for decorative effects is limited to a few elements at entrances, windows, or arches. Palestinian architecture is more restrained in this regard than Arab architecture in general, where structural clarity is sometimes masked by decorations.
   b. The form's simplicity of the traditional building, the massing of single buildings as well as groups of buildings and the adherence to a uniform scale are the basic means of creating harmony between house and landscape, house and house or village and landscape. The juxtaposition of houses creates a repetitive rhythm of mass and void that covers the land without destroying its relief. The human scale is maintained in the traditional architecture, where the principal masses, as masonry works, automatically introduce a clear definition of scale. Yet each gate, door, window or arch dimension is in reasonable relation to necessity and importance.
   c. The shapes of walls and roofs normally adhere to the simple geometry of squares, rectangles and



Architecture in Palestine. Fig. 13 Basic schemas of the central hall traditional house. Drawings by the author.

trapezoids. Spans and cantilevers are strictly limited. The repetitions of similarly shaped openings reinforce continuity and their irregular distributions within one elevation sometimes create pleasant diversity.

3. Palestinian traditional architecture occupies its place naturally and without pretension. It is imbedded in a landscape humanized by countless terraces, and built of the materials furnished by the environment. The balance of massing and the harmony of forms were exemplary, and the arrangement of the houses reflects deep understanding of the environment, and is indicative of a remarkable social balance.
4. However, by the end of the nineteenth century this architecture lost two of its most important qualities: the flexible inner space and public participation in the building process.

Arithmetic in India: *Pāṭīgaṇita*

Takao Hayashi

Pāṭīgaṇita, which literally means "mathematics (*gaṇita*) by means of algorithms (*pāṭī*)," is the name of one of the two main fields of medieval Indian mathematics, the other being *bījagaṇita* or "mathematics by means of seeds." The two fields roughly correspond, respectively, to arithmetic (including mensuration) and algebra.

The compound *Pāṭīgaṇita* seems to have come into use in relatively later times. In older works, the expressions, *gaṇitapāṭī* and *gaṇitasya pāṭī* (mathematical procedure, i.e., algorithm), are common, and sometimes the word *pāṭī* occurs independently. *Pāṭīgaṇita* is also called *vyaktagaṇita* or "mathematics of visible (or known) [numbers]," while *bījagaṇita* is called *avyaktagaṇita* or "mathematics of invisible (or unknown) [numbers]." Some scholars maintain that the word *pāṭī* originated from the word *paṭṭa* or *paṭa* meaning the calculating board, but its origin seems to be still open to question.

The division of mathematics (*gaṇita*) into those two fields was not practiced in the *Āryabhaṭīya* (AD 499), which has a single chapter called *gaṇita*, but it existed in the seventh century, when Brahmagupta included two chapters on mathematics in his astronomical work, *Brāhmasphuṭasiddhānta* (AD 628). Neither the word *pāṭī* nor *bījagaṇita* occurs in the book, but chapter 12 (simply called *gaṇita*) deals with almost the same topics as later books of *pāṭī*, and chapter 18, though named *kuttaka* or the pulverizer (solution of a linear indeterminate equation), has many topics in common with later books of *bījagaṇita*. Śrīdhara (ca. AD 750) is known to have written several textbooks of *pāṭī* and at least one of *bījagaṇita*.

Extant works of *pāṭī* include Śrīdhara's *Pāṭgaṇita* (incomplete) and *Triśatikā* (and *Gaṇitapañcaviṃsi*?), Mahāvīra's *Gaṇitasārasaṃgraha* (ca. AD 850), chapter 15 (*pāṭī*) of Āryabhaṭa's *Mahāsiddhānta* (ca. AD 950 or 1500), Śrīpati's *Gaṇitatilaka* (incomplete) and chapter 13 (*vyaktagaṇita*) of his *Siddhāntaśekhara* (ca. AD 1050), Bhāskara's *Līlāvatī* (AD 1150), and Nārāyaṇa's *Gaṇitakaumudī* (AD 1356).

A book (or chapter) of *pāṭī* consists of two main parts, namely, fundamental operations (*parikarmāṇi*) and "practical problems" (*vyavahārāḥ*). The former usually comprises six or eight arithmetical computations (addition, subtraction, multiplication, division, squaring, extraction of the square root, cubing, and extraction of the cube root) of integers, fractions, and zero, several types of reductions of fractions, and rules concerning proportion including the so-called rule of three (*trairāśika*). The latter originally consisted of eight chapters (or sections), i.e., those on mixture (*miśraka*), mathematical series (*śreḍhī*), plane figures (*kṣetra*), ditches (*khāta*), stacking [of bricks] (*citi*), sawing [of timbers] (*krākacika*), piling [of grain] (*rāśi*), and on the shadow (*chāyā*).

To this list of the practical problems, Śrīdhara added in his *Pāṭīgaṇita* one named "truth of zero" (*śūnyatattva*). A large portion of the work including that chapter is, however, missing in the only extant manuscript. The way the *Gaṇitasārasamgraha* of Mahāvīra divides its contents into chapters is unusual, but still it can be characterized as a book of *pāṭī*. It is quite rich in mathematical rules and problems.

In his *Līlāvatī*, Bhāskara separated the rules on proportion from the arithmetical computations, and created with them a new chapter named *prakīrṇaka* (miscellaneous [rules]), in which he also included the *regula falsi*, the rule of inverse operations, the rule of sum and difference, etc. After the ordinary topics of practical problems, he treated *kuṭṭaka* as well as *ankapāśa* or the nets of numerical figures (combinatorics). Written in elegant but plain Sanskrit and organized well, the *Līlāvatī* became the most popular textbook of *pāṭī* in India.

In his *Gaṇitakaumudī*, Nārāyaṇa included in the practical problems not only *kuṭṭaka* and *aṇkapāśa*, but also *vargaprakṛti* or the square nature (indeterminate equations of the second degree including the so-called Pell's equation), *bhāgādāna* or the acquisition of parts (factorization), *aṃśāvatāra* or manifestation of fractions (partitioning), and *bhadragaṇita* or mathematics of magic squares. These topics had already been dealt with to a certain extent by his predecessors, but he developed them considerably. He also investigated new mathematical progressions, some of which turned out to be useful when Mādhava (ca. AD 1400) and his successors obtained power series for the circumference of a circle (or π), sine, cosine, arctangent, etc.

Arithmetic in Islamic Mathematics

Julian A. Smith

Mathematics flourished during the golden age of Islamic science, which began around the seventh century AD and continued through to about the fourteenth century. Both arithmetic and algebra were advanced dramatically by Muslim mathematicians, who adopted Indian innovations such as decimal numbers and considerably extended them – they also developed earlier Greek concepts of geometry, trigonometry, number theory and the resolution of equations. Islamic mathematicians did far more than just copy Greek and Indian techniques – their additional researches developed and systematized several fields of mathematics. Even modern mathematical language, including terms like "algebra", "root" and "zero", owes an important debt to Arabic scientists. Algebra, for example, comes from the ninth-century Arabic Astronomer and mathematician al-Khwārizmī (ca. 780–ca. 850), whose book *Algebra* (*al-Kitāb al-mukhtaṣar fī ḥisāb al-jabr wa 'l-muqābala*) described techniques of transposing quantities from one side of an equation to another (*jabr*), then simplifying them (*muqābala*).

Yet while Arabic contributions to algebra have been widely discussed by historians of science and culture, their parallel work in arithmetic has been until recently far less well known. During the early nomadic period of Arabic history, numbers were given names – and around the time of the Prophet Muḥammad (ca. 570–632), the letters of the Arabic alphabet were often used as numerals. However, it was not until the rise of Islam in the seventh and eighth centuries that a recognizably modern system of arithmetic was developed. Muslim arithmetic operations were largely based on ancient Greek definitions, but Islamic scholars pioneered new techniques, including the network or lattice method (*shabaqah*) to multiply numbers, and various techniques of long division.

Muslim mathematicians are best known for their contributions to the pivotal system of modern "Hindu–Arabic numerals" – i.e. the technique of expressing all numbers through the repeated use of a few basic symbols. Though originally invented in India, Arab scholars dramatically improved both the writing and manipulation of decimal numerals, and also developed the Hindu idea of positional notation. It is not known exactly when Indian mathematicians began using decimal numbers, but they seem to have been in place by the early sixth century AD – astronomer Āryabhaṭa I (476–ca. 550) did not use them, but they were employed in a limited way by the middle of the sixth century. Decimal numbers were quite popular and spread quickly – by the seventh century, they had reached Iraq and the Middle East, and were praised by Syrian Nestorian bishop Severus Sebokht (fl. AD 630), who considered this new Hindu arithmetic "done with nine signs" even more ingenious than the calculations of Greek mathematicians. Arabs began using Hindu decimal arithmetic around the seventh century, but it was not until the ninth century that Arabic works describing this type of reckoning appear. The earliest known Arabic treatise on decimal arithmetic, *Kitāb al-hisāb al-hindī* (Book of Addition and Subtraction According to the Hindu Calculation), was written by Al-Khwārizmī around AD 800 – the Arabic text is lost, but a twelfth century Latin translation is still extant.

Al-Khwārizmī is better known among historians of Muslim mathematics for his many contributions to algebra. Yet his investigations into arithmetic were equally important, and were so widely read in the medieval Latin West that they later gave Europeans one of their early names for arithmetic, the "algorism" or "algorithm". Al-Khwārizmī's book treated all arithmetic operations, spreading knowledge of Hindu techniques throughout the Muslim world. Another important early treatise that publicized decimal numbers was Iranian mathematician and astronomer Kūshyār ibn Labbān's (fl. 1000) *Kitāb fī uṣūl ḥisāb al-hind* (Principles of Hindu Reckoning), a leading arithmetic textbook.

Coupled to the important development of decimal numbers was the equally significant Arabic use of the *sifr* (meaning "empty"), or zero, again from Indian roots. An early symbol for zero appears in an AD 876 inscription at Gwalior, India; in the Arab world, Kūshyār introduces the zero in the tenth century as a sign to be placed "where there is no number".

Though scholars concede that much of Arabic arithmetic has its ultimate origins in India, Muslim mathematicians were the first to integrate the various discoveries of Hindu mathematicians into a coherent whole. Historian J. L. Berggren, for example, concludes that while the Hindus were the first to use a "cipherized, decimal positional system", the Arabs pioneered in extending this system to "represent parts of the unit by decimal fractions". In Europe, meanwhile, the zero and decimal system were not widely used until the late twelfth century.

Following al-Khwārīzmī, many Arabic mathematicians developed Indian techniques of arithmetic over the next few centuries. The astronomer, translator, and editor al-Kindī (801–ca. 873), for example, wrote several important treatises on arithmetic, including manuscripts on the use of Indian numbers, on lines and multiplication with numbers, on measuring proportions and times, on numerical procedures and cancellation, and many more.

Two centuries later, al-Karajī of Baghdad (fl. 1020) wrote mathematical works that led to his being called "the most scholarly and original writer of arithmetic" by historian Al-Daffa. Al-Karajī's works included a manuscript on the rules of computation entitled *Al-Kafī fī al-Ḥisāb* (Essentials of Arithmetic), and *al-Fakhrī fī' ljabr wa'l-muqābala*, which was named after his longtime friend, the Baghdad grand vizier.

The depth of early Islamic knowledge of arithmetic is often quite unexpected. Arabic mathematicians were well aware of the existence of irrational numbers, and sometimes developed complex theories to explain their properties. Persian poet and philosopher 'Umar al-Khayyām, or Omar Khayyam (ca. 1048–ca. 1122) and Persian astronomer Naṣīr al-Dīn al-Ṭūsī (1201–1274) both argued that every ratio of two magnitudes can be considered a number, whether that ratio be commensurable (rational) or incommensurable (irrational). Islamic arithmetic used many of the same Hindu techniques for operating with irrationals as it did with rationals. Also from Indian sources came various operations with numbers, including transformations such as $\sqrt{x^2y} = x\sqrt{y}$ and $\sqrt{xy} = \sqrt{x}\sqrt{y}$.

Islamic arithmeticians did not accept everything offered them by Hindu scholars. For example, negative numbers, long a staple in Indian arithmetic, were transmitted to the Arab world but rejected by it – Arabic mathematicians instead held that negative numbers did not exist.

Modern notation for fractions is also based in part on Muslim arithmetic. Celebrated Hindu mathematicians such as Bhāskara II (1114–ca. 1185) wrote common fractions by just writing a numerator above a denominator, but the idea of a line of separation between the numerator and denominator was an early Islamic development. Decimal fractions, meanwhile, appear in seminal tenth century Arabic texts, such as the *Kitāb al-fuṣūl fi'l ḥisāb al-hindī* (Book of Chapters on Hindu Arithmetic), written by Damascus mathematician al-Uqlīdisī (fl. 952). In the late twelfth century, al-Samaw'al (fl. 1172) used decimal fractions for division, root extraction and approximation. By the fifteenth century, decimal fractions had been formally named and systematically developed, but they were not widely used in Europe until the Dutch physicist and engineer Simon Stevin (1548–1620) published *La Thiende* (The Tenth) in 1585, and Scottish mathematician John Napier (1550–1617) reintroduced his decimal point in the early seventeenth century.

While Arabic mathematicians pioneered in decimal arithmetic, they also made considerable contributions to the ancient sexagesimal (base 60) system of arithmetic, which had been developed by the Babylonians in Mesopotamia around 2000 BCE. This system was widely used for astronomical calculation throughout the ancient world, particularly in Alexandrian astronomer and geographer Claudius Ptolemy's (ca. AD 100–170) cosmological treatise, *Almagest*, which was later adopted by Islamic scholars as the theoretical base of their astronomy. Sexagesimal addition, subtraction, multiplication and division became so commonplace among Islamic astronomers it was renamed "the astronomer's arithmetic". Arabic astronomers and mathematicians such as Kūshyār and Samarqand's al-Kāshī (fl. 1406–1429) used sexagesimal numbers to determine approximate roots, extract square roots and even find the fifth roots of certain numbers.

Islamic arithmetic was often influenced by the needs of astrology, talismans and sorcery, as in the casting of horoscopes and magic spells. Muslim mathematicians such as Syrian scholar Thābit ibn Qurra (ca. 836–901) and Tunisian historian lbn Khaldūn (1332–1406) studied amicable numbers, or number pairs where the sum of the factors of each number is equal to the other number. Two hundred and twenty and 284 are amicable numbers, because the sum of the factors of 284 (1 + 2 + 4 + 71 + 142) equals 220, and vice versa.

Muslim mathematics was also affected by practical considerations such as problems of inheritance and finance, and the need to calculate events in the lunar-based Islamic calendar. For example, al-Khwārizmī devoted the second half of his treatise on algebra to the question of '*ilm al-farā'iḍ*, or the calculation of shares of an estate given to various heirs. These problems employed the arithmetic of fractions, and were heavily influenced by religious law and custom. A typical example treated by al-Khwārizmī was to calculate the shares of a dead woman's estate that would accrue to her husband, her son, and her three daughters. As the law required that the husband receive a fourth and each son get twice what a daughter would receive, al-Khwārizmī simply divides the estate into 20 parts, giving five to the husband, six to the son, and three to each daughter. Similar problems involved the topic of *zakāt*, which was the calculation of the share of private wealth that various persons would pay to the community each year.

Islamic arithmetic was often ingenious. Arabic scholars gave us much of the modern system of arithmetic, and while many of its foundations were borrowed from Indian and Greek sources, it is clear that Islamic mathematicians united the various strands of arithmetic into a form recognizable to us today.

Armillary Spheres in China

Jiang Xiaoyuan

The equatorial armillary sphere was a traditional Chinese astronomical instrument used to observe celestial bodies in an equatorial coordinate system. Its origin is still not very clear. Astronomer Luoxia Hong (ca. 100 BCE) of the Western Han Dynasty was probably the first maker of this instrument which possessed a very basic form.

The early equatorial armilla was composed of two layers: the outside layer included a meridian circle, equatorial circle, and vertical circle – all three of these were fixed. The inside layer included a polar axis, right ascension circle, and sighting tube. The right ascension circle could rotate around the polar axis, and the sighting tube could rotate in the right ascension circle freely so it could point to everywhere in the sky.

In the Tang Dynasty (AD 618–907), a third layer was added to the equatorial armillary which included an ecliptic (the band of the zodiac through which the Sun apparently moves in its yearly course) circle and a circle of the moon's path. Astronomers could then measure three coordinate systems with one instrument, but the three-layer armilla was too complex to observe, so from the Northern Song Dynasty (AD 960–1126) a course of simplification was begun. The third layer was canceled, and the so-called "abridged armilla" (*Jian Yi*) appeared. It is in fact two different instruments (one equatorial armilla and one altazimuth) on the same pedestal.

The equatorial armilla was one of the most important astronomical instruments in ancient China. It was the result of the equatorial tradition of Chinese astronomy which lasted more than 2,000 years. In ancient China, armilla (and almost all astronomical instruments) were only made by the imperial government, so their size was always very large.

A

Armillary Spheres in India

K. V. Sarma

The armillary sphere, known in Hindu astronomy by the terms *Golabandha* and *Gola-yantra* (Globe instrument), was constructed from early times for study, demonstration, and observation. Among texts and commentaries which have either brief mention or detailed treatment of the armillary sphere, the following might be mentioned: *Āryabhaṭīya* of Āryabhaṭa (b. 476), *Pañcasiddhāntikā* of Varāhamihira (505), *Śiṣyadhīvṛddhida* of Lalla (eighth century), *Brāhmasphuṭasiddhānta* of Brahmagupta (b. 628), *Siddhāntaśekhara* of Śripati (1039), *Sūrya-siddhānta, Siddhāntairomaṇi* (*Golabandhādhikāra*) of Bhāskara II (b. 1114), and *Goladīpikā* of Parameśvara (1380–1460).

The movable and immovable circles which form parts of the instrument are made out of thin bamboo strips, the earth and the celestial bodies are of wood or clay, and the lines are connected by means of strings. The axis is made of iron and is mounted on two vertical posts, so that it is possible to rotate the sphere as needed.

The *Goladípikā* describes the construction of a simple *Golabandha* with two spheres, the inner one representing the *Bhagola* (Starry sphere) moving inside an outer sphere which represents the *Khagola* (Celestial sphere), both fitted on the same central axis. The movements of the planets, etc. are projected and measured on these spheres. A circular loop made of a thin bamboo strip kept vertically in the north–south direction represents the solsticial colure[1] (*Dakṣiṇottara*). Another similar circle fixed to the former in the east–west direction would be the equinoctial or celestial equator (*Ghaṭikā-maṇḍala*). Still another circle fixed around these, cutting them at right angles and making crosses at the four cardinal points, represents the equinoctial colure. The celestial equator is graduated into 60 equal parts and the other two into 360 equal parts. Another circle is fixed passing through the east and west crosses and inclined at 24° north and south of the zenith and the nadir – this would be the Ecliptic (*Apama-vṛtta*). Several smaller circles are now constructed across the solsticial colure on either side of the celestial equator and parallel to it, at the required declinations – these would be the diurnal circles (*Ahorātra-vṛttas*), of different magnitudes. The orbits of the Moon and other planets are now constructed, crossing the ecliptic (the band of the zodiac through which the Sun apparently moves in its yearly course) at the nodes (*pātas*) of the respective planets and diverging from it, north and south, by their maximum latitudes at 90° from the nodes. A metal rod is inserted through the north and south crosses to form the central axis. This figuration is called the Starry sphere (*Bhagola*).

Three circles are constructed outside the *Kha-gola* (Celestial sphere). The horizontal circle is called the horizon (*Kṣitija*), the east–west circle is called prime vertical (*Samamaṇḍala*), and the north–south circle is called the meridian (*Dakṣiṇottara*). A model of the Earth in spherical form is then fixed to the center of the axis. This would be the figuration at zero latitude.

If the armillary sphere is to be used in any other place, two holes are made in the Celestial sphere at a distance equal to the latitude of the place, below and above the south and north crosses, and the axis of the Starry sphere is made to pass through them. It is also necessary, in this case, to construct a circle called the equinoctial colure (*Unmaṇḍala*), which passes through the two ends of the axis and the east and west crosses. To keep the two sets of circles in position, wooden pieces are fixed to the axis in between them, so that the spheres do not get displaced.

The inner Starry sphere revolves constantly, while the Celestial sphere remains stationary, and directions are reckoned therefrom. A diurnal circle with its radius equal to the sine latitude is also constructed with a point on the central axis as the center, just touching the horizon. The sine and cosine of the place can be measured on this circle.

While the armillary sphere described above is more for study and demonstration, certain other texts speak of more circles and also enjoin observation of celestial bodies. Thus *Brāhmasphuṭasiddhānta* (XXI. 49–69) prescribes the construction of 51 movable circles, *Śiṣyadhīvṛddhida* speaks of diagonal circles (*Koṇa-vṛttas*) and spheres for each planet, and *Siddhānta-śiromaṇī* adds a third circle called Dṛggola outside the *Khagola* (Celestial sphere). According to *Śiṣyadhīvṛddhida* the *lagna* (Orient ecliptic point) and time are also found by means of the armillary sphere.

Āryabhaṭa

R. C. Gupta

Āryabhaṭa (b. AD 476) was a celebrated astronomer and mathematician of the classical period of the Gupta dynasty (AD 320 to ca. 600). This era is called the Golden Age in the history of India, during which Indian intellect reached its high water mark in most branches of art, science, and literature, and Indian culture and civilization reached a unique stage of development which left its deep impression upon succeeding ages. Āryabhaṭa played an important role in shaping scientific astronomy in India. He is designated as Āryabhaṭa I to differentiate him from Āryabhaṭa II, who flourished much later (ca. AD 950–1100) and who wrote the *Mahāsiddhānta*.

Āryabhaṭa I was born in AD 476. This conclusion is reached from his own statement in the *Āryabhaṭīya*: "When sixty times sixty years and three quarters of the *yuga* (now *Mahā*) had elapsed, twenty three years had then passed since my birth" (III, 10).

Since the present *Kaliyuga* (the last quarter of the *Mahāyuga*) started in 3102 BCE, Āryabhaṭa was 23 years old in 3600 minus 3101, that is in AD 499. The exact date of birth comes out to be March 21st, when the Mean Sun entered the zodiac sign of Aries in AD 476. The significance of mentioning AD 499 is that the precession of equinoxes was zero at the time, so that the given planetary mean positions did not require any correction. According to some commentators, AD 499 was also the year of compostion of the *Āryabhaṭīya*.

We have no knowledge about his parents or teachers, or even about his native place. Āryabhaṭa composed the *Āryahhaṭīya* while living at Kusumapura, which has been identified as Pāṭaliputra (modern Patna in Bihar State), the imperial capital of the Gupta empire. It is possible that Āryabhaṭa headed an astronomical school there.

The association of Patna, where Āryabhaṭa taught and wrote on mathematics and astronomy, with his professional career, does not settle the question of his birthplace, but it may have been a place where he was educated.

Āryabhaṭa's fame rests mainly on his *Āryabhaṭīya*, but from the writings of Varāhamihira (sixth century AD), Bhāskara I, and Brahmagupta (seventh century), it is clear that earlier he composed an *Āryabhaṭa Siddhānta*. Although voluminous, the *Āryabhaṭa Siddhānta* is not extant. It is also called *Ārdharātrika Tantra*, because in it the civil days were reckoned from one midnight to the next. Its basic parameters are preserved by Bhāskara I in his *Mahābhāskarīya* (Chap. VII). Rāmakṛṣṇa Ārādhya (AD 1472) has quoted 34 verses on astronomical instruments from the *Āryabhaṭa Siddhānta*, of which some were devised by Āryabhaṭa himself.

The *Āryabhaṭīya* is an improved work and the product of a mature intellect. Considering the genius of Āryabhaṭa, it is easy to agree with the view that he composed it at the age of 23. The date is also in fair agreement with the recent research and analysis by Roger Billard. Unlike the *Āryabhaṭa Siddhānta*, the civil days in the *Āryabhaṭīya* are reckoned from one sunrise to the next – a practice which is still prevalent among the followers of the Hindu calendar. The *Āryabhaṭīya* consists of four sections or *pādas* (fourth parts):

1. *Daśagītikā* (10 + 3 couplets in Gīti meter)
2. *Gaṇitapāda* (33 verses on mathematics)
3. *Kāla-kriyāpāda* (25 verses on time-reckoning)
4. *Golapāda* (50 verses on spherical astronomy)

That the *Āryabhaṭīya* was quite popular is shown by the large number of commentaries written on it, from Prabhākara (ca. AD 525) through Nīlakaṇṭha Somayāji (ca. 1502) to Kodaṇḍarāma (ca. 1850).

An Arabic translation of the *Āryabhaṭīya* entitled *Zīj al-Ārjabhar* was made in about 800, possibly by al-Ahwāzī. In spite of the *Āryabhaṭīya's* popularity, H. T. Colebrooke failed to trace any work of Āryabhaṭa anywhere in India.

The use of modern scientific methodology, as described by Roger Billard in his *L'astronomie indienne*, along with new ephemerides, clearly shows that both of Āryabhaṭa's major works were based on accurate planetary observations. In fact, the use of better planetary parameters, the innovations in astronomical methods, and the concise style of exposition rendered the *Āryabhaṭīya* an excellent textbook in astronomy. In opposition to the earlier geostationary theory, Āryabhaṭa held the view that the earth rotates on its axis. His estimate of the period of the sidereal rotation of earth was 23 h, 56 min, and 4.1 s, which is quite close to the actual value.

Āryabhaṭa has been also considered the father of Indian epicyclic astronomy. The resulting new planetary theory enabled Indians to determine more accurately the true positions and distances of the planets (including the sun and the moon). He was the first Indian to provide a method of finding celestial latitudes. He also propounded the true scientific cause of eclipses (instead of crediting the mythlogical demon Rāhu). In fact his new ideas gave rise to the formation of a new school of Indian astronomy: the Āryabhaṭa School or *Āryapakṣa*, for which the basic text was the *Āryabhaṭīya*.

Exposition and computation based on the new astronomical theories were made easy by Āryabhaṭa, because of the development of some mathematical tools. One of them was his own peculiar system of alphabetic numerals. The 33 consonants of the Sanskrit alphabet (Nāgarī script) denoted various numbers in conjunction with vowels which themselves stood for no numerical value. For example, the expression *khyughṛ* (=*khu* + *yu* + *ghṛ*) denoted

$$2 \times 100^2 + 30 \times 100^2 + 4 \times 10^3 = 4,300,000,$$

which is the number of revolutions of the sun in a Yuga.

The development of Indian trigonometry (based on sine instead of chord, as the Greeks had done) was another of Āryabhaṭa's achievements which was necessary for astronomical calculations.

Because of his own concise notation, he could express the full sine table in just one couplet, which students could easily remember. For preparing the table of sines, he gave two methods, one of which was based on the property that the second order sine differences were proportional to sines themselves.

Āryabhaṭa seems to have been the first to give a general method for solving indetermininate equations of the first degree. He dealt with the subject in connection with the problem of finding an integral number N which will give a remainder r when divided by an integer a, and s when divided by b. This amounts to solving the equations

$$N = ax + r = by + s.$$

Although at present the topic of indeterminate analysis comes under pure mathematics, in ancient times it arose and was used for practical and astronomical problems. In fact, Āryabhaṭa successfully used his theory of indeterminate analysis to determine a mean conjunction of all planets at the zero mean longitude at the start of the *Kaliyuga* (3102 BCE). Recently it has been shown that his algorithm solves more general problems than the Chinese remainder theorem, and works irrespective of the sign of numbers.

The solution of a general quadratic equation and the summation of certain series were some other algebraic topics dealt with by Āryabhaṭa. The methods of adding an arithmetical progression were known in all ancient cultures, but he was perhaps the first to supply a general rule for finding the number of terms (n) when the first term (a), the common difference (d) and the sum (s) were given. His solution is a root of the quadratic equation

$$dn^2 + (2a - d)n = 2s,$$

which comes from the usual formula for the sum of an arithmetical progression.

In geometry, his greatest achievement was an accurate value of π. His rule amounts to the statement

$$dn^2 + (2a - d)n = 2s.$$

This implies the approximation 3.1416 which is correct to its last decimal place. How he arrived at this is not known.

From what we know about Āryabhaṭa, it is clear that he was an outstanding astronomer and mathematician. His scientific attitude, rational approach, and mathematical methodology ushered in a new era in the history of the exact sciences in India. It was quite befitting that the first Indian satellite launched on the 19th April 1975 was named Āryabhaṭa.

Asada Goryu

Nakayama Shigeru

Asada Goryu (1734–1799) was a Japanese astronomer who was instrumental in turning Japanese astronomy and calendrical science away from the traditional Chinese style and toward Western models.

In adopting the traditional idea of secular diminution of tropical year length, astronomers at the time were required only to account for the ancient records and modern data of Chinese solstitial observations by a single formula. Classical Western data, such as those listed in the *Almagest* of Ptolemy, became available to Asada through the Jesuit treatises. He endeavored to synthesize Western and Chinese astronomy and to give a numerical explanation, by means of a single principle, of all the observational data available to him – old and new, Eastern and Western.

Copernicus appears in the Sino-Jesuit treatises, not as an advocate of heliocentricism but as an observational astronomer and the inventor of the eighth sphere of trepidation. He is said to have believed that the ancient tropical year was longer than that of the Middle Ages, which in turn was shorter than the contemporary constant. Asada, perhaps struck by this passage, formulated a modified conception in which the length of the ancient tropical year tended to decrease until it reached a minimum in the Middle Ages and to grow longer afterward, varying in a precession cycle of 25,400 years.

It is apparent that what Asada really intended to do was account for the newly acquired Western data. His basic goal, that of "saving the ancient records" by numerical manipulation, differs not at all from that of the traditional approach. His consideration of the precession cycle was theoretical decoration.

Astrolabe

Julian A. Smith

The astrolabe is a portable wooden or metal astronomical instrument which is used to measure the positions and altitudes of celestial bodies, to find the observer's time or latitude, or to solve other mathematical problems. In its complete form, it consists of a main body, or flat plate ("mater" or "mother") to which is attached a series of smaller plates (called climates) engraved with various coordinate lines, according to various latitudes. An alidade, a rotatable straight rule with sights used to find altitudes, is fastened to the back. Attached to the front, above the climates, is a smaller fretted circular plate called the rete – this is a moveable map of the heavers, with pointers indicating various stars. The whole rotating assembly is fastened together by a pin through the center of the mater and climates, and it is secured at the top by a wedge-shaped piece of metal called the horse, after its fanciful resemblance to a horse's head.

To use the astrolabe, an observer would typically rotate the alidade until a star became visible through the sights, and then read its altitude in degrees from a scale on the back of the instrument. Then one would turn the rete until that star corresponded to the almucantar (curves representing parallels to the horizon) for the right altitude. The time could then be determined from the place of the "sun" on the instrument. Astrolabes could measure solar time, sidereal time, and time in unequal hours, depending on how the hour lines were marked.

Although the astrolabe is usually considered an Arabic invention, its true roots go back to the mathematical astronomers of ancient Greece – the word itself comes from the Greek terms for a "star-taking" instrument. Engraving great circles and hour lines demanded considerable skill – in essence, the instrument-maker had to collapse a three-dimensional celestial sphere into the flat, circular plane of the astrolabe. Some historians attribute this discovery to Appolonius of Perga (ca. 262–ca. 190 BCE), but according to Otto Neugebauer, the planispheric or stereographic projection of the heavens upon a flat surface was first accomplished by Greek astronomer Hipparchus of Nicea/Rhodes (ca. 190–ca. 120 BCE). In addition, Hipparchus may have built simple astrolabes, consisting of solid sky maps covered with open networks of lines. Finally, he is credited with developing the projection for an anaphoric clock, an ancestor of the astrolabe. This is an axle with a large circular star map, laid out in a stereographic projection – attached to it is a smaller stationary grill showing the projection of the horizon, and a visible hemisphere for a given latitude. The dial is powered by a clepsydra, and as it rotates, a model of the sun traces out the hours of the day. The anaphoric clock was described by Roman engineer Vitruvius (ca. 25 BCE), and may have been built in the famous Athenian "Tower of the Winds" around 50 BCE.

The first clear descriptions of the construction of the astrolabe occur in the *Planisphere* of Alexandrian astronomer Claudius Ptolemy (ca. 150 AD). By this time, the complexity of various lines had made the astrolabe's covering bulky, a problem Ptolemy solved by switching the lines to the mater and the star map to the rete. The astrolabe was further developed in the works of Greek mathematician Theon (fl. AD 360–380), now lost, and John Philoponus (fl. 520), both of Alexandria. Syrian Severus Sebokht (fl. 630) also wrote an early treatise on the astrolabe.

Medieval Islamic scientists took the basic planispheric astrolabe of Hellenistic astronomers and improved it dramatically between AD 700–1500, applying it to questions of astronomy, surveying, mathematics, geography, and much more. In AD 843, Baghdad mathematician al-Khwārizmī (fl. AD 810–850) claimed his astrolabe could solve 43 problems – a century later, Persian astronomer al-Ṣūfī (AD 903–986) said that it could answer a thousand astronomical questions. David King divides Arabic astrolabe innovations into five basic categories: the making of tables, nonstandard retes, qiblas, multiple climates, and the development of three new forms of the instrument.

Astronomers like al-Farghānī of Baghdad (ca. 830–ca. 861) compiled numerical tables of radii and center distances of both azimuth and almucantar circles for every degree of latitude and azimuth, for every terrestrial latitude. These tables, which exceeded 13,000 entries, were used extensively by Arabic astronomers alongside geometric projections to construct astrolabes for different latitudes. Islamic astronomers also constructed nonstandard retes, which would symmetrically represent the otherwise dissimilar northern and southern halves of the ecliptic (the band of the zodiac through which the Sun apparently moves in its yearly course). The Oxford myrtle astrolabe is an example.

Arabic astrolabists inscribed specific markings on their instruments, corresponding to Islamic prayer times and directions. By the thirteenth century, they engraved lists of cities with latitudes, longitudes, and Mecca directions, known as qiblas – this would help observers orient themselves for prayers. Arabic astrolabes also developed multiple plates or climates, giving astronomical tables usually found in handbooks or textbooks. An early example is referred to by Abū Jaʿfar al-Khāzin (d. 961/971).

Finally, Islamic scientists developed at least three new types of instrument: the linear, universal and geared astrolabes. The linear astrolabe consists of a series of scales on a stick which represents the meridian for a given latitude, to which are attached a series of threads through which one can perform all the standard operations of an astrolabe. This was invented by Iranian mathematician Sharaf al-Dīn al-Ṭūsī (d. ca. 1213), and was known as "al-Ṭūsī's cane." The universal astrolabe was developed by Ḥabash of Baghdad (d. ca. 864–874), and Alī ibn-Khalaf (al-Shakkāz) in Toledo in the eleventh century, who devised a special shakkaziya plate for it. Though powerful, it was not widely known, and was reinvented in early fourteenth century Syria. This astrolabe could determine the risings, culminations, and settings of celestial bodies at all latitudes using a single plate. Astronomer al-Zarqāllu (Azarquiel) of Toledo (ca. 1029–1087/1100) simplified this by replacing the rete with an alidade having a movable cursor, and by putting the ecliptic and star pointers on the shakkaziya plate. Geared astrolabes contained complex mechanisms to reproduce the motion of the sun and moon mechanically – their date of invention is unknown, but they were described by Persian astronomer al-Bīrūnī (ca. 973–1048).

The astrolabe was reintroduced into Europe from the Arabs by the tenth century. Gerbert of Aurillac, Pope Sylvester II (ca. 945–1003), imported much astronomical knowledge into the medieval Latin west from Islamic sources, and may have used the astrolabe as a teaching tool. Meanwhile, Hermannus Contractus (1013–1054) transmitted many Arabic concepts in his two influential Latin treatises on the astrolabe: *De Mensura Astrolabii* and *De Utilitatibus Astrolabii*. Ptolemy's *Planisphere* was translated by Hermann the Dalmatian in the twelfth century, and in 1276, an influential Arabic astrolabe treatise by the Egyptian Jew Māshāʾallāh (fl. 762–ca. 815) was translated into Latin, where it formed the basis for the first English book on the astrolabe, by poet Geoffrey Chaucer (ca. 1340–ca. 1400) in 1391.

Though the astrolabe was widely developed in Arab countries, it was virtually ignored in the East. Joseph Needham says that Chinese astronomers made no astrolabes of their own, though they did develop the anaphoric clock independently. The reasons are twofold: Chinese scientists instead developed sophisticated globes and armillary spheres quite early, and they lacked the analytical techniques in their mathematical astronomy which led to the stereographic projection in the West. Needham suggests the astrolabe was imported to China from Persia in 1267 by the Maraghan Observatory astronomer Jamāl al-Dīn ibn Muḥammed al-Najārri, but the mathematical projections remained obscure until the arrival of the Jesuits in the sixteenth century.

Indian scientists also borrowed the astrolabe from Islamic sources. Astronomer Bhāskara II (1114–ca. 1184) used spherical astronomy to construct a wheel-like instrument, called the *phalaka yantra*, which essentially served the same purpose as a primitive astrolabe. However, the true planispheric astrolabe, the *ustaralava*, was first imported by Muslims in the thirteenth century – a Damascus astrolabe of 1204 is still preserved in the Rampur State Library. The astrolabe was described in detail in the *Yantrarāja* of Mahendra Sūri in 1370 – this work is based on Islamic sources. Lahore later became a center for its construction, under families of instrument makers like those of Shaikh Allāh-Dad (fl. 1570–1660). Indian astronomers also developed some of the largest astrolabes in the world. The great brass astrolabe at the Jaipur observatory of Sawai Jai Singh (1686/8–1743) is 3 m tall, 2.12 m across, and weighs over 400 kg. Jai Singh's *Yantrarājaracanā* also gives instructions for astrolabe construction based on stereographic projections.

The astrolabe was popular as an astronomical instrument until long after the introduction of the telescope in the early seventeenth century. It survived another century, until it was replaced in the 1730s by English astronomer John Hadley's (1682–1744) reflecting quadrant, a precursor to the sextant.

Astrology in Babylonia

Nicholas Campion

The rediscovery of astrology in the twentieth century west is one of the principal phenomena in popular culture. Most histories of the subject from Thorndike (1923–1958) to Tester (1987) assume a fundamental conceptual and technical break between Babylonian and Greek astrology in the last centuries BCE, and that western astrology also effectively came to an end in the late seventeenth century, when it lost its intellectual respectability. The Encyclopaedia of Religion (Culianu 1987: 472) stated categorically that 'astrology, a product of Hellenistic civilisation, appeared at the end of the third century BCE', completely denying any Mesopotamian connection. Chambers Encyclopaedia was more circumspect, considering that 'It was in Greece, about the fourth century BCE that astrology underwent a great development and was regarded as regulating all things in the universe, including the fates of men (1970: 724)'. However, while it is clear that astrology, like any other belief system, experiences periods of reinvention as it passes between different cultures and periods, it is possible to identify a fundamental continuity from the earliest Babylonian astrology to the present day. Contemporary popular astrology may therefore be seen as a remarkable revival of the practical applications of an ancient non-Western astronomy, that of Mesopotamia of 4,000 years ago.

Mesopotamian Astrology

The civilisations of Mesopotamia flourished between 2,000 and 5,000 years ago. Like many societies, they adhered to the belief that the terrestrial, physical and human worlds were so intimately connected to the celestial, intangible and divine realms as to effectively constitute a single entity. The natural environment, it was believed, provided the principal means of communication between humanity and the pantheon of invisible gods and goddesses. From this sense that the entire world was alive, there developed various means of reading divine intentions, and the practice of omen (from the Latin meaning 'sign') divination relied on the assumption that any visible natural phenomenon, whether predictable or not, might represent an attempt by a god or goddess to communicate their intentions or instructions to humanity.

Divination took on many forms, from the rolling of dice to the royal reliance on extispicy, or divination from livers. Gradually, over the second millennium BCE, astrology (the divinatory use of celestial phenomena) appears to have grown in importance. As it did so it encouraged the increasing observation of planetary and stellar patterns, and ultimately, by the seventh to eighth centuries BCE, their extrapolation into the future. Thus, by the time that the Greek astronomers first began to speculate on the nature of the heavens, the Mesopotamian astrologers had made the crucial transition from a purely observational astronomy, to one which was both mathematical and predictive.

There are a number of very good reasons for studying the history of Mesopotamian astrology.

Firstly, it offers a point of entry into understanding Mesopotamian culture. Then there is the question of the astronomical records, which were not only used by the ancient Greeks, but are of relevance for modern science. The use of eclipse records to demonstrate that the slowing in the Earth's rotation is much greater than previously thought is ample demonstration of the value of such ancient observations (Stephenson 1998). But there is also the vexed question of the connections between the endeavours of Babylonian astronomers and astrologers and their counterparts in the Greek world, and the extent to which classical culture borrowed from the Mesopotamians. Such issues run to the heart of European respect for the Greeks as inventors of the western rational and scientific tradition, and raise deep questions concerning European self-identity, and the ambivalent relationship between the Occident and Orient. At the broadest level then, we are not just examining the history of culture or science, but touching on issues which are as alive today as they ever were.

Questions of Definition

The interlocking relationship between Mesopotamian astrology and astronomy, has a particular relevance to contemporary debates on the nature of science and perceptions of its relationship with 'superstition' or 'rational' and 'magical' thought. Indeed, no study of Mesopotamian astrology can begin until we have at least acknowledged such questions of definition (Bottéro 1992: 125–137). Indeed, modern comparisons may counter a natural tendency to see ancient cultures as being so inherently different to our own that they can never be approached. All we can do is remember that our descriptions of Mesopotamian thought can never entirely recapture its true nature.

Whereas modern definitions generally categorise astronomy, the observable measurement of the heavens, as scientific, and astrology, the interpretation of those measurements, as superstitious, the Mesopotamian experience suggests that those definitions are fluid and might even be reversed. For the sake of simplicity I shall stick to modern usage and I shall use astronomy when talking specifically about measurement of the heavens, and astrology when discussing the interpretation of those measurements.

The final problem of definition concerns the alternative use of the terms Mesopotamian and the more common Babylonian. Mesopotamia is a geographical designation for much of the area covered by modern Iraq. Between the mid-third millennium and the end of the first millennium BCE the region passed through a series of political eras from the period of the city states of Sumer and Akkad through the Babylonian and Assyrian empires, a second Babylonian empire, Persian and Greek Seleucid periods. Given that Babylon appears to have retained a special cultural status from around 1800 BCE onwards, the terms Babylonian and Mesopotamian are often used interchangeably to describe the astrology of the entire region (Koch-Westonholtz 1995).

The Modern Sources

This is a fast moving field, due to the sheer volume of primary source material which has either only recently become available or is yet to be translated. The difficulties involved in working out what the Mesopotamians actually thought, though, are genuinely problematic. Even slightly differing nuances between different translations can suggest entirely different conclusions. For example, one version of the Moon's function in the creation epic, the Enuma Elish (V.13) – 'When Above' – is to 'to make known the days' (Heidel 1942: 44–5) while another is 'to measure time' (Jacobsen 1946: 181). The latter expands the use of the moon to announce the name or nature of the day, to the notion that in the second millennium BCE the Mesopotamians had a concept of time as a continuous entity which can be understood mathematically.

The Origins of Astrology

In 1997 Carlos Jaschek (135–145) set out a standardised pattern for the development of astronomy, moving from the measurement of solar and lunar risings and settings to the identification of first individual stars and then planets, the creation of calendars (to facilitate political order), and the recognition that celestial movements are periodic, allowing the crucial transmission from an observational to theoretical astronomy. In this process astrology occupies a crucial place between these last two stages, its requirement for correct forecasts eventually making it essential to predict future planetary positions.

However, we really have little idea of how complex divinatory practices evolved in Mesopotamia, although a number of explanations have been proposed. They may, for example, have 'developed from a simple folk practice, capable of giving yes–no answers to specific questions, to a systematised science, covering nearly all observable phenomena and permitting detailed predictions of unanticipated events, as well as giving detailed answers to queries' (Koch-Westonholtz 1995: 14).

All accounts of astrology's origins are speculative, limited as they are by serious source problems and the tendency to apply modern theories in what might be an inappropriate manner. Could the development of astrology be the direct consequence of what we might call an 'environmental theology'? From the title of Jacobsen's description of the Mesopotamian cosmos, 'The Cosmos as a State' (1946), we derive the term Cosmic State to describe societies in which the earthly system is thought to be inseparable from the celestial. The Mesopotamian system was obviously autocratic in the sense that once a royal order had been given only the astrologers could amend it. Actually, even though the king had the power to dismiss or punish astrologers who gave him poor advice, it is a debatable point as to who was the master.

The reasons that one culture should develop a belief in astrology and another should not be found partly in environmental factors. It is useful to make distinctions in this respect between Egyptian culture, which developed a highly codified astral theology, and Mesopotamian, which made the leap from the use of the stars as religious objects to their application to forecasting. It is true that both cultures believed that the stars offered a means of communication between the divine and humanity, and that they applied this knowledge to political management, but astrology is essentially an extrapolation from astral religion, distinguished by its complexity. The most obvious natural difference between the two cultures is found in Mesopotamia's essential physical insecurity (Jacobsen 1946: 126–127). Mesopotamia had no natural boundaries, was surrounded by hostile enemies, and the flooding of the rivers on which its agriculture depended was erratic. By contrast Egypt was well protected by desert, had few neighbours, and could rely totally on the Nile's annual flood. Such environmental factors fed directly into political cosmology and conduct.

The proposition that the development of astrology was a direct response to collective insecurity has been challenged firstly on the general grounds that it represents the inappropriate projection of modern concerns on to an ancient society, and secondly by the specific argument that the omen literature indicates a society which was very certain of its beliefs (Koch-Westonholtz 1995: 17–18).

If the environment produces political forms then politics produces divination. Jacobsen found evidence in the idea of the divine assembly and in mythical claims that the divine pantheon took its decisions democratically, at least in part. In the Enuma Elish (VI.17–18) Marduk assembles the divine council and gives it its orders, yet his supremacy was not unqualified: destiny itself was determined by seven other gods (VI.81). This is a persuasive argument which gives us further insights into the motives behind divination. Not only was the city or temple assembly obliged to ascertain its divine counterpart's views before it could reach satisfactory solutions to the many mundane problems it had to consider, of drainage and irrigation or disputes over field boundaries, but it seems that decisions were reached by consensus. We can imagine situations in which extispicy or the casting of lots might have been the only way to break an impasse. Oppenheim (1977: 208) supports Jacobsen's view that divination emerged as a possible solution to the difficulties involved in political decision making, pointing out that it might have social functions. He drew attention to the casting of lots to determine the division of an estate amongst the sons. We may discern a process by which scientific thought imitated political behaviour.

The second development was the emergence of sacred kingship, an institution which took on different forms in each culture, whether in Egypt or Mesopotamia (Engnell 1943; Frankfort 1948). In Mesopotamia the monarch was but a human servant of the gods whereas the Egyptian pharaoh was himself divine. Babylon was built as the gods' sanctuary on earth and the city's heart was the Esagila, Marduk's temple and the residence of Ea and Enlil. The physical hierarchy of earth and heaven was therefore reflected in a political order in which the king was subordinate to the divine council, headed by Enlil, or to Marduk.

Thus the king's greatest attribute, perhaps even more than military prowess, was the wisdom necessary to navigate his way through a world of omens, dreams and oracles, to understand and heed the advice of the astrologers and to perform the correct action at the appropriate moment. Kingship was a sacred office (Engnell 1943) and divination was no mere optional accessory; it was a central part of the political machinery.

Others have proposed purely religious reasons. Leo Oppenheim has argued that third millennium BCE Sumerian religion was underpinned by an earlier near-Eastern formulation which reveals the existence of 'an age-old pre-deistic deterministic concept of life' (1964: 203–204), and which was conducive to astrology's development. This proposition is supported by the astrologers' letters from the Assyrian period, in which there are frequent references to auspicious times to undertake rituals. The Mesopotamians' purpose was to describe the world. Having done that divination allowed them to participate in its management through divination and, increasingly, astrology.

The Development of Astrology

The earliest examples of astrological practices have been traced to the third millennium, but the arguments are currently widely challenged. In 1939 Jacobsen found evidence of the use of an eclipse in 2403 BCE (1939: 203–204), but his account relies too heavily on the reconstruction of missing words in broken tablets. There are a number of examples of astrological omens dated to the reigns of Sargon of Akkad (ca. 2334–2279 BCE), and Ibi-Sin (ca. 2028–2024 BCE) and Shulgi (ca. 2094–2047 BCE) of Ur (Weidner 1928–1929: 231, 236; Walker 1982: 22). Although some scholars, such as David Pingree (1998: 125) regard these tablets as genuinely Sumerian, there is some scepticism about their precise origin, and it is thought that they may represent later accounts written as if they were omens from earlier times (Rochberg-Halton 1988b: 7, n 32, Koch-Westonholtz 1995: 35). This is a fairly standard practice in prophetic literature, occurring notably, and almost two millennia later in the Book of Daniel, which was written perhaps 300 years after the time in which it is supposedly set. A similar practice is found in extispicy, and there are references to liver omens relating to rebellion against Ibi-Sin apparently written 50 years after the event (Bottéro 1987: 131). There is also the problem that some of the eclipses mentioned could not have occurred as claimed (Koch-Westonholtz 1995: 35).

We do know, however, that the Sumerians watched the sky, naming some of the constellations and planets, and that these played a role in their religion. For example, the goddess Nisaba, who may have been an antecedent of the god Nabu, who himself was associated with Mercury, was said to measure heaven and earth, to know the secrets of calculation and, together with Suen, the lunar deity, to 'count the days'. Her temple in the city of Eresh was called the *e-mul-mul*, the 'House of Stars', and she was the owner of a lapis lazuli tablet which is known variously as the *dub mul-an* or *dub mul-an-ku*, 'the tablet with the stars of the heavens' or 'the tablet with the stars of the pure heavens'. Her associated functions as goddess of grain and as the expert on accounting and the fair management of resources hint at both the practical uses of astronomy and the benefits of a well-regulated calendar in maintaining social order.

A sophisticated astrology had developed by the reign of the Babylonian emperor Ammisaduqa, Hammurabi's great–great grandson, from the survival of the so-called Venus Tablet (Reiner and Pingree 1975; Van der Waerden 1974: II, 50–58). The tablet contains 59 omens based on the first and last visibilities of Venus, each of which will occur twice in one of the planet's 584-day synodic cycles. The omens are grouped into 8-year cycles and have attracted attention partly on account of their use in the dating of Ammisaduqa's reign and hence the chronology of the old Babylonian Empire. Nothing could illustrate better the source problems afflicting Mesopotamian studies, at least before the first millennium: even when we have historical chronicles and astronomical records, it is still impossible to agree on a definitive date. The tablet tells us that by the middle of the second millennium BCE consistent astronomical observations were being made for the express purpose of producing astrological omens, anticipating divine intentions, predicting the weather (and hence agricultural productivity) and preparing for possible political crises. The first omen, which is typical in the information it gives, set the tone:

> In month XI, 15th day, Venus in the west disappeared, 3 days in the sky it stayed away, and in month XI, 18th day, Venus in the east became visible: springs will open, Adad his rain, Ea his floods will bring, king to king messages of reconciliation will send (Pingree and Reiner 1975: 29).

This observation was made in late winter, following the Full Moon (the 15th) in the 11 month. The 3-day period represents the shortest possible time that Venus might be invisible, following its last appearance in the west as morning star and its reappearance in the east as evening star. The omen reveals information about Babylonian astronomy, astrology and politics. Regarding astronomy, it was understood that Venus as morning and evening star was the same body. Second, although their records were based on continual observation, not on extrapolation into the future, it is clear that they did recognise the concept of planetary periods (Pingree 1998: 126) and hence that they either could not or did not feel the need to calculate future planetary positions. Moreover, given that the purpose of the omens was to correlate astronomical patterns with terrestrial events, the tablets have a historical function. The Venus Tablet provides a deeply practical rationale for astrology's apparent popularity: used exclusively by the kings it provided the government with 'the hope of stealing a march on fate and forestalling catastrophe by a timely recognition of divine intentions' (Frankfort 1978: 255).

There are a number of other astrological tablets from the Old Babylonian period, including some eclipse omens, but following the Venus Tablet, the two most substantial sources are Enuma Anu Enlil ('when the gods Anu and Enlil…'), a comprehensive compendium of astrological lore which includes material dating back to the Venus Tablet, and Mul Apin, the first great star catalogue, both of which are known from Assyrian tablets of the early first millennium BCE. However, there are suggestions that both may have been compiled in the second millennium, a far from controversial idea in view of the Enuma Anu Enlil's inclusion of the Venus Tablet. Thus while the first three centuries of the first millennium offer us virtually no sources whatsoever, suggesting that either astrology and astronomy were ignored, or that the records were destroyed or, if they survived, have yet to be discovered, there is circumstantial evidence of intense astrological and astronomical activity over the same period.

The full text of Enuma Anu Enlil was excavated in the ruins of Ashurbanipal's library at the Assyrian capital, Nineveh. It consisted of around 6,500–7,000 omina, grouped into some 70 tablets, of which 13 are now available in translation or transliteration (Reiner and Pingree 1975, 1981; Rochberg-Halton 1988b; Van Soldt 1955; see also Baigent 1994: 67–75; Koch-Westonholtz 1995: 74–82). An indication of the prevailing astronomical priorities is revealed in a breakdown of the topics covered. Twenty-two tablets cover the moon, while a further 18 concern the sun. Of the remainder, five relate to Venus, perhaps four to Mars, two to Jupiter three to thunder and lightning and only one to the Pleiades. The absence of specialised tablets for Mercury and Saturn indicates the lack of attention paid to the planets as opposed to solar and lunar phenomena. The small proportion of material of attention paid to Jupiter is most mysterious in view of the fact that Marduk, the planet's god, was Babylon's presiding deity.

Mul Apin is usually described as an astronomical compendium but clearly served an astrological function (Hunger and Pingree 1989). The extant tablets date from the eighth century, although may either have been compiled by 1000 BCE or be based on observations as far as back as 1350 BCE. The date of its compilation, though, is less important than the fact that, with Enuma Anu Enlil, it indicates that the scholars of the Assyrian Empire were deeply concerned with the mapping and naming of the heavens. This may be why they began to keep comprehensive records of lunar eclipses, beginning on 6 February 747 BCE, in the reign of Nabonassar.

The dramatic reassertion of Assyrian power under Tiglath-Pileser III (745–728 BCE) marks astrology's reappearance on the public stage. The evidence for this lies in the remarkable increase in extant astrological texts, but the reasons are far from clear. Sargon II (721–705 BCE) was perhaps the first of the new line of Assyrian monarchs to take an astrologer on his military campaigns, and an inscription from a tablet in the Louvre recording his attack on Musasir suggests that the timing of his invasion may have been arranged by reference to astronomical factors (Koch-Westonholz 1995: 153).

Astrology was essentially a means of communication, similar to prayer in that it was conducted with an invisible partner, yet in that it utilised the technology of planetary observation and measurement, its function might be comparable to that of modern information technology. Certainly its perceived advantages were similar, and the observation of Jupiter's movements prior to Sargon's campaign offered intelligence of a similar character to that provided by modern satellites in preparing for military action. Modern technology reveals the disposition of enemy forces, while the location of the stars also indicated the strength of Sargon's opponents.

Sargon's lessons were not lost on his successors, Sennacherib (704–681), Esarhaddon (680–669) and Ashurbanipal (668–627). These kings maintained astrologers across the empire who effectively formed a political class, sending reports and letters to the emperor, offering the best possible advice on the basis of their observations (Oppenheim 1969). These paint a portrait of a society in which the scribes maintained their personal relationships with each other and with the king, offering sometimes contradictory advice on astronomical observations and astrological predictions, finding excuses for their mistakes and claiming due credit for their successes (Baigent 1994: 50–57).

The astrologers' communications reveal an astronomy which was still based on daily records, with the result that no stellar observations could be made nor omens taken in inclement weather – except for meteorological ones. It was precisely those elements in astronomy which were unpredictable which preoccupied the Babylonians for, if the cycles of the sun, the moon and the seasons represented the endlessly repeating rhythms of fate, rich variety in natural and celestial phenomena offered a chance to negotiate with fate by opening a dialogue with the gods. Thus astronomy was directed to goals which were theological and political, rather than scientific in the modern sense of examining celestial phenomena for its own sake.

Great emphasis was placed on other meteorologically induced phenomena, such as the presence of haloes around stars and planets, as well as their colour or brightness, all of which were unpredictable. Neither was astrology absolutely distinct from other forms of divination, as Sargon II's inscription makes clear. The sun's main role was as representative of the oracle god, Shamash.

Having made their observations, the astrologers' first task was to communicate their findings to the king and offer whatever advice they felt necessary. This might be no more than to stay in the palace (SAA: 320). The king was also required to pray, offer sacrifices and perform rituals, each of which might have its own auspicious time. When there was no other solution to a threatening omen, a substitute king was appointed (Bottéro 1992: 138–155). A letter from the astrologer Mar Istar suggested that a substitute be allowed to sit on the throne for 100 days before meeting his fate, a euphemism for death (LAS: 292).

The astrological reports are couched in more formal terms than the letters, and tend to concentrate on prediction rather than advice. The information they contain makes no explicit distinction between planets, stars, and other celestial matters: 'If the Pleiades enter the moon and come out to the north: Akkad will become happy; the king of Akkad will become strong and have no rival' (SAA: 443), 'If Adad (the storm god) thunders in Tishri (month 7); there will be hostility in the land' (SAA: 444) and 'If Jupiter passes to the right of Venus: a strong one will conquer the land of the Guti in battle' (SAA: 448).

Political demands heightened the need for accuracy of forecasting and observation and resulted in a renewed attempt to perfect astrology's predictive powers. A further innovation was taken in the mid-seventh century with the production of the so-called Astronomical Diaries, compiled almost continuously for over 600 years from 652–647 BCE (Sachs and Hunger 1998–1999). The diaries are records of astronomical, meteorological and political events, presumably as a means of establishing common patterns. They represent a fresh determination in the ongoing attempt to create an empirically based astrology, in which both planetary phenomena and their relationship to political and economic matters might be properly understood.

It might be that the success of the Assyrian regime encouraged the Diaries' compilation. It may equally be the case that the Empire's collapse in 626 BCE concentrated the astrologers' minds on the maintenance of stability and the need to perfect astrology's ability to predict and avert political crises. The relationship between intellectual endeavour and political change is a complex one. The bulk of extant astrological reports cease about 30 years before the fall of Assyria and, while there might be later examples, we lack the ability to date them with any certainty. It is argued that the evidence for a change in astrology coinciding with the collapse of the Assyrian empire lie in the Chronicles, not the Reports to the kings (Berger 1999). It is, though, the results of this work, not its motives, which proved most important. The period from the eighth to fifth centuries witnessed a scientific revolution, first the creation of mathematical models for the calculation of planetary positions in advance, and secondly the development of horoscopic astrology – planetary omens based on the date of birth – and the invention of astrological techniques which did not require direct observation.

That a cultural revolution occurred under the Assyrian Neo-Babylonian and Persian monarchies is not questioned. But what is not fully understood is its nature, partly because it involved dramatic changes in both astronomy and astrology, paralleled by profound religious developments.

The Ritual Calendar

Astronomy possessed one great function, the improvement and eventual perfection of astrology's role in managing the state. An essential component of political management was the regulation of the calendar. Tablet VI of the Enuma Elish describes how Marduk ordered the Moon to mark out its synodic period, with a hint (the tablets are broken) that its crucial phases signified the moments when he communicated destiny to the watching astrologers, and that these were thus important moments for divination.

Each month began with the rising of the crescent moon; the new moon's first appearance after the spring equinox marked the beginning of the first month, Nisan. The problem, though, was the need to keep the lunar months in some sort of relationship with the solar year, and this necessitated the insertion of intercalary months. The 'Diviners Manual', dating from the early first millennium (Oppenheim 1974) gave the rules for intercalation, although the sheer variety of calendars used in the third millennium and the fact that in the Old Babylonian period 2 or 3 years in a row might contain intercalary months, suggests that there was no single set of recognised systems. It must be possible that divination (perhaps including extispicy) played as much a role on the selection of years for intercalation as did astronomy, and the purpose may have been to shift the average beginning of the year. In addition, kings in the Old Babylonian period often added intercalary months at the beginning of their reigns.

The fear that astronomical phenomena might occur on the wrong day is demonstrated vividly in the astrological reports. The Assyrian astrologer Balasœ advised the king that if the new moon occurs in the first or the full moon is seen on the 14th, then 'the land will become happy', but if the full moon took place on the 12th then 'business will diminish…a strong enemy will oppress the land' and, even though 'the king of Akkad (i.e. Assyria) will bring about the downfall of his enemy', the prognosis is 'bad for Akkad…good for Elam and the Westland (Amurru)', in other words, favourable for Babylon's hostile neighbours (SAA: 87–89).

We also have examples of Marduk's own planet, Jupiter, breaching its order by remaining visible for 5 days longer than expected. The astrologer Mar-Ishtar reported that it appeared on the sixth Simanu (month 3), close to Orion and in the way of Anu, and each of these three factors carried its own warning in the Enuma Anu Enlil. However, the planet then remained visible for another 4 days, an omen so bad that no ritual could appease divine wrath, and all communication with heaven was broken off.

The Planets

Even though the Mesopotamians identified dozens of different deities, and acknowledged the existence of hundreds of others who were not even given names, one god was not necessarily entirely separate to another. Thus, Enlil, the originator of earthly kingship, played a role which tended to merge with that of Marduk, the supreme king, who was himself venerated as the 'Enlil of the gods' (Parpola 1997: LXXIV) or described in terms usually reserved for solar deities.

There is evidence that the planets themselves have been seen as gods (Koch-Westonholtz 1995: 120–121), but the consensus amongst Assyriologists is generally that the planets were not themselves divine, but were manipulated by the gods. Ninurta was normally the god associated with Saturn, but in the Mul Apin (II.i,5) we read about ‘Mercury whose name is Ninurta’. This blurring of identities is of considerable significance for astrology, in which the relationship between gods and planets was similarly flexible.

The astrology of the Enuma Anu Enlil and the Mul Apin tends to make little distinction in terms of astrological significance between the planets and the brightest stars, such as Sirius, or the most prominent constellations, such as Orion or Ursa Major. However, the planets were obviously distinguished by their erratic movements, and were known in Sumerian as the *udu.idim.mes*, or wild sheep (Akkadian *bibbu*). Time and space were as interdependent in the Babylonian cosmos and the crucial considerations in a planetary observation were its position, which indicated the terrestrial region at which the omen was directed and the nature of the predicted event (e.g. being in Scorpio could mean an attack by Scorpions), and time (either of night or month), which might indicate the location of the event. In addition there was the question of whether the phenomena was on time (favourable), early or late (unfavourable).

Attention was paid to a planet’s colour and brightness and careful observations were made of acronycal rising (the last visible rising in the evening after sunset), heliacal rising (first visible appearance on the eastern horizon before sunrise) and heliacal setting (the last visible setting after sunset). The birth charts began to include lunar and planetary latitude as well as zodiacal position.

In the Mul Apin (II.i,1–6) the sun and the five planets are classed as the six gods who travel in the path of the moon. Each planet possessed a range of associations with deities, colours, times of year and with each other. They indicate the presence in Babylonian astrology of one of the central features of classical and medieval astrology, a web of relationships between planets and zodiac signs without which it would often have been impossible to reach a firm conclusion or offer definite advice.

The Sun

The Sun was known in Sumerian as Utu, in Akkadian as Shamash, its *bit nisirtu* (treasure) was the Hired Man (Aries) and in the Mul Apin its corresponding calendric event was the spring equinox. Utu and Shamash are also the names of the solar deities but the two words could mean either the visible body or the hidden power within it, i.e. the god. Shamshu was also used for the solar body.

Nineteen of the tablets in the Enuma Anu Enlil were devoted wholly or partially to the sun, mainly to its rising or eclipses, but its invisibility at night imposed a clear restriction on its astrological use, for however many omens were devoted to its colour or relationship with clouds, as soon as it appeared the stars vanished. However, as a god of justice Shamash became the god to whom oracles were addressed, presiding over the art and science of divination from entrails.

The Moon

The oldest of the Sumerian celestial divinities was the moon god, Nanna or Suen, a name later contracted to Sin, by which the moon is generally known in the cuneiform texts. Nanna may refer specifically to the full moon and Suen to the crescent moon, while there also appears to be a third name, Asim-babbar, the new light. Nanna was the presiding god of third dynasty Ur, and when the moon was invisible Nanna was believed to have gone to the netherworld to judge the dead, along with Utu, and special offerings were made. Fourteen tablets in the Enuma Anu Enlil were devoted to the moon’s appearance and a further eight to lunar eclipses, which were thought to represent a demonic attack on Nanna. Nanna travelled the heavens in a boat and had associations with bulls and cowherds. His *bit nisirtu* was Mul Mul, ‘the Stars’, or Pleiades. Aside from the Enuma Anu Enlil, about half of the astrological reports deal with lunar phenomena. The reasons are obvious, for the moon is the second brightest celestial object after the sun, it possesses the fastest and most dramatic cycle, moving rapidly from one phase to another and, unlike the sun, can be tracked at night and hence form relationships with the stars, visibly passing through constellations.

Saturn

The planet Saturn is sometimes referred to as Ninurta in the texts, but also as *udu.idim.sag.us* (Akkadian *kajamanu*) meaning ‘the steady’ or ‘the stable planet’. Saturn has no single tablet dedicated to it in the Enuma Anu Enlil and only 25 mentions in the reports published by Hunger, in spite of the fact that Ninurta was the son of Enlil and god of the thunderstorm, the spring flood and the plough. Indeed the name may mean ‘Lord Plough’. The god had an earlier form as Imdugud (the hailstone), and was also commonly known as Ningirsu (perhaps indicating the flood waters). He also had a military role as the ‘thunder’ of the war chariot. The planet was also known as Mul Utu, the star of the Sun, a connection which may derive from a shared concern with justice and may be evident in the fact that Saturn's *bit nisirti* is in Zibanitu (Libra), opposite the Sun's in Aries.

Jupiter

We might have imagined that Jupiter, as the planet sacred to Marduk, would have more omens devoted to it than any other planet, and the fact that it does not tells us that astrology was not simply a direct projection of theology on to the stars. It was not thought necessary to devote a large number of omens to the chief god, who merited less attention in the literature than the moon or Venus. The planet Jupiter was given various names. It was known as *sagmegar* ('the bearer of signs to the inhabited world') when it was in the eastern sky, *sulpaea*, ('lord of the bright rising') at its heliacal rising, *nebiru* ('crossing') when culminating at the meridian, *muludaltar* ('the heroic one'), *mul.babbar*, ('the white star'), *Bel* ('lord') or just simply Marduk. Jupiter might signify the moon in what might have been an imitation of Saturn's relationship with the Sun, and although its proximity to the moon was in general a bad omen, its presence during a lunar eclipse cancelled the evil omen. Together with Shamash, Jupiter was 'Lord of the secrets of Akkad', and its brightness was therefore good for the king and the state. It was associated with the summer solstice in the Mul Apin and its *bit nisirti* was the Crab.

Mars

Mars invariably sent evil omens, being associated with Nergal, a god of the underworld, forest fires, fever, plague and war. When the planet was not known directly as Nergal, it was called *sanumma* (different, i.e. hostile), *nakru* (enemy), *sarru* (liar), *lemnu* (evil), *ahu* (strange) or *sa* (red). In the Mul Apin it is referred to as Salbatanu, a name which may mean 'the incalculable star' or 'constantly portending pestilence'. Mars' malefic tendencies were heightened when it was bright, diminished when it was faint, and when it was at its reddest it might signify prosperity but also an epidemic of plague. Its *bit nisirti* was the Goat-Fish and in the Mul Apin it was linked to the winter solstice.

Venus

The planet was the subject of one of the first extant body of omens, and its goddess, the Sumerian Inanna (Akkadian Ishtar) was the most important single female deity, on a par with Sin and Shamash, with whom she forms a trinity, and even with Ea and Enlil. Her worship extended throughout the near East, and in Syria she was known as Astarte (Heimpel 1982). In the texts the planet is usually known as *dil-bat* or *dele-bat*, 'the brightest star', or Ishtar. Although Venus was invariably female there was a Semitic male version of Ishtar, and sometimes the morning star was considered to be male (and malefic). In other traditions it was the evening star that was male. However, this bisexuality does not appear in the extant omen literature and Venus' mere appearance was often considered to be benefic. Venus' *bit nisirti* was Anunitu (Pisces), and the planet was seen as the precursor of spring.

Mercury

Mercury was known as *gu.ud* (Akkadian *sihtu*), 'the jumping one', and in the Mul Apin is consistently linked with Ninurta, the god normally connected with Saturn. Mercury is more usually identified as the planet of Nabu, the son of Mercury, and is therefore connected to the crown prince. Thus, if Mercury approaches Regulus (*mul-lugal*, the 'king-star') this warns of an attempt by the heir to seize the throne (SAA: 245). While Mercury's appearance warned of rain and flood, Nabu himself was the scribe of the gods. In this role he wrote the destinies, announcing divine intentions to the diviners and astrologers, and thus joined Ea and Marduk as a god of wisdom. Mercury's *bit nisirti* was Ab.sin (Virgo) and in the Mul Apin the planet was regarded as the precursor of autumn.

The Development of Birth Charts

There is one notable development in the astrological literature which coincides with the collapse of the Assyrian empire, and that is the apparent termination of the series of astrological reports and letters to the kings. If this is true then one reason could be that the new astronomical accuracy destroyed astrology's theological premise – that the stars and planets could be manipulated at will by the gods and goddesses (Koch-Westonholtz 1995: 51–52; Berger 1999), even if weather phenomena remained unpredictable. Whatever the reason, out of this period emerged the form of divination which has since, more than any other, been associated with the term astrology – the prediction of destiny on the basis of planetary positions at birth.

According to Jacobsen (1976: 108), it was believed in the second millennium BCE that the 'time of the shaping of the child in its mother's womb is one during which it is susceptible to both good and bad influences and so is the moment of birth; an incautious word then may saddle the child with any manner of unpropitious fate'. Given that astrology relied on signs rather than influences, one would still have thought that the diviners present at birth would have been listening keenly to the gods' and goddesses' words expressed through the stars.

It may be that the birth chart was less an entirely new form of astrology than a variant form of divination, one created from the combination of the celestial omens of the Enuma Anu Enlil and the large corpus of birth omina (Rochberg-Halton 1989: 110). Such omens were normally taken from abnormal or 'monstrous' births, mainly of animals, can be dated back to the second millennium BCE, and were collected in the Summa Izbu (Leichty 1970; Jastrow 1914). Some birth omina might include references to the date of birth and probable destiny. There was also, within the near East, a tradition of birth rituals.

Whatever the case, it seems clear that the birth chart was an entirely Mesopotamian invention. There is actually some considerable confusion over the use of the term horoscope. Literally this is translated as 'watcher', 'observer' or 'marker of the hour', the term applied to the sign or degree of the zodiac ascending over the eastern horizon.

The development of birth charts placed fresh requirements on the astronomers, for while astrology had always been based on the observation of nocturnal messages from the gods, and had ignored phenomena which could not be seen, children had a habit of being born during daylight hours. Sachs (1952: 52) speculates that there may therefore have been a halfway stage in which prediction of individual destiny was based on various combinations of visible and invisible planets at birth.

We do know, though, that the earliest surviving birth chart was cast for a nameless child, apparently born on 29 April 410 BCE (Sachs 1952: 54–57). The text gives the date, the names of the child's father and grandfather, Shuma-usur and Shumma-iddina, the relevant astronomical details and just one surviving line of astrological interpretation which Sachs reconstructs as '(Things?) will(?) be good before you'. The rest of the tablet is missing apart from two lines which read 'Month Du'uz, year 12…[ye]ar(?) 8…', suggesting that forecasts for specific dates might have been included.

We can draw various conclusions from this chart, concerning both the history of astrology and the broader cultural context. It is instructive, for example, that Mercury was not given a zodiac sign position, for its proximity to the Sun rendered it invisible, suggesting that it was not taken into consideration. The positive tone of the astrological reading implies that the astrologer may have used the planetary 'rulerships' characteristic of Greek astrology, giving the reading a favourable gloss.

The development of the birth chart opened the door to the full development of Greek horoscopic astrology, the use of ascendants, the 12 houses (divisions of the diurnal circle), and the belief that accurate astrological investigation must be based on exact timing. The path was set for the development of the highly detailed technical procedures of Hellenistic astrology which have survived intact in Indian astrology, were adhered to strictly by medieval astrologers and still form the basis of modern western astrology. The first cuneiform birth chart was discovered in the late nineteenth century and published in 1888. When Sachs published his collection in 1952 there were just six cuneiform birth charts known. By 1989, the total had risen to just 32, including four birthnotes. This must represent a fraction of the charts cast in the Persian and Seleucid eras.

If astronomy's increasing accuracy had provoked a seventh century crisis in astrology, then it is clear that in the fifth century a close and symbiotic relationship had been restored (Van der Waerden 1974: 128). The new astronomy, which calculated planetary positions for decades ahead, may have been both motivated by the new developments in astrology, and made them possible. As to which came first, we cannot say. But new studies suggest that that the priests, the astronomers and the astrologers were usually the same people (Rochberg 1993; Parpola 1993), implying that the intimate relationship between theology, divination and science, was as strong as ever. Here we have a picture of theology encouraging the development of scientific astronomy, rather than inhibiting it.

The other main innovation was the development of the zodiac, the division of the ecliptic into 12 equal divisions. Our earliest evidence for the existence of the zodiac occurs on a lunar tablet dated to 475 BCE, and a tablet of 419 BCE gives the positions of planets in the signs, almost certainly as an aid to drawing up birth charts (Van der Waerden 1952–1953; Koch Westonholtz 1994: 174). The development of the zodiac required the production of another form of astronomical document, the Almanacs, which survive for the years between 262 BCE and 75 CE (Sachs 1948: 279–280; Rochberg 1993: 41).

Babylonian astrology can be described as practical theology, its express function being to enhance dialogue with the gods. Bartel van der Waerden set out a seductively neat scheme in which the development of first millennium BCE astronomy and astrology is related to a steady drift towards monotheism. He identified three main phases in which religion, astronomy and astrology progressed together from the simple observational astronomy, stellar polytheism and omen astrology of the beginning of the first millennium to the monotheistic religion, mathematical astronomy and natal astrology of its end (1974: II, 127–128, 178). This is a point of view challenged by many historians of religion, and as applied to Mesopotamia, the supposed connections between astronomy and religion are roundly rejected by some scholars. At the very least, van der Waerden's generalisations provide a worthwhile inter-disciplinary model for approaching developments in the history of astronomy.

There is one last point to make about the development of the birth chart, and that is that it represented a move away from an astrology which was structured by astronomical observation to one directed by worldly mundane concerns. That is, rather than waiting for a celestial omen to interpret, and having nothing to say if it did not appear, the astrologers were now obliged to construct omens for terrestrial events over which they had no control. Simple observation was no longer enough. The new astrology required that planetary positions should be plotted whether they were visible or not.

The Development of the Zodiac

The mathematical methods used by the Mesopotamian astronomers are well documented (van der Waerden 1974; Neugebauer 1975: II). The three principal priorities of second millennium astronomy were fairly straightforward: to record the rising and setting of stars and planets, and to quantify and calculate such phenomena as the length of lunar visibility in the beginning, middle and end of the month and the length of day through the year. It is the development of the zodiac, though, without which classical and medieval astrology would never have existed in any recognisable form, which is of most immediate interest for the history of astrology. Mesopotamian astronomy's enduring contribution to late astrology is undoubtedly the creation of the 12 signs of the zodiac, the equal-sized divisions of the ecliptic which are the most familiar feature of modern popular astrology. The first step to their formation was the creation of the constellations.

All theories concerning the reasons for the creation of constellations are essentially speculative. The creation of calendars for agricultural purposes, or the use of the heavens for navigation requires only the recognition of single bright stars, not the fabrication of unlikely images such as the Aquarian water-pourer. The creatures identified in the sky are, perhaps, more likely to be the consequence of mythical and religious projections and we may assume that the constellations' creation was initiated at whatever time human beings began observing the heavens, worshipping the stars, keeping a rough calendar, creating art, or all four. Gurshtein (1993, 1998) controversially gives a date of around 14000 BCE for the beginning of this process, and argues that the naming of important constellations was related to precession of the equinoxes and the sun's shift in relation to the stars. Owen Gingerich (1984: 219–220) lent his authority to the possibility that some of the constellations, notably the Great Bear may date from the last ice age. Rogers (1998) suggests that in the Mesopotamian period one set of constellations had religious origins, another agricultural applications.

Individual fixed stars offer a natural frame of reference for locating planetary position and it appears that by the Old Babylonian period, a system had been established which grouped stars according to the calendar. Three groups of 12 stars were arranged in three 'paths' (translated as 'bands' below) across the sky, related to the three creator gods, Anu, Ea and Enlil (Mul Apin: Gap A 1–7, Hunger and Pingree 1989: 88–89; Koch-Westonholtz 1995: 24–25).

The lists of the 36 stars which are divided between the three ways are preserved in three copies known to Assyriologists as 'astrolabes' but to the ancient scribes themselves as the 'three stars each' (Van der Waerden 1949). A system of 36 constellations, the so-called 'decans', which were supposed to rise at intervals of 10 days throughout the year, can also be found on coffin lids from the Egyptian Old Kingdom, from around 2100 BCE, and in the royal tombs of the New Kingdom, ca. 1500–1000 BCE (Neugebauer 1955b; Van der Waerden 1949: 7–8).

The evolution of the 36 stars was accompanied by a parallel development, the differentiation of the 18 constellations 'which stood in the path of the moon', the first known attempt to relate a sequence of constellations to a planet. The full list of these is given in the Mul Apin (I.iv, 33–39, Hunger and Pingree 1989: 68–69):

Mul.Mul The Stars (i.e. the Pleiades)
Mul GALENA The Bull of heaven (Taurus)
Mul SIPA.ZI.AN.NA The True Shepherd of Anu (Orion)
Mul SU.GI The Old Man (Perseus)
Mul GAM The Crook (Auriga)
Mul MAS.TAB.BAGAL.GAL The Great Twins (Gemini)
Mul AL.LUL The Crab (Cancer)
Mul UR.GU.LA The Lion (Leo)
Mul AB.SIN The Furrow (Virgo)
Mul Zi-ba-ni-tu The Scales (Libra)
Mul GIR.TAB The Scorpion (Scorpio)
Mul Pa-bil-sag The god Pabilsag (Sagittarius)
Mul SUHUR.MAS The Goat-Fish (Capricorn)
Mul GU-LA The Great One (Aquarius)
Mul KUN mes The Tails (Pisces)
Mul SIM.MAH The Swallow (SW Pisces)
Mul A-nu-ni-tu The goddess Anunitu Mul HUN-GA The Hired Man (Aries)

This list seems to be a clear attempt to formulate a lunar zodiac based on visible constellations. However, it clearly represents a stage towards the formulation of a solar zodiac and most of the future zodiac signs are identified.

The process by which the establishment of a constellational lunar zodiac and the attribution of astrological meaning to stars or groups of stars led to the creation of the 12-sign zodiac is not clear. Clearly planetary meanings depended partly on their position in relation to the stars, and the Enuma Anu Enlil contains omens such as 'If Mars approaches the Scorpion: there will be a breach in the palace of the prince' (50.111.8a, Reiner and Pingree 1981: 41). However, we cannot be sure whether the crucial factor here was Mars' position in the sky, or whether the constellation Scorpio was thought to contain meaning. The astrological letters and reports contain similar observations, referring to stars as well as constellations, suggesting that in the eighth century there was still no neat and all-encompassing division of the sky into distinct regions.

Van der Waerden speculates that the formulation of 12 signs of 30° each was a projection on to the sky of the 12 months and 360 days of the year. In the Enuma Elish (II, 27–32) Tiamat creates 11 creatures to fight with her, including a few who share identities with constellations, including 'the great lion, the mad dog, and the Scorpion-man'.

The equal-sized signs of the Mesopotamian zodiac were defined by relation to the stars, and lunar tables in the fourth to second centuries BCE indicate that the vernal equinox took place at 8° or 10° Aries, as measured from the vernal point. The zodiac signs evolved as a system of measurement, but were also assigned astrological meanings. Indeed they have been described as 'mighty powers' (Van der Waerden 1952–1953: 224). An additional advantage, though, was to be the ability to tabulate planetary positions in terms of zodiac degrees. The 12 signs did not replace the three ways or constellations, but could be used alongside them. Thus a tablet of 164 BCE records that Halley's comet had been 'seen in the east in the path of Anu in the area of Pleiades and Taurus, to the west… and passed along in the path of Ea' (Stephenson and Walker 1985: 24).

The attention paid to the variable timing of new and full moons gives us an insight into the mind of the Assyrian astronomers. They obviously knew that there was an inevitability about both the moon's synodic cycle, for without it they would not have had the month, and the sun's annual rhythm, for without that there would have been no years. Yet they clearly believed that it was possible for the gods to manipulate the moon's synodic period within certain limits. This might suggest that there was an awareness that the universe operated within mathematical limits, and that the gods and goddesses themselves were subject to the same destinies as was humanity.

A study of planetary measurements in horoscopes (Rochberg 1998) suggests the possibility of continuing theological motivation, for planetary synodic periods were recorded only when the planet occupied the same sign as the Sun. To be sure, this might have been because such information told the astrologer whether the planet was visible or not, but there might also be a trace here of the Sun's growing religious significance. However, even if religious considerations did remain high, increasing levels of observational accuracy were required to provide for astrology's increasing demands in the Persian period, such as the dedekatemoria (see below), divisions of the zodiac signs by 12.

Mesopotamian Cosmology: The Cosmic State

In what sense was Babylonian astrology scientific? There is a clear argument that it was not, given that it did not fulfil one of the criteria of modern science, namely verification of predictions through large samples in controlled conditions. The astrologers' success was measured in terms of one-off forecasts, a satisfactory means of measuring success at the time, if not to modern scientists. When the astrologers were wrong it was seen as a result of human error, not a sign of the fallibility of the essential hypothesis that the stars were conveying messages from the gods. The statement that divination equals science may seem a strange one by modern standards, but not if the definition focuses on the logical procedures of prediction and ignores the surrounding belief system.

The fundamental process involved in all divination was one of circumstantial association. In other words, if event y correlates with sign x, then when x next appears, y will happen. If we again remove the gods from the equation then there is no direct link between x and y. That is, the 'signs indicated events in a variety of ways, mostly by means of schematic symmetries, associations and analogy. The relationship between the sign (*ittu*) and its prediction (*parassu*) had no component of causation, nor necessity of any particular temporal relation, be it synchronistic or sequential' (Rochberg-Halton 1998: 52). Although the gods caused both the omen and the succeeding event, there was no cause and effect relationship between the two. Thus if Babylonian astrology was scientific it was because it relied on a deductive methodology and logical inferences made on the basis of empirical observation, and emphatically not because it posited a set of physical relationships between stars and society.

Larsen argues that if the development of modern science has seen the replacing of 'imaginary representations of "intentional" causes by the representation of unintentional and inevitable relationships' (1987: 208), then by removing the intentions of the gods from the equation, we are left with the inevitable relationship between present omen and future event, between astronomical observation and political action. A relationship which is inevitable rather than intentional, so this argument runs, is scientific.

Babylonian astrology's scientific qualities are also said to be evident in its foundation in empirical observation, its mathematical rigour and the value-free objective procedures which meant that there was no bias in the forecasts, which might imply criticism of the king's conduct as much as praise. Just as scientific method can be seen as a mode of enquiry so astrology might be seen as language, yet one with a code which was written into the fabric of the universe. To this end the Babylonians compiled list of lexigraphical correspondences between stars, gods, mundane objects, terrestrial events and geographical regions which are themselves identified as characteristic of astrology's scientific nature (Larsen 1987).

Christopher Walker concluded his 1982 lecture on 'Episodes on the History of Babylonian Astronomy' in Toronto with a wry comment on the contemporary world: 'That brings Babylonian astrology home to anybody who reads the popular newspapers nowadays' he said, 'and sadly for the historians of science one has to remark that to the Babylonians this represents the goal of their previous researches' (1982: 26). As we prepare for manned flights to Mars and as the Hubble Space Telescope peers into the origins of the universe, tens of millions of people in the western world turn every day for advice or entertainment to the sort of simple omens given to the Old Babylonian monarchs 4,000 years ago. A folkloric approach to the study of contemporary astrology, of the type developed by James Frazer at the turn of the century, would see it as a fossil survival of Babylonian cosmology, retaining the outer forms but not the inner meaning.

Astrology in China

Ho Peng Yoke

In traditional China there was no distinction between astronomy and astrology. The common word *tianwen* covered both. There was also no distinction between astronomy and astrology in Europe before the end of the seventeenth century. According to the *Oxford English Dictionary*, there were two kinds of astrology (a) natural astrology, which involved the calculation and foretelling of natural phenomena, as the measurement of time, fixing of Easter, predictions of tides and eclipses, and also of meteorological phenomena and (b) judicial astrology, which was the art of judging the reputed occult and nonphysical influences of the stars and planets on human affairs, also known as star divination or astromancy. Since the end of the seventeenth century the term natural astrology was replaced by astronomy and meteorology, while judicial astrology became the astrology commonly known today.

Traditional Chinese astrology included the two elements of natural and occult science. The latter provided the motivating force that enabled Chinese astronomers to produce comprehensive and continuous observational records for almost two thousand years. These records are of interest to modern astronomers, but they were never made with such an intention. They were meant primarily to enable the emperor to have foreknowledge of future events concerning himself, his imperial household, his senior officials, his empire, his subjects, and foreign countries. Astronomical observations also played a part in the calculation of calendars that gave auspicious and ominous times and dates for various kinds of events in daily life, ranging from wedding ceremonies to having a bath or a haircut. Traditional Chinese judicial astrology differs from its counterpart in Europe in that it was tailored exclusively to serve the emperor and not the individual. Officially this system is now obsolete among the Chinese, but unofficially there were some whispers linking the event of the demise of their Great Helmsman to the 1976 Tangshan earthquake. What is popularly known today as Chinese astrology is not the traditional official Chinese astrology referred to above. Official and popular astrology are two different entities.

Official astrology found its place in the "Astronomical Chapters" of the Chinese Dynastic Histories, beginning with the *Shiji* (Historical Memoirs) of Sima Qian (145–186 BCE). Based on the traditional Chinese belief in the close relationship between heaven (*tian*), earth (*di*), and man (*ren*), the emperor was regarded as the representative of heaven on earth – human actions on the part of the emperor and celestial phenomena had mutual effects. Chinese astrologers divided the whole sky visible to them, making the stars and asterisms correspond to geographical regions. Almost all of them corresponded to China and only a few smaller asterisms corresponded to neighboring countries.

The Polar Star, which was supposed to remain stationary, was regarded as the counterpart of the emperor in heaven. Perhaps because there was seldom any bright star near the North Pole, and the scope for making predictions would be much more limited when a star was far away from the ecliptic (the band of the zodiac through which the Sun apparently moves in its yearly course) beyond the reach of the planets, a number of other stars were also designated to represent the emperor. The asterisms in the circumpolar region, known as the *Ziweiyuan* (Purple Subtlety Enclosure), included those that represented the emperor, the empress, the imperial concubines, and the crown prince. There were stars representing his hierarchy of officials, including ministers and military commanders, and there were stars representing the utilities in the palace, for example the kitchen. The region was enclosed by two chains of stars, representing the walls of the Forbidden City. Many parts of the Forbidden City and the circumpolar region shared the same names. Outside the "walls" of the circumpolar region was the Plough (*Beidou*), an important asterism in both Chinese astrology and Daoism.

Next come the asterisms along the ecliptic. Two other special regions, the *Taiweiyuan* (Great Subtlety Enclosure) and the *Tianshiyuan* (Celestial Market Enclosure), were located there. The former again pertained to the emperor, his household, and his official hierarchy and the latter to the general state of economy in his empire. Distributed along the ecliptic were the 28 lunar mansions. They were used to make a wide range of predictions, from flood and drought in the empire to military activities among the border tribal people. The asterisms near the 28 lunar mansions were also significant. The astrologer could observe, for example, four stars in Pisces, called *Yumyu* (Cloud and Rain) to make a forecast for rain, thus performing the task of the modern meteorologist.

The Sun was the most important astrological object, because it represented the emperor. Solar eclipses and sunspots reflected blemishes on the part of the emperor.

Likewise lunar eclipses referred to the empress. The astrologer looked for the presence of planets, comets, and novae near a particular star or asterism to predict an event and where it would happen. The astrologer also noted changes in the color or brightness and scintillation due to atmospheric conditions. He also observed aurora borealis and clouds, noting their color and shape. These were particularly important in the battlefield for gaining advanced information on enemy movements and the outcome of the combat. The astronomical bureau also produced an astrological almanac using the art of *zheri* (calculations of auspicious and inauspicious days) to work out days and times that were auspicious or unlucky for certain events in private and social life, for example having a bath or a haircut, meeting a friend, doing a business transaction, moving house, and holding a wedding ceremony.

There were often occasions when the astrologer was required to give an answer to a specific event, for example when something was lost, when a candidate set out to take the civil examinations, when two armies were facing each other preparing for battle, and so on. There were three sophisticated techniques of divination which fell within the syllabus of candidates taking examinations in the astronomical bureau in the Song Dynasty, namely *taiyi* (Supreme Unity), *dunjia* (Concealing the *jias*), and *liuren* (Six *rens*). These three methods did not restrict themselves to the imperial family and the official hierarchy.

Naturally the common people also wished to have foreknowledge of their individual fate and destiny. The Chinese developed many systems for this purpose, but none of them relied on direct astronomical observation. In the strict sense of the word they hardly qualify to be called astrology. However they generally employed the results of astronomical observations and calculations by using some or all the elements of year, month, day, and time. Furthermore, at least one of the systems contains traces of Greek and Hindu astrology. There are two systems of fate calculation in general circulation among the Chinese today, namely the *Ziping* method and the *Ziwei doushu* method. These two systems of fate calculation do not rely on direct observations of the stars and in the *Ziwei doushu* horoscopes are worked out without requiring the practitioner to know how to identify the stars that occur in the horoscope.

The history of fate calculation in China is rather obscure as this was not regarded as an orthodox branch of study, and experts writing on this subject often used imprecise language to put off the uninitiated. By the Han period (206 BCE–AD 220), Confucian scholars were talking about three types of human fate (*sanming*). One was endowed during birth and was the only element that could be calculated. One was under the influence of good or evil deeds, and one was governed by catastrophic events that would overrule the first two. It is interesting to draw comparisons with the Han scholars' contemporaries in Europe where the Romans were adopting Stoicism as their state philosophy, believing in the devotion to duty while leaving things to the inevitable. The Chinese had a different belief in life, by talking about three types of life rather than one. To the Chinese it was only the fated life that was predictable, but any predicted event was by no means inevitable. It might be changed according to one's deeds, or by what we nowadays describe as an "act of God". The Chinese system gave encouragement to lead a good life. In this respect it certainly sounded more attractive than Hellenistic astrology.

At first it seems that only the year of birth of the person concerned was taken into account. Even today some Chinese still speak about the "twelve animal cycle" of the years they were born. As time went by, first the month, then the day, and finally the hours (or rather double hour) of birth were gradually included to develop newer systems. The *Ziping* method is one of the most sophisticated systems of fate calculation. It is attributed to Xu Juyi, said to have lived during the latter half of the tenth century. He was the first to use the time of the day for fate calculation. Many books were also attributed to him, but we do not know exactly which were actually written by him. The most authoritative and comprehensive text that we have on the *Ziping* method is the *Sanming tonghui* (Confluence of the Three Fates) written by Wan Minying during the Ming period (1368–1644). Since then the system has frequently been revised to keep abreast with changes in social structure. This can be testified to by the large number of books written on this subject in China, Hong Kong, Japan, and Korea during the past few decades.

However, back in the third century Indian astrology had entered into China when the *Sārdulakarnāvadāna* was translated, introducing the names of the "Seven Luminaries" (Sun, Moon, and the five planets) and the *nakṣatras* (Moonstations). In the year 718 Gautama Siddhārtha translated the *Navagrāha* calendar and introduced the names of two imaginary heavenly bodies, *Rahu* and *Ketu*. Some time afterward a Nestorian named Adam translated a work called *Simenjing* (lit, Book on Four Departments). This book has long been lost, but it could have been a translation of Ptolemy's *Tetrabiblos,* according to recent Japanese authorities on the subject such as Kiyoshi Yabuuchi. Michio Yano has suggested that another book with the title *Duliyusijing* carried the name of Ptolemy in a corrupted form. Hellenistic astrology also went from Persia to China through Korea. Another important route taken by Hellenistic astrology was through India, where it was modified under the influence of Hindu astrology. Tantric monks played an important role in the introduction of this form of astrology to China. Amoghavajra (705–774) produced a book known under its abridged title *Xiuyaojing* (Book on the *Nakṣatras* and the Luminaries), in which the 12 signs of the zodiac appeared for the first time in China. Thus by the eighth century imported systems of astrology with Hellenistic and also often Hindu roots had become quite popular. A number of actual horoscopes cast during the Tang period are preserved in the *Qinding gujin tushu jicheng* (Imperial Encyclopedia), edited by Chen Menglei et al. in 1726.

Changes took place when new ideas came into the same melting pot with something that was originally in it. Traditional Chinese star names and astrological terms were adopted by the new imports. Gradually the latter became sinicized. One can hardly notice the Hellenistic and Hindu origin of the *Ziwei doushu system* by looking at its name alone. We do not know when exactly the term "*Ziwei*" was first used here. During the Tang period several names were used; among them was the term *Taiyi.* The "star" *Taiyi* played the same role as the "star" *Ziwei* in the modern system, and both have somewhat similar reference to the occupant of the most supreme position below or above. The term *Ziwei doushu* first appeared in the title of a book incorporated in the Daoist *Tripitaka*, the *Xu Daozang* in 1607. Similarly traditional fate calculation methods were at the same time influenced by imported cultures. The Ziping system for example employs a cycle of 12 phases, reminiscent of the 12 *Nidānas* in Buddhism.

Astrology in India

Vijaya Narayan Tripathi

In India, astrology, *Jyotiṣa*, is defined as *Jyotiṣam sūryādi grahāṇām bodhakamśāstram*, the system which explains the influences of the sun, moon, and planets.

Indian astrology came explicitly to light around 1200 BCE, when the monk Lagadha compiled the *Vedānga-Jyotiṣa* on the basis of *Vedas*, in which lunar and solar months are described, with their adjustment by *Adhimāsa* (lunar leap month). *Ṛtus* (seasons), years, and *yugas* (eras) are also described. Twenty-seven constellations, eclipses, seven planets, and twelve signs of the zodiac were also known at that time.

In the period from 500 BCE to the beginning of the Christian era some texts were written on the subject of astrology. Nineteen famous sages composed their *Siddhāntas* (texts). *Candra-prajnapti*, *Sūrya-prajnapti*, and *Jyotiṣakaraṇḍaka* were written. The *Sūryasiddhānta*, the ancient text of Indian astrology, was composed around 200 BCE.

In the first five centuries of the Christian era, there were some important contributions by Jain writers. *Angavijjā* is a large collection about *Śakuna* (omens). *Kālaka* and *Ṛṣiputra* also contributed around this time. At the end of the fifth century, Āryabhaṭa I mentioned in his text *Āryabhaṭīya* that the sun and stars are constant and that day and night are based on the movement of the earth.

The period AD 500–1000 was very productive. Lallācārya, the disciple of Āryabhaṭa, composed two texts – *Śiṣyadhīvṛdhi* and *Ratnakoṣa* – dealing with mathematical theories. The astrologer Varāhamihira composed several texts, and his son Pṛthuyaśā composed a brief horary called *Ṣat-Pañcāśikā*. Bhāskarācārya I wrote a commentary on the *Āryabhaṭīya* in the seventh century, and Brahmagupta composed the *Brāhmasphuṭasiddhānta* and the *Khaṇḍakhādyaka* around AD 635. Other scholars wrote commentaries on the texts of their predecessors and independent texts of their own.

In 1000–1500, there was a great deal of enhancement to the literature concerning the construction of astronomical instruments for observation. In the twelfth century, Bhāskara composed the famous text *Siddhāntaśiromaṇi*. The *Līlāvatī* of Rājāditya is another of the texts of that century. In the fifteenth century, Keśava wrote more than ten books, and his son Gaṇeśa composed the *Grahalāghava* at the age of 13.

Many more texts and commentaries were written from the sixteenth century onward. A few noteworthy ones are: *Tājikanīlakaṇṭhī* of Nīlakaṇṭha (sixteenth century), *Meghamahodaya* by Meghvijayagaṇi (seventeenth century), *Janmapatrīpaddhati* by Lābhacandragaṇi (eighteenth century), and the nineteenth century works of astrologer Bāpūdeva Śāstri.

A knowledge of *pañcānga* is a prerequisite to understanding the subject of astrology. This is the fivefold system of *tithi* (lunar day), *vāra* (weekday), *nakṣatra* (asterism), *yoga* (sum of the solar and lunar longitudes), and *karaṇa* (half lunar day). *Tithi*, the lunar date, is the duration of time in which the Moon moves 12°. The 15 *tithis* of the white fortnight (from new moon to full moon) are:

1. *Pratipadā*
2. *Dvitīyā*
3. *Tṛtīyā*
4. *Caturthī*
5. *Pañcamī*
6. *Ṣaṣṭhī*
7. *Saptamī*
8. *Aṣṭamī*
9. *Navamī*
10. *Daśamī*
11. *Ekādaśī*
12. *Dvādaśī*
13. *Trayodaśī*
14. *Caturdaśī*
15. *Purṇimā* (15 × 12° = 180°)

In the black fortnight (from full moon to new moon), the 15th day is called *Amāvasyā* and the remainder are the same as above. *Tithis* are classified into five groups: *Nandā* (*tithis* 1,6,11), *Bhadrā* (2,7,12), *Jayā* (3,8,13), *Riktā* (4,9,14), and *Pūrṇā* (5,10,15).

The seven *vāras* (weekdays) are based on the names on the *grahas*: Sun, Moon, Mars, Mercury, Jupiter, Venus, and Saturn.

Astrology in India. Table 1 Twenty-seven *nakṣatras* (asterisms)

Kṛttikā	*Rohiṇī*
Mṛgaśiras	*Ārdrā*
Punarvasu	*Puṣya*
Āśleṣā	*Maghā*
Pūrvāphālgunī	*Uttarāphālgunī*
Hasta	*Citrā*
Svātī	*Viśākhā*
Anurādhā	*Jyeṣṭhā*
Mūla	*Pūrvāṣāḍhā*
Uttarāṣāḍhā	*Śroṇā*
Śraviṣṭhā	*Śatabhiṣaj*
Pūrva-Bhādrapada	*Uttara-Bhādrapada*
Revatī	*Aśvinī*
Bharaṇī	

There are 27 *nakṣatras* (asterisms) bifurcating the ecliptic into 27 parts, each of 13.33°. These are mentioned in Table 1.

The ecliptic is again bifurcated into 12 parts through *Rāśis* (signs, each of 30°). The 12 signs are equal to 27 *nakṣatras*, or 1 sign = 2.25 constellations. For example, *Aśvīnī*, *Bharaṇī*, and one-quarter of *Kṛttikā* make the sign *Meṣa* (Aries). The remaining three quarters of *Kṛttikā, Rohiṇī*, and half of *Mṛgaśira* make the sign *Vṛṣa* (Taurus). The same pattern holds true for the other signs: *Mithuna* (Gemini), *Karka* (Cancer), *Singh* (Leo), *Kanyā* (Virgo), *Tulā* (Libra), *Vṛścika* (Scorpio), *Dhanu* (Sagittarius), *Makara* (Capricorn), *Kumbha* (Aquarius), and *Mīna* (Pisces). Thus 27 constellations represent 12 signs.

Yoga is the sum of the solar and lunar longitudes. If the sum of their degrees is between 0° and 13.33°, that is called *Viṣkambha Yoga* – from there until 26.66° it is *Prīti* – up to 40° it is *Āyuṣmāna*. The remaining yogas are *Saubhāgya, Śobhana, Atigaṇḍa, Sukarmā, Dhṛti, Śūla, Gaṇḍa, Vṛdhi, Dhruva, Vyāghāta, Harṣaṇa, Vajra, Siddhi, Vyatīpāta, Varīyāna, Parigha, Śiva, Siddha, Sādhya, Śubha, Śukla, Brahma, Aindra*, and *Vaidhṛti* (13.33° × 27 = 360°).

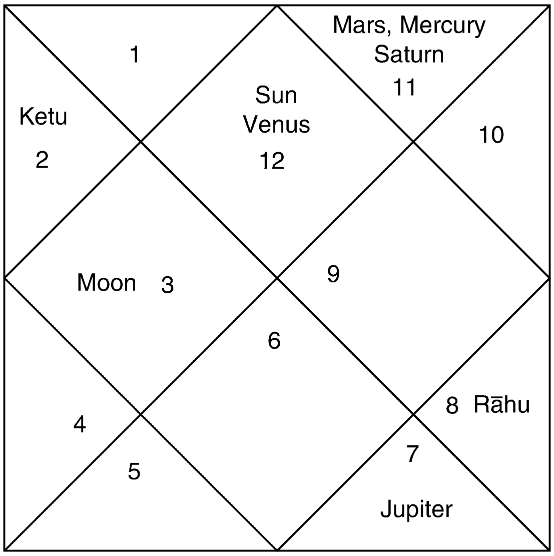
Karaṇa (constant or moveable) is the half part of the *tithi*. Constant *Karaṇa Śakuna* belongs to the second half of *Caturdaśī Catuṣpada* and *Nāga* to that of *Āmāvasyā* in the black fortnight, while *Kistughna* exists in the first half of the *Pratipada* of the white fortnight in every lunar month. The remaining 14.5 *tithis* of the white and 13.5 *tithis* of the black fortnight contain eight rounds of seven moveable *Karaṇas*: *Bava, Bālava, Kaulava, Taitila, Gara, Vaṇija*, and *Viṣṭi*.

The subject matter of astrology may be divided into five groups: *Saṃhitā, Siddhānta, Jātaka, Praśāna,* and *Śakuna*. In ancient India, *Saṃhitā* was the miscellaneous collection of astrological materials out of which the remaining four grew.

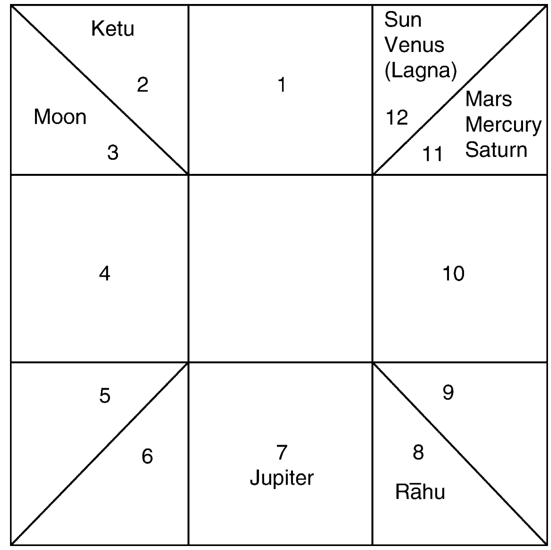
Siddhānta or *Gaṇita* refers to mathematical calculations about time, distance, and position of the planets. On the basis of the proper positions of 12 signs and nine planets, a chart containing 12 chambers may be sketched. In northern, southern, and eastern India, astrologers sketch Charts 1–3 which are called *Janmāṇga* or ascendant.

Astrology in India. Table 2 Positions of *grahas* (planets) on 21 March 1994 at 6:02 a.m. at Varanasi

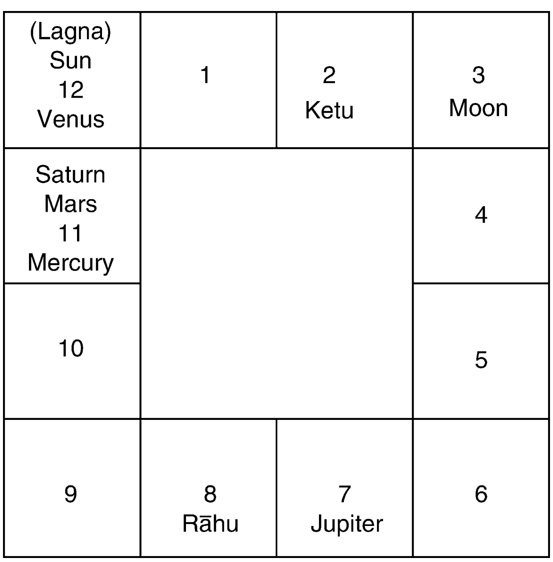
***Grahas* (planets)**	**Sun**	**Moon**	**Mars**	**Mercury**	**Jupiter**	**Venus**	**Saturn**	***Rāhu***	***Ketu***
Rāśi (sign)	11	2	10	10	6	11	10	7	1
Anśa (degree)	6	15	16	9	23	22	8	3	3
Kalā	21	7	57	51	19	13	21	3	3
Vikalā	27	45	18	17	40	8	21	44	44



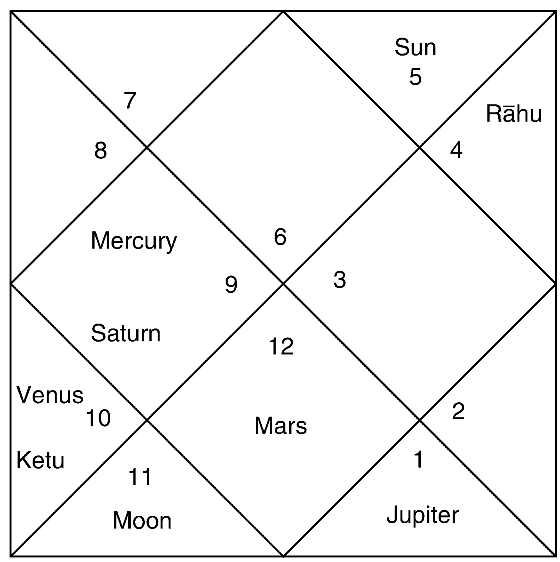
Astrology in India. Chart 1 Ascendant as sketched in northern India.



Astrology in India. Chart 3 Ascendant as sketched in eastern India (West Bengal and Orissa).



Astrology in India. Chart 2 Ascendant as sketched in southern India.



Astrology in India. Chart 4 Navamanśa chart.

Jātaka (native) is the person about whom a prediction is made on the basis of a birth chart. Twelve houses represent the health, wealth, brother/sister, mother, offspring, diseases/enemies, wife/husband, death, fate, father, income, and expenses, as in Chart 1. *Daśās* (periods) are defined in numerous ways. The period of any planet becomes favorable or harmful according to its position and power in the horoscope (Chart 4).

There are many other astrological methods in India. As an example, in the Kerala system, numbers are assigned to alphabets, and the astrologer advises the person to say the names of a flower, river, or god on which the calculation depends.

Astrology is applied to many aspects of Indian life. There are rules concerning times for traveling, planting, and building. Favorable times for the preparation of medicines and treatment are also prescribed.

Astrology in Islam

Richard Lemay

A few considerations about the historical development of the term and concept of astrology as an intellectual discipline are in order, so as to avoid the many misconceptions that prevail in this field of historical enquiry.

The first question concerns the terminology applicable in medieval Arabic culture. What we consider astrology in our epistemology has very little connection with its medieval definition. Horoscope-making and interpreting are of course part of the game but with a rather remote bearing on its definition as a science in medieval eyes. In the mind of medieval Arab writers there is but one science of the sky with the moving bodies set in it. It was called *ʿīlm an-nujūm* (science of the stars) and it consisted of two distinct treatments of the subject matter of the heavens: a purely mathematical one or *ʿīlm al-falak* corresponding to our astronomy, and a humanistic but rather conjectural one which aimed at deducing from the celestial motions their probable significance for the evolution of human affairs, more directly what we now call astrology. The name for this latter discipline was *ʿīlm aḥkām an-nujūm* (science of the judgments of the stars): hence the new term *scientia iudiciorum* or judicial astrology in medieval Latin culture. The two methods of treatment were indissolubly linked in the overall picture, and it must be further stressed that the dominating interest of medieval Arabic civilization was the "science of the judgments of the stars." On the practical level, the second portion of this dichotomy was considered an art, and the term *ṣanʿa* applied to it was the equivalent of any other trade or profession.

There were three levels through which Arab authors would approach the study of astrology: a first level through the general science of the stars which could be a predominantly philosophical enquiry bordering on what may be actually labeled cosmology. A second level, purely mathematical, consisted of the consideration of the movements of the spheres, of the celestial bodies they contained, and of phenomena affecting them. This approach corresponded more closely to our astronomy. A third level was in the extension of the above observations to judge their probable impact upon human affairs. The technique of these judgments (*aḥkām*) was determined according to very intricate rules embodied in the age-old lore of astrology proper: but the three levels were considered together to constitute the one science of the stars (*ʿilm an-nujūm*).

This tripartite structure of the science of the heavens among medieval Arab writers was not entirely their creation, for the historical event of early Arab conquests of the entire Middle East had put the young Arab civilization in direct contact with both the still active Hellenistic (Alexandrian) world of thought thriving in Egypt and in the Eastern Mediterranean on the one hand, and the very ancient Babylonian, Persian, and even Hindu cultural traditions on the other. In examining medieval Arabic astrology it is wise to keep in mind these major cultural orientations varying in importance according to the stages of those historical convergences. During the first century of Arab conquests, which corresponds roughly with the rule of the Umayyad Caliphate of Damascus (660–750), the predominant cultural influence came from Syria and Egypt, in which Hellenistic culture and further Christianized Hellenism dominated. Even so, the impact of Greek learning was not directly linked at first with classical Greek science or philosophy, but rather with its late Hellenistic phase heavily marked by neo-Platonic and Alexandrian speculation or mysticism (hermeticism). The full force of the Greek example of learning and of its formative impact on Arabic astrology emerged only under the Abbasid rule (beginning in 750), tentatively at first under al-Mansūr (754–775) and Harūn al-Rashīd (786–809), but dramatically under al-Maʾmūn (813–833) through the direct importation of the works of thinkers and of scientists such as Aristotle in physics and cosmology, and of Ptolemy in astronomy/astrology. Al-Maʾmūn established at Baghdad an astronomical observatory and *Bayt al-Ḥikma* (House of Wisdom) endowed with a great library. It was because of these favorable conditions that the science of astrology, like philosophy and medicine, took its definite hue in Arab literature under the label of *falsafa* (a transliteration of the Greek term philosophy). Maʾmūn's patronage brought scientists and philosophers from all over the Muslim empire. It was likely in the midst of this intellectual fervor that the greatest writer in Arab astrology, Abu Maʿshar, came from his native Balkh in Khurāsān (now Afghanistan) to settle in Baghdad. Although Abū Maʿshar's major work, the *Kitāb al-mudkhal al-kabīr* (Greater Introduction to Astronomy, AD 848) was completed during the generation following the death of al-Maʾmūn (AD 833), its success in molding the framework of Arab astrology that merged the diverse astrological traditions of Greece, Persia, and India must be ascribed to the lively interest in *falsafa* engendered by al-Maʾmūn's sponsorship. With Abū Maʿshar's work, Arab astrology acquired its definitive structure, the result of a syncretism of all Middle East traditions under the umbrella of Aristotelian cosmology and Ptolemaean astronomy/astrology.

Abū Maʿshar came to be quoted as the authority, even by those who criticized him (al-Bīrūnī, Ibn Ridwān). His *Kitāb al-mudkhal al-kabīr* became the "bible" of Arabic astrology because it buttressed the science with a theoretical foundation based on *falsafa*, with Persian and Hindu traditions more or less coherently merged into it. Yet it provided only the introductory theory of astrology as part of the science of Nature. Further extension of the science of judgments of the stars to the full range of human affairs was seen as a kind of adjustment to their inevitable cosmic framework. Arabic astrological science came to include these five principal divisions.

1. A theoretical or introductory part (*mudkhal*) exploring its foundations in physical science and metaphysics. Here Abū Maʿshar's *Kitāb al-mudkhal al-kabīr* shared ultimate authority together with Ptolemy's *Tetrabiblos*.
2. A section dealing with Nativities (*mīlād, mawālīd*) which consisted of drawing up diagrams (horoscopes) of the state of the sky at the time of any beginning. Its most natural occasion was at the time of birth (hence "nativities"), or even of conception when possible, and it would be held as an indication of the probable unfolding of the various life circumstances of the individual person or object for whom it was drawn up. It is not without interest to recall that before the establishment of individual identity status such as birth registers, beginning with the sixteenth century in Europe, natal horoscopes constituted the most reliable record of the chronological span of individual lives. Not every one was born of sufficiently wealthy or honorable stock to be able to afford this luxury. Abū Maʿshar himself lamented the fact that he did not know the exact date of his birth, to compensate for which he had drawn up for himself a "general" (approximative) horoscope.
3. Interrogations (*masāʾīl*) which dealt mostly with enquiries about objects hidden or lost, innermost thoughts or intentions, purposes, etc. A kind of oracle, it aimed to assist individuals in their important decision making or help recover missing objects.
4. Elections or Choices (*ikhtiyārāt*), which were concerned with determining the most favorable moment for starting on important undertakings, such as the construction of cities, opening of hostilities in wartime, investiture or inauguration, or starting on a journey.
5. Weather predictions or meteorology, which were almanacs which astrologers operating for courts, cities, or institutions like universities would issue at the beginning of each new year, as part of their official duties. Weather predictions were of course a prime concern in any predominantly agrarian society.

The art or trade of the astrologer on the other hand was referred to by the term *ṣanʿa* and was treated like any other profession. More specialized applications of astrological science still flourished beside the main stream, particularly in medicine where some Greek treatises of Hippocrates (*On Airs* and *De hebdomadibus* for instance) and Galenic ones about duration of pregnancy were merged into astrological prognostication (*taqdimat al-maʿrifa*) and enjoyed enormous vogue among physicians. Finally all sorts of "predictions" or "interpretation of signs" proliferated in a number of specialized practices of quackery into which some pretense of astrological judgments was introduced. Some of these are chiromancy (interpretation of lines of the hand), spatulomancy (interpretation of form of shoulder blade), and sternutomancy (on sneezing).

An influential sequel to Abū Maʿshar's *Greater Introduction* appeared by Aḥmad ibn Yūsuf, a physician, mathematician, and astrologer of the Tūlūnid era (870–904) in Egypt. Aḥmad wrote a chronicle of this Turkish dynasty and he authored several works of mathematics. He put together an astrological compendium which he entitled *Kitāb aṭh-Ṭhamara* (Liber Fructus). Since it comprised 100 short propositions, each one accompanied by a substantial commentary, it came to be designated as *Centiloquium*. In fact its major doctrines are taken straight from Abū Maʿshar's *Kitāb al-mudkhal al-kabīr*. The very passage in Abū Maʿshar's work which probably gave Aḥmad the inspiration for his forgery is met in a special section of the magnum opus (III, 1–2) where Abū Maʿshar enumerates the six benefits to be derived from astrological science, the most alluring of which are the "fructus" (*ṭamara*) to be anticipated from it.

These two works by Abū Maʿshar and by Ibn Yūsuf, respectively, the second in the footsteps of the first, influenced the West from the time of their translation into Latin during the twelfth century until the demise of astrology as a science in the Scientific Revolution of early modern times. The nature, influence, and significance of Arabic astrology in the East and the West during the Middle Ages were polarized around the success of these two major works.

Astronomical Instruments in India

YUKIO ŌHASHI

Astronomical knowledge in India can be traced back to the Vedic literature (ca. 1500–500 BCE), the earliest literature in India, but no astronomical instrument is mentioned there. Naked eye observations of the sun, moon, and lunar mansions were carried out. It is not clear whether five planets were observed or not.

There is a class of works called *Vedāṅga*, probably composed toward the end of the Vedic period, which is regarded as auxiliary to the Veda. It consists of six divisions, including *Jyotiṣa* (astronomy) and *Kalpa* (ceremonial). The *Kalpa* further consists of four divisions, including *Śulba* (method of the construction of the altar). The earliest astronomical instruments in India, the gnomon and the clepsydra, appear in the *Vedāṅga* literature.

The gnomon (Sanskrit: *śaṅku*) is used for the determination of cardinal directions in the *Kātyāyana-śulbasūtra*. A vertical gnomon is erected on a leveled ground, and a circle is drawn with a cord, whose length is equal to the height of the gnomon, with the center the foot of the gnomon. At the two points where the tip of the gnomon-shadow touches the circle, pins are placed, and they are joined by a straight line. This line is the east–west line.

The annual and diurnal variations of the length of the gnomon-shadow are recorded in the political work *Artha-śāstra* of Kauṭilya, the Buddhist work *Śārdūlakarṇa-avadāna*, and Jaina works such as the *Sūrya-prajñapti*. These records seem to be based on observations in North India.

The clepsydra is mentioned in the *Vedāṅga-jyotiṣa*, the *Artha-śāstra*, and the *Śārdūlakarṇa-avadāna*. It was like a water jar with a hole at its bottom from which water flowed out in a *nāḍikā* (one-sixtieth of a day).

Toward the end of the *Vedāṅga* astronomy period, certain Greek ideas of astronomy and astrology had some influence in India from the second to the fourth century AD. After that, Hindu astronomy (*Jyotiṣa*) established itself as an independent discipline, and several fundamental texts called *Siddhāntas* were composed. I call this period, from about the end of the fifth to the twelfth centuries AD, the classical *Siddhānta* period. The main astronomers who described astronomical instruments are Āryabhaṭa (b. AD 476), Varāhamihira (sixth century AD), Brahmagupta (b. AD 598), Lalla (eighth or ninth century AD), Śrīpati (eleventh century AD), Bhāskara II (b. AD 1114), and the anonymous author of the *Sūrya-siddhānta*. The *Siddhāntas* composed by Brahmagupta, Lalla, Śrīpati, and Bhāskara II contain special chapters on astronomical instruments entitled *Yantra-adhyāya*. The Sanskrit word *yantra* means instrument. No observational data are recorded in the *Siddhāntas*, and the extent of actual observations in this period is controversial. Roger Billard maintained that astronomical constants in the *Siddhāntas* were determined by actual observations, while David Pingree argued that they were exclusively borrowed from Greek astronomy. In this connection, we should note that the method of determination of astronomical constants by means of observations was correctly explained by Bhāskara II. Let us see the instruments in this period.

The gnomon (*śaṅku*) was continually used in this period. The theory of the gnomon – such as the relationship between the length of gnomon-shadow, the latitude of the observer, and time – was developed in this period, and a special chapter called *Tripraśna-adhyāya* in the *Siddhāntas* was devoted to this subject. Trigonometry, invented in India, was fully utilized for this purpose.

The staff (*yaṣṭi-yantra*) is a simple stick, used to sight an object. There are some variations of the staff, such as V-shaped staffs for determining angular distance with the help of a graduated level circle.

The circle instrument (*cakra-yantra*) is a graduated circular hoop or board suspended vertically. The sun's altitude or zenith distance is determined, and time is roughly calculated from it. Variations of the circle instrument are the semicircle instrument (*dhanur-yantra*) and the quadrant (*turya-golaka*).

A circular board kept horizontally with a central rod is the chair instrument (*pīṭha-yantra*), and a similar semicircular board is the bowl instrument (*kapāla-yantra*). They determine the sun's azimuth, and time is roughly calculated from them.

A circular board kept in the equatorial plane is the equator instrument (*nāḍīvalaya-yantra*). It is a kind of equatorial sundial. The combination of two semicircular boards, one of which is in the equatorial plane, is the scissors instrument (*kartarī-yantra*). Its simplified version is the semicircular board in an equatorial plane with a central rod.

The Indian armillary sphere (*gola-yantra*) was based on equatorial coordinates, unlike the Greek armillary sphere, which was based on ecliptical coordinates, although the Indian armillary sphere also had an ecliptical hoop. Probably, the celestial coordinates of the junction stars of the lunar mansions were determined

Astronomical Instruments in India. Fig. 2 *Dhruva-bhrama-yantra*.

by the armillary sphere since the seventh century or so (see Plate 2). There was also a celestial globe rotated by flowing water.

The clepsydra (*ghaṭī -yantra*) was widely used until recent times. Unlike the clepsydra of the *Vedāṅga* period, which was the outflow type of water clock, the clepsydra of this period is a bowl with a hole at its bottom floating on water. Water flows into the bowl, and it sinks after a certain time interval. The Chinese Buddhist traveler Yijing (AD 635–713) recorded the actual use of the clepsydra of this type. The clepsydra can be seen in use in a museum at Kota (Rajasthan) (see Plate 1). Several astronomers also described water-driven instruments such as the model of fighting sheep.

The board instrument (*phalaka-yantra*) invented by Bhāskara II is a rectangular board with a pin and an index arm, used to determine time graphically from the sun's altitude (see Fig. 1). This is an ingenious instrument based on the Hindu theory of the gnomon.

The astrolabe was introduced into India from the Islamic world at the time of Fīrūz Shāh (r. AD 1351–1388) of the Tughluq dynasty. Fīrūz Shāh's court astronomer Mahendra Sūri composed a Sanskrit work on the astrolabe entitled *Yantra-rāja* (King of Instruments, the Sanskrit term for the astrolabe) in AD 1370. This is the earliest Sanskrit work on Islamic astronomy. Use of the astrolabe rapidly spread among some Hindu astronomers, and Padmanābha (AD 1423) and Rāmacandra (AD 1428) described the astrolabe in their works.

Some new instruments were made in the Delhi Sultanate and Mughal periods. Padmanābha invented a kind of nocturnal instrument called *dhruva-bhrama-yantra* (polar rotation instrument) (see Fig. 2). It was a rectangular board with a slit and a set of pointers with concentric graduated circles. Adjusting the slit to the direction of α and β Ursae Minoris, time and other calculations could be obtained with the help of pointers. Its backside was made as a quadrant with a plumb and an index arm. Thirty parallel lines were drawn inside the quadrant, and trigonometrical calculations were done graphically. After determining the sun's altitude with the help of the plumb, time was calculated graphically with the help of the index arm.

Later, Cakradhara described the quadrant as an independent instrument, and a more exact method to calculate time was explained.

Astronomical Instruments in India. Plate 6 The Miśra-yantra in Jai Singh's observatory at Delhi.

Another new type of instrument in this period was the cylindrical sundial called *kaśā-yantra* (whip instrument) by Hema (late fifteenth century AD) or *pratoda-yantra* (whip instrument) by Ganeśa (b. AD 1507) (see Fig. 3). It is a cylindrical rod having a horizontal gnomon and graduations of time according to the vertical shadow below the gnomon.

The quadrant and the cylindrical sundial exist in the Islamic world also, but the possibility of their influence on these Indian instruments is still to be investigated.

The Mahārāja of Jaipur, Sawai Jai Singh (AD 1688–1743), constructed five astronomical observatories at the beginning of the eighteenth century. The observatory in Mathura is not extant, but those in Delhi, Jaipur, Ujjain, and Banaras are (Plate 3). There are several huge instruments based on Hindu and Islamic astronomy. For example, the *samrāṭ-yantra* (emperor instrument) is a huge sundial which consists of a triangular gnomon wall and a pair of quadrants toward the east and west of the gnomon wall. Time has been graduated on the quadrants (Plates 4).

By this time, European astronomy had begun to be introduced into India, and Jai Singh had certain information about it. The earliest European style astronomical observatory in India is a private one of William Petrie, an officer of the British East India Company, which was set up in 1786 at his residence in Madras.

Astronomical Instruments in the Islamic World

David A. King

Most Islamic observational instruments are lost and known to us only through texts. The state of documentation of the other, smaller Islamic astronomical instruments that do survive leaves much to be desired. Many of the most important instruments are still unpublished, and much that has been written on instruments is on a very amateur level. For these reasons a project has been underway in Frankfurt to catalogue all Islamic instruments (and European ones) to ca. 1550 as well as various historically significant later Islamic pieces.

Also the most important writings on instruments have not yet received the attention they deserve. For example, a hemispherical observational instrument for a fixed latitude was devised by the tenth century astronomer al-Khujandī, the leading instrument maker of the early period, and this was modified in the twelfth century to serve all latitudes. There are no surviving examples, and the available manuscripts have yet to be studied. An important work on instruments was compiled in Cairo ca. 1280 by Abū ʿAlī al-Marrākushī – this has yet to be subjected to a detailed analysis. The author collected all of the treatises on instruments known to him and incorporated them into his book. An exciting find of the 1980s was a treatise by the early fourteenth century Cairo astronomer Najm al-Dīn al-Misrī. In this the author described and illustrated over 100 different instrument types, including every kind of instrument known to him as well as those he invented himself. This treatise is now published with an exhaustive commentary. The same holds for the earliest surviving corpus of texts on the astrolabe, quadrant, and sundials by al-Khwārizmī.

Armillary Spheres and Globes

In the eighth century al-Fazārī wrote a treatise on the armillary sphere, called *dhāt al-ḥalaq*, which means "the instrument with the rings." No early Islamic armillary spheres survive, but several other treatises on it were compiled over the centuries. The earliest treatise in Arabic dealing with the celestial globe, called *dhāt al-kursī* (the instrument with the stand) or simply *al-kura* (sphere), was written by Qusṭā ibn Lūqā in the ninth century. This treatise by Qusṭā, who was one of the most important translators of Greek works into Arabic, remained popular for a millennium. Of the various surviving celestial globes, which number over 100, none predates the eleventh century.

The spherical astrolabe, unlike the armillary sphere and the celestial globe, appears to be an Islamic development. Various treatises on it were written from the tenth to the sixteenth century, and only one complete instrument, from the fourteenth, survives. In the ninth century Ḥabash wrote on the spherical astrolabe, the armillary sphere, and the celestial globe, as well as on various kinds of planispheric astrolabes.

Astrolabes

Al-Fazārī also wrote on the use of the astrolabe (Arabic *asṭurlāb*). The tenth century bibliographer Ibn al-Nadīm states that al-Fazārī was the first Muslim to make such an instrument – he also informs us that, at that time, the construction of astrolabes was centered in Harran and spread from there. Several early astronomers, including Ḥabash, al-Khwārizmī, and al-Farghānī, wrote on the astrolabe, and introduced the features not found on earlier Greek instruments, such as the shadow squares and trigonometric grids on the backs and the azimuth curves on the plates for different latitudes, as well as the universal plate of horizons. Also extensive tables were compiled in the ninth century to facilitate the construction of astrolabes.

Another important development to the astrolabe occurred in Andalusia in the eleventh century, when al-Zarqāllu devised the single universal plate (*ṣafīḥa*) called *shakkāziyya* and the related plate called *zarqālliyya* with two sets of *shakkāziyya* markings for both equatorial and ecliptic coordinate systems. The latter was fitted with an alidade bearing a movable perpendicular straight edge (transversal). Several treatises on these two instruments exist in both Western and Eastern traditions of later Islamic astronomy – the Europeans knew of them as the *saphea*. Ibn al-Zarqāllu's contemporary, ʿAlī ibn Khalaf, wrote a treatise on a universal astrolabe that did not need plates for different latitudes. This treatise exists only in Old Spanish in the *Libros del Saber*, and was apparently not known in the Islamic world outside Andalusia. The instrument was further developed in Syria in the early fourteenth century: Ibn al-Sarrāj devised in Aleppo a remarkable astrolabe that can be used universally in five different ways.

The astrolabes made by Muslim craftsmen show a remarkable variety within each of several clearly defined regional schools. We may mention the simple, functional astrolabes of the early Baghdad school – the splendid astrolabe of al-Khujandī of the late tenth century, which started a tradition of zoomorphic ornamentation that continued in the Islamic East and in Europe for several centuries – the very different astrolabes of the Andalusian school in the eleventh century and the progressive schools of Iran in the thirteenth and fourteenth centuries – and the remarkable instruments from Mamluk (thirteenth and fourteenth century) Egypt and Syria. In the early fourteenth century Ibn al-Sarrāj of Aleppo, a school unto himself, produced the most sophisticated astrolabe ever made. After about 1500 the construction of astrolabes continued in the Maghrib, in Iran, and in India until the end of the nineteenth century. Many of these instruments, especially those from Iran, were beautiful objects of the finest workmanship.

Quadrants

Another category of observational and computational devices to which Muslim astronomers made notable contributions was the quadrant, of which we can distinguish three main varieties. Firstly there is the sine quadrant with an orthogonal grid. This instrument, in a simpler form, had already been described by al-Khwārizmī and was widely used throughout the Islamic period. Some Islamic astrolabes display such a trigonometric grid on the back. The grid can be used together with a thread and movable marker (or the alidade of an astrolabe) to solve all of the standard problems of spherical astronomy for any latitude. Secondly there is the horary quadrant with fixed or movable cursor. This instrument is described already in an anonymous ninth century Iraqi source and was likewise commonly used for centuries (albeit usually without the cursor, which is not essential to the function of the device). A set of arcs of circles inscribed on the quadrant display graphically the solar altitude at the seasonal hours (approximately, according to an Indian formula). Other Islamic quadrants from the ninth century onwards had markings for the equinoctial hours. The instrument can be aligned towards the sun so that the time can be determined from the observed altitude using the grid. Again this kind of marking was often found on the back of astrolabes. Thirdly there is the astrolabic quadrant displaying one-half of the altitude and azimuth circles on an astrolabe plate for a fixed latitude, and a fixed ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course). The effect of the daily rotation is achieved by a thread and bead attached at the center of the instrument rather than by the movable astrolabe rete. The quadrant with astrolabic markings on one side and a trigonometric grid on the other generally replaced the astrolabe all over the Islamic world (with the notable exceptions of Iran, India, and the Yemen) in the later period of Islamic astronomy.

Sundials

We learn from Islamic tradition that the pious Umayyad Caliph ʿUmar ibn ʿAbd al-ʿAzīz (fl. Damascus, 718) used a sundial to regulate the times of the daytime prayers in terms of the seasonal hours. The earliest sundials described in the Arabic astronomical sources are planar, usually horizontal, but also vertical and polar. The mathematical theory for computing the shadow for the seasonal hours at different times of the year and the corresponding azimuths was available from Indian sources, which seem to have inspired the Islamic tradition more than any of the available Greek works. The treatise on sundial construction by al-Khwārizmī contained extensive tables displaying the polar coordinates of the intersections of the hour lines with the solstitial shadow traces on horizontal sundials for 12 different latitudes. The treatise on sundial theory by Thābit ibn Qurra contains all the necessary mathematical theory for constructing sundials in any plane – likewise impressive from a theoretical point of view is the treatise on gnomonics by his grandson Ibrāhīm.

The earliest surviving Islamic sundial, apparently made in Córdoba about the year 1000 by the Andalusian astronomer Ibn al-Ṣaffār, displays the shadow traces of the equinoxes and solstices, and the lines for the seasonal hours as well as for the times of the two daytime prayers. There is a world of difference between this simple, carelessly constructed piece and the magnificent sundial made in the late fourteenth century by Ibn al-Shāṭir, so devised that it can be used to measure time with respect to any of the five daily prayers. In the late period of Islamic astronomy a sundial was to be found in most of the major mosques.

Miscellaneous

Muslim astronomers devised several multi-purpose instruments. Notable examples are the rule (*mīzān*) of al-Fazārī, fitted with a variety of non-uniform scales for various astronomical functions, and the compendium of Ibn al-Shāṭir, comprising a magnetic compass and qibla-indicator, a universal polar sundial, and an equatorial sundial. Of particular interest is three circular qibla-indicators made in Isfahan ca. 1675 (but invented much earlier) which consists of a cartographic grid with Mecca at the center, so devised that the qibla can be read off the outer scale and the distance from Mecca can be read off the non-uniform scale on the diametrical rule.

There are several Islamic treatises on eclipse computers and planetary equatoria for determining the positions of the planets for a given date. With these the standard problems of planetary astronomy dealt with in *zījes* are resolved mechanically, without calculation. Treatises on eclipse computers are known from the early tenth century, and al-Bīrūnī in the early eleventh describes such an instrument in detail. A newly discovered manuscript (not yet available for research) contains a treatise by the tenth century Iranian astronomer Abū Jaʿfar al-Khāzin describing an equatorium called *Zīj* al-Safāʾiḥ (the Zīj of Plates). The only known example of this instrument, made in the twelfth century, is incomplete: it is in the form of an astrolabe with tables engraved on the *mater* and additional markings for the foundation of an equatorium. Otherwise the only known early Islamic treatises on planetary equatoria are from eleventh century Andalusia. The most interesting aspect of the equatorium described by al-Zarqāllu is the ellipse drawn on the plate for the center of the deferent of Mercury – it seems that he was the first to notice this characteristic of Mercury's deferent. Al-Kāshī, the leading astronomer of early fifteenth century Samarqand, has left us a description of a planetary equatorium with which not only ecliptic longitudes but also latitudes could be determined and eclipses calculated.

Astronomical Instruments in Japan

Nakamura Tsuko

Beginning around the sixth century, Japan was under the strong cultural influence of China (via Korea), and astronomy was no exception. Although by the beginning of the eighth century an institutional form of the Chinese Astronomical Office had been introduced into the Japanese court government along with primitive gnomons and water clocks, astronomy as a science did not become part of Japanese society, and only the astrological aspects of Chinese astronomy survived. This situation continued for many centuries throughout medieval times, partially due to the domestic turmoil caused by frequent civil wars. It was not until after the shogun Tokugawa Ieyasu finally ruled over Japan in 1615 that the Japanese people could afford to nurture their own culture. In the mid-sixteenth century, European astronomy was first brought by the Christian missionaries from Portugal and Spain, though their influence did not last long. The reason was that the shogunal government ousted them because it suspected that the true aim of the Christian missionary activities in Japan was political occupation. Thereafter, import of foreign books relating to the Western religion and culture was strictly prohibited, and only Dutch traders were allowed to come to Nagasaki.

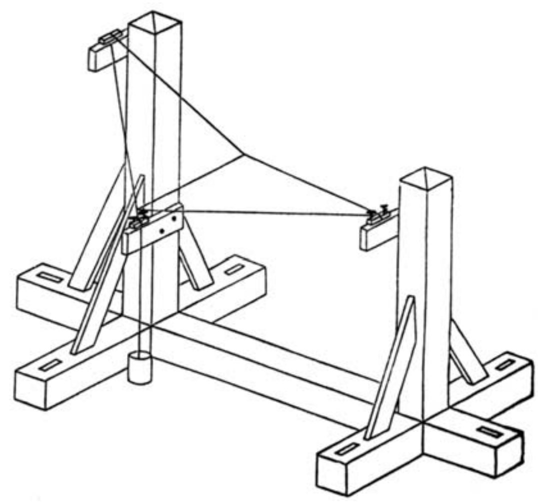
Astronomy as a science and the development of astronomical instruments started from the seventeenth century in Japan (Nakayama 1969). In the 1680s, Shibukawa Harumi was nominated to be the first astronomical officer of the shogunate, after the government adopted his proposed new luni-solar calendar. For observations in this calendar reform, he made a gnomon with an apparatus to sharpen the blurred shadow of the sun. He also constructed an armillary sphere of 90 cm in diameter which was a simplified version of the traditional Chinese armillary sphere, and he measured the positions of many stars with it to produce the first Japanese star map. His compiled star catalog reveals that the observational error of his armillary sphere was about half a degree, though this instrument has since been lost. The only existing armillary sphere actually used for astronomical observations is the one preserved at Sendai City Observatory, which is about 100 cm in diameter and made of bronze with scales of half a degree interval.

After Harumi, there was no one to inherit and develop his scientific achievements till the advent of the eighth shogun Tokugawa Yoshimune in the 1710s. He was deeply interested in the natural sciences and made efforts to organize and cultivate the study of science. In 1729 he relaxed the ban of importing Chinese books written by Jesuit priests in China and also allowed Dutch interpreters at Nagasaki to learn Dutch books. This was because, he recognized the superiority of Western astronomy over Chinese traditional astronomy and planned a calendar reform using Western astronomy. He took some astronomers and mathematicians to the shogunal astronomical office and ordered an optician from Nagasaki to devise good telescopes for astronomical observations. Yoshimune himself was also engaged in astronomical observations by inventing a few new armillary spheres and transit quadrants. Despite Yoshimune's enthusiasm, his intended calendar reform was unsuccessful, due to the poor abilities of the shogunal astronomers and the opposition of the court astronomers based at Kyoto.

Because of the hereditary system for the position of the shogunal astronomers, the scholastic ability of some amateur astronomers overpowered that of the shogunal astronomers around the end of the eighteenth century. The shogunate eventually summoned the two civil astronomers of Osaka, Takahashi Yoshitoki and Hazama Shigetomi, to take leadership for a new calendar reform as the shogunal astronomers (Watanabe 1987). The former was superior in theoretical astronomy and the latter in developing astronomical instruments. Before their nomination to the position, they already possessed some knowledge of Copernican and Keplerian theories of planetary motions learned through Sino-Jesuit astronomical books, and they also devised accurate astronomical instruments by consulting *Lingtai Yizhi* (Astronomical Observatory Instruments, by Verbiest et al. 1674). This book described with many detailed illustrations the structure and usage of several new astronomical instruments constructed by the Jesuit astronomers serving the Qing Dynasty, which were hybrids of the traditional Chinese instruments and European ones invented by people such as Tycho Brahe.

The principal instruments among the ones produced by the Takahashi–Hazama group were the quadrant of 195 cm in radius with a telescope and the wire meridian transit of about 3.6 m in height, both installed at the shogunal observatory of Edo (ancient Tokyo). The quadrant was equipped with a diagonal subscale, which was reinvented by Brahe, so that it could measure stellar positions (altitudes) with an error of 10–15 arcsec. For measuring the meridian-transit time of stars, they used an astronomical pendulum clock which was also devised by the Takahashi–Hazama group with hints from *Lingtai Yizhi*. This astronomical clock could give stellar-transit timings with an accuracy of about one second. Although several such astronomical clocks made before 1850 still exist, all the instruments used at the shogunal observatory of Edo were lost or destroyed in the disorder of the Meiji Restoration in 1868.

Ino Tadataka, one of Takahashi's disciples, conducted a large-scale land survey all over the Japanese archipelago starting from 1800. This was the first scientific expedition of geodesy conducted in Japan. Although the methods of mapmaking and measuring instruments by Ino were not innovative ones, his 16-year-long enthusiasm led him to complete the entire map of Japan. For the fieldwork, he designed and constructed a few portable quadrants for astronomical latitude observations; the most frequently used one has the quadrant whose radius is 115 cm. Analysis of his field notes shows that the accuracy of single observations with this quadrant was about 20–30 arcsec. Ino also used a transportable wire transit (Fig. 1) for observing the meridian passage of stars along with a pendulum clock. This transit instrument was not useful for determining longitudes of triangulation points because of the lack of a precise chronometer, but it was mainly used for maintaining the local time. As for azimuth measurements, he devised semicircular magnetic compasses with an alidade. His 57-volume azimuthal catalog of more than 2,200 triangulation points reveals that the typical error of Ino's azimuth measurements was 5′. All of those instruments are now preserved at Ino's memorial museum. Astronomers of the Takahashi–Hazama group including Ino did not adopt the Vernier subscale but exclusively adhered to the diagonal subscale for precise measurements.



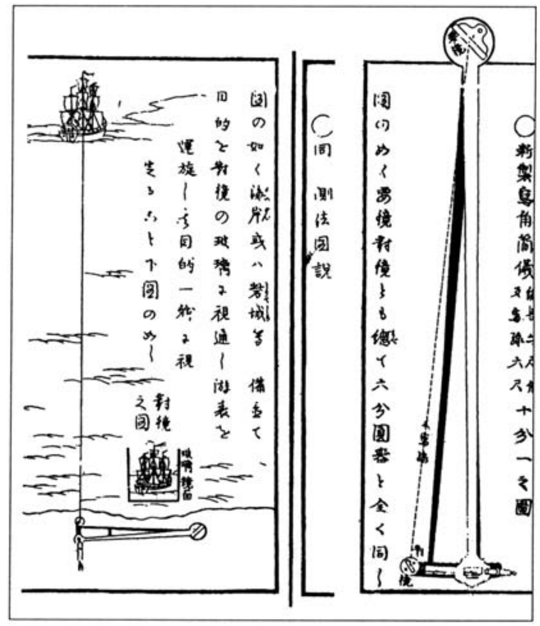
Astronomical Instruments in Japan. Fig. 1 Transportable wire meridian transit used by Ino Tadataka in his land survey expedition of Japan (Otami 1932).

Telescopes

Telescopes in Japan have a fairly long history. As far as historical records tell us, the first introduction of a telescope into Japan goes back to 1613, when a captain of the British East India Company offered a telescope to the first Shogun Tokugawa Ieyasu for trade promotion; this telescope does not seem to exist now. The earliest existing telescope in Japan was the one owned by Tokugawa Yoshinao, the ninth prince of Ieyasu (now preserved at the Tokugawa Fine Arts Museum). Since Yoshinao died in 1650, it means that his telescope was produced in or before that year. Our recent investigation made clear that this telescope was of the Schyrlean type, made of four convex lenses giving erect images, with a magnifying power of about four. Analysis of the design, the fabrication method, the surface decoration of the telescope, and the relating historical episodes all suggest that it was not a Western make at all but produced around the southern coastal area of China, or Taiwan, or Nagasaki, by the East Asians. In the 1720s, the optician of Nagasaki, Mori Nizaemon, responding to the order of the Shogun Yoshimune, produced at least several telescopes for astronomical observations, a few of which still exist. The largest one has a tube length of 340 cm with an objective lens diameter of 73 mm, giving the magnifying power of about 10. It is likely that the shogunal astronomers used this telescope for observations of the planetary surfaces.

Around the 1790s, Iwahashi Zenbei of Osaka started production of refractor telescopes on a commercial basis. His telescopes were characterized by special decorative patterns on the tube surface, so that plenty of imitations and fakes with similar decorations appeared at later times. High-quality telescopes by Iwahashi gave the magnifying power of more than 10–20.

Because the Iwahashi's family continued to fabricate their telescopes for four generations, they are most commonly seen in museum collections and antique markets. All the telescopic tubes and caps from Yoshinao's to Iwahashi's were produced by the traditional technique called *Ikkan-bari*, which utilizes paper and thin wood glued with *urushi* lacquer. In 1834, the gunsmith, Kunitomo Tobei, succeeded in completing his first Gregorian reflector telescope for the first time in Japan (Yamamoto 1937). Currently four brass telescopes of nearly the same size (with an inner tube diameter of 62 mm) are identified as his products. Although it is quite unknown how he could polish the bronze primary mirrors without knowledge of Western modern optics and a mirror-grinding machine, Foucault's method of mirror testing has revealed that at least a few of Kunitomo's telescopes possess parabolic surfaces nearly as accurate as those of contemporary Gregorian telescopes. With one of them, Kunitomo made continuous observations of sunspots for more than 1 year, and during that time he independently discovered the penumbra of the sunspot. It is a shame that his excellent engineering could not find any successors, as pioneering achievements like Kunitomo's have often had a similar fate in the history of Japan.



Astronomical Instruments in Japan. Fig. 2 Drawing of Murata's range finder (1852).

Octants and Sextants

Octants and sextants are certainly worth mentioning in the history of Japanese astronomical instruments. Dutch sailors first brought octants, superb handy navigational and astronomical instruments, into Japan in the 1770s. Because of having no previous information on the principle of an octant and the Vernier subscale inscribed on its arc, both the issues greatly annoyed Japanese astronomers (Nakamura 2002). Only the practical usage of an octant on the sea had been known since 1782, through a Japanese translation of the Dutch book on octants written by Cornelis Douwes (1749). It was not before 1800–1810 that scholars in Japan began to understand how an octant works and the principle of the Vernier subscale. Since at that time the shogunal government kept a strict seclusion policy and prohibited construction of ships large enough to enable remote voyages, the Japanese had no chance to use octants and sextants in ocean navigation. This motivated some people to apply octants in measuring angles of distant targets on the ground. Several books explaining how to use octants and sextants in land surveying were written up to the middle of the nineteenth century. One problem with an octant in measuring angles of ground targets was systematic errors due to the parallax caused by a separation between the two mirrors comprising major components of an octant. On the contrary, some land surveyors, like Murata Sajuro, made positive use of the parallactic problem. He introduced, in his book of 1852, a range finder which is a heavily deformed octant having a very wide mirror separation (Fig. 2); Murata's book describes range finders with mirror separations of 1.8 m, 3.6 m, and 5.4 m. The left panel of Fig. 2 indicates that this instrument was invented for military purposes to measure the distance of a ship on the sea. After the Meiji Restoration of 1868, modern astronomical instruments imported from Europe soon replaced all the Japanese ones.

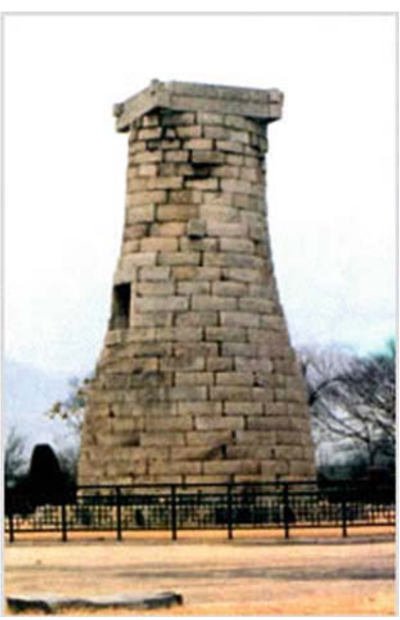
Astronomical Instruments in Korea

YOUNG-HO HAHN

As a country which shares its border with China, ancient Korea also shared many of her neighbor's astronomical achievements. Korea adopted Chinese calendars as a standard and kept identical seasons of the year. But rulers of the Korean peninsula had also tried to establish an independent calendar system, especially during the Chosun dynasty (1392–1910). They attempted to bring out their own almanac at the same level of precision as the Chinese one. Several astronomical projects carried out under the initiative of King Sejong are the best-known examples of such efforts. From 1432–1439 a platform, *Ganeuidae*, for the royal observatory was built in the palace and every necessary astronomical instrument was added to it.

Korea has one of the world's oldest observatories, *Chomsungdae*, shown in Fig. 1. It was built in the early seventh century. Another observatory was constructed in the early tenth century and is also extant. Unfortunately only a small number of astronomical instruments and records prior to the fifteenth century have survived. But, as these observatories show, there had been many attempts to read heavenly phenomena even before the Chosun began.



Astronomical Instruments in Korea. Fig. 1 World's oldest observatory, *Chomsungdae* in Kyongju.

All the astronomical instruments mentioned in this article, although many of them have been lost and are known only through records, are those made during the Chosun period. King Sejong's projects were very important to Korean astronomy. In addition to establishing the first independent calendar, *Chiljeongsan*, various instruments, such as equatorial torquetums [the torquetum or turquet is an instrument designed to take and convert measurements made in three sets of coordinates: horizon, equatorial, and ecliptic], armillary spheres, celestial globes, sundials, and auto-striking clepsydras, were introduced. Some of them were made after Chinese models and others were original. The most comprehensive description of Sejong's instruments is in Needham's *The Hall of Heavenly Records* (1986).

When Japan invaded Korea in 1592 and burnt down the royal palaces in Seoul, almost every instrument was lost, and Sejong's astronomical instruments were burned. Parts of these were restored after the war according to original designs. While the Court of Chosun was struggling to rebuild after successive raids by Manchurian Qing, Jesuit missionaries in China worked to change the Chinese calendar system to that based on Western astronomy. Officials and scholars of Chosun had to confront unfamiliar Western mathematics and astronomy to catch up with the advanced Chinese calendar. Using projection geometry, they made planar instruments such as astrolabes and sundials for themselves. Finally at the end of the eighteenth century, the Korean royal observatory was able to create a pair of unique Western-style sundials.

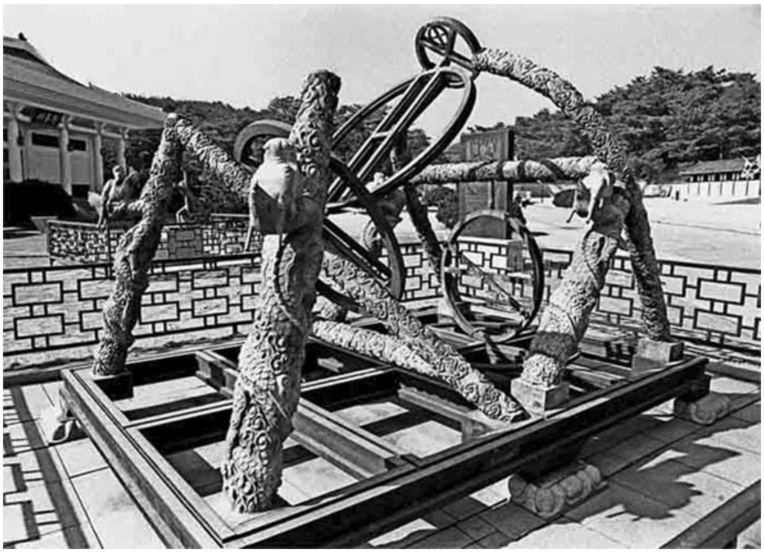
Each instrument that follows is classified according to its structure and function.

Equatorial Torquetums

An approximately 7 m high, 10 m long and 7 m broad platform of the royal observatory was named *Ganeuidae*, because the equatorial torquetum, *Ganeui*, the largest representative of Sejong's observing instruments, was installed on it.

The Korean *Ganeui* was based on Guo Shou-Jing's *Jianyi*, shown in Fig. 2. Guo, of the Chinese Yuan dynasty, invented a new instrument by taking equatorial and meridian rings out and eliminating ecliptic and selenic rings from the traditional armillary sphere. Details of *Jianyi* (literally, simplified instrument) are described and illustrated in Needham's *Science and Civilisation in China*, vol.3 (1959).

Sejong's officials made a wooden prototype and checked the exact polar elevation of Seoul. They completed a bronze-cast *Ganeui* in 1433. Although much simpler in shape than an armillary sphere with multiple-layered rings, the full-scale Simplified Instrument was too large to handle easily. In 1434 King Sejong ordered his scholars to make a smaller version,



Astronomical Instruments in Korea. Fig. 2 Reconstructed Model of Simplified Instrument *Ganeui* in Yeoju.

Astronomical Instruments in Korea. Fig. 3 Reconstructed Model of Small Simplified Instrument *Soganeui* in Yeoju.

Astronomical Instruments in Korea. Fig. 4 Sun-and-Star Time-Determining Instrument *Ilseongjeongsieui* Reconstructed.

and they made two copies of the portable *Soganeui* (Small Simplified Instrument), shown in Fig. 3.

Sejong's astronomers also created a unique observing device, *Ilseongjeongsieui* (Sun-and-Star Time-Determining Instrument). As its name implies, this instrument was both a sundial and stardial. With triple equatorial dial plates, double axially protruded polar-sighting rings, an alidade, and two sighting threads, the direction of the sun and some specified stars near the north pole could be read. This in turn revealed the time of observation. Figure 4 shows the reconstructed model of the round-the-clock time-determining instrument.

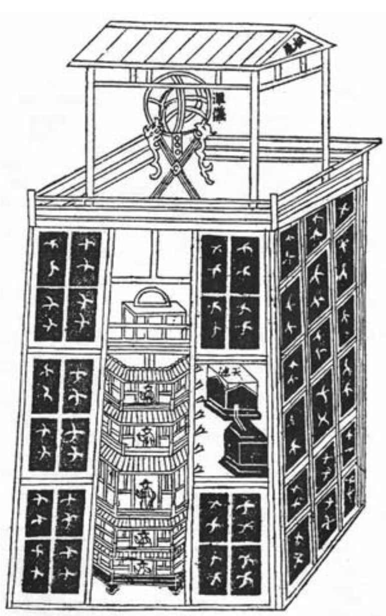
Armillary Spheres, Celestial Globes, and Astronomical Clocks

After Guo Shou-Jing's *Jianyi*, armillary spheres in East Asia were based on the Simplified Instrument, not on platforms of observatories. They became the driving mechanism of the indoor astronomical clock. Although the first Chinese astronomical clock dates back to the second century AD, it was at the end of the eleventh century that Su Sung's *Shuiyunyixiangtai* (Water-Powered Sphere and Globe Tower), appeared in China. The inner rings of the armillary sphere and the star-embedded sphere of the celestial globe were rotated by a water wheel in accordance with each heavenly body. The sketch of the clock tower in Fig. 5 is taken from Su Sung's book, and more details of this gigantic clock may be found in Needham's *Heavenly Clockwork* (1986).

China's long tradition of astronomical clocks culminated in Su Sung's work in the Sung dynasty. During the succeeding Yuan period, such water-driven clocks as Guo Shou-Jing's Lantern Clepsydra and Emperor Shun-Ti's Palace Clepsydra were made. But they were not classified as astronomical clocks because they did not have any devices like spheres or globes to indicate heavenly motions.

King Sejong revived the East Asian tradition of astronomical clocks in Korea by equipping a water-operated sphere and globe near his observatory. Except for the layout and size of the instruments, the basic structure of Sejong's clock is thought to be the same as Su Sung's.

In 1438 the artisan Jang Young-Sil made one more water-powered astronomical clock, *Heumgyonggaknu*, close to King Sejong's inner palace. The Clepsydra of the Respectful Veneration Pavilion, although it vanished long ago, is one of the most spectacular astronomical clocks ever made in Korea.



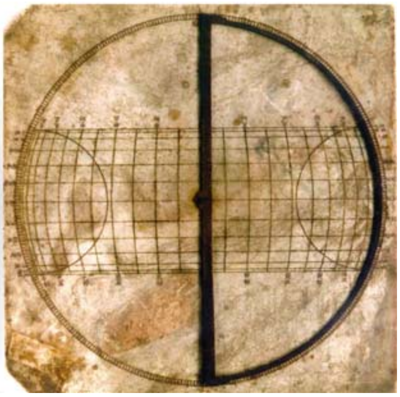
Astronomical Instruments in Korea. Fig. 5 Su Sung's Water-Powered Sphere and Globe Tower.

A ball-shaped golden figure moved round the 7 ft. high mountaintop while keeping the same polar distance and directions of rising and setting to the sun for each season. Below the sun image stood four jade female gods at the four cardinal points, each with an animal-figured direction god. The ringing of a golden bell in the hand of a god and the turning of the accompanying animal god announced the beginning and middle of the double hours. There was a high platform at the southern foot of the mountain, on which hammers struck their respective instruments to announce the assigned double hour or night watch. On the ground level 12 jade gods surrounded the mountain, paired with each hour god. In addition to the extra platform carrying an inclined vessel, there were paintings of rural scenery during the four seasons and wooden carvings of men, birds, and plants.

This splendid clepsydra was totally destroyed and restored twice over 200 years. Two decades after the abolition of *Heumgyonggaknu*, Yi Min-Cheol made an armillary clock as the successor of Jang Young-Sil's clockwork in the mid-seventeenth century. The new armillary clock was derived from Sino-Korean astronomical clepsydras, but it had a considerably different appearance. Yi built a cabinet in which water-operated driving mechanisms and a time-announcing apparatus were contained. An armillary sphere, as a part of astronomical clock, was installed on the plinth connected to the box.

Song Yi-Young, in close cooperation with Yi Min-Cheol, made an additional weight-driven armillary clock at the same time in 1669. Instead of Yi's water-powered device he adopted the driving mechanism that had been applied to Western mechanical clocks. Fortunately, as shown in Fig. 6, an improved version of Song's armillary clock has survived and is preserved in the Museum of Korea University, Seoul.

Astronomical Instruments in Korea. Fig. 6 Armillary clock in the Museum of Korea University, Seoul.

Astronomical Instruments in Korea. Fig. 7 Korean relics of celestial planisphere (left) and universal astrolabe (right).

Needham devoted one whole chapter of *The Hall of Heavenly Records* (1986) to describing this clock; he wrote that the Song Yi-Young/Yi Min-Cheol clock deserved widespread recognition as a landmark in the history of East Asian horology.

Western astronomy and astronomical instruments began to spread to Korean scholars from the early part of the eighteenth century. Hong Dae-Yong made the last astronomical clock in East Asia. He coupled a mechanical clock directly with the sidereal components of his armillary sphere and attached kinds of differential gears to distinguish solar and lunar motions from sidereal movement.

In 1789 the royal observatory made an equatorial armillary sphere to correct the records of meridian transits. Taking a Westernized, Chinese armillary sphere as a model, Kim Young made Chosun's first observing armillary sphere that could measure heavenly bodies at the accuracy level of 15 s.

Astrolabes

The early Jesuit missionaries introduced astrolabes to China. Books on planispheric or universal astrolabes had been published in Chinese during the first quarter of the seventeenth century. However, the actual astrolabes did not arouse as much interest from Chinese scholars as the books introducing those instruments. Thus China did not leave any trace that showed practical uses for Western-style astrolabes except the celestial planisphere, *Pinghunyi*.

More than 100 years later, Korean scholars made all the Western planar instruments for themselves from reading these foreign books. But the planispheric astrolabe was uncommon in Korea too. The plate of the Western astrolabe was replaced with the planispheric star chart in *Pinghunyi*, and the rete was revised simply to an arc of horizon on the eastern instrument as shown in Fig. 7. Although several celestial planispheres have been handed down, universal astrolabes are very rare. Moreover, no planispheric astrolabe has survived.

Astronomical Instruments in Korea. Fig. 8 A scaphe sundial *Angbuilgui.*

Sundials

Ancient Korea contributed to the diversity of sundials by adding her unique shadow-tracking instruments. Especially during King Sejong's reign, several distinguished solar devices were invented and equipped. The best-known representative is the scaphe sundial, *Angbuilgui*. This sundial, shown in Fig. 8, has a hemispherical surface of grid lines. Since the end point of the gnomon coincides with the center of the sphere, the shadow of the sharp end is cast to the grid surface always at a right angle and can be read clearly and accurately even at times near sunrise and sunset. The scaphe sundial was used as a main time indicator throughout the Chosun dynasty.

During the eighteenth century a few horizontal sundials were made; they replaced the role of the scaphe sundial in the Court. The new Western-origin sun trackers had the simple appearance of a flat slab, although the construction of the shadow lines was not easily attainable. Once the geometrical essentials to construct foreign sundials became known, the royal observatory preferred to make horizontal instruments rather than the scaphe sundial with its hemispherical surface of shadow lines.

Among these horizontal sundials, *Ganpyongilgui* and *Hongaeilgui* are quite unique. In 1785 these two were carved side by side on the same 1.3 m-long stone table as shown in Fig. 9. The stone slab with 52 cm width is now preserved in the Royal Relic Exhibition Hall of Deoksu Palace in Seoul.

Ganpyongilgui was based on a Rojas type universal astrolabe and *Hongaeilgui* on a planispheric astrolabe. But the way they were developed was far from simply duplicating the original instruments. The inventor of these sundials, probably one of the high officials of the royal observatory, must have been a master of the principles of planispheric projection to carry out significant modifications for these particular horizontal instruments.

The grid lines of the Rojas type universal astrolabe, *Ganpyongeui* in Korean, can be obtained by an orthographic projection, whose center of projection is at infinity outside the equinox of the celestial sphere. By analogy, it can be said that *Ganpyongilgui* is a Rojas type sundial since its grid lines were also drawn by orthographic projection. The center of projection of this sundial was located at infinity outside the zenith of Seoul. As the center of projection was moved from infinity outside the equinox to that of local zenith, the straight season lines of the astrolabe *Ganpyongeui* were transformed to parallel ellipses of the sundial *Ganpyongilgui* because the inclined circles were projected orthographically.

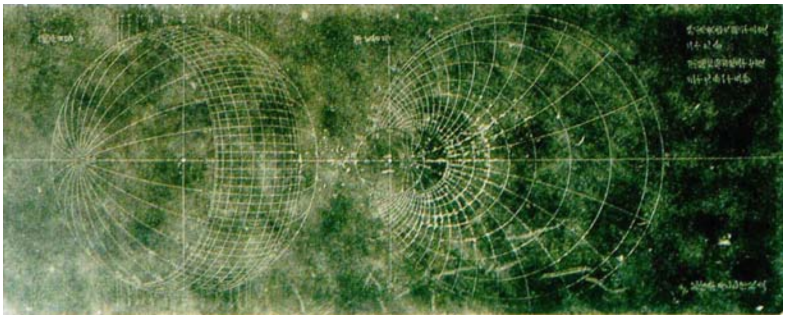
The name of the other sundial was *Hongaeilgui*. Its origin can be traced from the name *Hongaetongheon*, the planispheric astrolabe. The ecliptic on the rete and the lines on the plate of a planispheric astrolabe are obtained by stereographic projection from the south celestial pole. The same rule of projection was followed to get the star chart of a celestial planisphere. Moreover, the season and hour lines of *Hongaeilgui* were also drawn by stereographic projection.

The way to get the grid lines for *Hongaeilgui* is sketched briefly in Fig. 10. Unlike having the center of projection at infinity as in an orthographic projection, the center of the stereographic projection remains on the surface of the celestial sphere. Whenever curves on a sphere are mapped onto a flat surface, there are two characteristic features of the stereographic projection. One is the preservation of the circle and the other the rule of conforming. Every circle on the sphere maps onto a plane as a circle by the rule of preserving the circle. And, according to conforming, two circles that intersect at a certain angle will intersect at the same angle on the mapped surface.

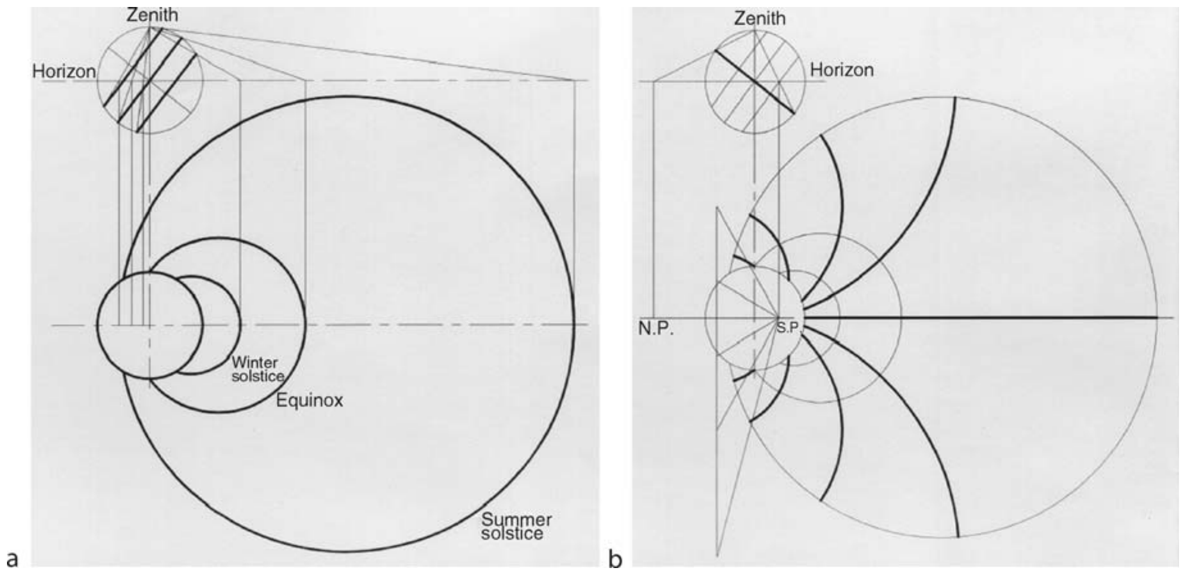
The sun is traced for the Korean planispheric sundial, *Hongaeilgui*. The altitudinal and azimuthal data are cast as shadows of the gnomon onto the surface of the sun tracker. Season and hour lines were constructed as grids on the sundial. By shifting the center of projection to the local zenith, the horizontal coordinates of the sphere were transformed to the polar coordinates. The equatorial coordinates were mapped to the sundial as the bipolar coordinates of the season and hour lines as shown in Fig. 10. The direction of the shadow directly gives an azimuthal coordinate and its length; the altitude of the sun yields a radial coordinate through a simple transformation:

$$\frac{r}{R} = \tan\left(\frac{90^\circ + \beta}{2}\right) = \frac{1+\sin\beta}{\cos\beta} = \frac{1}{a} + \sqrt{1+\frac{1}{a^2}}$$

where r is the radial coordinate, R is the radius of the base circle representing horizon, β is the altitude of the sun, and a is the length of the shadow when the height of the gnomon equals unity. With the polar



Astronomical Instruments in Korea. Fig. 9 *Ganpyongilgui* (left) and *Hongaeilgui* (right).



Astronomical Instruments in Korea. Fig. 10 Stereographic projection of *Hongaeilgui*; (a) season lines, and (b) hour lines.

coordinates of the shadow in hand, the point that specifies the current date and hour would be located from the bipolar coordinates.

This Korean horizontal sundial is more of a graphical calculator than a mere time indicator. Most problems concerning the position of the sun throughout a year could be answered straightforwardly without any further calculation. While keeping the geometric characteristics and drawing procedure unchanged, the well-established astrolabe was completely modified by a Korean expert to an extraordinary sundial.

Astronomical Monuments in Polynesia and Micronesia

César Esteban

The pre-European inhabitants of the Pacific islands were skillful and frequent inter-island navigators. The most accurate directional indicators used by the Polynesian and Micronesian islanders – still used today in several parts of Oceania – were the rising and setting positions of stars (Grimble 1931; Goodenough 1953; Akerblom 1968; Gladwin 1970; Lewis 1994). The measurement of stellar positions and their movement over the celestial sphere was an important task for the ancient seafarers. In fact, astronomy was treated as a branch of navigation by the ancient Tongans (Collocott 1922) and, as the Jesuit priest Fr. Cantova reported from castaways from Woleai (Caroline Islands) at Guam in 1721, "The only thing they learn are some vague principles of astronomy to which most apply themselves due to its usefulness in navigation" (Lewis 1994: 112). The navigators defined the sailing directions by the use of "star compasses", which divide the horizon into a number of parts identified by the rising and setting positions of the stars. There is ample evidence of the use of a 32-direction "star compass" by the ancient and contemporary navigators of the Caroline Islands (Goodenough 1953: 5–24; Gladwin 1970: 147–165; Lewis 1994: 102–111). The references for the use of a "star compass" in Polynesia are ancient and scarce. The most detailed one is by Andía y Varela, who led a Spanish expedition to Tahiti in 1774 (Corney 1914, 2: 284–285; Lewis 1994: 84).

There are few ethnohistoric references about systematic observation of the Sun or Sun worshiping in Polynesia. For example, Behrens, in 1737, says that in the early morning, Easter Island inhabitants "had prostrated themselves towards the rising sun and had kindled some hundreds of fires which probably betokened a morning oblation to their gods" (Behrens 1908: 133). There are some vague indications of solstitial observation in pre-European Pukapuka and New Zealand (Beaglehole and Beaglehole 1938: 349; Makemson 1941: 85–86) and more explicit ones in Hawai'i (see Kirch 2004a, and references therein). However, the most clear evidence of Sun observations is in Mangareva (Gambier Islands), where Buck (1938: 414–415) indicates that "two stones were set up to form sights" to determine the solstices exactly.

There are several ethnological studies about Polynesian names of stars, constellations, and the calendar, the most important compilations being those by Makemson (1941) and Johnson and Mahelona (1975). In a recent synthesis of historical anthropology, Kirch and Green (2001: 260–276) have reconstructed essential aspects of ancient Polynesian time reckoning and ritual cycle. They describe:

1. An annual seasonal cycle divided in two parts originally based on a wet–dry seasonality and the yam cultivation cycle;
2. A sidereal cycle based on the observation of the heliacal and acronychal rising of the Pleiades (named Mataliki in Proto-Polynesian);
3. An agricultural annual lunar calendar of 13 months; and
4. A system of intercalation for keeping the synchronization between the lunar calendar and solar year. This system was based on the observation of Pleiades risings but, in some cases, at least in Mangareva and Hawai'i, also on solar observations at solstices.

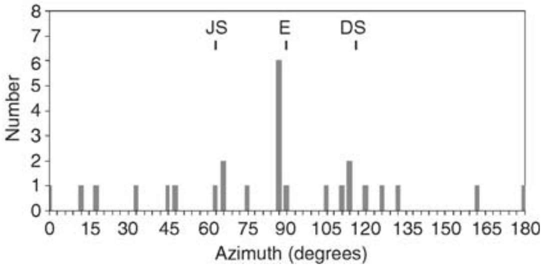
It is surprising that there have been rather few attempts to correlate the ethnographic material about celestial lore and the alignments of the ubiquitous ceremonial stone structures across the whole Pacific area.

There are few archaeoastronomical studies in Polynesia and they are not systematic except for Easter Island and – in recent years – Hawai'i. In the case of Micronesia, the situation is even worse. As far as I know, there has been no archaeoastronomical fieldwork on orientations of prehistoric Micronesian stone monuments. In the following, I will review the main results of different research works in the Pacific area. Not all the islands groups are included because an important number of them are lacking any kind of archaeoastronomical study.

Ferdon (1961) made the first report of astronomical alignments in Polynesia as part of the investigations of the Norwegian Archaeological Expedition to Easter Island in 1955–1956. This author proposed that a group of cup-marked boulders (the so-called Sun stones) at the village of Orongo was oriented astronomically; however a reanalysis made by Lee and Liller (1987) has shown that such claims can be discounted. The archaeologist Mulloy (1975) discovered the unusual orientation of one of the scarce inland *moai* platforms (the moai are the large imposing Easter Island statues): Huri A Urenga, which faces the point where the Sun rises at the June solstice. Liller and Duarte (1986) performed an excellent analysis of the orientations located at this monument, reinforcing the astronomical interest of the site and finding other possible astronomical orientations. Mulloy (1961) and Smith (1961) also reported possible solar alignments in other coastal *moai* platforms of Easter Island, such as those of Vinapu 1 and 2 (December solstice sunrise and equinox sunrise, respectively) and Tepeu (December solstice sunrise).

Liller (1989) has made a systematic study of orientations defined by several hundred *ahu*[1] and *moai* platforms on Easter Island, finding that there is marginal evidence of alignments related to the solstices or equinoxes. He finds a definite trend among coastal *ahu* being oriented parallel to the coast (approximately 90%), with the sculptures or *moai* facing out to sea. Considering the *ahu* with long sides non-parallel to the shoreline (a sample of 26 *ahu*) there is an overwhelming tendency for these monuments to be oriented in the direction of the equinox rising points and an extra one or two *ahu* aligned in the direction of the solstice rising points (Fig. 1). Regarding the inland platforms, Liller finds there is a weak tendency to have the *moai* look in the direction of the rising of the Sun at the June solstice, and Huri A Urenga stands out as the most remarkable case. Very recently, Edwards and Belmonte (2004), considering the outstanding ethnographic importance of Matariki (the Pleiades star cluster see, for example, Van Tilburg 1994: 100–103) and Tautoru (Orion's Belt) as markers of ceremonies and agricultural

[1] An *ahu* is a raised platform inside a temple.

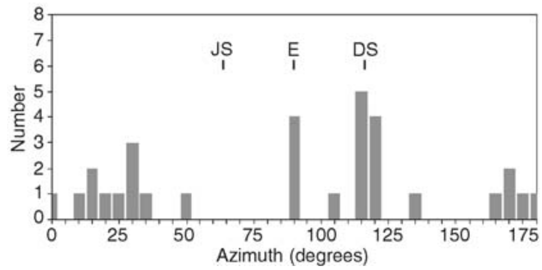


Astronomical Monuments in Polynesia and Micronesia. Fig. 1 Number histogram of the orientations of the perpendicular to the long side of 26 *ahu* within 500 m of the coast and with long axes skewed by more than 20° to the adjacent shoreline of Easter Island measured by Liller (2000b). Data are binned in 3° interval. JS, E, and DS indicate the azimuths of the rising sun at June solstice, the equinoxes, and December solstice, respectively. Note the overwhelming tendency of east–west orientations. Diagram adapted from Liller (2000b).

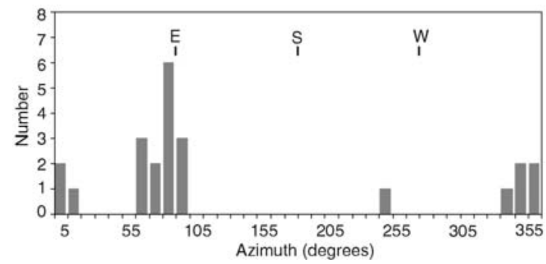
activities in the traditional calendar of Easter Island and the absence of solar references or cults, propose that the aforementioned solstitial and equinoctial alignments of the *ahu* platforms could be interpreted as being instead alignments to the Pleiades and Orion's Belt risings or settings. The declination of those asterisms are incidentally very similar to those of the Sun at the June solstice (Pleiades) and to the Sun at the equinoxes (Orion's Belt).

Since the pioneering studies of the Hawaiian stone temples (*heiau*) by Stokes in 1906–1909 (published in 1991: Stokes 1991), Emory (1924) and Bennett (1931) it has been usually considered that the orientation of the *heiau* was determined by the local topography and environmental considerations, commonly facing the sea or valley. Moreover, as Kirch (2004a) has pointed out, the rich Hawaiian ethnohistory is largely silent about *heiau* orientations. Only the native Hawaiian scholar Malo (1951) indicates that the cardinal directions could have been important for the positioning of the audiences in the *heiau* during the ceremonies. Chauvin (2000) defends the low probability of premeditated solar alignments in the stone temples considering that neither solstices nor equinoxes played any role in the Hawaiian calendar or in religious practices. On the other hand, Kirch (2004a) indicates that the major Hawaiian deities were associated with particular directions and seasonal orientations on the basis of what is known of traditional Hawaiian theology. This assertion suggests that the finding of astronomical alignments in temple platforms may not be disregarded. On the other hand, Ruggles (2001) is also optimistic, at least in the possibility of some symbolic celestial connections in the *heiau* taking into account the large number of names of stars and other celestial objects in the traditional Hawaiian names for places in the landscape. Ethnographical data give evidences of solar observations among the ancient Hawaiians. For instance, Kamakau (1976: 13–14) indicates the existence of persons who observe the stars and a class of priests who advised concerning building and locating temples who were skilled in reckoning the months of the year and following the Sun movement. He (1976: 14) also describes solar observation from the island of Kaua'i based on the rising or setting of the Sun over relevant topographic features of the horizon in particular moments of the year.

Rubellite Johnson carried out the first archaeoastronomical studies in Hawai'i in the 1980s. Da Silva and Johnson (1982) first suggested a possible "astronomical-directional register" in the Ahu a 'Umi Heiau, a platform located on the island of Hawai'i, the highest and the farthest inland heiau of the Hawaiian archipelago. Johnson (1993) also studied the small island of Kaho'olawe, where oral tradition suggested that it had once been a place of important astronomical and navigational activity. Meech and Warther (1996) have made an interpretation of some *hula* or sacred chants of the Hawaiians in terms of astronomical alignments that can be found in the archipelago, specially related to the solstices. However, reassessments based on more precise measurements have shown that the alignments claimed by those authors are not sufficiently precise in most cases (Ruggles 1999). Moreover, the results obtained by Ruggles seem to indicate an interest in solar zenith passage as much as and perhaps more than in the solstices. In a subsequent paper, Ruggles (2001) presents a systematic study in Kaua'i trying to correlate ritual and sky traditions with the architectural alignments of a large sample of *heiau*, a promising new approach in Polynesia where many traditions are still alive or collected in the rich ethnological legacy. In this last study, Ruggles finds no consistent patterns with regard either to orientation upon topographic features or to orientation upon celestial objects, although some intriguing relationships are found in some particular sites. However, other works have been successful in finding rather clear astronomical orientations in ancient Hawaiian temples. Liller (2000a) has studied the orientations of 32 stone temples in the tiny Necker Island. This island has two relevant particularities: (a) it has an astonishingly large number of temples considering the small size of the island; (b) the island center is located almost exactly at the latitude of the Tropic of Cancer in the year AD 1000. This last particularity implies that the ancient inhabitants of Necker would have realized that the Sun was directly at their zenith at midday of the June solstice. In fact, Liller has found that nine of the 32 temples of Necker are aligned with the setting June solstice and/or the rising December solstice (Fig. 2). Finally, Kirch (2004a) has



Astronomical Monuments in Polynesia and Micronesia. Fig. 2 Number histogram of the orientations of the perpendicular to the back side of 32 *stone temples* of Necker Island (Hawai'i Archipelago) measured by Liller (2000a). Data are binned in 5° intervals. JS, E, and DS indicate the azimuths of the rising sun at June solstice, the equinoxes, and December solstice, respectively. Note that the *temples* show two preferred orientations: one east–west and the other around the December solstice sunrise. Diagram adapted from Liller (2000a).



Astronomical Monuments in Polynesia and Micronesia. Fig. 3 Number histogram of the orientations of 23 *heiau* at Kahikinui (Maui Island, Hawai'i Archipelago) measured by Kirch (2004a). Data are binned in 10° intervals. The position of the cardinal points is indicated by letters. The data show three clear concentrations: one facing the east, another facing east–north–east, and a third one facing north, Kirch (2004a) believes these orientations were deliberate and likely related to a particular god of the Hawaiian pantheon.

performed an analysis of the orientations of a sample of 23 *heiau* of Kahikinui (Maui Island). This author has found that temple foundations tended to have three preferred orientations: east, east–north–east, and north (Fig. 3). Kirch has correlated these results with ethnohistoric and ethnographic data proposing that:

a. The east orientations may be associated with god Kane, because this deity was associated with the Sun and the east direction;
b. The east–north–east cluster of orientations may be related to either the summer solstice sunrise or the rising of the Pleiades. In fact the acronychal rising of this asterism determined the onset of the Makahiki season and the new year, this group of temples may be dedicated to the god Lono, who was linked to the annual rising of the Pleiades;
c. The temples oriented to the north face the summit of the high mountain Halekeala ("House of the Sun") and may be dedicated to Ku, a deity linked to high mountains, the sky, and to forest.

Archaeoastronomical studies in islands of Eastern Polynesia, apart from the aforementioned ones for Easter Island and the Hawai'ian archipelago, are very scarce and recent. Liller (1993) presents an analysis of orientation data (obtained from direct measurements by the author and from good quality topographical maps) of over 50 ceremonial stone platforms in various archipelagos of Polynesia (Society Islands, Hawaiian Islands, Rarotonga, and the Trilithon of Tonga) finding no clear astronomical trends except perhaps in some isolated cases. In a subsequent paper, Liller (2000b) gives an excellent review of archaeoastronomical fieldwork carried out in Polynesia and presents some new results based on the reanalysis of large sets of published plans from the literature and some other new data obtained by the author. Concerning the archipelagos of Eastern Polynesia, Liller presents histograms of orientations of temples belonging to the Tuamotus (52 temples) and the Society Islands (105 temples) as well as some preliminary and sparse data of Mangareva, the Cook Islands, and the Australs. The general conclusion of that paper is that the orientation of the Polynesian ceremonial platforms was controlled by the physical situation. Most of the monuments are located on the shore and lie parallel or perpendicular to the immediate shoreline. Astronomical alignments are present only in some isolated cases. The remarkable *mara'e*[2] Tapu-tapu-a-tea, possibly one of the most important in all Polynesia, located on Rai'atea (Society Islands) has its long inland-facing wall oriented to an azimuth of $6^\circ 3'$. Liller (2000b) suggests that the perpendicular to the wall may be oriented to the rising point of the southern portion of the constellation of Orion: perhaps Orion's Belt or Rigel. Other important *marae* of the Society Islands, such as those of Tainu'u (Rai'atea), Matairea-rahi and Anini (Huahine), Marotetina (Borabora), Mahaiatea (Tahiti), and Tetii (Mo'orea), are also oriented to within a few degrees of that of Tapu-tapu-a-tea (Liller 2000b). This finding could be relevant in the context of the ethnohistorical accounts of Henry (1928: 363) who writes the following concerning the birth of heavenly bodies in ancient Tahitian tradition: "the chiefs of the skies… were royal personages… from the period of darkness, and they each had a star. They bore the names of those stars, and those names have been perpetuated in their

[2] *Mara'e* (also spelled *mala'e* or *maa'e*) are stone or coral slab temples.

Astronomical Monuments in Polynesia and Micronesia. Fig. 4 *Left*: The Ha'amonga-a-Maui trilithon seen from the south (Heketa, Tongatapu Island, Kingdom of Tonga). This is a unique monument in Polynesia that stands about 5 m tall. *Right*: View of the eastern horizon as seen from the lintel of the trilithon. The position of the rising points of the Sun at solstices and equinoxes has been cleared of vegetation by the Tongan authorities. The lintel is aligned approximately along the December solstice. The current Tongan monarch, King Taufa'ahau Tupou IV, discovered this alignment. Images taken from Esteban (2002–2003). Reproduced with permission of University of Texas Press.

temples in this world." This account suggests that the finding of stellar alignments in the *mara'e* cannot be considered strange (Kelley and Milone 2005: 347). On the other hand, unpublished archaeological surveys of *mara'e* in the Faaroa Valley (Rai'atea) and Matairea Hill (Huahine) carried out by Edmundo Edwards indicate that a fraction between 20% and 30% of the monuments show solstice orientations, although Liller (2000b) considers that Edward's results, at least for Huahine, are only circumstantial.

As in the case of the aforementioned Necker Island in the Northern Hemisphere, there are several islands of Eastern Polynesia located close to – in this case – the Tropic of Capricorn. Tubua'i (Australs) was located only 23 km north of this tropic in AD 1000 (Liller 2000a). Vérin (1969) found that four out of six mara'e reported on this island show alignment with the December solstice sunset. However, Edwards (2003) indicates that those presumed orientations could be only accidental considering that the nearby shoreline has precisely the same orientation. This last author reports a survey of 92 *mara'e* on Ra'ivavae (Australs), an island also very close to the Tropic of Capricorn, finding that about 14% of the monuments are astronomically oriented. In particular, the large *mara'e* Unuaru (whose walls are not parallel to the shoreline), as well as other mara'e of Ra'ivavae, are oriented very close to the true north.

The Mangareva Islands (also known as Gambier Islands) are the only case in Polynesia where there is unequivocal ethnohistoric evidence for systematic solar observations. The account of the priest Honoré Laval provides a description of traditional Mangarevan time reckoning and the methods of solar observations at solstices and the places where they were performed (Laval 1938: 213–215). Peter Buck (1938) gives another detailed ethnographic account about these activities. Here are some relevant astronomical information (see Kirch 2004b):

a. Solstice observations were used to keep the lunations in sequence with the solar year and to divide the year into two seasons;
b. The locations for solstitial observations are given. The observatory at Atituiti, named Te Rua Ra (the pit of the Sun), is said to be the "most favorable position" for this purpose;
c. In at least one site, upright stones are used to mark the rising Sun at December solstice, and the backsight was a big flat stone;
d. The observation of solar risings and settings on distant topographic markers were used to achieve precision;
e. The movement of a shadow cast by a certain mountain was also used as a solstitial marker.

Kirch (2004b) has rediscovered the precise site of the Atituiti observatory, finding an uncommon platform oriented along the cardinal directions and the central flat boulder where observations were performed. That author has been able to confirm the most important aspects of the ethnohistoric records. For example, the position of the December solstice sunset coincides with the western edge of the high cliff Ana Tetea (the burial place of two renowned high chiefs of Mangareva) on Agakauitai Island; the shadow of Auorotini (Mount Duff) is also cast onto the central flat boulder during the June solstice.

In the Kingdom of Tonga we have a remarkable and unique monument in Polynesia: the Ha'amonga-a-Maui (Burden of Maui) trilithon,[3] which according to tradition, was built in AD 1200 (see Fig. 4). In 1967, the current monarch, King Taufa'ahau Tupou IV, discovered that the lintel is aligned along the sunrise at December solstice; this was later confirmed by Liller

[3] A trilithon is a structure consisting of two large vertical stones supporting a third stone set horizontally across the top.

(1993) and Esteban (2002–2003). According to Collocott (1922), “the Tongan year is said to have begun at about the same time as the Christian year” and this fact would indicate a possible calendrical importance of the December solstice. As has been commented before, Makemson (1941) and other authors state that in most of the Polynesian archipelagos (including Tonga), the new year began in late November or early December with the first Moon after the acronychal rising of the Pleiades. These dates are not far off but obviously do not coincide with the December solstice. In any case, as Esteban (2002–2003) has suggested, the solstitial orientation of the trilithon may be accidental because its axis is roughly parallel to other related archaeological structures and to the nearby shoreline. Some controversy was raised by the presence of an enigmatic zigzag figure carved into the top of the lintel of the trilithon whose axes point roughly to the two rising solstice directions. However, Dhyne (1994) argues that there are reasons to believe that the marks were made relatively recently.

The most common archaeological features of Tonga are round or rectangular mounds of earth with considerable size range. These mounds can be house platforms, burial mounds, *esi* mounds (resting places for members of the chief’s family), and mounds for pigeon snaring (McKern 1929). The *esi* and pigeon mounds are usually situated upon natural rises that command a splendid view of the surrounding countryside. The anthropologist Wragge (see Liller 2000b; McKern 1929: 17) reported that the *esi* platform called Makahokovalu in Uiha Island (Ha’apai group) was a religious site connected with ancient Sun worshipping. However, McKern (1929: 17) and Gifford (1924: 68) failed to find any archaeological or ethnological evidence of Sun worship in the island. Liller (2000b) reports that in McKern’s plan of Makahokovalu the long axis is oriented at an azimuth of 2° (perpendicular 92°) suggesting some solar relation, but this is also the orientation of the nearby shoreline. Esteban (2002–2003) has estimated the approximate orientation of the ramps of the mounds from the plans published by McKern finding no clear trends.

Since the burial mounds of Tongan commoners are just earth mounds, the sites relating to the chief and royal family have stone facing and are often loosely called *langi*. The *langi* are large rectangular monuments with stone slab retaining walls, generally consisting of a number of terraces in the manner of truncated pyramids. One of Collocott’s (1922) informants suggested a connection between the skies and the great burials at Mu’a (Tongatapu Island) and elsewhere, and it is worthy of note that sky and vault are called by the same name: *langi*. In a detailed study of the largest collection of *langi* at Mu’a, Esteban (2002–2003) finds that the general disposition of the tombs is parallel to the shoreline, although much less probable stellar orientations related to sailing directions are also discussed by that author.

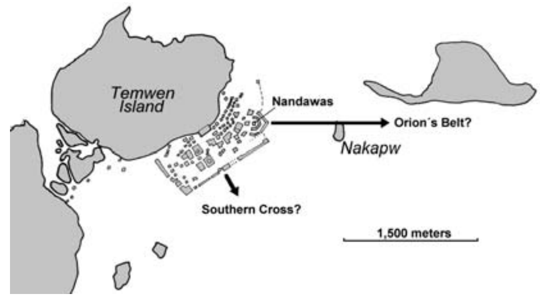
Bellwood (1978) reports that Samoan ethnographic records indicate the existence of open spaces for ceremonies (*mala’e*) as well as god-houses. Scattered among Samoan settlements are the so-called star mounds. They are large, raised platforms with several rounded projections extending from the central area and built with a loose rubble of basaltic stones. The interpretation of star mounds has been controversial. Modern informants tend to view them as pigeon-snaring mounds. No evidence of use for habitation or burial was found. The mounds were perhaps also used for religious purposes, as some ethnological references have pointed out (Davidson 1979) and also for some divination rituals, as it is indicated in the information panels of the Tia Seu Lupe (literally “earthen mound to catch pigeons”) star mound in Tutuila Island (American Samoa). Esteban (2002–2003) considers it impossible to define useful alignments in these kinds of mounds taking into account their common irregular shape and large number of rounded irregular projections.

The island of Sava’i (Independent Samoa) has what is quite probably the largest surviving prehistoric monument in Polynesia, the Pulemelei stone mound. It is a huge flat-topped and roughly rectangular structure that covers 60 by 50 m at the base and is 12 m high. There are slightly sunken ramps to the top on the eastern and western slopes. It was most probably an important ceremonial center. It is located inside a coconut tree plantation, almost completely overgrown, being very difficult to make any precise measurement of the walls or the horizon. However, Talbot and Swaney (1998: 141) and Esteban (2002–2003) agree that the mound is roughly squarely oriented with the cardinal points. In any case, the monument needs to be cleared of vegetation before one can obtain precise bearings of its massive walls and a desirable analysis of the astronomical horizon.

The largest island of the Republic of Palau (in Micronesia) is Babeldaob. From the astronomical point of view, the most interesting prehistoric remains known in Palau are the unique sculpted stone faces at Melekeok, on the eastern coast of Babeldaob. They are nine stones ranging from 1 to 2.5 m in height and arranged very precisely in two rows parallel to the nearby shoreline. All the surviving stones are facing the sea. Morgan (1988: 14–15) collected the following legend concerning the origin of these stones: Odalmelech, the god of Ngermelech Village in Melekeok, “and his councilmen set out to lay a huge stone work over the village ground. That night, they started bringing in huge reef stones for the project, but the work was only partially completed when dawn approached. Odalmelech, seeing that his cohorts could not accomplish the project before daylight, called his crew together and told them of the shame of being caught working in the morning sun. So he ordered his crew to carve all their faces on the monoliths and place them to eternally face the rising sun." This story indicates the possible astronomical motivation of the site. Esteban (2002–2003) finds that the orientation of the faces may be close to the June solstice rising based on the site plan published by Morgan (1988: 13). Direct measurements and additional ethnographic data on the site are necessary to check this suggestive finding.

Nan Madol, in Pohnpei Island (Federated States of Micronesia) is the largest archaeological site in Micronesia and perhaps of all the Pacific Islands. It consists of 92 human-made rectangular islets separated by many waterways. The islets are generally surrounded by retaining walls of long, naturally prismatic basalt which are often built up over foundations of immense basalt boulders. The site was constructed on a reef located in the southeast side of Pohnpei which is called Sounahleng or "Reef of Heaven." All the islets have proper names, and some of them have names related to the sky or stars (Morgan 1998: 66–67). Nan Madol is divided into two areas. The northeast area is Madol Powe, the mortuary zone where the priests dwelled. The southwest area is Madol Pah, the administrative sector, where royal dwellings and ceremonial areas were located.

Most of the islets, and specially those of Madol Pah, are oriented relative to a well-defined northeast-to-southwest axis. Nandauwas, the royal mortuary islet in Madol Powe, which is located on the eastern edge of the whole complex, is the most magnificent example of prehistoric architecture in all of Micronesia. It is interesting to note that Nandauwas and its immediate neighbors are the only islets in Nan Madol which are not oriented along the general northeast-to-southwest axis but along a due east–west axis. Esteban (2002–2003) has made a rough preliminary archaeoastronomical analysis of the main axes of the complex (Fig. 5) based on the 1981 US Geological Survey map (1:10,000) of the zone and the detailed plan of the site published by Morgan (1988: 66–67). The perpendicular to the general northeast-to-southwest axis of most of the islets is facing toward the center of the Southern Cross at the dates of use of the site. On the other hand, the perpendicular to the sea-facing wall of Nandauwas points almost exactly due east, perhaps to the equinoxes or to Orion's Belt. From the works by Goodenough (1953: 5–24) and Gladwin (1970: 148–160), we see that the Southern Cross and Orion's Belt are among the most important asterisms for contemporary navigators of the Caroline Islands because they define the directions of south and due east of their star "compass" (see Lewis 1994: 103). It is worth noting that the orientation of monumental tombs



Astronomical Monuments in Polynesia and Micronesia. A possible astronomical interpretation (Esteban 2002–2003) of the orientations of the main axes of the complex is indicated. Figure taken from Esteban (2002–2003). Reproduced with permission of University of Texas Press.

of other important megalithic sites of Pohnpei seem to be also oriented toward the east, as those of Sapwtakai (see the plan published by Morgan 1988: 83) and Panpei West (see map in Rainbird 2004: 192). It would be very interesting to carry out precise archaeoastronomical fieldwork on Nan Madol (and other megalithic sites at Pohnpei and Kosrae islands) to check if these preliminary findings on the map are correct and explore further the promising astronomical potential of this remarkable site.

Astronomy

Roger B. Culver

Astronomy, the study of celestial objects, is a universally human endeavor whose roots lie deeply buried in prehistory. For the sky-watcher devoid of optical aid, the heavens can be thought of as a sort of earth-centered celestial sphere on to which have been sprinkled hundreds of tiny points of light we have called the stars. Half of this inverted bowl of blackness is almost completely dominated by the dazzling presence of the sun, the most prominent and important of the celestial objects. Such is the sun's brilliance that any attempt to view this object directly is to risk serious eye damage or even total blindness. As a result of the earth's spinning motion or rotation, an observer at a given location on the earth sees a sky that alternates between a daytime sky dominated by the sun and a nighttime sky characterized by its absence. As the earth turns on its axis, the sun appears to rise up from a given observer's eastern horizon, pass through a "high noon point" or maximum angle above the horizon, and then descend toward the western horizon. Approximately one half an earth rotation later, the sun once more rises to repeat the cycle. This rising and falling effect is not limited to the sun. As the earth rotates relative to all celestial objects, they too appear to go through the rising and falling diurnal motions of the sun. Since the rate of the earth's rotation is very nearly constant, this diurnal motion of the sun and stars has long been employed as an important and reliable way of measuring time. The earth's rotation also creates the illusion that the stars of the celestial sphere seem to revolve about two imaginary points located exactly opposite each other. One, the south celestial pole, is visible only from the southern hemisphere of the earth, while the other, the north celestial pole, is visible only from the northern hemisphere. The earth's long-term precessional motion carries the locations of these celestial poles along a 47° diameter circular path among the stars once every 26,000 years. From time to time, a relatively bright star can be found near the position of one of the celestial poles for a few centuries. Such is the case at present for the north celestial pole, which is currently located near the fairly bright star Polaris, the Pole Star.

In addition to its daily rising and setting, the sun also appears to travel along a great circle on the celestial sphere, which is called the ecliptic. This latter movement is the direct result of the earth's orbital motion about the sun. As the earth arcs along in its orbital path, the apparent position of the sun relative to the more distant background stars appears to change. For an observer on the earth, the sun thus seems to creep gradually from west to east among the stars, completing an entire 360° journey around the ecliptic in exactly the same 1 year time interval it takes the earth to complete one orbital revolution about the sun. The background stars hence appear to be gradually overtaken in the western sky by the sun as it moves eastward along the ecliptic, engulfed by the solar glare for a month or so, and then reemerge in the predawn sky as the sun leaves them behind in its ongoing easterly movement. The overall result of this annual movement of the sun is a seasonal parade of the heavens in which different stars are visible at different times of the night at different times of the year.

The earth's axis of rotation is also found to be tilted at an angle of 23 1/2 degrees off the vertical to the earth's orbital plane. As the earth orbits the sun, this tilt causes the sun to shine alternately more directly on the northern hemisphere and less on the southern hemisphere and then vice versa over the span of a simple year. This effect is observable as a yearly variation of the sun's highest altitude above the horizon at a given location, and as a change in the time that the sun spends above the horizon. Thus when the sun is shining most directly on the northern hemisphere at the time of the summer solstice, the sun's diurnal motion in the northern hemisphere is characterized by long days and short nights, and in the southern hemisphere by short days and long nights. Half an orbital revolution or 6 months later at the time of the winter solstice, when the sun is shining more directly on the southern hemisphere, the lengths of night and day are reversed. Halfway between these extremes the sun shines directly down on the earth's equator twice each year. On these dates, the lengths of the days and nights all over the earth are equal, except at the poles, and hence these dates are said to be the equinoxes. It is this combination of the tilt of the earth's axis of rotation and the earth's orbital motion that gives rise to our cycle of seasons here on the earth.

Firmly entrenched in second place in the brightness hierarchy of celestial objects is the moon. Although not as important as the sun, the moon, none the less, exerts several significant influences on the earth, most notably as the chief agent by which tides are produced in the world's oceans. The reflected sunlight we receive from the moon is over one million times fainter than that emanating from the sun, and as a result, the moon can be readily viewed against the backdrop of the stars of the night sky. As the moon orbits the earth in space, it appears to traverse a great circle about the celestial sphere in a fashion not unlike the annual motion displayed by the sun. There are however some important differences between the lunar motion and that of the sun. The moon swings along an apparent path that is tilted at an angle of about five degrees to the ecliptic and takes one-twelfth of the sun's time to make a single journey about the celestial sphere. The moon thus moves at an average rate of about half a degree per hour relative to the background stars, an angular speed easily detectable over the course of a single night by a naked eye observer.

Although the moon's half degree angular diameter is almost exactly the same as that of the sun, the diminished brightness of the moon permits us to look directly upon its face without fear or danger. As a result, the moon presents a number of most interesting and fascinating phenomena to the naked eye observer. Perhaps the most familiar of these is the set of seeming shape changes or phases exhibited by the moon as it journeys about the celestial sphere. These phases arise from the fact that as the moon orbits the earth, the half of the moon's spherical surface which faces the sun, and is hence illuminated by the sun's light, is viewed at different angles by an observer situated on the earth. When the moon is very nearly lined up between the earth and the sun, almost all of the moon's sunlit hemisphere faces away from the earth, and all we see of the moon is a very thin crescent of light. As the moon moves toward progressively larger angular distances from the sun, the thickness of the crescent grows or waxes until the angle between the moon and the sun as seen from the earth is 90°. At this point we see exactly one half of the moon's sunlit surface and the moon appears to have a semicircular or "quarter-moon" shape. As the sun–moon angular separation increases past 90°, the moon takes on a bulging or gibbous shape whose thickness continues to grow until the moon is very nearly opposite the sun in the sky. When this configuration occurs, the entire sunlit hemisphere of the moon faces the earth, and the now circular-shaped moon is said to be a "full" moon. After passing through the full phase, the moon's shape changes now proceed in reverse order, successively passing through waning gibbous phases, a second or last quarter phase, and finally a waning crescent phase as the angle between the moon and the sun decreases from 180° to nearly zero. The waning crescent moon eventually slides into the predawn solar glare for a few days and then reemerges as a silvery crescent-shaped "new" moon in the postsunset twilight.

The moon is also unique among celestial objects in that it is the only one for which surface detail can be easily viewed with the unaided human eye. This detail manifests itself in the form of the dark areas on the moon's disk which are called maria or seas and the light areas called continents. This terminology dates back to the Western European Renaissance observers of the moon who imagined the lunar surface to be divided between bright land and dark waters.

In addition to the sun and moon, human beings have recognized since prehistoric times that five other naked eye objects also move about the sky relative to the back-ground stars. These star-like wanderers are called planets, and historically have enjoyed the appellations of the gods and goddesses of ancient Greek and Roman mythology. The five so-called naked eye planets have been named, in order of their increasing distance from the Sun, Mercury, Venus, Mars, Jupiter, and Saturn. A sixth planet, Uranus, possesses a brightness which is just at the limit of naked eye visibility, but the planetary nature of this object does not seem to have been recognized until the English astronomer William Hershel accidentally stumbled upon it in 1781.

Two of the planets, Mercury and Venus, have orbits about the sun which are interior to that of the earth. As a result of this orbital geometry and the sun's gravitationally induced faster orbital speeds, these planets exhibit a marked pattern in their appearances in the earth's sky. In a typical cycle, the planet is first visible as an evening "star" in the west after sunset, then appears to move out to a maximum angle of greatest elongation away from the sun before retreating back into the sun's light. After several days or weeks, the planet reemerges from the solar glare, but this time as a morning "star" in the predawn sky. The planet once more moves out to an angle of greatest elongation and then drops back into the solar light. The swiftly moving planet Mercury goes through a complete cycle of appearances or synodic period in about four months, while Venus, whose orbital speed is more closely matched to that of the earth, takes a year and a half for its cycle of appearances. Typically Mercury's appearances as a morning or evening star last about three weeks, while those of Venus extend over several months at a time.

Visually, the plant Mercury appears in the sky as a sparkling object having a somewhat reddish-orange tint. Its apparent brightness is actually comparable to the brightest stars, but because it is almost always observed in twilight, it is usually not as impressive an object as it otherwise might be. The most spectacular of the naked eye planets and the third brightest object in the sky behind only the sun and moon is the planet Venus. The orbital path of Venus can carry it out to an angle of greatest elongation as large as 47°, or about twice that exhibited by the planet Mercury. Thus it is possible to observe this splendid object for as long as 4 h after sunset or before sunrise. At its greatest brilliancy, the soft white light of Venus has even been observed to cast very faint shadows as it gleams in the darkness of the predawn or postsunset night sky.

The three remaining naked eye planets Mars, Jupiter, and Saturn, move in vast orbits about the sun which are exterior to the orbit of the earth. As a result, these planets appear most of the time to move about the celestial sphere in a fashion similar to the west to east movement exhibited by the sun and moon. The times required for each of these planets to make a complete cycle about the celestial sphere, however, are far longer than those for the sun and moon. Mars, for example, completes a single journey around the celestial sphere in just under 2 years, while Jupiter and Saturn require nearly 12 and 30 years, respectively, to complete similar journeys. As the faster moving earth catches up to and passes one of these exterior planets, the planet exhibits an illusionary phenomenon in the earth's sky called retrograde motion in which the given planet seems to stop its normal west to east motion among the stars, moves "backward" or east to west for several months, stops again, and then resumes its direct or west to east movement. In the midst of its retrograde motion, a given planet will appear to be opposite the sun's position in the celestial sphere as sun from earth. When such a configuration occurs, the planet is said to be "in opposition to the sun," or more simply, "at opposition." At the time of a given planet's opposition, the earth makes its closest approach to the planet, and as a result, the planet shines more brightly than at any other time. Moreover, at opposition the planet rises at sunset, sets at sunrise, and is thus visible throughout the night.

Visually, the planet Mars is perhaps the most remarkable of the exterior planets owing to its distinctly reddish hue. At times of closest approach to the earth, the apparent brightness of this ruddy world is exceeded only by that of the sun, Moon, and Venus. When Mars is not at a close opposition, the fourth brightest object in the sky is the yellowish-white planet Jupiter which shines some ten times more brightly than the average of the brightest of the background stars. The golden-colored planet Saturn is the most distant of the naked eye planets from both the earth and the sun, and thus exhibits a reduced apparent brightness which is comparable to the average of the brightest background stars.

While the paths of the planets about the celestial sphere are not coincident with the ecliptic, they are, none the less, nearly coplanar with it. As a result, the sun, moon, and five naked eye planets move about the celestial sphere in a relatively narrow band of sky centered on the ecliptic which is called the zodiac. Because the sun, moon, and planets move along the zodiac at differing rates, it is possible for objects in the sky to appear to pass close to other objects along the zodiac. When such a passage occurs, the resulting configuration of the two objects is said to be a conjunction. Conjunctions can occur among the sun, moon, and planets, as well as between these moving objects and the bright stationary stars which are to be found along the zodiac. From time to time conjunctions can involve three or more objects, and on rare occasions a conjunction can be so close that the two objects cannot be seen as separate with the unaided eye.

In addition to the imaginary band of planetary paths that is the zodiac, there exists a quite real band of diffuse light, called the Milky Way, which is stationary relative to the stars and girds the celestial sphere like a gigantic faintly glowing heavenly belt. The Milky Way is the naked eye manifestation of the vast galactic system of gas, dust, and stars in which our sun is located. The Milky Way Galaxy, as this system is called, is in the shape of a huge, flat pinwheel which has a substantial bulge at its center. Our sun is situated about two-thirds of the way toward the outer edge of this system, and as a result, our view of the summertime Milky Way in the northern hemisphere is the more prominent one, since at this time we are looking toward the direction in which most of our galaxy is located. On the other hand, in the northern hemisphere winter, our view is now directed away from the galactic center toward the less prominent regions of the galaxy, with the visual result that the wintertime Milky Way is much fainter than its summertime counterpart.

Off the plane of the Milky Way, there exist approximately a dozen or so lesser diffuse objects which are visible to the naked eye and are also set in fixed positions among the stars. Modern telescopic observations reveal that these "fuzzy patches of light" are in reality quite a diverse lot, including clouds of glowing gas, star clusters, and even other galaxies well outside of our Milky Way.

From time to time transitory apparitions and events occur in the sky which can be as awesome as they are spectacular. One such event is a total eclipse of the sun. When the moon passes directly between the earth and the sun, a moving shadow of the moon about 240 km wide is cast upon the surface of the earth. An observer located in the shadow's path will see the sun's disk gradually covered by the dark lunar disk until the sun's light is almost completely blotted out. During this "total" phase of the eclipse, only the light from the sun's outermost atmospheric layers is visible and a darkness comparable to a full moon night descends on the land for a time period ranging from a few seconds to as long as 7 min. Finally the moon moves out of its direct alignment between the earth and the sun, and the sun reemerges to its full disk and full brightness.

The sun, earth, and moon can also align in such a way that the moon passes into the earth's shadow, thereby producing a total eclipse of the moon. When such an event occurs, an observer on the earth sees a full moon gradually enter the curved shadow of the earth. When the moon is totally immersed in the earth's shadow, it can take on a variety of ruddy hues ranging from an almost totally darkened red to a bright coppery shade of red–orange. This illumination even at the total phase of a lunar eclipse is caused by sunlight being refracted on to the moon's surface by the earth's atmosphere. The variety of colorations exhibited during various lunar eclipses is thus the direct result of the weather conditions in the earth's atmosphere, especially the degree of cloud cover at key locations around the earth. Typically the eclipsed moon spends an hour or so in the total phase before reemerging from the earth's shadow and regaining its full moon brilliance.

Every few years or so the night sky is visited by a strange apparition, a diffuse "long-haired" star-like object called a comet. Comets are known to be collections of ices, dust grains, rocks, and frozen gases which wheel about the sun in huge elongated orbits which alternately carry them from relative proximity to the sun out to the most distant parts of the solar system, thousands of earth–sun distances away. As a comet approaches the sun, the sun's radiant energy causes the ices and frozen gases to evaporate into a glowing coma which surrounds the dust and rocks at the comet's nucleus. As this diffuse, star-like object draws ever closer to the sun, the solar proton wind and radiation pressure drive material out of the diffuse head into a long, streaming tail which can extend over millions of miles of space. For several weeks, like a cosmic messenger, a comet will approach the sun, blossom with a flowing tail, and then fade into the cold blackness that is the periphery of the solar system.

The debris left behind by both these interlopers as well as from the formation process of the solar system permeates the interplanetary medium. As the earth sweeps along its orbit, it is constantly bombarded by objects ranging in size from tiny grains of dust up to small asteroids several kilometers in diameter. Fortunately collisions with the latter are extraordinarily rare! When a given interplanetary particle, called a meteoroid, strikes the earth, it does so at speeds as high as 50 km s^{-1}. At such speeds, friction with the earth's atmosphere causes the object to heat up quickly and glow brilliantly as it falls toward the earth. An observer at the earth's surface sees this event as a "falling star" or "shooting star." Most of the time, such objects disintegrate in the upper layers of the earth's atmosphere, but occasionally a meteoroid is able to traverse the earth's atmosphere and strike the earth's surface. Such an object is then referred to as a meteorite.

Occasionally the earth passes through a large stream of meteoric debris left behind by a comet. Under these conditions, large numbers of meteors can be seen in the form of a meteor "shower." During a typical meteor shower, one can see anywhere from 15 to 60 meteors per hour above the normal sporadic or background meteor counts of about six meteors per hour. About three or four times per century the earth strikes a particularly large and dense aggregate of meteoroids. Under these circumstances, thousands of meteors per hour flash across the heavens in a display of celestial fireworks which is unmatched anywhere else in the natural world.

From time to time in the remote recesses of interstellar space a star will end its life in a spectacular event called a supernova explosion. For a few days the energy output of this dying object rivals that of all the stars in an entire galaxy. If a supernova detonation occurs at a distance sufficiently close to the earth, the observed result is the transitory appearance of a "new" star in the terrestrial night sky. For time periods ranging from a few days to several months, the star shines at or near its maximum brightness before fading back into naked eye invisibility. One of the more notable of these objects was observed in the year AD 1054. At its maximum brightness, the supernova of 1054 was nearly three times brighter than the planet Venus and could be readily seen in broad daylight. The remains of this stellar blast can be telescopically viewed today as the tattered and twisted gaseous cauldron called the Crab Nebula.

Unlike the mathematical and monolithic universality which characterized the scientific philosophy emergent from the Western European Renaissance, the explanations tendered for the considerable array of celestial phenomena by non-western cultures as well as those of pre-Renaissance Europe and the Mediterranean were far more qualitative in nature and represented a diversity of ingenious viewpoints that were nearly as numerous as the cultures from which they sprang. Generally such explanations appear in a given culture in the form of myths, legends, and folklore, and pay considerable homage to the observed characteristics of the sky and its resident objects. As such, they represent the beginning attempts on the part of human beings to provide rational explanations consistent with observations for the variety of events which occur in the physical world, thereby making that world more comprehensible.

Perhaps the most familiar example of this process in action is to be found in the myths and legends pertaining to the fixed stars. Out of the more or less random distribution of stars in the night sky, one can imagine a variety of figures, shapes, and patterns not unlike the variety of faces and forms that one often fancies in the puffy clouds of a springtime sky. In some instances, a given pattern of stars can bear a striking resemblance to a familiar terrestrial entity. For virtually every culture, such similarities were not fortuitous, but in fact were intrinsic characteristics of the sky which were significant and demanded explanation. The most common approach was to regard the sky as a kind of "Celestial Hall of Fame" into which various legendary characters from a given culture's folklore had been inducted for various reasons. Such "inductees" thus became figures outlined in stars or constellations. The outline of some of the constellations are so compelling in their shapes that a variety of far-flung cultures would often envision very similar portraits for a given star group. Thus, the stars of the highly prominent wintertime constellation of Orion, for example, seem to outline a very fit and trim individual possessed of considerable physical strength. Thus Orion, the mighty hunter of Greek mythology is also al-Babādur (The Strong One) for the Arabs, the great hunter "Bull of the Hills" for the Blackfoot Tribe of the western Canadian plains, and the "Slender First One" to the Navajos of the American southwest. As one might expect, there is also a considerable amount of variation in the sky pictures of various cultures. Even though the J-shaped array of summertime stars which we call Scorpius the Scorpion has been widely depicted as a celestial version of its earthly arachnid namesake, there are many other interpretations of this asterism from other cultures. The Polynesians, for example, saw this star group as the fishhook of their great hero Maui, while the Chinese viewed it as the noble Azure Dragon, the Bringer of Spring. To the Mayas of Central America these stars represented the death god Yalahau, the lord of blackness and waters.

The constellations through which the sun, moon, and planets travel in their respective journeys about the celestial sphere were quite naturally assigned a particularly significant status as the constellations or signs of the zodiac. Traditionally there are 12 such constellations, each of roughly equal extent along the zodiac, and which include Aries the Ram, Taurus the Bull. Gemini the Twins, Cancer the Crab, Leo the Lion, Virgo the Virgin, Libra the Scales, Scorpius the Scorpion, Sagittarius the Centaur-Archer, Capricornus the Sea-Goat, Aquarius the Water Carrier, and Pisces the Fishes. In addition to the standard 12 constellation zodiacs employed by a majority of the world's cultures, the zodiac has been variously divided throughout human history into as many as 28 constellations by the Chinese and as few as six by the early Euphratean cultures. The denizens of the zodiac exhibit a considerable variation from culture to culture. The Aztec zodiac was graced with the starry presence of a frog, a lizard, a rattlesnake, and a jaguar, while that of the Incas contained a tree, a bearded man, a puma, and the sacred cantua plant.

Numerous explanations were offered for the observed movement of the sun, moon, and planets along the zodiac, virtually all of which centered on the basic idea that only gods and goddesses could possess the power to move among the stars. In the case of the sun the concept was further reinforced by the fact that to look directly on the face of the sun's disk was to incur the sun deity's wrath in the form of severe damage to one's eyes. Thus the sun was the sun god Amon-Ra to the Egyptians and the sun goddess Amaterasu to the early Japanese, and so on.

Eclipses and conjunctions in the sky have also inspired a number of mythologically based explanations. In the Hindu culture, for example, the mortal Rāhu is said long ago to have attempted to partake of the forbidden nectar of immortality. The god Viṣṇu was told of Rāhu's transgression by the sun and moon, and as punishment Viṣṇu proceeded to decapitate Rāhu. Ever since, Rāhu has sought to take vengeance on the sun and moon by pursuing them across the sky in an attempt to eat them. Once in a while, at the time of an eclipse, Rāhu actually catches either the sun or the moon and attempts to devour his prey. As the sun or moon is devoured, it gradually disappears into Rāhu's throat for a time before reappearing at the base of his severed neck as Rāhu attempts to swallow. The entire event is observed here on the earth as an eclipse of the sun or moon.

The sky watchers of antiquity were able to identify a number of basic characteristics relating to the background objects of the celestial sphere. The recognition of the variety of intrinsic colors that characterize the stars, for example, is manifested in names for stars such as the Arabic *Qalb al*ᶜ *Aqrab* (Heart of the Scorpion) for the bright red star Antares located at the center of Scorpius and the Hindu *Rohini* (Red Deer) for the ruddy star Alphard in the chest of the constellation of Hydra the Sea Serpent.

Bright stars near the celestial poles have held great meaning and significance to the watchers of the sky. In the third millennium BCE the north celestial pole was located in the constellation of Draco the Dragon near a second magnitude star called Eltanin. Because the heavens of the day appeared to rotate about this star, it was quite literally regarded as an object of pivotal importance. As a result, Eltanin was worshipped by a number of cultures, including the Egyptians who used this star to align a number of their important buildings and structures. As the earth's axis of rotation has precessed, other stars have taken on the mantle of Pole Star, most notably by the stars Thuban in the constellation of Draco and Kochab in the constellation of Ursa Minor, the Lesser Bear, and in more recent cultures by the star Polaris at the tip of the tail of Ursa Minor. Both Kochab and Polaris were regarded by the Chinese as Da Di the Great Imperial Ruler of the heavens, about whom the other stars circled in homage. The Pawnee tribe of the American plains named Polaris "The Star That Does Not Walk Around." To the Pawnee this star was related to the god Tirawahat, and as such, was chief over all the other stars. It was this star that saw to it the other stars did not lose their way as they moved across the sky.

Attempts to explain the true nature of the diffuse objects that dot the sky are understandably less prolific in light of the difficulties that are often encountered in observing them. The major exception is, of course, the Milky Way. Of the diffuse objects detectable in the heavens with the unaided eye, the Milky Way is far and away the most extensive and prominent. This delicate band of light which is also highlighted by an array of brighter stars has thus inspired a variety of explanations which include its portrayal as a celestial river by the Chinese and Japanese, as a Path of Souls to an eternal home by the Algonquin tribe of the Lake Ontario region of southern Canada, and as a band of glowing cinders by which one could find one's way home when lost in the darkness by the Bushmen of Africa's Kalahari Desert.

As imaginative and rational as they were, however, the explanations advanced by different cultures for the variety of celestial phenomena observed in the heavens generally became intertwined with the religious beliefs and societal mores of these cultures. As a result, there was a marked tendency for the explanations of celestial phenomena to take on dogmatic qualities in which they were seldom questioned or challenged by alternate points of view. Moreover, the lack of a telescopic astronomy placed severe and fundamental limitations on the level of insight that was possible regarding the nature of celestial objects. Thus the explanations proposed for various celestial phenomena tended to remain largely unchanged in a given culture, and whatever changes that did occur were not so much the result of additional observational insights, but rather due to a gradual evolution brought on as these explanations were passed on from generation to generation or from culture to culture. Even while armed with an impressive instrumental technology, however, human beings still continue to struggle with questions relating to the fundamental nature of what we see in the sky.

Certain observable aspects of the heavens readily lend themselves to practical usage here on the earth, and the greatest levels of achievement enjoyed by non-western astronomers have come in the discovery, recognition, and application of these characteristics. Systematic observations of the sky reveal, for example, that many celestial phenomena, most notably the diurnal and annual motions of the sun and the cycle of lunar phases, occur with precise and predictable regularity. This observable fact of the heavens has thus been employed by cultures worldwide as a method of accurate time keeping.

The diurnal rising and setting of the sun, with its alternating cycle of daylight and darkness, is the shortest and most convenient unit of astronomical timekeeping, and as a result human beings the world over have employed it, quite literally, as an integral part of their daily lives. A second, much longer unit of astronomical time is defined by one complete journey of the sun around the ecliptic. This annual astronomical cycle is of considerable importance owing to the fact that it is intimately related to the cycle of seasons which occur here on the earth. The cycle of seasons, in turn, is virtually identical to the cycle of vegetative growth and those of some animal activity and migrations. Thus agricultural methods and hunting techniques developed by various cultures were necessarily tied deeply to the cycle of seasons and the sun's annual journey along the ecliptic. Intermediate in length between the day and the year is the time interval required for the moon to pass through one complete cycle of its phases. The lunar cycle is particularly attractive as a timing cycle due to the fact that the ever-changing shape of the moon is readily observable on a daily basis. Sequences of shapes inscribed on Cro-Magnon cave walls and artifacts strongly suggest their use as lunar phase timing devices in just this fashion. Similar sequences carved by the inhabitants of Nicobar Island in the Bay of Bengal are known with certainty to be employed for this purpose.

Unfortunately these cycles are not quite numerically compatible with each other. For example, there are about 365 days in a year, but in reality it takes the sun precisely 365.242199 days to complete one cycle around the ecliptic. Similarly there are 29.530588 days to a cycle of lunar phases and 12.36827 cycles of lunar phases in a year. These discrepancies can create difficulties if one wishes to reckon the time of the year, the start of a given season, or the date of an important religious holiday by simply counting the number of days which have elapsed from some defined starting point such as the day of a solstice or equinox. If one counts the number of days as the year progresses, for example, one would find that after 365 days had passed, the sun would not quite yet have completed its journey around the ecliptic, and after 366 days had elapsed, the sun would have moved slightly past one complete cycle. Over several years' time such an effect can add up to a significant discrepancy between the sun's actual position along the ecliptic and the position dictated by the day count. As a result, a variety of schemes, called calendric systems or calendars, have been developed by various cultures around the world which are designed to synchronize two or more astronomical cycles. The most familiar of these is the addition of 1 day to our calendar every fourth or leap year in order to keep the day count in a given year in agreement with the sun's actual position along the ecliptic.

A number of ingenious techniques were developed by various cultures to monitor the astronomical timekeeping process. The Aztec Temple Mayor, now buried beneath modern Mexico City, was designed in the fifteenth century with two spires that provided a V-shaped notch through which the rays from a sun rising at the time of an equinox shone on to the temple of Quetzalcoatl. At no other times of the year would a rising sun produce this effect. Thus the Aztec temples served quite nicely and deliberately as a device with which the Aztec calendar could be corrected whenever necessary. Similar structural alignments are to be found at Stonehenge in England, in the temples of ancient Egypt, and among the buildings of the ancient peoples of the American Southwest. The Mayas of ancient Mesoamerica developed not only astronomical alignments for many of their structures, but also an incredibly accurate but somewhat complicated astronomical calendar which was based on the annual solar cycle and the synodic period of the planet Venus. The Maya calendar was accurate to within 1 day every 5,000 years. By contrast, the simpler Gregorian calendar used by contemporary society is accurate to within 1 day in 3,300 years.

In addition to the structural alignments, various cultures have also employed natural terrain as calendar correctors. On the top of Fajada Butte at the mouth of Chaco Canyon in the American Southwest, for example, there stand three rock slabs, each of which is about 3 m in height. On the rock wall behind these slabs a first millennium AD people called the Anasazi carved a spiral petroglyph in such a way that precisely at noon of the day of the summer solstice, a dagger-shaped beam of sunlight would neatly slice the petroglyph exactly through its center. Through this clever manipulation of sunlight, the Anasazi were able to mark the time of the summer solstice precisely.

The Hopi and Zuni tribes, also of the American Southwest, make use of a so-called sunrise horizon calendar. As the sun moves along the ecliptic, the points of sunrise and sunset along the horizon at a given location exhibit an annual cyclic shift in which the sunrise and sunset points appear to migrate along the horizon from south to north while the sun is moving from the winter solstice to the summer solstice and then north to south along the horizon while the sun is moving from the summer solstice to the winter solstice. As the sunrise and sunset points pass over various key landmarks along the horizon, each passage is taken as a signal to begin the appropriate agricultural activity such as planting various crops, harvesting, etc.

In addition to timekeeping, earth–sky relations can also be employed to find one's way about the surface of the earth. Such techniques are referred to overall as celestial navigation and have been of considerable importance to human cultures, particularly those which are maritime in nature. There are a number of aspects of the heavens which readily lend themselves as navigational aids. As the earth spins on its axis, for example, a star at or near the celestial pole will not appear to change its position in the sky significantly. More importantly, the point on the horizon directly beneath such a star will also remain in a relatively fixed position as well. Thus for observers in the northern hemisphere, the relatively bright star Polaris is located very close to the north celestial pole, and the point on the horizon directly beneath this signpost star has been used for centuries by northern hemisphere peoples to mark the direction we call north.

Other cultures took advantage of the fact that the angular distance of the pole star above the horizon as well as the locations of the rising and setting points of bright stars and constellations along the horizon changed with one's location on the earth's surface. Thus the Caroline Islanders of the central Pacific skillfully navigated by means of this star compass in which 32 points on the horizon were defined by the rising and setting points of bright stars and constellations such as Vega, the Pleiades, Antares, and the Southern Cross. The Polynesians employed a device called the sacred calabash, which was a gourd into which four holes were bored at the same height near the neck. The gourd was then filled with water to the level of the holes. Using the water level as a horizon, altitudes of stars were then measured by sighting through one of the holes over the opposite edge of the gourd. Thus armed with what was in effect the equivalent of our modern sextant, the Polynesians became most adept at deep-water navigation.

Systematic observations of the heavens also reveal that there exist a number of correspondences between celestial events and configurations and natural phenomena here on the earth. For example, the Egyptians recognized that the annual flooding of the all-important Nile River was at hand when the bright star Sirius made its heliacal rising or first appearance out of the predawn solar glare. The Incas of the South American Andes Mountains noticed that the cantua plant blossomed beautifully each year when the sun was located in our zodiacal constellation of Cancer, but which they named appropriately from their observations as the asterism of the sacred cantua plant. The heliacal risings of the bright stars Rigel, Aldebaran, and Sirius served to warn the tribes of the high plains of western America that cold weather was at hand. In light of such readily observable earth–sky correspondences, it was very logical to assume that similar correspondences exist between celestial phenomena and human affairs. Thus evolved the endeavor which we now call astrology.

Whether the astrological leap of logic from earth–sky to human–sky correspondences is a valid one has, of course, been a topic of considerable debate for many centuries, and since the 1600s the premise that such human–sky correlations exist has been emphatically rejected by western science. Nevertheless, astrology, more so than either timekeeping or celestial navigations, demands access to careful and ongoing observations of the entire heavens for the purpose of interpreting the significance here on earth of what is seen to occur in the sky, and whenever possible, to predict future events in the sky as well. Thus a well-developed astrology in China was certainly an important factor in the preparation of the earliest known star catalog in the fourth century BCE, and in the recording of a variety of celestial events, most notably the transitory appearances of sunspots and astrological omens such as comets, which were referred to as *huixing* (broom stars or sweeping stars) and of novae and supernovae explosions, which were called *kexing* (guest stars or visiting stars). So detailed were the records of the Chinese, Japanese, and Korean observations of the supernova event of AD 1054, for example, that modern astronomers were easily able to identify its present remains as the Crab Nebula in the constellation of Taurus, despite the fact that the event went virtually unobserved and unrecorded in Western Europe.

From some cultures, most notably those of the Mayas, Egypt, China, and the Islamic world, careful observations of the sky combined with centuries of relative social and political stability to make possible the discovery of much more subtle and long-term astronomical cycles. The Mayas, for example, were aware of the long-term reappearances of the planet Venus and built the planet's 584-day synodic period into their calendar. Both the Chinese and Islamic observers were aware of the fact that the lunar nodes, or the points on the celestial sphere where the moon's orbit crosses the ecliptic, drift in a westerly direction along the ecliptic at a rate of one complete revolution every 18.6 years and used this knowledge to predict the occurrences of both lunar and solar eclipses.

The Chinese and Islamic observers also recognized that the sun's equinox points drift in a westerly direction along the ecliptic at a rate of nearly 1° per year and made appropriate adjustments in their respective star catalogs and calendric systems in order to account for the protracted effect of this equinotical precession. Awareness of the shifting equinoxes may have also been the province of the Egyptians as well. A number of additions and reconstructions are found to exist in Egyptian temples and other structures which strongly suggest an architectural response to just such long-term changes in the positions of the equinoxes.

Astronomy of the Australian Aboriginal People

Roslynn D. Haynes

The Australian Aborigines were almost certainly the world's first astronomers. Their complex systems of knowledge and beliefs about the heavenly bodies have been handed down through song, dance, and ritual for some 40,000 years, predating by many millennia those of the Babylonians, the ancient Greeks, the Chinese, or the Incas. The legends which have survived, until very recently, within a virtually unchanged cultural context, show how natural phenomena, including celestial bodies and events, were assimilated by the Australian Aborigines into a holistic value system which was predicated on the close relationship of the individual with the whole natural world: It is significant, in this regard, that theirs was the only known culture with no myth of alienation from Nature, such as the expulsion from Eden of the Judeo-Christian tradition. On the contrary they believed that through their Great Ancestors of the Dreaming they, too, were continuing co-creators of the natural world. Hence they used their knowledge of the stars not only to predict and explain natural occurrences but also to provide celestial parallels with tribal experiences and behavioral codes.

The Aborigines' knowledge of the "crowded" southern sky was probably the most precise possible for people dependent on naked-eye astronomy. They made accurate observations, not only of first- and second-order stars, but also of the more inconspicuous fourth-magnitude stars. Pattern was apparently more important in recognition than brightness, for the Aborigines often identified a small cluster of relatively obscure stars while ignoring more conspicuous single stars in the vicinity. Thus the people of Groote Eylandt named as *Unwala* (the Crab) the small cluster of relatively insignificant (average magnitude 4.4) stars Sigma, Delta, Rho, Zeta and Eta Hydrae, while disregarding the adjacent bright stars Procyon (α Canis Minoris) and Regulus (α Leonis) (magnitude 0.36 and 1.35, respectively) which are not part of an obvious group. Members of the Boorong tribe of the Mallee District of Victoria limited their identification procedures to linear patterns of three or more stars. Unlike the familiar Greek designations, based on a join-the-dot pictorial image, the Aborigines identified a group of stars with the whole cast of characters in a story, the relationship being conceptual rather than visual. Color was also an important factor in the aboriginal designation of stars. The Aranda tribes of Central Australia distinguish red stars from white, blue, and yellow stars. They classify the bright star Antares (α Scorpii) as *tataka indora* (very red) while the stars of the V-shaped Hyades cluster are divided into a *tataka* (red) group and a *tjilkera* (white) group. The former are said to be the daughters of the conspicuously red star Aldebaran (α Tauri).

The Aborigines also differentiated between the nightly movement of the stars from east to west and the more gradual annual shift of the constellations. From this latter displacement they devised a complex seasonal calendar based on the location of constellations in the sky, particularly at sunrise or sunset. The Aranda and Luritja tribes around Hermannsburg in Central Australia knew that certain stars lying to the south, namely *Iritjinga* and the Pointers of the Southern Cross, are visible throughout the year, although their position in the sky varies. This amounts to a realization that stars within a certain distance of the South Celestial Pole never fall below the horizon.

Yet what the Aborigines did with their astronomical knowledge was fundamentally different from the procedures of Western science. Tribal Aborigines paid no attention to two of the most basic concepts of western science, numeracy and temporality; they made no measurements of space or time, nor did they engage in even the most elementary mathematical calculations. Their observations of the stars were conducted for essentially pragmatic reasons. Either they were an attempt to discover predictive correlations between the position of the stars and other natural events important to the survival of the tribe – the availability of specific foods or the onset of particular weather conditions, or they provided a system of moral guidance and education in tribal lore – a function regarded as equally necessary to the continuation of tribal identity.

As hunter – gatherers, dependent for their survival on a foreknowledge of environmental changes, the Aborigines noted the correlation between the movements and patterns of stars and changes in the weather or other events related to the seasonal supply of food. Thus the significance attributed to these sidereal occurrences varied with the diet and lifestyle of different tribes. On Groote Eylandt the appearance in the evening sky toward the end of April of Upsilon and Lambda Scorpii indicated that the wet season had ended and that the dry south-easterly wind or *marimariga* would begin to blow, causing changes in climate and animal behavior. At nearby Yirrkalla the appearance of Scorpio in the morning sky in early December heralded the arrival of the Malay fishermen who came in their canoes to collect trepang or *bêche de mer* which they sold to the Chinese. In winter, the most spectacular individual stars in the southern sky are Arcturus (α Bootis) and Vega (α Lyrae). When Arcturus could be seen in the eastern sky at sunrise, the Aborigines of Arnhem Land knew that it was time to harvest the spike-rush or *rakia*, a reed valuable for making fish traps and baskets for carrying food, and a local legend about Arcturus served as an annual reminder of this. On the other hand, amongst the *Boorong* tribe of the Mallee district of western Victoria, Arcturus was personified as *Marpeankurrk* the tribal hero who showed them where to find *bittur*, the pupa of the wood ant, a staple item of diet during August and September. The constellation Lyra represented the spirit of *Neilloan*, or the Mallee-hen who taught the tribe how to finds its eggs, an important source of food in October. Other notable events, like the ripening of tubers and bulbs and the appearance of migratory birds and animals, were correlated with specific positions of Orion, the Pleiades and the Southern Cross at different seasons of the year. For the Pitjantjatjara tribe in the Western Desert, the appearance of the Pleiades in the dawn sky in autumn was the sign that the annual dingo-breeding season had begun. Fertility ceremonies were performed for the dingoes, or native dogs, and some weeks later the tribe raided the lairs, culling and feasting on the young pups. The legends ensured that these nutritional associations were not forgotten and stressed their importance for the continuing survival of the race.

Equally important to the preservation of the tribe was its sense of identity, involving tribal beliefs orally transmitted across generations. These myths outlined the role of the Ancestors of the Dreaming in the scheme of the universe and the behavior appropriate to their descendants. Explanations of natural events which emphasized pattern, order, and laws, rather than unpredictable effects, reinforced the sense of an organic relationship between natural phenomena and social behavior. Many of these legends involved the constellations, so that the night sky provided a periodic reminder of the moral lessons enshrined in the myths.

Like all explanatory systems, including Western science, these legends represented attempts to understand, predict, and hence to obtain some control over the natural world. However, unlike the essentially analytical, materialistic, and particularizing approach of Western science, the underlying premise of all the aboriginal myths was a belief in the close spiritual unity of human beings, not only with other species, but also with inanimate objects. Astronomy was an integral part of the Aborigines' total philosophy about the natural world, so the legends emphasized the parallels between the personified heavenly bodies and their earthly counterparts, humanizing and integrating natural phenomena with tribal institutions and customs.

The meaning which a tribe attributed to the celestial bodies was conceptual rather than perceptual. It could not be understood by personal experience or by the intellect, but only through initiation into tribal lore which stressed the intimate, causal association between physical events and the human dramas of good and evil. Lessons about compassion, brotherhood, and respect for the land as Mother, the prohibition of incest and adultery, and taboos on killing or eating totemic animals were nightly reinforced by being enacted in the sky world which thereby established the universal validity of the tribe's ethical laws.

The many and diverse aboriginal myths associated with the heavenly bodies include stories about the Sun, the Moon, the Milky Way, the Magellanic Clouds, Mars, Venus, and the several constellations which form distinctive patterns in the southern sky – notably the Southern Cross and its pointers, the Pleiades, Orion's Belt, Scorpio, Gemini, and Aldebaran. The following are a representative selection of these myths.

In most of the Aboriginal creation stories, the Sun is the life-giving spirit. Amongst the Murray River tribes the origin of the Sun is linked to the tossing of a giant emu egg into the sky where it struck a heap of dry wood and burst into flame, bringing light to the hitherto dark world. Thereupon, the Great Spirit *Baiame*, seeing how much the world was improved by sunlight, decided to rekindle the woodpile each day.

In contrast to the ancient Greeks, the Amerind Indians and the Quechua Indians of Peru, all of whom designated the Sun as male and the Moon as female, whereas the Australian Aborigines represented the Sun as female and the Moon as male. In most areas, the Sun is regarded as a woman who daily awakes in her camp in the east and lights a fire to kindle the bark torch she will carry across the sky, thus providing the first light of dawn. She decorates herself with powder made from crushed red ochre, coloring the clouds red in the process. At evening she renews her powder in the western sky before beginning her long passage underground back to her camp in the east. It was probably this underground journey which was instrumental in the classification of the Sun as female, for her torch is thought to bring warmth and fertility to the interior of the Earth, causing the plants to grow. However, in Arnhem Land, where the Sun sets in the sea, she is thought to become a great fish, swimming under the Earth to return in the east next morning while the Moon becomes a fish, passing beneath the earth during the day.

The Moon, being male, is generally accorded greater status, and in many areas powers of death and fertility are accorded to him. An eclipse of the Sun is interpreted as indicating that the Moon Man is uniting with the Sun Woman. Several legends have evolved to account for the Moon's cycles. In coastal areas the correlation between the phases of the Moon and the tides was noted. In Arnhem Land and Groote Eylandt, where high tides occur when the new or full Moon sets at sunset or sunrise, respectively, and low tides when the moon is in the zenith at sunrise or sunset, the local Aborigines believe that the high tides, running into the Moon as it sets into the sea, make it fat and round. (Although the new Moon may appear thin, they deduce from the faint outline of the full circle that it too is round and full of water.) Conversely, when the tides are low, the water pours from the full Moon into the sea below and the moon consequently becomes thin.

In most areas the Moon was regarded as more mysterious, and hence more dangerous, than the Sun. Because of the association of the lunar cycle with the menstrual cycle, the Moon was linked with fertility and young girls were warned against gazing at the Moon unless they wished to become pregnant.

The Milky Way was regarded by the Aborigines as a river in the Sky World, the large bright stars being fish and the smaller stars water-lily bulbs. Central Australian tribes believed that the Milky Way divided the sky people into two tribes and thus it served as a perpetual reminder that a similar equitable division of lands should be observed between neighboring tribes. Various legends regarding taboo marriages, adultery, and reminders to celebrate tribal heroes, many of them involving a moral lesson, have evolved in different areas to account for the formation of the Milky Way and the dark region, known to Europeans as the "Coal Sack."

A Queensland version of the origin of the Milky Way associates it with *Priepriggie*, an Orpheus-like hero, as famed for his songs and dances as for his hunting. When he disappeared, his people tried unsuccessfully to perform his dance until they heard singing in the sky. Then the stars, hitherto randomly dispersed, arranged themselves to the rhythm of *Priepriggie's* song. Thus the Milky Way serves as a reminder that the tribal hero should be celebrated with traditional songs and dancing.

Because of its diagrammatic shape, the Southern Cross features in association with various characteristic objects in different areas. Around Caledon Bay on the east coast of Arnhem Land, it is taken to represent a stingray being pursued by a shark – the Pointers. On Groote Eylandt, where fish is the staple diet, the four stars of the Cross represent two brothers, the *Wanamoumitja* (Alpha and Beta Crucis), and their respective camp fires (Delta and Gamma Crucis) where they cook a large black fish (the Coal Sack) which they have caught in the Milky Way. The Pointers are their two friends, the *Meirindilja*, who have just returned from hunting. Desert tribes, on the other hand, see in the kite shape of the Cross the footprint of the wedge-tailed eagle *Waluwara* while the pointers represent his throwing stick and the Coal Sack his nest.

Venus, the Morning Star, was an important sign to the Aborigines, who arose at early dawn to hunt. It, too, was personified and frequently associated with death. Arnhem Land legends identify the home of the morning star, *Barnumbir*, as Bralgu, the Island of the Dead. Afraid of drowning, *Barnumbir* could be persuaded to light her friends across the sea at night only if she were held on a long string by two old women, who at dawn would pull her back to Bralgu and keep her during the day in a basket. Because of this connection, the morning star ceremony is important in the local rituals for the dead since a dead person's spirit is believed to be conducted by the star to *Bralgu.*

One of the most widespread Aboriginal myth cycles concerns the constellations of Orion and the Pleiades and these bear a striking similarity to the Greek story of the seven daughters of Atlas who, when pursued by Orion, flew into the sky as doves to form the constellation of the Pleiades. All identify them with a group of seven young women and nearly all portray them as fleeing from the amorous hunter Orion who, in some versions, is castrated as a punishment and warning to other potential wrongdoers. The whole cluster of Pleiades stories therefore forms part of a much larger group of myths of sexual conquest and submission.

Amongst the Pitjantjatjara tribe, the practical connection between the dingo-breeding season and the appearance of the Pleiades in the dawn sky in autumn is preserved in a local legend. The *Kungkarungkara* or ancestral women kept dingoes to protect them from a man *Njiru* (Orion), but he succeeded in raping one of the girls, the obscure Pleiad, who died. Even though the women assumed their totemic form of birds and flew into the sky to escape from him, he defies their dingoes and follows the women across the sky, armed with a spear (the stars of Orion's Belt) which has ritual phallic significance. Like the Greek Orion, *Njiru* was also a hunter, and pairs of smaller stars which arise near the constellation of Orion are said to represent his footsteps as he pursues the *Kungkarungkara.*

At Yirrkalla on the coast of Arnhem Land, the constellation of Orion is regarded as a group of fisherman arriving from the east in a canoe with a turtle they have caught, while the Pleiades represent their wives in another canoe with two large fish. As they approached the shore a heavy storm capsized the canoes, drowning the people. All the representative stars are visible in the sky during the wet season – a warning against the dangers of fishing when storms are imminent. In north-eastern Arnhem Land the story carries the added moral that the fishermen drowned as a punishment for catching catfish, forbidden to this tribe by totemic law.

Although relatively insignificant to the naked eye, the Large and Small Magellanic Clouds feature in many aboriginal legends as the camps of sky people. On Groote Eylandt they are believed to be the camps of an old couple, the *Jukara*, grown too feeble to catch their own food. Other star people catch fish and lily bulbs for them in the Milky Way and bring them to the *Jukara* to cook on their fires. The space between the Clouds is their cooking fire, while the bright star Achernar (Alpha Eridani, magnitude 0.49) represents their meal. This story suggests a celestial model of compassion for the aged. At Yirrkalla the Magellanic Clouds are said to be the homes of two sisters. During the middle of the dry season the elder sister (Large Cloud) leaves her younger sister (Small Cloud), but during the wet season she returns so that they can collect yams together. This story reflects the observed fact that at this latitude (12° S) only the Small Cloud is visible during most of the dry season (April to September), whereas both Magellanic Clouds can be seen during the wet season.

Meteors have been variously interpreted by different aboriginal tribes. In north-eastern Arnhem Land, because of their speed and unpredictability, they are believed to be spirit canoes carrying the souls of the dead to their spirit home in the sky. To the Tiwi tribe of Bathurst and Melville Islands, each is the single eye of the one-eyed spirit men, the *Papinjuwari*, who steal bodies and suck the blood of their victims, and their evil eyes are seen blazing as they streak across the sky looking for their prey. In other legends, meteors are associated with fire and linked to the waratah plant, *Telopea speciosissima*, a member of the Protea family, which is resistant to fire and whose brilliant red flowers seemed to the Aborigines like sparks from a fire. This was why, in the early years of white settlement, some Aborigines brought waratahs to the European blacksmiths: they identified the sparks from the anvil with the sparks from meteors and hence with the waratahs.

From this selection of star legends, it will be apparent that, with the possible exception of meteors (and even they can be regarded as recurrent events), the Aborigines' concern was not with extraordinary occurrences, but with the regular patterns of natural phenomena. The star legends served the purpose of integrating a potentially alien universe into the moral and social order of the tribe – by "humanizing" species and natural objects and ascribing to them behavior patterns and motivations which accorded with those of the tribal unit.

Such a philosophy serves a number of important social functions. In the first place it engenders a level of confidence about Man's place in the universe, not as a superior being but as an equal partner; in this it fulfils a role comparable to that of technology which also offers a level of some control over the environment. Secondly, this philosophy cultivates respect for the inanimate world as well as the animate since, through the indwelling power of the Ancesotrs, all creatures and things partake of the same spiritual identify as Man himself. Thirdly, the legends provide a justification for the customs, rites, and morality of the tribe, since these are reflected and enacted in the Sky-world.

The aboriginal myths are not fatalistic as astrology purports to be. Although they link certain natural events with a seasonal configuration of the sky, they make no deterministic predictions about individual lives; the moral values enshrined in the legends are held to be true for the *whole* tribe.

The most radical difference between the vitalistic beliefs which underlie these myths and the materialistic philosophy of western science concerns the relationship of the observer to the observed. In Newtonian science, the observer is assumed to be independent of, and distinct from, the object observed, which, in turn, is regarded as uninfluenced by the observer. Hence, the relationship between physical objects can be validly expressed in mathematical terms which remain true irrespective of the observer. The Aborigines, on the other hand, did not conceive of themselves as observers separated from an objectified Nature, but rather as an integral part of that Nature. The meaning of the celestial bodies, as of everything else in the environment, was neither self-evident nor independent of the observer; rather it depended on the degree of initiation into tribal lore which elucidated the links between tribal customs and natural phenomena. Without this knowledge the individual was disoriented and powerless in an alien universe.

Astronomy in China

Ho Peng Yoke

Chinese astronomy became a subject of long debate among historians and astronomers in the first half of the twentieth century. Some based their argument on the *Shujing* (Book of Documents) and concluded that Chinese star clerks had already made astronomical observations between 2000 and 3000 BCE. Richard Schlegel even asserted that they knew about the 28 lunar mansions as long ago as the year 1600 BCE. Others doubted the reliability of the records in the *Shujing* claiming that Chinese astronomy could not have originated earlier than 500 or 600 BCE. Some said that Chinese astronomy originated from India, others said from Arabia, and there were yet those who said that it was from Mesopotamia. Joseph Needham, for example, favors a Mesopotamian origin.

Recent archaeological studies carried out in China have thrown more light on early Chinese astronomy and enabled scholars to re-examine some of the old interpretations. Archaeologists have been hard at work during the last two decades to establish the Xia dynasty, which, according to tradition lasted from the twenty-first century BCE to the sixteenth century BCE, and which has until now been regarded as legendary. They have yet to recover written records of that period. Erlitou in Henan province, where bronze vessels dating back to the year 1700 BCE were recovered in 1971, is one of their important sites. Even the records in the *Shujing* have recently been re-examined by comparison with computed ancient astronomical phenomena.

In the oracle bone writings we can find records of eclipses, novae, and names of stars and some asterisms. The records indicate that the Yin people between the fourteenth and twelfth centuries BCE were already using a lunisolar calendar, where 1 year consisted of 12 moons or lunar months of either 29 or 30 days each, with an extra month known as the intercalary month added about every 3 years. From about the sixth century BCE until the use of the telescope for astronomical observations in Europe in the seventeenth century, Chinese star clerks kept the most consistent and continuous astronomical records on eclipses, comets, novae, sunspots, and aurora borealis in the whole world. Star catalogs were produced during the Warring States period (481–221 BCE) by Gan De, Shi Shen, and Wu Xian. Chinese astronomical records have found many applications in modern astronomy. One application is in the calculations of the period of Halley's comet. The Crab Nebula has been identified with the supernova observed in China in the year 1054. The first pulsar was discovered in 1967. It was found to be near a site where a "guest star" was recorded by the Chinese. A "guest star" in Chinese astronomy could refer to a supernova or nova, but it could also mean a comet or even a meteor, depending on the context. In this case it refers to a supernova or nova. As a result some astronomers made use of Chinese records in their attempts to discover other pulsars. Chinese records on sunspots have been used to determine sunspot cycles, and recently they were used in the study of the variation of the earth's period of rotation. There are many other applications for Chinese astronomical records, such as in a recent study of the Star of Bethlehem in the Bible.

There has been a prolonged dispute since the last century over the question of the origin of the 28 Chinese lunar mansions. These are 28 asterisms distributed along the ecliptic (the band of the zodiac through which the Sun apparently moves in its yearly course). The moon changes its position among the stars night after night, and appears successively in each of these asterisms, appearing from the earth as if it changes its lodging each night. Hence they were known as lunar mansions or lodges. Chinese astronomers also picked one of the stars in every lunar mansion as a reference point from which distances of other stars in its vicinity were measured. The stars used as reference points were called determinant stars. In ancient Hindu astronomy there were 27 *nakṣatras*, each of which had a principal star (*yogatara*). Nine of the *yogataras* are identical with the Chinese determinant stars. Some thought that the lunar mansions and the *nakṣatras* had a common origin, often with Sinologists and Indianists taking opposite sides. Before a conclusion was reached came a third contender, the *al-manāzil*, the moon-stations in Muslim astronomy. Then it was argued that Muslim astronomy was predated by Hindu astronomy. During the middle of the 20th century the most favored candidate was Mesopotamia, from which ancient Chinese astronomy and others were thought to be originated. This is the view favored by Joseph Needham. The argument against China's favor until then was that all the names of the 28 lunar mansions were not found earlier than the fourth century BCE. However, in the year 1978 the names of all the 28 lunar mansions were found inscribed on the lid of a lacquer casket of the early Warring States period, showing that the 28 lunar mansions were already there in China not later than the fifth century BCE. Chinese archaeological discoveries in the second half of this century and recent archaeological excavations carried out in India have also shown that both Chinese and Indian civilizations existed much earlier than they were thought. Whether the lunar mansions in Chinese astronomy were influenced by the Hindu *nakṣatras* or whether it was the other way round is an open question. Perhaps there was no influence between the two systems at all. The important thing in the study of history of science and civilization is to learn about mutual exchange of ideas among different cultures rather than to engage in futile disputes, claiming priorities and making scores in meaningless contests, in which there is no prize for the winner other than false pride.

The earliest existing Chinese documents on astronomy are two silk scrolls discovered in the Mawangdui tombs in Changsha, Hunan province in the year 1973. One of them, the *Wuxingzhan* (Astrology of the Five Planets) contains records of Jupiter, Saturn, and Venus, the accuracy of which suggested the use of the armillary sphere for measurement. These records were made between 246 and 177 BCE. The other, the *Xingxiangyunqitu* (Diagrams of Stellar Objects and Cloud-like Vapors of Various Shapes) illustrates different types of comets. Among the ancient astronomical instruments discovered by archaeologists are the bronze clepsydra from the tomb of Liu Sheng of the second century BCE and a bronze sundial of the Eastern Han period (25–220). The title of an early Chinese book on astronomy and mathematics, the *Zhoubi suanjing* (Mathematical Manual of Zhoubi), calls to mind either the Zhou dynasty or the circumference of a circle, and the vertical side of a vertical right-angled triangle. The book contains the so-called *Zhoubi* or *Gaitian* cosmological theory in which the heavens are imagined to cover a flat earth like a tilted umbrella, and shows paths for the sun at different seasons of the year. From the positions of the stars and planets mentioned in the text, Japanese scholars established a period between 575 and 450 BCE for the observations and inferred that the book was written within the same period. Christopher Cullen recently showed that the book could well be a work of the early first century.

During the second century Zhang Heng (78–139) constructed an armillary sphere as well as a seismograph for making astronomical observations and for detecting the direction of earthquakes. An armillary sphere consisted of a system of rings corresponding to the great circles of the celestial sphere and a sighting tube mounted in the center. With such an instrument Chinese astronomers could measure the positions of heavenly bodies. The mounting of the Chinese armillary sphere deserves special attention. As pointed out by Needham, it has always been equatorial unlike its counterpart in Europe which was ecliptical, but only changed to equatorial in modern telescopes. The new armillary sphere made by Zhang Heng resulted in more accurate observations and better star maps.

An important role of Chinese astronomy was calendrical calculation. The emperor regarded calendar making as one of his duties associated with the mandate that he received from Heaven. The Chinese calendar took into account the apparent cycle of the sun and the cycle of the moon, both of which, as we know, cannot be expressed in an exact number of days. The astronomer responsible for constructing a lunisolar calendar had to make accurate observations of the sun, the moon, and the planets, but however accurate his observations and his calculations, his calendar would sooner or later, in just a matter of decades, get out of step with observations. Hence throughout Chinese history no less than one hundred calendars had been constructed. Besides, sometimes there were also unofficial calendars adopted in certain regions in China. During the seventh century Indian calendar-making made its presence felt in China. We can read the names of a number of Indian astronomers and calendar experts who lived in Changan, the capital of Tang China.

In the early days of the Tang dynasty the calendar officially adopted was the *Lindeli* calendar constructed by the great early Tang astronomer, mathematician and diviner Li Chunfeng (602–670). By the early eighth century a new calendar became overdue. Eventually the old calendar was replaced by the *Dayanli* calendar constructed by the Tantric monk Yixing (683–727). Yixing's secular name was Zhang Sui. He is regarded as the most outstanding astronomer of his time for his recognition of the proper motion of the stars. In the year 721 the Tang emperor Xuanzong entrusted Yixing with the task of constructing a new calendar. To do this he constructed new astronomical instruments, including an armillary sphere moved round by wheels driven by water, and he also carried out a large scale research project to measure the length of the earth's meridian. He employed the method of difference, involving equations of the second degree, as well as the method of the remainder theorem in the *Suanzi suanjing* to calculate his new calendar.

From the late seventh century Indian Tantric monks had also come to reside in the Tang capital. Later Yixing made frequent contact with them and assisted them in the translations of some of their *sūtras* into Chinese. Yixing could have acquired from them some knowledge of astrology and mathematics, including the idea of a spherical earth and the sine table. There were then three clans of Indian calendar experts living in the Tang capital, namely the Siddhārtha clan, the Kumara clan and the Kaśyapa clan, of which the Siddhārtha clan was the most active and famous. At least two members of that clan had served as Directors of the Astronomical Bureau. The most distinguished member was Gautama Siddhārtha, who constructed an iron armillary sphere when he was director and translated the *Navagrāha* calendar into Chinese in the year 718. Most important of all, he compiled the *Da-Tang Kaiyuan zhanjing* (Prognostications Manual of the Kaiyuan Period of Tang Dynasty) between the years 718 and 726. The word *Navagrāha* means the "Nine Luminaries," namely the Sun, the Moon, Mercury, Venus, Mars, Jupiter, Saturn, and two imaginary planets *Rahu* and *Ketu.* Although this calendar was never adopted in China, it found its way from there to Korea, where it was used for a period of time.

During the Song dynasty (960–1279) astronomers made more accurate astronomical observations using new and larger armillary spheres. They constructed several such instruments, the most famous of which was that made by Su Song (1020–1101). It was an armillary sphere driven by a water-wheel using the principle of escapement. A full-scale study of Su Song's instrument is given in Joseph Needham's *Heavenly Clockwork.* Su Song's instrument was both an armillary sphere and a clock, but it was known only as an armillary sphere. Hence until it was pointed out by Needham, Price, and Wang Ling, nobody knew that the clock already existed in China when Matteo Ricci introduced the clock in the late sixteenth century.

Astronomy during the Mongol period (1271–1368) was closely connected with the name of Guo Shoujing (1231–1316), the last of the great traditional Chinese astronomers. The *Shoushili* calendar that he constructed was the most advanced and accurate calendar ever produced in traditional China. It was made possible by the precise instruments he built and the method of finite difference he used in his calculations. This was also the time when astronomers from the Arab world came to work in China. The Muslims were still active in the Astronomical Bureau when the Jesuits came toward the end of the sixteenth century. The Jesuits arrived at a time when Chinese astronomy was in a state of stagnation, when no one with the knowledge and skill of Guo Shoujing could be found. The Chinese learned pre-Copernican astronomy from them. Modern astronomy came to China only around the middle of the nineteenth century. It did not take long for Chinese astronomy to join the mainstream of modern astronomy. Just as Nakayama Shigeru said that the history of Japanese astronomy was the history of Chinese astronomy in Japan, Chinese astronomy has already become modern astronomy.

Astronomy in Egypt

Gregg De Young

We have few written records dealing with the heavens, and those that we possess are derived from the Greek astronomical tradition and therefore are very late in Egyptian history. Thus, in order to assess the astronomical knowledge of ancient Egypt, we rely on such limited pieces of evidence as "diagonal calendars" that decorate some Middle Kingdom (ca. 2150–1780 BCE) coffins, orientation of tombs and pyramids relative to the cardinal compass points, and astronomical ceilings used in temple or tomb decorations.

Recent evidence from the area of Napta Playa indicates that observations of the heavens were already well developed during the predynastic period (prior to 3100 BCE) of Egyptian history. Here, an ordered array of stones grouped in a rough circle around a central stone are reminiscent of the artificial arrangement of megaliths at Stonehenge, although the Egyptian arrangement is much older.

One of the primary incentives for study of the heavens in ancient Egypt seems to have been to establish the cultic calendar on a firm basis. This cultic calendars growing out of less formal agricultural and ritualistic calendars, defined the beginning of the year with the heliacal rising of Sothis (modern Sirius). For administrative purposes, a civil calendar was superimposed upon the older luni-stellar cultic calendar. The determination of the year was not defined on astronomical evidence, however, but on counting off 365 days from the beginning of the year. Because the civil year contained exactly 365 days, it was typically out of step with the natural or solar year. The two coincided only every 1,460 astronomical years (the so-called Sothic cycle).

The civil year was divided into 36 "decans" of 10 days each, to which five epagomenal days were added. These "decans," represented in the "diagonal calendars", were associated with nightly timekeeping in temples for religious observance. Since it was essential to predict the coming of the dawn for temple rituals, each hour of the night was associated with one or more bright stars whose heliacal rising would signal the end of night. Since the sun moves slightly slower than the stars in its apparent circling of the earth, any chosen star will rise farther and farther in advance of the sun, so that it is an effective indicator of the dawn only for about 10 days, after which another decan star or stars will herald the coming sunrise.

The determination of cultic celebrations, however, continued to be based largely on lunar phenomena. In order to correlate the two calendars, the Egyptians used the observation that there are very nearly 309 lunar cycles in 25 civil years. In general, any two successive lunar months had 59 solar days, but every four years the last two months were given 60 days, a correction reminiscent of our leap year. This correlation allowed the priests to predict with fairly consistent accuracy where lunar festivals should fall within the civil calendar, obviating the necessity to observe the heavens in order to determine the time for a particular festival.

It has often been noted that pyramids, and especially the pyramids of the Giza plateau, as well as numerous tombs, seem to be aligned in accord with the cardinal compass directions. The precision of such alignments points to an astronomical determination of the cardinal directions, although we do not know precisely how this was done. The older hypothesis was that a level artificial horizon was constructed, against which the rising and setting points of a given star would be marked. Bisection of the angle between these two points, as measured from the center of the artificial horizon, determines true north. This technique, although possible, appears cumbersome. A relatively simpler method would have been to erect a gnomon perpendicular to the earth and construct around it a circle of arbitrary radius. Mark the two points at which the shadow of the gnomon touches this circle. The bisection of the angle formed between these two observations and the gnomon determines true north. We have, however, no surviving evidence to reveal which of these two procedures the ancient Egyptians used. (It is also fair to say that many temples and tombs are not so precisely oriented – many merely face the Nile, which flows roughly from south to north, without regard for local geographical variations.)

The scanty surviving evidence suggests that the Egyptian observer of the heavens used only the simplest of observational tools, and even these may not have been used extensively prior to the New Kingdom period (ca. 1550–1085 BCE). Nocturnal observations typically involved a *merkhet* (a palm rib notched at its wider end, used in conjunction with a plumb line) to determine the zenith transit of a celestial object. Daytime observations generally involved determination of solar altitude using length of shadows. These measurements were made using a horizontal graduated bar, with a small block perpendicular at one end to cast a shadow on the horizontal bar. Herodotus reports that the Egyptians knew sundials, but the surviving evidence favoring that view is extremely scanty. The shadow clock, however, does suffer from the same problems as the sundial. Both are constructed to divide the day into equal parts, although the inclination of the earth's axis creates unequal lengths of days throughout the year, complicating any attempt to regulate time through astronomical observations.

When astronomical observations were not possible, the Egyptians sometimes used a kind of water clock similar to a Greek clepsydra to determine hours. Here water is allowed to escape from a container of known volume through a small orifice at the base. The interior is graduated to show the lapse of time. The ancient Egyptians apparently did not appreciate that the rate of outflow is not constant. Here, too, we find that a considerable degree of inaccuracy or indeterminacy seems to have been routinely accepted.

Astronomical ceilings are among the most striking pieces of evidence concerning the ancient Egyptian's knowledge of the heavens. Central to these documents are a group of figures whose composition and orientation change very little with time. These are usually considered to represent the circumpolar constellations, although all attempts to match these figures with visible star groupings, apart from the foreleg (Big Dipper), have so far been unsuccessful. In addition to these groupings, there are often iconographic and inscriptional references to the naked-eye planets and to individual bright stars (most notably Sothis/Sirius). All of this indicates that the ancient Egyptians were careful observers of the night sky, although probably not overly concerned with reducing these observations to mathematical models of the kind found in Greece.

We know very little about practitioners of astronomy. Only in very rare instances do the funerary titles indicate someone who may have observed or studied the heavens for some specific purpose beyond personal curiosity. The evidence indicates, however, that there was a continuing effort to observe and describe celestial phenomena.

Astronomy in Hawai'i

Rubellite K. Johnson

There were two important tasks that drew on ancient Hawaiians' understanding of space and time. One was constructing a ritual calendar for determining the length of the day, week, month, and year; the other was navigating on the seas between island destinations.

The first, calendrics, was the responsibility of the priests, among whom were stargazers called *kilo hoku*, from *kilo* (to observe or to watch), and *hoku* (star). The same stargazers, however, observed more than stars. They knew the sun's motions and those of the moon and the planets, but the stars were the most challenging.

Let us look at this from the standpoint of the student who starts out in "class," which was a place set aside for men and boys to worship the gods. In a place where men only spoke with one another in the men's eating house, the *hale mua*, the "front" (*mua*) house in the compound of the household (*kulana kauhale*), a young boy began his training in these subjects. Since they were part of required religious training, he found himself within rock-walled enclosures, or temple (*heiau*) grounds set aside for men's worship, the *tabu pule* scheduled through seven nights, *na la kapu kauila*, totalling 56 nights in an eight-month period. The 240-day tabu period was followed by 120 days of the *makahiki* season during which taxes (*auhau*) were collected.

No one knows how astronomical subjects were taught, although some information has survived through stories and chants from the migration period of discovery and exploration, with wayfinding practice associated mainly with places visited in ancestral lands to the south. The sun's motion between the north and south and across the equator may have been the first fundamental horizon system to be learned, combined with the observations of stars nearest the rising and setting points of the sun in the morning and evening.

The sun's rising (*hiki*) gives the cardinal direction east its name: *hikina*. When above the horizon, it is *kau*, to be placed or to be hung, but it also means to set, as of the sun afloat westward, *kau lana ka la*. When the sun sets, it "enters" (*komo*) into the world below, so that cardinal direction west is called *komohana*, the "entering" place of the setting sun. When the sun has stopped on its northern journey, that point is called the sun "afloat," *kau lana ka la*. Its daily motion as it arches upward from its eastern azimuth or "pit" (*lua*) to local zenith (*nu'u*) and after noon "declines" ('*aui*) is called *ka'a, ka'a ka la ma lalo*, the sun moves down. When it crossed the equator, the sun was said to "trample" (*ke'ehi*) the "diaphragm" (*houpo*) of the god Kane (*ke'ehi i ka houpo o Kane*), the sun being the "eyeball" of Kane (*Kane 'onohi o ka la*). This is the basic compass, adding north for the right ('*akau*) and south for the left (*hema*) sides of the body.

The days were counted as nights of the moon, and there were two revolutions tracked, one synodic, and the other sidereal. Each "night" was clocked into quarters. The clock began at midnight, called *Kau*, or *Aumoe*, the latter meaning "time of sleep." Kau situates the clock on meridian, as at midnight and so also at noon, so the midday was also called Kau. When the sun was in the zenith (*nu'u*, *lolo*) it was called *kau ka la i ka lolo*, the "sun was over the brain (*lolo*)." This position of the sun, not only on meridian but in the zenith as well, took place twice in the year – once when the sun was going north, between May and June, and again when the sun was going south, between June and July. People today may call this "Lahaina noon," but generally the zenith sun appears at the southernmost part of the island of Hawai'i, about 19° north about May 15th (although the date is variable). All other "noons" when the sun is on meridian are called *awakea* after Sky Father, Wakea, whose name is synonymous with noon and the center of the celestial equator, called *Ka Piko o Wakea*, the "Navel of Wakea" (Sky Father). Piko means "center of the body," which has three such piko: one at the top of the skull in the soft spot, the fontanel; one at the navel, and one at the midpoint of the genital area in line with the piko in the middle of the skull. When one lies down, then the piko at the center of the horizontal body, called the '*opu*, is in contact with navel center of Mother Earth, *Ka Piko o ka Honua*. "The Navel of the Earth," or terrestrial equator, which extended beyond earth into the sky is *Ke Ala i Ka Piko o Wakea* (Path to the Navel of the Sky); *Ka Piko o Wakea* is the celestial equator.

The clock having thus two *Kau*, midnight and midday, is an indigenous concept of the "mean day," by which day and night are divided into equal parts. There were no hours, except the quartering for the night, commencing about sunset (i.e., 6:00 p.m.), called a "corner" (*kihi*), and the next "corner" at sunrise, *Kihi puka*; puka means "to emerge," as a celestial body, whether sun, moon, stars, or planets. Between the kihi corners were the *pili* quarters, meaning "close to," as in *pili 'aumoe*, about 9:00 o'clock at night, and *pili puka*, about 3:00 a.m., meaning "close to sunrise." From these data it is appears that the shape of the Hawaiian clock between the two Kihi is angular rather than circular, perhaps a rectangular shape. The day clock is spread out on both sides of noon (Kau, Awakea) by morning (*kakahiaka*), afternoon ('*auinala*, from '*aui*, "to decline," as of the sun), and evening (*ahiahi*). Day and night are *ao* (daylight) and *po* (night).

The moon was regarded as feminine, as passive light or a reflection of the goddess Hina, perceived as ruling the tides, as well as growing sea life on and around the living reef. Each night of the moon had a separate name through one synodic revolution of the moon, or that passage from the first crescent perceived in the west until it returned to that point again in 29.5–30 nights.

The new moon, or dark phase, was *Muku* (cut off or severed). Hina, the moon goddess, was thought to have gone into and through the Milky Way (*Ka Wai Ola a Kane*, "Living Waters of Kane"), in which her dying soul (*Mauli*) revived in the life-giving semen of the creator god. Her spirit was the last crescent waning moon (*Mauli*). On the night of Muku, Hina's spirit was in the Milky Way. After Hina comes through the *Wai Ola a Kane*, the first braid of her gray hair is seen at Hilo after sunset, low on the horizon, alive again. The waxing (*ho'onui*) moon begins at Hilo, moving south until first quarter at 'Ole, thus:

Muku	0	"cut-off"	New moon, dark phase
Hilo	1	"braid"	Moon in the west
Hoaka	2	"tusk" (moon shad ow, boar tusk)	
Ku-kahi	3	Ku-1 "cusp" (moon going south)	
Ku-lua	4	Ku-2	
Ku-kolu	5	Ku-3	
Ku-pau	6	Ku-end	
'Ole-ku-kahi	7	'Ole-1 "eye-tooth" (moon in the south)	
'Ole-ku-lua	8	'Ole-2	No planting nights
'Ole-ku-kolu	9	'Ole-3	Moon southeast
'Ole-pau	10	'Ole-end = one *anahulu* decan week of 10 days	

These ten "nights," or 10 days, were the first *anahulu* decan week of the month and year. In this circuit of 10 days the lighted part of the moon's crescent increased as the moon continued southward. This was followed by two more anahulu decan weeks of rounding (*poepoe*) of the moon when the lit portion lost its "cusps" (*Ole*, milk teeth) until the fully lit circle, after which it began to wane or "shrink" ('*emi*) back to the dark phase of new moon (Muku).

Huna	11	"hidden" as cusps of the moon
Mohalu	12	Shaula, in Scorpius
Hua	13	Jupiter = one-half sidereal lunation
Akua	14	God (moon in the east)
Hoku	15	Star (full moon)
Mahealani	16	16th moon (full moon)
Kulu	17	"drop" (waning moon)
La'aukukahi	18	"plant" 1 (moon going north)
La'aukulua	19	"plant" 2
La'aupau	20	"plant end" = two anahulu decan weeks
'Ole-ku-kahi	21	'Ole-1 (quarter moon, north)
'Ole-ku-lua	22	'Ole-2
'Ole-pau	23	'Ole-end
Kaloa-ku-kahi	24	Ka(na)loa 1"god of the sea" (fishing)
Kaloa-ku-lua	25	Ka(na)loa 2
Kaloa-pau	26	Ka(na)loa-end
Kane	27	Milky Way = one sidereal lunation
Lono	28	Lono (moon west of north)
Mauli	29	"spirit"
Muku	30	"cut-off" = three anahulu decan weeks =one synodic lunation

The ritual period of tabu days during eight months of the year was coordinated between synodic and sidereal lunations, zenith stars, and azimuths of sun and stars in the ecliptic. [The following is excerpted (and readjusted) from Johnson 2000.]

> The first ritual tabu period of the month, called a pule period, was imposed on the night of Hilo and raised on the morning of Kulua…
> This period of the Ku pule tabu amounted to 2 and 1/2 days, between Hilo, Hoaka, Kukahi, Kulua…
> During the poepoe rounding decan of the waxing moon, the tabu pule period was called the tabu of Hua, imposed on the night of Mohalu (12th night) and raised on the morning of Akua (14th night), i.e., from Mohalu, to Hua, and Akua. This added 1 and 1/2 more days to the 2 and 1/2 day Ku tabu before first-quarter moon…
> A tabu pule period was assigned to the god Ka(na) loa. Imposed for 1 and 1/2 days, it began on the night of 'Olepau and ended on the morning of Ka (na)loa-ku-lua, i.e., from 'Olepau to Kaloakukahi and Kaloakulua…
>
> After Kaloa-pau came the 27th night of Kane when began the tabu pule for this god on 1 and 1/2 days, from the night of Kane to the morning of Mauli, i.e., Kane, to Lono, and Mauli. While including the 28th night of god Lono, no tabu pule was set aside for the god Lono during the month.

(1) Tabu pule of Ku	2 1/2 nights	Hilo, Hoaka, Kukahi, Kulua
(2) Tabu pule of Hua	1 1/2 nights	Mohalu, Hua, Akua
(3) Tabu pule of Kanaloa	1 1/2 nights	Olepau, Kaloakukahi, and Kaloakulua
(4) Tabu pule of Kane	1 1/2 nights	Kane, Lono, Mauli

The tabu period was in force for 240 days and relaxed for 120 days, beginning in the month of October, or the last month of the summer (Kau) season. This anticipated the shift of prevailing winds from the southwest (Kona) and the beginning of the agricultural year, *makahiki*, in November when the Pleiades star cluster (*Makali'i*) was expected to rise above the eastern horizon in the evening, opposite the sun and after the new moon in November.

David Malo, native Hawaiian scholar at Lahainaluna Seminary in the mid-nineteenth century, said:

> The makahiki period began in Ikuwa, the last month of the period called Kau, and the month corresponding to October, and continued through the first three months of the period Hooilo, to wit: Welehu, Makalii and Kaelo, which corresponded with November, December, and January…
>
> There were eight months of the year in which both chiefs and commoners were wont to observe the ordinary religious ceremonies, three of them being the Hooilo months of Kaulua, Nana, and Welo, corresponding to February, March, and April; and five, the Kau months of Ikiiki, Kaaona, Hinaiaeleele, Hilinaehu, and Hilinama, which corresponded to May, June, July, August and September" (Malo 1951: 141).

The moon calendar was a coordination of synodic revolutions of the moon between Hilo and Muku of 29.5 to 30 days/nights of the month with sidereal lunations of 27.3 days/nights based on the transit of the meridian by a star, probably during quarter moon ('Ole nights) until the next transit.

What is the significance of the sidereal/synodic count in lunations of the moon's revolution around the earth and sun in one year? (1) The principle of the sidereal count is that, with respect to a star on the meridian, the moon's period of revolution around the earth is 27.3 days (Kane is the 27th night of the lunation). (2) The principle of the synodic count says that from its starting point at new moon, until it returns to that point, the moon revolves around the earth once every 29.5 days. Thus, (3) For every sidereal revolution of the moon around the earth in 27.3 days, the earth moves 1/13th of its orbit around the sun (with respect to a star on the meridian).

What was then the mode of intercalation to coordinate the sidereal with synodic lunations? We may only infer how that would have been done.

1. If we erase the 1/3rd fraction (Kane = 27 nights)
2. Then: 27 days × 13 months = 351 days = 1 sidereal year
3. We intercalate the fortnight (14 days) = 365 days = 1 tropic year
4. If we include the 1/3rd fraction, then: 13 sidereal months = 27.3 × 13 = 351.39 days
5. Intercalate 13.86 days = 365.25 days

This segment in *Kumulipo Mind* explored the relationship between the indigenous system and that borrowed from nineteenth century European calendrics after contact:

> This formula provided an iconography of time in the sacred structure of temples and ritual schedule to a numerology, such as 16 sidereal lunations is equivalent to 32 fortnights (13.5 days × 16) and 432 days, the significance of which has been explored in the discussion of the decan system and tropic (Johnson 2000: 111–112).
>
> Perhaps by pure chance the formula appears again in the Babylonian use of base 60 in the division of time connected to the earth's rotation on its axis such that 15 degrees equal one hour circle of the earth's rotation, thus:

1. 1 minute = 60 seconds
2. 60 minutes = 1 hour
3. 1 hour = 3,660 seconds
4. 24 hours = 1 day
5. 1 day = 1,440 minutes
6. 1 day = 86,400 seconds
7. 12 hours = 43,200 seconds
8. 6 hours = 21,600 seconds
9. 3 hours = 10,800 seconds
10. 11/2 hours = 5,400 seconds
11. 3/4 hour = 2,700 seconds
12. 3/8 hour = 1,350 seconds

By this may be comprehended that the basic determination is made that the "turning" (kahuli) of the earth on its axis, or because of its rotation, creates the meridian, called *kaupoku o ka hale*, the 'ridgepole of the house' (meaning the house of God, the heiau), cutting the night/day into two halves by which celestial bodies ascend to the zenith (nu'u) and transit by descent to the horizon.

The motion, however, is the earth rotating on its axis, which could not be seen except as a change.

> 'O ke au i kahuli, wela ka honua
> 'O ke au i kahuli, lole ka lani…
> In the time of turning over and around,
> The earth became hot; the sky changed"
> [Wa Akahi, Kumulipo].
>
> The passage of time is then measured by equalizing time on either side of the meridian, as between noon and midnight, or midnight to midnight, or noon to noon. The clock is geared to time elapsing between meridians, rather than between sunset and sunrise, or vice versa. The Hawaiians, like the Babylonians, had discovered the "mean day". By it they set their clock to keep track of the length of one day as from one midnight to the next.

The apparent movement of the sun was observed along the horizon between November and February as a slow period (actually, of the earth's orbit around the sun) and the fast sun between March and October. Perhaps the ancients had determined when the sun appeared to have crossed the celestial equator sometime in April and again in October, or the minor axis of the ecliptic, the major axis between January and July constituting the anomalistic, rather than the tropic year (i.e., the orbit of the earth around the sun).

This was essentially the story of demigod Maui lassoing the sun to make it go more slowly during the winter months by tying down all 16 legs of the sun to a *wiliwili* tree on the western slopes of Haleakala in east Maui. The sun's motion north and south between the solstices was perceived as the motion of a spider (*ke ala a ke ku'uku'u*) as it laid down a web of the celestial grid through which the stars are tracked in their fixed courses from east to west in the night sky.

Finally, as in classic cosmologies of the Mediterranean and Eurasian systems, the sky becomes a pictorialized storyboard conveying by imagery and metaphor the positions and movements of constellations as characters from the ancestral heroic traditions of the past, so that the sky is not filled with nameless lights. The following is part of a continuing quotation excerpted from *Kumulipo Mind*:

> The 'way of the spider' is known in Hawaii as the ecliptic, Ke-ala-a-ke-ku'uku'u 'pathway of the spider' (ku'uku'u, 'to let down, as a net') who is called Tukutuku-raho-nui (spider-of-large-scrotum) 'Great Spider', Tahitian (and Tuamotuan) tutelary deity of net-weaving in the Tahaki cycle. The pathway of this spider was shown on the navigation gourd (ipu makani) diagrammed by Kaneakaho'owaha, counselor to Kamehameha I, in old Hawaii. It had several markings: the celestial equator, Ka Piko o Wakea 'The Navel of Wakea (Sky Father)'; the ecliptic, Ke ala a ke Ku'uku'u 'The Path of the Spider', which was divided into four parts:

1. The limit of the sun's path in the north on the 15th or 16th day of the month Kaulua (June, for Gemini), the summer solstice, Ke Ala Polo-hiwa a Kane "The Black Shining road of Kane"
2. The limit of the sun's path in the south on the 15th or 16th day of the month Hilinama (December, unidentified), Ke Ala Polohiwa a Kanaloa "The Black Shining Road of Kanaloa"
3. The eastern quarter, Ke Ala'ula a Kane 'The Dawning of or the 'Bright (Red) Road of Kane'
4. The western quarter, Ke Ala Ma'awe'ula a Kanaloa 'The Red-Track (as of a spider's thread, from *awe*, strand, thread; '*awe*, tentacle) of Kanaloa'

> A line was drawn in by burning in (pyrogravure) between the North Star (Polaris) and the Southern Cross, indicating the meridian. From another tradition of the navigation gourd, according to Theodore Kelsey, the night sky was graphed, in the form of a net (koko) woven over the calabash of mesh squares, a grid numbering twenty-four to thirty-six spaces (maka), as of a net ('upena), called na maka o 'Alihi 'the eyes of 'Alihi. Below the rim of the gourd, securing the mesh to the rim, was a red cord of 'olona twine called the 'Alihi, corresponding to the name of Tahaki's loyal cousin and helper, Karihi, who assisted Tahaki in reaching the sky world (Kelsey, in Johnson and Mahelona 1975: 150–152).
>
> The Hawaiian navigation gourd net which bears the name of Karihi as the supporting red cord, 'alihi, and the 'eyes of Karihi', na maka o 'Alihi, is a parallel to the net of Tahaki fashioned by Tukutuku-raho-nui 'Great Spider' (Tahiti) whose path was outlined between the solstices and equinoxes on the ecliptic.

Tahaki's birth, like that of Maui, was in a West Polynesian home, and the place where Hema (Sema) was 'caught by the 'A'aia' was in Kahiki-west, or Viti, meaning in the direction of Fiji. In the Ulu genealogy, Kaha'i appears in the tenth generation after Maui.

In Hawaiian myth the spider's web as the shape of the spider in the sky is a form of the supernatural hero, Kana, son of Haka-lani-leo and Hina, chief and chiefess of Hilo, island of Hawaii. Kana was the grandson of Uli, the goddess, and Ku. Uli was the sister of the sky god Wakea and Manu'a (god of the underworld). The name Manu'a belongs to Samoa.

Kana is born supernaturally as a rope which was thrown into a pig pen and forgotten. He is the 12th son. The spirit of the cast-away baby visits the grand-mother Uli, and she recovers the neglected rope, putting it into a calabash of water where it grows 40 fathoms in 40 days, or one fathom a day, but no more than 400 fathoms.

In the meantime Kana's older brother, Niheu, who is only half as tall (five feet) as his ten brothers, is the only person able to lift the ten-fathom one-yard-long great *ulua* fish. Niheu tells his father he is unable to rescue his mother.

Kana is sought to help Hina because of his superb stretching powers, so Kana is sent by Uli to help Niheu rescue Hina from Keoloewa of Moloka'i. Meanwhile Keoloewa orders the turtles to raise the fortress, Ha'upu, on Moloka'i, higher. Niheu tries to climb it but is distracted by the plover who plucks five hairs from his head, whereupon Niheu falls, breaking his leg. (All of Niheu's strength is in his hair, which is never cut). So Kana employs his bodies to reach Haupu fortress:

> …Kana was very angry, for he knew that now they would have a great deal of trouble in rescuing their mother again. Kana turned over in the mats and having thus broken the ropes, stood up. The king saw that this man was taller than his fortress. As Haupu was slowly raised higher and higher, Kana

> stretched his body, first his human body, then his rope body, next his *convolvulus* (morning glory) vine body, his banana (cordage) body, and last his spider web body." (Fornander 1969: II: 16–18).

In a Kaua'i variant the motif of Kana's changing the hill by stamping (on) it with his foot (*ke kapua'i a Kana; kapua'i*, measuring foot; (vs.) *wawae*, "foot," as of the body) is repeated. The name of the hills raised by the turtles, both on Moloka'i and Kaua'i, is Haupu:

> Kana was afraid that it would reach too high, so he stretched himself up until his body was no larger than a spider's web. When he was tall enough, he put his foot on top of the mountain and crushed it down" [Another trait of his demigod is that he possessed two large, staring eyes].

In the tale of Kana the spider's web is the equivalent of the cord kept in a calabash of water. The cord measures out from the calabash, forming a 40–400 fathom rope. This may be interpreted again as the bailing gourd (*Hina-ke-ka*) filled with water and kept on the canoe.

The god of the golden plover, *kolea*, was Lono-kolea-moku, symbolized as a red stone in the heiau foundations at Cape Kumukahi, Puna, Hawaii. The rock was the first in a row of five stones, four of which were called "The Wives of Kumukahi," spaced around the cape and used to mark positions of the sun at its northern (*Hanakaulua* [Gemini]) and southern (*Kanono*, unidentified) limits.

The name Kumukahi (First Foundation) given to the easternmost point of land in the Hawaiian group is associated with the migration of Mo'ikeha from Tahiti. His younger brother, Kumukahi, got off the canoe near the place bearing his name, while Mo'ikeha continued northward. Several others jumped ship between Hawaii and Kaua'i, and Mo'ikeha pressed onward with his companion, La'amaomao, who had the wind calabash (*Ipu makani a La'amaomao*). La'amaomao would call the winds into the *ipu* when they were too strong for the canoe or summoned them forth out of the *ipu* when the sea was dead calm. Yet, when Mo'ikeha sent Kila, his youngest son, to Tahiti to get another son (or nephew), La'amaikahiki, La'amaomao was not in the returning crew doing all of the navigation for Kila.

About four to five centuries later, in the sixteenth to twentieth generation after Mo'ikeha, his mother, La'amaomao-wahine, bequeathed the wind calabash of La'amaomao to Ku-a-Paka'a:

> When La'amaomao finished talking, she opened the cover of a large gourd (ipu nui) and drew out a certain small gourd (ipu hokeo 'u'uku) which had been woven tightly with 'ie (Freycinetia) cord with a cover (po'i) on top.
>
> Then she turned to her son: "I give this gourd to you, as its name was your grandmother's name and mine also, and within it are her bones. When she was alive, all of the winds of this archipelago were her servants, beneath a marvelous power which she received, and she gathered all of the winds into this gourd, and they are still in this gourd until now, and their names were committed to her memory, those from Hawaii to Ka'ula, and when there was no wind, she would remove the cover and call the wind, and the wind would then blow, and when the cover was replaced the wind would cease, and this gourd was famous as the 'Wind Calabash of La'amaomao'." (Nakuina n.d).

The account of the wind calabash of La'amaomao finds a parallel in the Rarotongan tradition of the wind god, Raka-maomao, whereas in Samoa La'amaomao was a war god. In the tradition of Rata, the wizard Nganahoa combats the demons of the sea in a floating calabash called a "red gourd" ('*ue kura*) from which he divines their approach and continues to warn the doubting Rata. Nganahoa, a wizard who flies kites, applies to Rata to go with him on his voyaging canoe to find Vahieroa. Rata considers him useless and leaves without him, but Nganahoa follows him on a large gourd floating on the sea:

> At the time that the canoe sailed away there were only eleven men on board. The canoe sailed on until the land was out of sight, when the crew descried a large gourd floating on the surface of the sea. The crew threw Ngana'oa and his gourd overboard, and left him to his fate (as they thought). …The canoe proceeded on its voyage, and had sailed on for some distance when the crew noticed another gourd floating on the ocean; they at once cried out, 'There is our 'ue-kura floating on the sea.' Rata heard them and called out, 'Pick it up.' They did so, and when they opened it they were again confronted by the glistening eyes of Nganahoa" (Nakuina 1910).

Nganahoa in this form is the bailing calabash, like Hina-ke-ka. In the Tuamotus, Nganahoa is a star represented in Rarotonga as a character prominent in the Rata story. Like Tahaki (Kaha'i), Rata (Laka), grandson of Tahaki, goes on a voyage to find his father, Vahieroa (Wahieloa).

In Hawaii, Nganahoa is the name of the phallic rock on Moloka'i, Ka Ule o Nanahoa (Penis of Nanahoa). This ule was Ul or Uun "Aldebaran" (Hyades, in Taurus) in Micronesian star names. Aldebaran was one of the "four royal stars" or "Guardians of the Sky" in Persian astronomy, 5,000 years ago, when it marked the vernal equinox (Allen 1963: 383–385).

A peculiar attribute of Nganahoa in the Rarotongan version is that when the bailing calabash was brought aboard the canoe, all that was seen inside were the staring eyes of the wizard. In the Ipu-makani-a-La'amaomao carried by Mo'ikeha on his journey, La'amaomao was, apparently, not a body on the canoe, but rather, the bones of an ancestor in the calabash by which Mo'ikeha called the winds to come out when the ocean was dead calm, calling them back when the winds were too strong.

> Aldebaran (Nganahoa, Ka Ule o Nanahoa, Ul, Uun] in Taurus has been an ancient ancestor of star-worshipping wind-watchers on deserts as well as oceans. That the gourd was encased in basketry in Hawaii is clear in the case of the wind calabash of La'amaomao, but the Unu o Lono shrine, as the Ipu o Lono god image in the hale mua men's eating house, was suspended from a net (koko), reminiscent of the net ('upena) that went across the sky in the Kaha'i story.

Often ignored but present in the tradition of the Ipu o Lono is a small note, "This image had suspended from its neck a gourd, ipu, which was perforated to receive a wooden bail" (Malo 1950: 88). This means that the larger gourd of Lono, the *unu* (temple), also carried the *ka* bailing cup, gourd symbol of the goddes Hina-ke-ka, canoe-bailer form of the moon (goddess) (Johnson 1989: 50).

> The Ipu-makani-a-La'amaomao wind calabash is, in part, derived from the Malay word for 'compass', *mata angin*, 'eye of the wind' (*angin*). The standard Polynesian wind compass had eight 'eyes' (*maka*) or as many as thirty-two wind directions ('Aitutaki, Cook Islands). Hina-ke-ka, the bailing gourd, was not the wind compass (Ipu-makani-a-La'amaomao). It was a reflecting mirror or an instrument used as a plumb bob or water level. The Nganahoa calabash carried by Rata (Laka) was thrown out into the sea ahead of the canoe.

If Rigi was the Milky Way in the Caroline Islands (Micronesia) whose worm body became the "Eyes of the Pleiades" (Mata-riki, Makali'i) and was the companion (*hoa*) of Rigi, Aldebaran? After the Pleiades sets, Aldebaran is right behind it all of the time. When the Pleiades rise, Aldebaran is right behind them again. It was called "The Follower" (Al Dabaran), i.e., of the Pleiades, originally given to the entire group of the Hyades (Allen 1963: 383–384). This composed the letter *A* as the *alpha* in the alphabet derived from the head of the bull consisting of Aldebaran as the eye in the face and the other stars above the head constituting the horns. This eye was the Ule o Nanahoa (Nganahoa) in the wind calabash of La'amaomao (Hawai'i) that had helped Rata sail his canoe in the lands between Samoa, Tonga, and probably, Rarotonga where the tradition is prominently remembered as it is in Hawai'i.

The sky was a place to picture the characters and creatures in the heroic Polynesian past. The major figure was the culture hero and demigod Maui-ki'iki'i-a-Kalana whose position in the stars favored the constellations of Hercules, Ophiucus beneath, and Sagittarius in the ecliptic to the south. Available to Maui in that hour circle and the adjoining one is the constellation of Scorpius, with which the hero pulled up the land of Hawai'i as a giant fish. Scorpius is pictured as the fishhook that Maui used (Ka makau nui o Maui), three stars lying from east to west above the bright star and mid-shank of the hook, Antares, first magnitude star in the fishhook constellation as it curves around Shaula (Mohalu) to Leshaa in the barb. From the city of Honolulu this "hook" rises over the crater of Diamond Head to the southeast and drags over the sky until it sets to the west. Maui in Hercules sets before the hook ascends, 180° away on the eastern horizon, or a composition of Maui's three brothers, Maui-mua, Maui-roto, and Maui-pae, who are the three stars in the Belt of Orion stretched over 10° on either side of the equator. They are pictured as sitting in a canoe as they are helping Maui to pull together the fish that Maui caught and which drifted into separate parts. They were told not to look back, and as one of the three brothers does look back, the fish comes apart again into separate islands. Otherwise they are three men in a boat in a canoe house straddling the equator. Beside the Belt of Orion in the place of his sword, the ancient Hawaiians evidently saw the same shape of a weapon, calling it Na Kao, the javelins, i.e., the Belt and Sword of Orion, or perhaps they mistook it for Na Ka o Makali'i, the bailers (i.e., bailing gourds) of Makali'i (in the Pleiades).

Another interesting facet of Scorpius is that it lies within the swirling, twisting motion of a stream or pond of water, the Milky Way, as it courses or spirals across the sky during its own moving about. It will be seen stretched across the sky as a diagonal, from northeast to southwest, and only certain stars and constellations lie in the stream, called the Wai Ola a Kane, or living waters of Kane, the creator-god. In the same stream lies a reptile or shark called 'Ai-kanaka, whose wife is the moon, Hina-hanai-a-ka-malama. Through the year the lizard or reptile will jackknife across the overhead skies as the swirling stream moves until it is lying from northwest to southeast. Then it lies in two separate streams across the north and across the south, and then arches around the entire visible horizon before it slips off the edge of the world and comes back again, spiraling across the sky from northeast to southwest.

This is the galaxy, and the center around which it spirals is the galactic equator, and by it the ancient priesthood also told time. The motion of breaking up of the spiral was called *Kaha'i, Ha'iha'i, Ha'imoha'i*, for another hero of the migrations, Kaha'i, who went to the skies on a rainbow to look for his missing father, Hema. Only certain stars and constellations are found in the *Wai Ola*, pictured also as a coconut tree, with branches opening to the north and the roots growing to the south. Sirius lies outside this swirl, seeming to be alone and thus called, Lono-meha, "Lone Lono." Another star that seems to shine alone and brightly to the north is Arcturus in Bootes, called Hokule'a, meaning "clear star" or "star of gladness," according to the Polynesian Voyaging Society which named the canoe after Arcturus.

Otherwise, the Milky Way was called the "spine," *Kuamo'o*, in which the following were always found: Castor and Pollux in Gemini, called the "Twins"; Mahana Kaulua, or Na Mahoe, the twin in front, Castor, Mahoe Mua, and the twin behind, Pollux; Mahoe Hope; the Hyades, Kaomaaiku or Kanukuokapuahi; the Magellanic Clouds, "butterflies," Pulelehuakea, Pulelehuaeli; stars in Lyra, Keoea, Keho'oea, and Scorpius.

In the opposite pole, Canopus was called the solitary "Lord of Space," Ali'i-o-Kona-i-ka-lewa. It occupies the pole at one time, the star Achernar at another, and then there is the Southern Cross, rising on its side in the east, then coming upright, before tilting to the west and going out of sight. Some Hawaiians see a triggerfish, *Humu*, as the *humuhumu-nukunuku-a-pua'a*, or pig-snout fish in which the pig demigod, Kamapua'a, made his journeys by sea assuming the form of a triggerfish. The snout of the fish is pointed downward and the fin upward. Others knew the Southern Cross as a "cross" Hoku Ke'a, or a batfish, one of the skates or rayfish with wings outspread, tail upward, guilty for stealing the moon and hiding her, mother of culture hero Maui-ki'iki'i-a-kalana. So Maui retrieved Hina from the clutches of the batfish by waiting for the demon fish to close all of its eight eyes in sleep before he cut all of them out of the head of the monster. Another *humu* star, meaning, to be sewn or patched together, *humu*, is Humu, or Altair in Aquila, west of Maui-ki'iki'i-a-kalana. The pole star to the north, Polaris, is called Hokupa'a, "Fixed Star," but then all stars fixed in their tracks were called *na hoku pa'a* as against "wandering stars" or planets, the *hoku ae'a*, "wandering" or "vagabond" stars. The whole constellation of the Big Dipper was called "The Seven," Na Hiku.

Below the pole starting with Perseus is a line of stars that meets up with the asterism of the Pleiades in the head of the Bull, Taurus. These stars are called *a line*, i.e., Ka Lalani. Near the Pleiades, called "Little Eyes", Makali'i, are the Hyades, which are the opening of the fireplace, *Ka Nuku o Kapuahi*, recalling perhaps, as on the island of Mangaia in the Cook group, that a tribe of people suffered being cooked alive in an oven. Aldebaran in the eye of the Bull is called *Ka Oma Aiku*, meaning the adze of Aiku, one of the heroes of the migrations in the south, also known as Aukele-nui-Aiku, a navigator who found the home of Pele's sister in Ra'iatea and Borabora. The other "twins," Mahapili, are in Scorpius. The orbit of the stars was called the "circular road," *Ala Poai*. For the most part, so many star names retained in the nomenclature are unidentified, indicating the loss of much that the ancients had identified about the sky concerning the heroic past of their own wanderings, as they often called it, to go over the horizon ever receding.

Astronomy of the Hebrews

Y. Tzvi Langermann

The Hebrew astronomical tradition that shall be surveyed in this essay is that tradition recorded in the Hebrew alphabet dealing with the motions of the heavenly bodies and the structure of the heavens. These writings utilize principally the Hebrew language, but include texts in languages such as Aramaic and Arabic that can be written out in Hebrew script. Topics of specifically Jewish interest, such as calendar computations and doctrinal matters, occupy only a minor portion of this literature. For the most part, the Hebrew astronomical tradition differs little from contemporary writings belonging to the traditions with which Jews found themselves in immediate contact at any given age and place. To the extent that these other traditions may be classified as non-Western, the Hebrew tradition may be by and large considered such.

The earliest substantive materials are found in the *Talmud* and *Midrash*. Most of the discussions center upon the structure and physics of the heavens. Of particular interest are several notices of disagreement between Jewish and non-Jewish experts, for example, on the question of whether it is the star itself, or the spherical shell within which the star was thought to be embedded, which moves around the earth. In other words, we have clear evidence that even at this early date Jewish scholars identified themselves with particular conceptions of the heavens. *Pirqei di-Rebbe Eliezer, Baraitha di-Mazalot*, and *Baraitha di-Shmuel* are three post-Talmudic writings whose precise dating is problematic but which certainly precede the flowering of the sciences under the Abbasids. The latter two are the earliest texts which preserve any mathematical astronomy, e.g., a computational scheme for shadows. In addition, al-Khwārizmī's treatise on the Jewish calendar, which belongs to the Arabic tradition but is almost certainly based on Jewish sources, exhibits positional data for the epoch of the Temple. All of this indicates that a Hebrew tradition, drawing upon Indian, Hellenistic, and other sources, had developed by the eighth century.

Without doubt the years spanning the ninth through sixteenth centuries were the most fecund for the Hebrew tradition. During this period, which is more or less commensurate with what Western historians have long called the medieval age, interest in astronomy was especially stimulated in Arabic speaking lands from Spain to Iraq. Contemporary Jewish writings consist for the most part of exposés or translations of the fruits of Arab science. Dozens of works were written, surviving in hundreds of manuscripts; only a few can be surveyed here. Abraham bar Ḥiyya created a Hebrew astronomical vocabulary that endured side by side with that developed by the Tibbons, the famous family of translators of Arabic literature. Abraham ibn Ezra's astrological writings were immensely popular both in the Hebrew original and in Latin translation. Both Abrahams utilize more ancient sources that are no longer extant. Isaac Israeli's *Yesod ʿOlam* is a thorough analysis of all of the astronomical and historical questions connected with the Jewish calendar; his book, written in 1310 in a polished Hebrew style, may be considered the pinnacle of the Spanish Hebrew tradition. All the same, Hispano–Jewish authors continued to produce treatises in Hebrew and Judeo-Arabic through the end of the fifteenth century. For instance, the work of Abraham Zacuto, so important for the Portuguese explorers, appeared around the time of the expulsion of Jews from Spain.

Southern France, Italy, and Byzantium were the other major centers of astronomical activity during this period. Emmanuel ben Jacob, Jacob Anatoli, and Mordecai Comtino are, respectively, perhaps the most important representatives of the Hebrew tradition in those lands. In those areas in particular, Jews drew upon Latin, Romance, and other literatures, as well as Arabic materials.

The two outstanding philosophers of this period, Moses Maimonides and Levi Gersonides, participated strongly in the Hebrew astronomical tradition. Maimonides' wrote a small work on the calendar, and he included in his great law code, the *Mishneh Torah*, a detailed scheme for computing the first visibility of the lunar crescent. However, Maimonides' weightiest contribution is the very high value which he placed on the study of astronomy within the context of his religious philosophy, something which encouraged many Jews to acquaint themselves with, at the very least, non-technical resumés of astronomical knowledge.

Levi Gersonides was without doubt the most creative representative of the Hebrew tradition, indeed one of the greatest scientists of his epoch. He too developed his astronomical views within the framework of a finely tuned and very comprehensive religious philosophy. Levi was both an observer and a theoretician, and, most notable, one of the rare breed who attempted to fit his own original theory, which had to answer to certain philosophical constraints, to his own observations. Among his other major achievements, Levi invented the Jacob's staff, a simple but accurate instrument for measuring the angular distances between stars; studied the errors involved in instrumental measurements; and arrived at a much greater (and hence more realistic) value for the distances of the stars than those accepted by his contemporaries.

Jews living in Islamic lands, most especially the Yemen, continued to study the ancient and medieval texts well into the twentieth century. In those countries the Hebrew tradition was maintained chiefly through the copying of manuscripts, often transcriptions of Arabic texts into the Hebrew alphabet. In European countries the study of Latin texts in Hebrew translation seems to have accelerated in the fifteenth and sixteenth centuries. Some three Hebrew translations of Georg Peurbach's *Theorica* were executed, and several Hebrew commentaries were written, *inter alia* by Moses Isserles of Cracow and Moses Almosnino of Salonika, both of whom were leading rabbis of their times.

There is little in the Hebrew tradition that reflects the great advances associated with the European scientific revolution. Joseph Delmedigo, a widely traveled Cretan who studied under Galileo, published the only lengthy and detailed Hebrew exposition of the new science. Other publications, such as Tuviah Cohen's *Maaseh Tuvia* (Tuvia's Opus), present the new science in somewhat abbreviated form; and yet other writings, such as Solomon Maimon's exposé of Newton's work, remain in manuscript. The Hebrew tradition revived during the nineteenth century, particularly due to the efforts of the *maskilim*, advocates for widening the intellectual horizons of Judaism, who published Hebrew scientific texts in a number of fields. With the re-establishment in the State of Israel of a native Hebrew speaking population, and, no less importantly, institutions interested in teaching and writing about astronomy in the Hebrew language, the quantity and scope of the Hebrew tradition have dramatically increased.

Astronomy in India

K. V. Sarma

Astronomy in India, as it was in other ancient civilizations, was interwoven with religion. While the different facets of nature, the shining of the sun, the waxing and waning of the moon, and the alternation of the seasons all excited curiosity and evoked wonder, religious practices conformed to astronomical timings following the seasons, equinoxes, solstices, new and full moons, specific times of the day and the like. In the Vedas, the earliest literature of the Hindus, mention of professions such as *Gaṇaka* (calculator) and *nakṣatra-darśa* (star-gazer), and the mention of a branch of knowledge called *nakṣatra-vidyā* (star science) are illustrative of the fascination that the celestial bodies exerted on the Vedic priests.

The Vedas and their vast ancillary literature are primarily works of a religious nature, and not textbooks on astronomy. Still, they inform about the astronomical knowledge, mainly empirical in nature and often mystic in expression, which Vedic Indians possessed and used in their religious life. One finds in the *Ṛgveda* intelligent speculations about the genesis of the universe from nonexistence, the configuration of the universe, the spherical self-supporting earth, and the year of 360 days divided into 12 equal parts of 30 days each with a periodical intercalary month. In the *Aitareya Brāhmaṇa*, we read of the moon's monthly elongation and the cause of day and night. Seasonal and yearly sacrificial sessions helped the priests to ascertain the days of the equinoxes and solstices. The shifting of the equinoxes made the Vedic priests correspondingly shift the year backward, in tune with the accumulated precession, though the rate thereof was not envisaged. The wish to commence sacrifices at the beginning of specific constellations necessitated the identification of the constellations as fitted on the zodiacal frame. They also noticed eclipses, and identified their causes empirically.

The computational components and work rules for times for Vedic rituals are to be found in the *Vedāṅga Jyotiṣa* (Vedic Astronomical Auxiliary), composed by Lagadha. On the basis of the astronomical configurations given in its epoch, the date of this text is ascertained to be in the twelfth century BCE. This work sets out such basic data as time measures, astronomical constants, tables, methodologies, and other matters related to the Vedic ritualistic calendar. It prescribes a 5-year lunisolar cycle (*yuga*) from an epoch when the sun and the moon were in conjunction on the zodiac at the beginning of the bright fortnight, at the commencement of the asterism Delphini (*Śraviṣṭhā*) of the (synodic month of) *Maghā*, and of the (solar month) *Tapas*, when the northward course of the sun began. The constants are contrived to be given in whole numbers for easy memorization. Accordingly, the *Vedāṅga Jyotiṣa* chose a unit of 1,830 civil days as its unit, which it divided into 5 years of 366 days each, the error of the additional 3/4 day in the year being rectified periodically. One thousand eight hundred and thirty days is equal to 62 synodic or lunar months of 29.5 days each, and 60 solar months. The two extra intercalary lunar months are dropped, one at the middle and the other at the end of the cycle, so that the two, the solar and lunar years, commenced together again, at the beginning of each cycle.

During the age that followed, a series of astronomical texts was written, mainly by 18 astronomers. Passages from some of these texts were quoted in later texts, and five of them were redacted by Varāhamihira (d. 587) in his *Pañcasiddhāntikā*. The texts of this age which are still available are the *Gargasaṃhitā*, *Parāśarasaṃhitā*, and the Jain texts *Sūryaprajñapti*, *Candraprajñapti*, and *Jambūdvīpa-prajñapti*. The astronomy contained in those is practically the same as that expounded in the *Vedāṅga Jyotiṣa* though with minor differences, including the shifting of the commencement of the year to earlier asterisms due to the precession of the equinoxes.

From about the beginning of the Christian era a number of texts were composed with the generic name *Siddhānta* (established tenet). The scope of these texts was wider, their outlook far-reaching, and their methodology rationalistic. Also, the science began to be studied for its own sake. The stellar zodiac was replaced with the 12-sign zodiac, and, besides the Sun and the Moon, the planets also began to be reckoned. Their rising and setting, motion in the zodiacal segments, direct and retrograde motion, times of first and last visibilities, the duration of their appearance and disappearance, and mutual occultation began to be computed. These and their synodic motion called *grahacāra* were elaborately recorded. Analyses of these recordings enabled the depiction of empirical formulae for computing their longitudes. While the use of the rule of three (*trai-rāśika*, direct proportion), continued fractions, and indeterminate equations helped computation, the use of trigonometry, both plane and spherical, and geometrical models enabled a realistic understanding of planetary motion, and developed rules, formulae, and tables. This resulted also in fairly accurate prediction of the eclipses and occultation of the celestial bodies. It is to be noted that in Indian astronomical parlance, the word *graha* signifies not only the planets Mars (*Kuja*), Mercury (*Budha*), Jupiter (*Guru*), Venus (*Śukra*), and Saturn (*Śani*), but also the Sun (*Ravi*, *Sūrya*), Moon (*Candra*), the ascending node (*Rāhu*), and the descending node (*Ketu*).

Yuga in Indian astronomy denotes a relatively large number of years during which a celestial body, starting from a specific point on its orbit, made a certain number of revolutions and returned to the same point at the end of the period. In the *siddhānta* texts the starting point is taken as the First point of Aries (*Meṣa-ādi*) (vernal equinox). Through extended observation over long periods, methods were formulated for ascertaining accurately the motion of the planets, as in the *Āryabhaṭīya*. Having obtained in this manner the sidereal periods of all the planets, their lowest common multiple was calculated backward to provide accommodation to the revolutions of the relevant celestial bodies. Thus the *Vedāṅga Jyotiṣa* used a 5-year *yuga* to accommodate only the sun and the moon. Later, the planets were included and the *Romakasiddhānta*, redacted by Varāhamihira, used a *yuga* of 2,850 lunisolar years, and the *Saurasiddhānta* used a *yuga* of 108,000 solar years. Āryabhaṭa (b. AD 476) formulated a *mahā-yuga* (grand cycle) of 4,320,000 years which was set to commence at the First point of Aries on Wednesday, at sunrise, at Laṅkā, which is a point on the terrestrial horizon of zero longitude, being the Greenwich meridian of Indian astronomy. He devised also a shorter *yuga*, called *Kali-yuga*, of 432,000 years, which commenced on Friday, February 18, 3102 BCE, where, however, the apogee and node were ahead by 90° and behind by 180°, respectively. Pursuing the same principle, other astronomers have devised *yugas* of different lengths, and still others have suggested zero corrections to the mean position of the planets at the beginning of the *yuga*.

Computing the longitude of a planet when the length of the *yuga* in terms of civil days, the *yuga* revolutions, and the time at which its longitude is required are given, reduces itself to the application of the rule of three, if the planetary orbits are perfect circles and the planetary motions uniform. Indian astronomers conceive their motion along elliptical orbits according to the epicyclic model or their own eccentric model. In the former, the planets are envisaged as moving along epicycles which move on the circumference of a circle, and in the latter, the planets are supposed to move along a circle whose center is not at the center of the earth, but on the circumference of a circle whose center is the center of the earth. Both models give the same result. Several sets of sine tables are also derived and several computational steps called *manda* and *śīghra* are enunciated to give the heliocentric positions in place of the geocentric.

When the true longitude of a planet at a particular point of time is to be found, the *ahargaṇa* (count of days) from the epoch up to the sunrise of the day in question is ascertained. To this is added the time elapsed from sunrise on the relevant day to the required point of time. Since the number of days in the *yuga* and the number of the relevant planetary revolutions (which are constants) are known, the revolutions up to the moment in question are calculated by the rule of three, and the completed revolutions discarded. The remainder would be the position of the mean planet at sunrise of the day in question at zero longitude (i.e., Laṅkā or Ujjain meridian). To get the correct longitude, four corrections are applied to the result obtained above. They are (1) *Deśāntara*, the difference in sunrise due to the difference in terrestrial longitude, (2) *Cara* (ascensional difference), due to the length of the day at the place, (3) *Bhujāntara*, the equation of time caused by the eccentricity of the earth's orbit, and (4) *Udayāntara*, the equation of time caused by the obliquity of the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course) with the celestial equator.

As a striking natural phenomenon, the eclipse had been taken note of and recorded in several early Indian texts. A solar eclipse was recorded in the *Ṛgveda*, where it describes how, when Svarbhānu (the dark planet *Rāhu* of later legends) hid the sun, sage Atri restored it, first as a black form, then as a silvery one, then as a reddish one, and finally in its original bright form. On account of the popular and religious significance associated with eclipses, their prediction assumed great importance in Indian astronomy. In the *Pañcasiddhāntikā*, details of the computation of the lunar eclipse were given in the *Vāsiṣṭha-Pauliśa* and *Saura Siddhāntas* with geometrical diagrammatic representation, and the solar eclipse in the *Pauliśa*, *Romaka*, and *Saura Siddhāntas*. The treatment in later *siddhāntas*, like those of Āryabhaṭa, Brahmagupta, Śrīpati and Bhāskara II, and also the *Sūryasiddhānta*, is accurate. A number of shorter texts also were written solely on the computation of eclipses, aiming at greater perfection.

The Vedas call the intrinsically dark moon *sūrya-raśmi* (sun's light), and thought that it was born anew every day in different configurations. Each of the 15 lunar days of the bright and the dark fortnights have high religious significance, and different Hindu rites and rituals are fixed on their basis.

From the early *siddhānta* age, computation of the moon's phases is referred to by the term *Candra-śṛṅga-unnati* (Elevation of the horns of the moon) and is computed elaborately. The first work to give this computation is the *Pauliśa Siddhānta*, which devotes an entire chapter to this subject. Most of the later *siddhāntas* also devote one chapter to the subject, adding corrections and evolving newer methods, and also giving graphical representations.

Still another topic which finds computational treatment in *siddhānta* texts is the conjunction of planets and stars. Two bodies are said to be in conjunction when their longitudes at any moment are equal. The conjunction of a planet with the sun is called *astamaya* (setting), with the moon is *samāgama* (meeting), and with another planet, it is *yuddha* (encounter). The conjunction of a planet with a star is similar, but with the difference that a star is considered a ray of light and has no *bimba* (orb) or motion. The computational methods followed are similar to those in the case of eclipses, with minor modifications. Full chapters are devoted in *siddhānta* texts to computing this phenomenon.

Although naked eye observations and the star-gazer (*nakṣatradarśa*) find frequent mention in Vedic literature, mechanical instruments are of a later origin. The earliest instruments used were the gnomon (*śaṅku*) for finding the cardinal directions, used in the *śulbasūtras*, and the clepsydra (*nāḍī-yantra*) for measuring time. The *Pañcasiddhāntikā* devotes one long chapter to "Graphical Methods and Astronomical Instruments." While Āryabhaṭa gives only the underlying principles in his *Āryabhaṭīya*, he has a long section of 31 verses on instruments in his *Āryabhaṭasiddhānta*. Almost all later *siddhāntas* have a full chapter on instruments, which include the armillary sphere, rotating wheels, and shadow, water, circle, semicircle, scissor, needle, cart, tube, umbrella, and plank instruments. Some of these are used for observation; others are for demonstration. After the advent of Muslim astronomy in India, the astrolabe became common and even Hinduized. A number of texts in Sanskrit also were written on the astrolabe, among which the *Yantrarāja* of Mahendra Sūri and *Yantracintāma* of Viśrāma are important. The pinnacle of this activity came with Sawai Jai Singh, ruler of Jaipur, who patronized a group of astronomers, built five huge observatories, in Delhi, Jaipur, Ujjain, Varanasi, and Mathura, and wrote the work *Yantrarāja-racanā* (Construction of Astrolabes).

Toward the early centuries of the Christian era, texts with the generic name *siddhānta* (tenet), in contrast to the earliest astronomical texts, were composed. These were mathematically based, rationalistic, and adumbrated by geometric models and diagrammatic representations of astronomical phenomena. While Varāhamihira selectively redacted in his *Pañcasiddhāntikā* five of the early *siddhāntas*, his elder contemporary, Āryabhaṭa (b. AD 499) produced a systematic *siddhānta* treatise entitled *Āryabhaṭīya*, in which he speaks also of the diurnal rotation of the earth. The work is divided into four sections, covering the following subjects: (1) planetary parameters and the sine table (*Gītikā-pāda*), (2) mathematics (*Gaṇitapāda*), (3) time reckoning and planetary positions (*Kālakriyā-pāda*), and (4) astronomical spherics (*Gola-pāda*). This *siddhānta*, which started the Āryabhaṭan school of astronomy, was followed by advanced astronomical treatises written by a great number of astronomers and was very popular in the south of India, where astronomers wrote a number of commentaries and secondary works based on it.

Brahmagupta (b. AD 598) started another school through his voluminous work *Brāhmasphuṭasiddhānta* in 20 chapters. This work shows Brahmagupta as an astute mathematician who made several new enunciations. He also wrote a work by the name of *Khaṇḍakhādyaka* in which he revised some of Āryabhaṭa's views. Among the things that he formulated might be mentioned a method for calculating the instantaneous motion of a planet, correct equations for parallax, and certain nuances related to the computation of eclipses. Brahmagupta's works are also significant for their having introduced Indian mathematics-based astronomy to the Arab world through his two works which were translated into Arabic in about AD 800.

Bhāskara I (ca. AD 628), who followed in Āryabhaṭa's tradition, wrote a detailed commentary on *Āryabhaṭīya* and two original treatises, the *Laghubhāskarīya* and the *Mahābhāskarīya*. Vaṭeśvara (b. AD 880) wrote his erudite work *Vaṭeśvarasiddhānta* in eight chapters, in which he devised precise methods for finding the parallax in longitude (*lambana*) directly, the motion of the equinoxes and the solstices, and the quadrant of the sun at any given time. He also wrote a work on spherics. Śrīpati, who came later (ca. AD 999), wrote an extensive work, the *Siddhāntaśekhara*, in 20 chapters, introducing several new enunciations, including the moon's second inequality.

The *Sūryasiddhānta*, the most popular work on astronomy in North India, is attributed to divine authorship but seems to have been composed about AD 800. It adopts the midnight epoch and certain elements from the old *Saurasiddhānta*, but differs from it in other respects. It promulgates its own division of time-cycle (*yuga*) and evinces some acquaintance with *Brāhamasphuṭasiddhānta*.

The *Siddhāntaśiromaṇi* of Bhāskara II (b. AD 1114) comprises four books: *Līlāvatī* dealing with mathematics, *Bījagaṇita* with algebra, *Gaṇitādhyāya* with practical astronomy, and *Golādhyāya* with theoretical astronomy. The author's gloss on the work which he calls *Vāsanā* (Fragrance) is not only explanatory, but also illustrative and highly instructive. Extremely popular and widely studied in North India, the work has been commented on by generations of scholars.

The *siddhānta* texts composed later, when Muslim astronomy had been introduced into India, bear its influence in the matter of parameters and models though the general set up remains the same. The more important among these are the *Siddhāntaśindhu* (1628) and *Siddhāntarāja* (1639) of Nityānanda, *Siddhāntasārvabhauma* (1646) of Munīśvara, *Siddhāntatattvaviveka* (1658) of Kamalākara, and the *Siddhāntasārakaustubha* (1732) of Samrāṭ Jagannātha.

In order to relieve the tedium in working with the very large numbers involved when the *mahāyuga* or *yuga* is taken as the epoch, a genre of texts called *karaṇas* was evolved which adopted a convenient contemporary date as the epoch. The mean longitudes of the planets at the new epoch were computed using the *siddhāntas* and revised by observation, and the resulting longitudes were used as zero corrections at the epoch for further computations. In order to make computations still easier, planetary mean motions were calculated for blocks of years or of days, and depicted in the form of tables. Each school of astronomy had a number of *karaṇa* texts, produced at different dates, and often exhibiting novel shortcuts and methodologies. While the North Indian texts had tables with numerals, South India, particularly Kerala, had its own traditions, and depicted the daily motions of the planets, sines of their equations, and other matters in the form of verses with meaningful words and sentences, employing the facile *kaṭapayādi* notation of numerals. The earliest *karaṇa* texts are the redactions by Varāhamihira in his *Pañcasiddhāntika* of the *Romaka*, *Pauliśa*, and *Saura Siddhāntas*, the epoch of all the three being 21st March, 505 AD.

Hindu religious life, which served as the incentive to the development of astronomy in India in its beginnings, has continued to be so even today for the orthodox Indian. The *pañcānga* (five-limbed) almanac, which is primarily a record of the *tithi* (lunar day), *vāra* (weekday), *nakṣatra* (asterism), *yoga* (sum of the solar and lunar longitudes), and *karaṇa* (half lunar day), can be said to direct and regulate the entire social and religious life of the orthodox Hindu. Though the primary elements of the almanac are identical throughout India, other matters like the sacred days, festivals, personal and community worship, fasts and feasts, social celebrations, customs, and conventions differ from region to region. These matters are also recorded in the almanacs of the respective regions. In order to bring about some uniformity in the matter, the Government of India appointed a Calendar Reform Committee in 1952 which made several recommendations, but conditions have not changed much.

In astronomy, as in other scientific disciplines, the Indian ethos had been to depict the formulae and procedures, but refrain from giving out the rationale, though much rationalistic work would have gone before formulation. This position is relieved by a few commentators, such as Mallāri in his commentary on the *Grahalāghava* of Gaṇeśa Daivajña and Śaṅkara Vāriyar in his commentaries on the *Līlāvatī* of Bhāskara II and the *Tantrasaṅgraha* of Nīlakaṇṭha Somayāji. It is also interesting that there are texts wholly devoted to setting out rationales, like the *Yuktibhāṣa* of Jyeṣṭhadeva. Even more interesting are texts like *Jyotirmīmāṁsā* (Investigations on Astronomical Theories) by Nīlakaṇṭha Somayāji, which open up a very instructive chapter of Indian astronomy.

Astronomy: Indian Astronomy in China

Yukio Ōhashi

Chinese astronomy and Indian astronomy were originally independent. Both of them already had developed when Indian astronomy was introduced into China along with Buddhism. The exact date of the introduction of Buddhism into China is not known, but it can be said that Buddhism was gradually introduced at the beginning of the Later Han (Eastern Han) dynasty (AD 25–220) or so. According to my study, the earliest information on Indian astronomy reached China at the time of the Later Han.

During the Sanguo (Three Kingdoms) period (AD 220–265), some Buddhist works, where information of Indian astronomy was included, were translated into Chinese. At the time of the Tang dynasty (AD 618–907), some detailed monographs of Indian astronomy and astrology were composed in China. There were some astronomers who were well versed in both Chinese and Indian astronomy. Yixing was one of them.

It is not known whether Chinese astronomy was introduced into pre-modern India or not.

Indian Astronomy in the Later Han Dynasty

At the time of the Former Han (Western Han) dynasty (206 BCE–AD 23), there was no apparent foreign influence on Chinese astronomy. As Buddhism was already known at the time of the Later Han dynasty, there was a possibility that certain aspects of Indian culture, including astronomy, were also introduced into China.

According to my research, some fragments of information about the Indian calendar reached China at the time of the Later Han dynasty (Ōhashi 1999). There are three reasons for my view:

1. When the Later Han *Sifen* calendar was compiled in AD 85, its first month was proposed to be large, although that was finally rejected. In the Chinese traditional calendar, the first month was small, because the first new moon occurs at the initial point of time, and the second new moon is included in the first day of the next month. To the contrary, the first month of the Indian traditional calendar was large, because the first new moon occurs at the initial point of time, and the second new moon is included in the last day of the same month. I suspect that the rejected proposal of the Later Han *Sifen* calendar might have been influenced by the Indian method.
2. The Later Han *Sifen* calendar has special days called *mori* and *mieri*, which did not exist in the Former Han dynasty. If 1 year is divided into 360 parts and 1 day is included within a part, the day is called *mori*. If the end of a day coincides with the boundaries of the parts, the day is called *mieri*. These days are of no use in Chinese traditional calendars, but they are similar to certain concepts of Indian traditional calendars, such as the method of intercalation in the *Arthaśāstra* (see the section on Yixing below; for details, see Ōhashi 2001).
3. In Chinese traditional calendars, midnight is considered the beginning of a day. However, when the date of the half moon and full moon was calculated in the Later Han *Sifen* calendar, daybreak was considered to be the beginning of a day. In Indian traditional calendars, sunrise is usually the beginning of a day. Therefore, the Chinese use of daybreak might have a connection with the Indian method.

From these three reasons, I suspect that certain information about the Indian calendar reached China.

However, the information must have been fragmental, and did not influence the Chinese calendar very much.

Indian Astronomy in Chinese Buddhist Texts

The *Madengqie-jing*

At the time of the Sanguo (Three Kingdoms) period (mid-third century AD), a Buddhist text called *Śārdūlakarṇa-avadāna* in Sanskrit was translated into Chinese by Zhu Lüyan and Zhi Qian as the *Madengqie-jing*. This is the first Chinese text where Indian astronomy and astrology are explicitly mentioned. This text explains lunar mansions and the astrology based on them at length and also mentions some calendrical information.

The astronomical system of the *Śārdūlakarṇa-avadāna* is similar to *Vedāṅga* astronomy, which is one of the six branches of auxiliary learning for the *Veda*. According to my research, *Vedāṅga* astronomy was produced in North India sometime between the sixth and the fourth centuries BCE (Ōhashi 1993). The description of astrology in the *Śārdūlakarṇa-avadāna* is also based on the Indian traditional system.

The original Sanskrit version of the *Śārdūlakarṇa-avadāna* has a description of the annual variation of the gnomon shadow, which is similar to that in *Vedāṅga* astronomy. The Chinese version, *Madengqie-jing*, also has a description of the annual variation of the gnomon shadow, but it is different from the Sanskrit original. Shinzō Shinjō, a pioneer of the study of the history of Eastern astronomy, pointed out that the description of the *Madengqie-jing* is based on the data around 43°N, and that the data might have been incorporated in Central Asia (Shinjō 1928: 217–218).

The *Śārdūlakarṇa-avadāna* was also translated into Chinese as the *Shetoujian-taizi ershiba-xiu jing* by Zhu Fahu at the time of Xi-Jin (Western Jin) dynasty (AD 265–316).

The *Daji-jing*

The *Daji-jing* (or *Dafangdeng-dajijing*) is a collection of *Mahāyāna* texts in Chinese. The *Yuecang-fen* (one text in the *Daji-jing*), which was translated by Narendrayaśa in AD 566, is the earliest Chinese text where zodiacal signs are mentioned.

The *Ricang-fen* (another text in the *Daji-jing*), which was translated by Narendrayaśa in AD 586, also mentions zodiacal signs. It is interesting to note that the annual variation of the length of daytime and that of the gnomon shadow, which are similar to those of the *Vedāṅga* astronomy, are mentioned there, but the position of the sun corresponding to their data is given with reference to zodiacal signs. This means that the system of *Vedāṅga* astronomy was still in use when Greek horoscopy reached India. *Vedāṅga* astronomy was widely used in India from sometime between the sixth and the fourth centuries BCE to sometime during the second and fourth centuries AD, and was mixed with the system of zodiacal signs which was introduced into India along with Greek horoscopy in the second or third century AD (Ōhashi 2002).

The *Ricang-fen* of the *Daji-jing* is, therefore, an important source for studying the history of Indian astronomy. It says that the length of daytime and nighttime is 15 *shi* (which corresponds to Indian *muhūrta* or 1/30 of a day) in the months of Scorpio and Taurus, and that daytime is 12 *shi* (minimum) and nighttime is 18 *shi* (maximum) in the month of Aquarius, and daytime is 18 *shi* and nighttime is 12 *shi* in the month of Leo. The length of daytime and nighttime changes linearly. The above-mentioned data look strange at first sight. The relationship between the length of daytime and nighttime and the sign of zodiac differs by one. For example, the above data tell that the vernal equinox occurs in the month of Taurus, and not in the month of Aries. The only possible explanation of this difference is that the data of the length of daytime and nighttime is for the beginning of the month, and the sign of the zodiac is for the end of the month. The linear function of the length of daytime and nighttime is the same in *Vedāṅga* astronomy. My studies reveal that this function is not the result of interpolation from the observational data around the solstices, but the result of extrapolation from the observational data around the equinoxes in North India. The *Ricang-fen* also gives the length of the midday gnomon shadow, which is basically the same as in *Vedāṅga* astronomy, which is also based on observational data from North India. Here, we can see that *Vedāṅga* astronomy was still widely used even after Greek horoscopy was introduced into India (Ōhashi 2002).

Indian Astronomy During the Tang Dynasty

The *Jiuzhi-li*

One system of Hindu Classical Astronomy was introduced into China. It was recorded in Chinese as the *Jiuzhi-li* (AD 718) of Qutan Xida, which is included in his (*Da-*)*Tang Kaiyuan-zhanjing*. The author, Qutan Xida (probably a Chinese transliteration of his Indian name Gotama Siddha), belonged to a family of Indian astronomers in China and was the director of the national observatory. In the title *Jiuzhi-li*, *jiuzhi* corresponds to the Sanskrit word *navagraha* ["nine planets", i.e. sun (Ravi or Sūrya), moon (Candra), five planets – Mars (Maṅgala), Mercury (Budha), Jupiter (Bṛhaspati or Guru), Venus (Śukra) and Saturn (Śani), Rāhu (ascending node of the lunar orbit) and Ketu (usually considered to be the descending node of the lunar orbit)]; *li* means calendar. This work explains the method for calculating the sun's longitude, the moon's longitude, and solar and lunar eclipses, etc. This text also contains a sine table. The work also says that Indian numerals are mentioned, but the actual shape of the figure has not come down in extant texts.

Kiyosi Yabuuti pointed out that some astronomical constants of the *Jiuzhi-li* are similar to the *Sūryasiddhānta*, which was summarized in the *Pañcasiddhāntikā* of Varāhamihira (sixth century AD). This is a text of the *Ārdharātrika* school of Classical Hindu Astronomy (Yabuuti 1944/1989, 1979; also see Yano 1979).

It is interesting to note that the traditional calendars of mainland Southeast Asia (except for Vietnam) and also the classical astronomy of Tibet are related to the *Ārdharātrika* school. It may be that the *Ārdharātrika* school was quite popular among Buddhists. The *Jiuzhi-li* has never been used as an official calendar in China, because the tradition of Chinese original astronomy was so strong.

Yixing

There was also a famous monk, astronomer Yixing (AD 683–727), who knew about Indian astronomy. For example, he mentioned the Indian zodiac in his *Dayan* calendar. However, he made his *Dayan* calendar in a Chinese traditional way. There is only one thing which I suspect shows Indian influence in his *Dayan* calendar. It is the change of the meaning of *mieri*.

Yixing explained the method to calculate the *mieri* as follows:

> If the *xiaoyu* (time in terms of 1/3040 day) of the mean new moon is less than *shuoxufen* (=1427), subtract the *xiaoyu* from the *tongfa* (=3040), and multiply the result by 30, and subtract the result from *miefa* (=91200). Divide the result by *shuoxufen*. The result is the number of days. Count the days from the mean new moon day and take the day after the resultant day. It is the *mieri*.

The meaning of this *mieri* is as follows. Let a synodic month be divided into 30 parts. Then, sometimes a part is included within a day. This kind of day is the *mieri* defined by Yixing. This *mieri* is similar to the "omitted *tithi*" in Indian calendars. In *Vedāṅga* astronomy, a *tithi* was a 1/30 part of a synodic month, where the equation of centre was not known. In Hindu Classical Astronomy, a *tithi* is a period of time during which the longitudinal difference of the sun and moon changes by 12°. If a *tithi* is included within a day, the *tithi* is called "omitted *tithi*". In Hindu traditional calendars, the name of a civil day is determined by the number of *tithi* at the beginning (sunrise) of the day. Therefore, the number of an omitted *tithi*, which does not include any sunrise, actually disappears from the calendar.

The significance of Yixing's definition is that when the sum of the *mori* (a day which is included within a segment of 1/360 of a tropical year) and *mieri* grows to 30, one intercalary month is produced. This way of thinking is similar to certain descriptions in Indian classics, such as the *Arthaśāstra*. A similar description is also found in a Chinese version of the Buddhist text *Lishi-apitan-lun*, translated by Zhendi at the middle of the sixth century AD.

I suspect that Yixing knew this Indian method, and changed the meaning of the *mieri* in order to make it meaningful in Indian calendrical context (Ōhashi 2001).

Other Texts in the Tang Dynasty

In addition to the above-mentioned texts, the *Suyao-jing* is also famous. In the title, *su* means lunar mansions, *yao* means planets and *jing* means canonical scripture. It is an astrological work which was compiled by Amoghavajra in the middle of the eight century AD. It is based on Indian horoscopic astrology.

There is also an astrological work with planetary ephemerides entitled *Qiyao-rangzaijue*, compiled by Jin Juzha, who is said to have been a Brahman priest from Western India, in the early ninth century or so. In the title, *qiyao* means seven planets, and *rangzaijue* means formulae to avoid disasters (caused by planets). This work is a kind of mixture of Indian astrology and Chinese astronomy. It includes the ephemerides of the five planets, Rāhu, Ketu and the sun. In Indian astronomy, Ketu usually means the descending node, or comets. However, Ketu in the *Qiyao-rangzaijue* is, according to Michio Yano's study, the apogee of the lunar orbit. This is a special feature of this work (Yano 1986).

We have seen some records of Indian astronomy in Chinese sources. We have to keep in mind that Indian influence on Chinese astronomy was very small. The tradition of Chinese original astronomy was very strong, and it seldom accepted foreign influence. However, we can find some exceptional influences in Chinese sources, and these exceptions draw attention to researchers.

Astronomy in the Indo-Malay Archipelago

GENE AMMARELL

All societies have their own systems of knowledge through which they seek to understand the natural environment and their relationship to it. Thus we may be better able to understand a society by going beyond the categories of Western science and begin to consider the interrelationship of a society with its environment from the viewpoint of the members of that society. It is this attempt to understand how members of a society, themselves, conceive of their environment that has come to be known as ethnoecology (Casiño 1967). Ethnoastronomy, the subject of this article, may be seen as a branch of ethnoecology wherein the interrelationship of human populations with their celestial environment is the focus of interest.

The modern nation states of Indonesia and Malaysia have a combined population of approximately 260 million and encompass the homelands of well over 500 distinct ethno-linguistic groups whose cultures and languages form part of a common Austronesian heritage, a heritage they share with the majority of the peoples of the Philippines, Polynesia, and Micronesia, among others.[1] Inhabiting mountainsides, river valleys, and coastal plains and faced with a somewhat unpredictable tropical monsoon climate, the peoples of Island Southeast Asia have developed diverse systems of agriculture that include both inundated rice farming and the shifting cultivation of rice and other food crops. Spread across an archipelago of over 17,000 islands (at least 6,000 inhabited), they have also developed sophisticated systems of navigation. These indigenous agricultural and navigational practices have been informed by an astronomical tradition that is, at once, unique to this cultural area and richly diverse in its local variation. This article describes several of the many techniques of astronomical observation that are known to have been employed by the peoples of Indonesia and Malaysia to help regulate their agricultural cycles and navigate their ships.

[1] In addition, there are at least 100 Papuan languages spoken in the Indonesian province of West Papua on the western half of the island of New Guinea.

The Celestial Landscape

The passage of time is mirrored in all of nature: in the light and warmth of day and the dark and coolness of night, in the flowering of plants, in the mating and migratory behavior of animals, in the changes in weather, in the ebb and flood of the tides, and in the recurring cycles within cycles of the sun, moon, planets, and stars as they transit the celestial sphere. Of these cycles, perhaps the most obvious is the diurnal rising and setting of the sun, moon, planets, and stars, as well as the synodic or cyclic changes in the phase of the moon and in the time of day that it rises and sets. More subtle than these might be the annual changes in the sun and stars: the north–south shift in the path of the sun across the sky (including its rising and setting points and its relative distance above the horizon at noon) and the appearance, disappearance, and reappearance of familiar patterns of stars at various times of night. To the trained eye, nature is replete with signs of diurnal and seasonal change. As an integral part of the natural landscape, these recurring celestial phenomena have long provided farmers and sailors worldwide with dependable markers against which operations, agricultural as well as navigational, can be timed.

Likewise, orientation in space and the art of wayfinding have often relied upon knowledge of these same celestial phenomena, the English term "orient," itself, having been derived from the Latin for "rise" and later associated with the East as the direction in which the sun appears at dawn. Although the times that individual stars rise and set shift gradually throughout the year, as viewed from a given latitude, the azimuths at which a star rises and sets varies only slightly over a lifetime, thereby providing a reliable "star compass" by which to determine direction. So, too, the sun, moon, and planets rise and set generally east and west, depending upon their individual cycles, affording additional guides by that people are able to orient themselves on the land as well as on the sea.

Agricultural Time Keeping

Many traditional, sedentary desert and plains cultures have used the shift in the rising and/or setting points of the sun along the horizon to both mark important dates and seasons and to commemorate the passage of years.

Desert and plains environments are conducive to the development and use of these horizon-based solar calendars: a permanent location from which to make sightings, a series of permanent distant horizon markers, either natural or manufactured, and a clear view are all that is needed for such a calendar. England's Stonehenge and Wyoming's Big Horn Medicine Wheel provide striking examples. Such conditions, however, are not common across much insular Southeast Asia. Here the landscape may consist of anything from a nearby or distant mountain to, more often, nearby trees; the horizon is, therefore, a rather undependable device against which to sight and measure the rising and setting positions of the sun. But in cultivated areas of the region, even from swiddens located deep within the rainforest, one can usually find a field or home site from which much of the sky is visible.

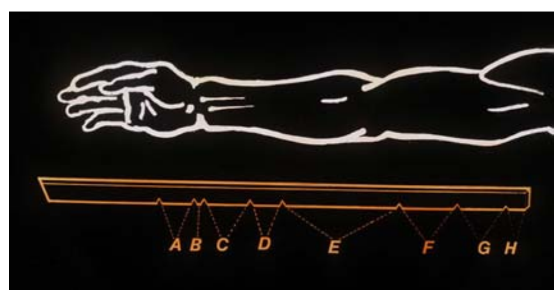
There are several types of observations of annually recurring celestial phenomena that can be made where permanent, distant horizon markers are not commonly available. These include cyclic changes in the phases of the moon, the annual changes in the apparitions of familiar groups of stars, and the annual changes in the altitude of the sun at noon. Here I present variations of these types of observations that we know have been practiced among traditional farmers of Indonesia. For the sake of clarity, they are grouped using Western astronomical categories as follows: solar gnomons, apparitions of stars at dawn and dusk, and lunar–solar and sidereal-lunar observations.

Solar Gnomons. Most often seen on sundials in western cultures, a solar gnomon is simply a vertical pole or other similar device that is used to cast a shadow. The altitude of the sun above the horizon varies not only through the day, however, but through the year as well. By measuring the relative length of this shadow each day at local solar noon, one can observe and more or less accurately measure the changing altitude of the sun above the horizon (or, reciprocally, from the zenith) through the year and, thereby, determine the approximate date.

Two distinct types of solar gnomons have been reported in the region. Both measure the altitude of the sun at local solar noon to determine the date. One type has been attributed to various groups of the Kenyah of the Apo Kayan of Kalimantan and may still be in use (Fig. 1).

It consists of a precisely measured (=span of maker's outstretched arms + span from tip of thumb to tip of first finger), permanently secured, plumbed, and decorated vertical hardwood pole (*tukar do*) and a neatly worked, flat measuring stick (*aso do*), marked with two sets of notches (Fig. 2). The first set corresponds to specific parts of the maker's arm and ornaments worn upon it, measured by laying the stick along the radial

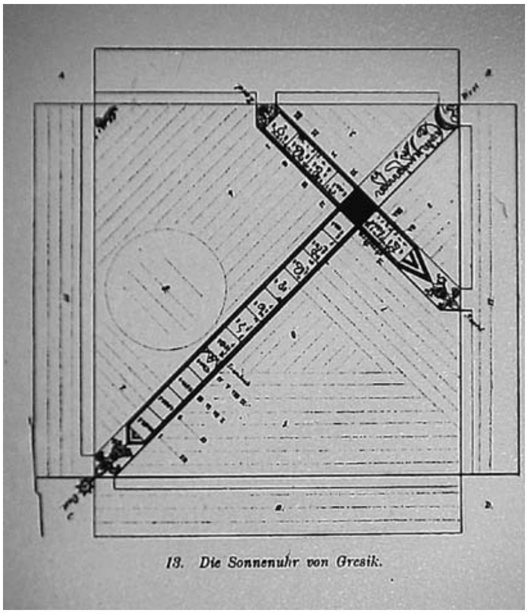
Astronomy in the Indo-Malay Archipelago. Fig. 1 Kenyah *tukar do* or solar gnomon (from Hose and McDougall 1912).



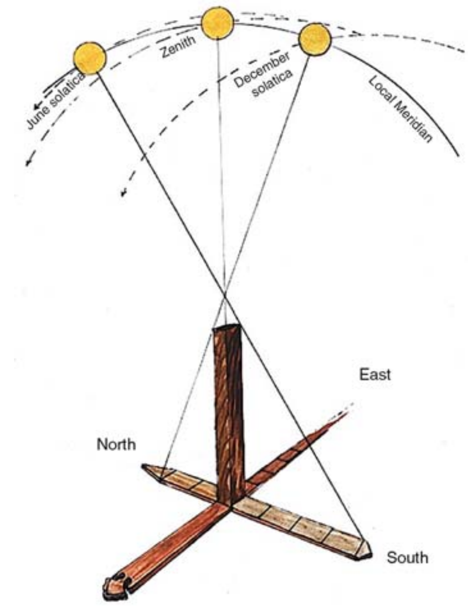
Astronomy in the Indo-Malay Archipelago. Fig. 2 Kenyah *aso do* or base of solar gnomon (adapted from Hose 1905).

side of the arm, the butt end against the inside of the armpit.

To mark the date, the measuring stick is placed at the base of the vertical pole, butt end against the pole and extending southward. This is done at the time of day that the shadows are shortest, local solar noon. On the day that the pole's noontime shadow is longest (the June solstice), a notch is carved on the other edge of the stick to mark the extent of the shadow made by the pole. This observation indicates that the agricultural season is at hand. From then on, the extent of the noonday shadow is recorded every 3 days as a record-keeping device. Dates, both favorable and unfavorable, for various operations in rice cultivation, such as clearing, burning, and planting, are determined by the length of the shadow relative to the marks on the stick



Astronomy in the Indo-Malay Archipelago. Fig. 3 The base of the *bencet* or solar gnomon showing the grid used to measure the length of the sun's shadow (Maass 1924).



Astronomy in the Indo-Malay Archipelago. Fig. 4 Javanese *bencet* and the annual motion of the sun (adapted from Aveni 1981).

that correspond to parts of the arm and to the marks made every 3 days (Hose 1905; Hose and McDougall 1912).

On Java a highly accurate gnomon, called a *bencet*, was in use from about AD 1600 until 1855 (Figs. 3 and 4) (Maass 1924; see also Ammarell 1996, 1998; Aveni 1981; van den Bosch 1980). A smaller, more portable device than that employed by the Kayan and Kenyah, the *bencet* divides the year into 12 unequal periods, called *mangsa*, two of which begin on the days of the zenith sun, when the sun casts no shadow at local solar noon, and another two of which begin on the two solstices, when the sun casts its longest mid-day shadows.

At the latitude of Central Java, 7° south, a unique condition exists which is reflected in the *bencet*. As the illustration shows, when, on the June solstice, the sun stands on the meridian (that is, at local solar noon) and to the north of the zenith, the shadow length, measured to the south of the base of the vertical pole, is precisely double the length of the shadow, measured to the north, which is cast when the sun, on the December solstice, stands on the meridian (at noon) south of the zenith. By simply halving the shorter segment and quartering the longer, the Javanese produced a calendar with 12 divisions, divisions that are spatially equal but which range in duration from 23 to 43 days. The 12 *mangsa* with their starting dates and numbers of days are shown on Table 1.

Apparitions of Stars at Dawn and Dusk. The second category of observational techniques regularly employed by traditional farmers of the region include all of those which involve apparitions of commonly recognized stars or groups of stars (which are herein referred to as "asterisms") at last gleam at dawn or first gleam at dusk.[2] Because of the earth's orbital motion about the sun, it can be observed that each star rises and sets approximately 4 min earlier each night. Similarly, each star appears to have moved about 1° west, when viewed at the same time, each night. As a result, around the time of its conjunction with the sun, any given star becomes lost in the sun's glare and is, therefore, not visible for approximately 1 month each year. It also means that the altitudes of stars above the horizon vary as a function of both the time of night and the day of the year, such that a certain star or group of stars, when observed at the same time each night (in this case near dusk or dawn) will appear at a given altitude above the eastern or western horizon on one and only one night of the year. Hence the use of any technique or device to measure the altitude of a star or group of stars as it

[2] I use the term "asterism" to refer to a commonly recognized patterned grouping of stars. While these groupings are often referred to generically as "constellations," I reserve the latter term to refer to the 88 bounded regions of the sky generally accepted by international scientific astronomers, these regions often named for asterisms found within their borders. Note, however, in Western starlore, there may be two or more asterisms within one constellation (e.g., the "Big Dipper" and the "Great Bear" in Ursa Majoris).

Astronomy in the Indo-Malay Archipelago. Table 1 The Pranatamangsa calendar (adapted from van den Bosch, p. 250)

Ordinal number	Name(s) of *Mangsa*	Duration (days)	First day(s) civil calendar
Ka – 1	*Kasa*	41	22 (21) June
Ka – 2	*Karo, Kalih*	23	2 (1) August
Ka – 3	*Katelu, Katiga*	24	25 (24) August
Ka – 4	*Kapat, Kasakawan*	25	18 (17) September
Ka – 5	*Kalima, Gangsal*	27	13 (12) October
Ka – 6	*Kanem*	43	9 (8) November
Ka – 7	*Kapitu*	43	22 (21) December
Ka – 8	*Kawolu*	26 (27)	3 (2) February
Ka – 9	*Kasanga*	25	1 March (ult. February)
Ka – 10	*Kasepuluh, Kasadasa*	24	26 (25) March
Ka – 11	*Desta*	23	19 (18) April
Ka – 12	*Sada*	41	12 (11) May

appears at first or last gleam can provide the observer with the approximate date.

I use the term "acronical" to refer to any stellar apparition that occurs at first gleam while "cosmical" is used to describe stars at last gleam. A subset of these, "heliacal" (Greek *helios*: "sun") apparitions of stars are those that occur just prior to and shortly after conjunction with the sun. The heliacal setting of a star or group of stars occurs on the date that the star or stars are last observed before conjunction, just above the western horizon at dusk. Likewise, the heliacal rising of a star or group of stars occurs on the date that the star or stars are first observed above the eastern horizon at dawn after several weeks' absence.

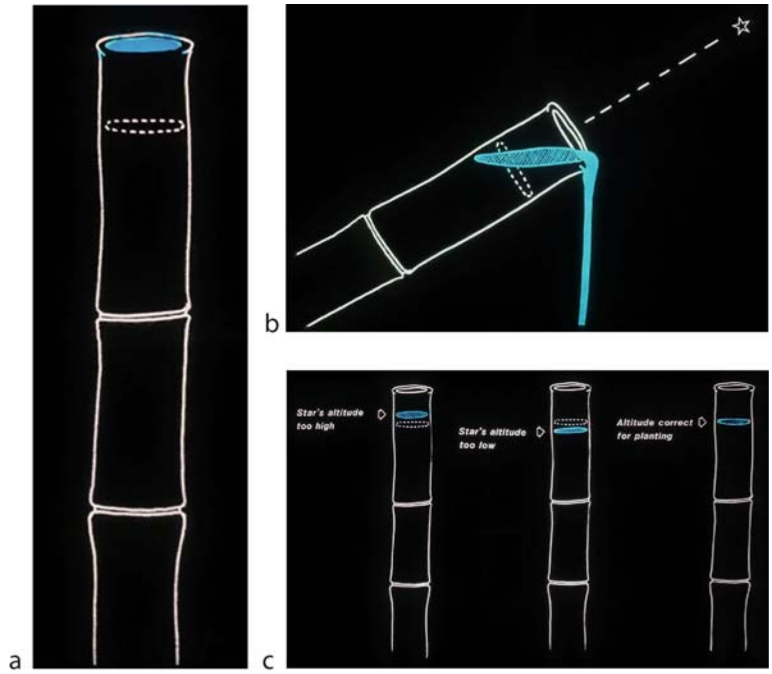
Just about 3 months after its heliacal rising, the star, now about 90° west of the sun, appears on the meridian at first gleam, an event that may be termed a "cosmical culmination" of the star. Two months later, the star is nearing opposition with the sun and undergoes an "acronical rising" in the east at first gleam. In less than 1 month, after opposition, the "cosmical setting" of the star is seen in the western sky. After two more months the star may be seen on the meridian at first gleam, accomplishing its "acronical culmination." Finally, about 3 months later, the star undergoes "heliacal setting" as the sun once again outshines it.

I would like to emphasize that these categories are taken from what is often referred to as the "exact science" of Western mathematical astronomy and are used here as a way of organizing and presenting this material to the Western scholar. The reader is cautioned that the actual observations made by indigenous farmers may not always be as precise as their assigned astronomical categories might imply. The demand for such precision varies greatly between and within cultures and with local environmental conditions. Here it would not be unusual to find a local farmer, for example, first noting the heliacal rising of the star cluster known in the West as the Pleiades at dawn several days or more after its mathematically calculated reappearance. Note that for convenience, I refer in this article to stars and asterisms by their accepted international scientific names. Where I know the name of a star or asterism in the indigenous language, I will note it as well.

The apparitions of stars at first and last gleam have been systematically observed by traditional cultures worldwide. From island Southeast Asia there are references in the literature, too numerous to describe in detail here, to the calendrical use at both dusk and dawn of the stars known internationally as the Pleiades, Orion and, to a lesser extent, Antares, Scorpius, and Crux (for more Indo-Malay examples, see Ammarell 1988, 1996; for examples from the Philippines, see Ambrosia, 1996). Culminations at both first and last gleam of the Pleiades, Orion, and Sirius are noted in the literature. Interestingly, the observation for calendrical purposes of such culminations seems to be unique to peoples of this culture area.

A small Dayak group related to the Kenyah–Kayan complex mentioned earlier practiced the first example in this category. Like their neighbors, they were swidden rice farmers. But unlike their neighbors who tracked the sun, they depended upon the stars to fix the date of planting. To do so, they nightly poured water into the end of a vertical piece of bamboo in which a line had been inscribed at a certain distance from the open end (Fig. 5a). The bamboo pole was then tilted until it pointed toward a certain star (unrecorded) at a certain time of night (also unrecorded), causing some of the water to pour out (Fig. 5b). It was then made vertical again and the level of the remaining water noted (Fig. 5c). When the level coincided with the mark, it was time to plant (Hose and McDougall 1912).

Near Yogyakarta, Central Java, a ritual practitioner was observed raising his hand toward the East in the direction of *bintang weluku* "plough stars" (Orionis) each day at dusk, rice seed in his open palm (Fig. 6).



Astronomy in the Indo-Malay Archipelago. Fig. 5 Bamboo device used by Kenyah–Kayan to measure the altitude of a star (adapted from Hose and McDougall 1912).

Astronomy in the Indo-Malay Archipelago. Fig. 6 Javanese ritual specialist holding rice in open palm at dusk, pointing toward the rising *bintang weluku* "plough stars" (Orionis).

On the night it reached the altitude such that kernels of rice rolled off his palm (angle of repose), it was time to sow seed in the nursery (van den Bosch 1980). Using a planetarium star projector, the author has determined the date of this event to be about 4 January (Ammarell 1996).

Lunar Calendars. Lunar calendars comprise the third category. These calendars are based upon the 29.5-day synodic period, usually measured from new moon to new moon and often subdivided by phase. Because there is not an even number of lunar months in a solar year and because agricultural cycles are, after all, tied to the solar year, simple lunar calendars alone are of little use in farming. But when they are somehow pegged to the solar year by reference to the apparent annual changes in the positions of the sun or stars or to other phenomena in nature that regularly recur on an annual basis, a lunar calendar can be of use to the farmer.

Indigenous lunar calendars fall into two general categories: lunar–solar and sidereal-lunar. Examples of the lunar–solar calendar include the Balinese ceremonial calendar, still in use, and the old Javanese *Saka* calendar, used from the eighth to the sixteenth centuries. Both are apparently of a common Hindu origin and are primarily lunar; both employ complex mathematical techniques to provide the intercalary days that periodically synchronize the lunar with the solar year (Covarrubias 1937; van den Bosch 1980).

A second type of lunar calendar, best described as sidereal-lunar, uses the apparitions at dusk and dawn of stars and asterisms as well as the appearance of other signs in nature (such as winds, birds and flowers) to determine which month is current. In these cases, it is only important to know which month it is for a few months each year (that is, during the agricultural season), thereby obviating the need for codified schemes for realigning the lunar with the solar/stellar year. Such "short" lunar calendars are found spread throughout the region (see Ammarell 1988). The Iban calendar provides a good example.

The Iban Calendar

Freeman (1970) describes the Iban as a riverine people practicing shifting agriculture in the vicinity of their longhouses, situated in low hills of Sarawak and West Kalimantan. The stars have played a central role in Iban mythology and agricultural practices. Several Iban stories tell how their knowledge of the stars was handed down to them by their deities and according to one village headman, "If there were no stars we Iban would be lost, not knowing when to plant; we live by the stars" (Freeman 1970:171). The Iban lunar calendar was annually adjusted to the cosmical apparitions of two groups of stars: the Pleiades and the three stars of Orion's belt.

The first observation was probably the most difficult. It was the reappearance of the Pleiades on the eastern horizon just before dawn after 2 month's absence from the night sky. This heliacal sighting, around 5 June of the civil calendar, informed the observer that the month, taken from new moon to new moon, that is current is, by convention, the fifth lunar month. It is during this month that two members of the longhouse went into the forest to seek favorable omens so that the land selected would yield a good crop. This may have taken from 2 days to a month, but once the omens appeared, they returned to the longhouse and work clearing the forest began. If it took so long for the omens to appear that Orion's belt rose before daybreak (heliacal rising around 25 June), the people had to "make every effort to regain lost time or the crop will be poor" (Freeman 1970:171). This reappearance of Orion at dawn occurred during the next or sixth lunar month, the time to begin clearing the land.

The remaining observations of the stars were more easily accomplished. They are all cosmical culminations, occurring "overhead" at last gleam, and could be seen to be approaching for several weeks. When the Pleiades underwent its cosmical culmination (3 September) and the stars of Orion's belt were about to do so (26–30 September), it was the eighth month and time to burn and plant. For good yields the burn should have occurred between the time that the two asterisms culminated at first gleam, usually when the two were in balance or equidistant from the meridian (16 September). Rice seed sown after the star Sirius had completed its cosmical culmination (October 15) would not have matured properly. It was okay for planting to carry into the tenth lunar month (October/November), but it had to be completed before the moon was full or the crop would fail. At this point the lunar calendar ended: only months five through ten were numbered and fixed while the remaining months varied according to how quickly the crop matured (e.g., *bulan mantun*, the "weeding month"). The lunar months from November to April were simply not numbered; it was difficult to see the stars during the rainy season and unimportant in any case.

Celestial Navigation

As we have just seen, the rice farmers of Indonesia have long noted correlations between celestial and terrestrial cycles and incorporated periodic changes in the sky into their agricultural calendars. Meanwhile, neighboring seafaring societies have used many of these same phenomena to orient themselves in both space and time for the purpose of navigation. Of these societies, the Bugis of South Sulawesi are perhaps the best known. Maintaining a tradition of seafaring and trade that spans at least four centuries, the Bugis are reputed to have established and periodically dominated strategic trade routes across Southeast Asia, stretching northeast from North Sumatra to Cambodia, north to Sulu and Ternate, and east to Aru and Timor. Their maritime prowess notwithstanding, Bugis systems of navigational knowledge and practice have only recently come under study (Ammarell 1995, 1999).

Bugis navigators still employ a system of dead reckoning that depends upon the knowledge of a variety of features of the natural environment to negotiate the seas in their tall ships. Although these features include land forms, sea marks, currents, tides, wave patterns and shapes, and the habits of birds and fish, navigators rely most heavily upon the prevailing wind directions, guide stars, waves, swells, and, increasingly, the magnetic compass.

Winds and Directions. The major wind patterns across island Southeast Asia are governed by the monsoons. In the Java and Flores Seas, from approximately May through October, winds from the east and southeast bring generally fair weather and steady breezes; from November through April, the west monsoon brings first calm air, then rain and squalls to the region. For the Bugis as well as a number of other regional ethnic groups whose languages share a common Austronesian heritage, these winds are of such fundamental importance that their names are synonymous with the local prevailing wind directions. Thus for the Bugis, both the monsoons and their prevailing directions in the vicinity of their homeland of South Sulawesi are: *bare'* "west" and *timo'* "east."[3]

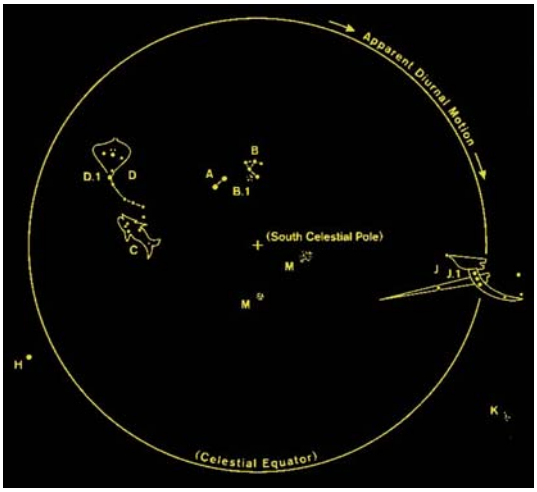
For the Bugis of the small coral islet of Balobaloang, located midway between Makassar on Sulawesi and

[3] For an exceptionally thorough historical and comparative discussion of concepts of orientation is several South Sulawesian languages, see Liebner (2005).

Bima on Sumbawa, trade routes are generally north and south across the Flores Sea. In principle, this allows them to take advantage of both easterly and westerly winds by reaching in either direction, although storms and heavy seas usually confined them, in the past, to port during the west monsoon. Formerly voyages were undertaken during the west monsoon only if the captain was hard pressed financially. Now, with motorization and larger ships, the voyaging season has been increasingly extended such that confinement to port is restricted to brief periods of severe weather, usually lasting no more than a week or two at a time.

Stars and Asterisms. Bugis navigators have long relied upon the stars and star patterns to set and maintain course. Although most sailors seem to know a few star patterns and their use, the navigators have been found to know many more. These star patterns, or asterisms, are known to rise, stand, and/or set above certain islands or ports when viewed from others and thereby pinpoint the direction of one's destination forming a "star compass." For example, in late July and early August *bintoéng balué* "Alpha&Beta Centauri" (Asterism A, Fig. 7) is known to make its nightly appearance at dusk in the direction of Bima as viewed from Balobaloang, that is, to the south.

As the night passes and a given asterism is no longer positioned over the point of destination, the navigator's thorough Gestalt-like familiarity with the sky allows him mentally to adjust to the new conditions: he can derive through visualization the points on the horizon at which the stars rise or set relative to wherever they currently appear. When a certain asterism simply is not visible, other associated but unnamed stars may be used to remind the navigator where the original asterism set or is about to rise or they may be used instead of the missing asterism. This, by the way, appears to be analogous to the "star path, the succession of rising or setting guiding stars down which one steers" described by Lewis for several cultures in Polynesia and Micronesia (1972:46–47). The stars identified by Bugis navigators are listed in Table 2 and illustrated in Figs. 7 and 8; those which are most relied upon will now be described.



Astronomy in the Indo-Malay Archipelago. Fig. 7 Bugis navigational stars: southern sky.

Perhaps the most frequently used asterism among the Bugis of Balobaloang is that *bintoéng balué*, mentioned above. These two bright stars are used to locate Balobaloang from Makassar and Bima from Makassar or Balobaloang. With regard to their rise/set points, navigators observe that they appear "in the south" at dusk during toward the middle of the east monsoon, the peak period for sailing; they further note that they rise "southeast" and set "southwest." Their brightness makes them visible even through clouds. The name *balué* is derived from *balu* that means "widow from death of the betrothed before marriage" with the affix *é* forming the definite article. Hence: "the one widowed before marriage." No graphical figure is attributed to this asterism.

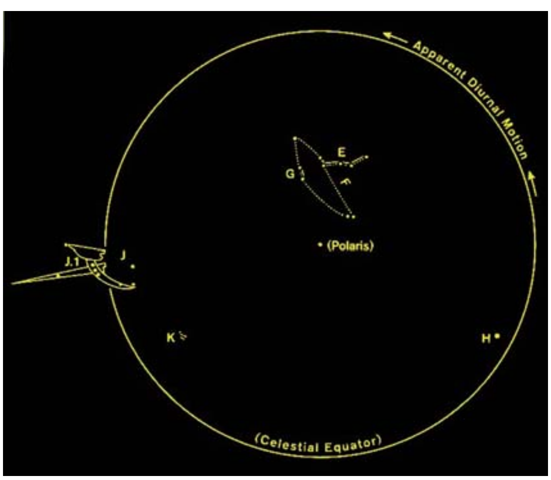
Just to the west of "Alpha&Beta Centauri" is *bintoéng bola képpang* (Crux), visualized as an "incomplete house of which one post is shorter than the other and, therefore, appears to be limping" (B in Fig. 7). Crux is used in conjunction with Alpha and Beta Centauri to navigate along southerly routes; like Alpha and Beta Centauri, it is known to set "southwest." Interestingly, it was emphasized that Crux is also used to help in predicting the weather. This asterism is located in the Milky Way that is known to the Bugis as *bintoéng nagaé* "the dragon," whose head is in the south and whose tail wraps all around the sky. As such, a bright haze of starlight surrounds Crux. On the eastern side of the house, however, there is a small dark patch totally devoid of light which is seen as a *bembé'* 'goat' (B.1 in Fig. 7). Between the squall clouds of the rainy season the goat in the sky may be seen standing, as goats are wont to do, outside the house trying to get in out of the rain. There are nights, however, when the goat is gone from the protection of the house. Hidden by haze, the missing goat portends a period of calm air and little rain.

In the northern sky the asterism that figures most prominently in Bugis navigation is known as *bintoéng kappala'é*, "the ship stars" in the international constellation of Ursa Majoris (two versions, E and F, in Fig. 8). The "ship" is used when traveling north and is known to rise "northeast" and sets "northwest" over Kalimantan from the port city of Makassar and from Balobaloang. Associations of this group of stars with the hull of a boat or ship appear to be common throughout the region.

Astronomy in the Indo-Malay Archipelago. Table 2 Bugis stars and asterisms familiar to navigators

Asterism	Bugis name[a]	English gloss	International designation
A	*bintoéng balué*	Widow-before-marriage	Alpha & Beta Centauri
B	*bintoéng bola képpang*	Incomplete house	Alpha–Delta, Mu Crucis
B.1	*bembé'*	Goat	Coal Sack Nebula in Crux
C	*bintoéng balé mangngiweng*	Shark	Scorpius (south)
D	*bintoéng lambarué*	Ray fish, skate	Scorpius (north)
D.1	(identified w/o name)	Lost Pleiad	Alpha Scorpii (Antares)
E	*bintoéng kappala'é*	Ship	Alpha–Eta Ursa Majoris
F	*bintoéng kappala'é*	Ship	Alpha–Eta Ursa Majoris; Beta, Gamma Ursa Minoris
G	*bintoéng balu Mandara'*	Mandar widow	Alpha, Beta Ursa Majoris
H	*bintoéng timo'* or *bintoéng timoro'* (Mak)[b]	Eastern star	Alpha Aquilae (Altair)
J	*pajjékoé* (Mak.)[b] or *bintoéng rakkalaé*	Plough stars	Alpha–Eta Orionis
J.1	*tanra tellué*	Sign of three	Delta, Epsilon, Zeta Orionis
K	*worong-porongngé bintoéng pitu*	Cluster seven stars	M45 in Taurus (Pleiades)
M	*tanra Bajoé*	Sign of the Bajau	Large and small magellanic clouds
[]	*wari-warié*	(No gloss)	Venus: morning
[]	*bintoéng bawi*	Pig star	Venus: evening
[]	*bintoéng nagaé*	Dragon stars	Milky way

[a]The Bugis term for "star(s)" is *bintoéng*; the suffix *é* may be translated as the definite article "the" in English.
[b]Although *timoro'* and *pajjékoé* are Makassar terms, they are more commonly used that the Bugis terms on Balobaloang.



Astronomy in the Indo-Malay Archipelago. Fig. 8 Bugis navigational stars: northern sky.

The two stars of *balu Mandara'* "widow of the Mandar" (G in Fig. 8) adjoin the "ship" and are likewise used to navigate northward. These two stars, Alpha and Beta Ursa Majoris, remind the Bugis of Alpha and Beta Centauri (thus the name *balu*), while "Mandar" recalls their northern seafaring neighbors.

Several asterisms and a planet are used for sailing east and west. They include: *timoro'* (Makassar) or *bintoéng timor'* (Bugis) "eastern star" (Altair; H in Fig. 8); *pajjékoé* (Makassar) or *bintoéng rakkalaé* (Bugis) "the plough stars" (Alpha–Eta Orionis; J in Figs. 7 and 8); *tanra tellué* "the sign of three" (Delta, Epsilon, Zeta Orionis; J.1 in Figs. 7 and 8); *wari-warié* [no gloss] or *bintoéng élé'* "morning star" (Venus in predawn sky); and *bintoéng bawi* "pig star" (Venus in evening sky), so named since it is believed that wild pigs will enter and destroy a garden or orchard when this object shines brightly in the west. Both the "pig star" and the "plough," by the way, speak to an agrarian lifestyle not practiced by Bugis seafarers but culturally shared with their kin who farm the lands of South Sulawesi as well as other islands of the archipelago. See Pelras (1987) for the astronomical knowledge of Bugis rice farmers.

Although the stars are useful guides, they are not always visible. Because it is possible to see landfall during the day, navigators appear to plan their voyages so as to maximize its usage. On a voyage from Balobaloang to Bima, the captain scheduled the departure for mid-afternoon allowing him to back-sight on Balobaloang and other islands of the atoll and observed the sun as it set in the west until dusk when Alpha and Beta Centauri appeared in the sky. There was, in fact, a period of about 30 min where both the receding island and the stars could be seen, providing a good opportunity to maintain course as attention was shifted from land forms to the stars.

Except during the height of the west monsoon, it is uncommon to experience extended periods of totally overcast skies. Should, however, the primary guiding asterism may be concealed by clouds, the navigator depends upon his knowledge of other asterisms or unnamed stars to fix his direction. If it is very cloudy, day or night, the navigator turns to wave directions and the magnetic compass to maintain course.

Although the more experienced navigators say that they could do without it and rely on wind, waves, and stars, the magnetic compass plays a central role in contemporary Bugis navigation and their presence should be of no surprise. Magnetic compasses, Liebner (2005) points out, have been used aboard the larger inter-island ships since the eighteenth century. On frequently sailed routes the helmsman knows from experience or from the navigator's instructions the proper compass bearing which will guide the boat toward its objective. At night under mostly clear skies, the helmsman points the ship's bow toward a succession of guide stars whose own azimuths change as the night passes. To compensate for this change, he checks the compass about once per hour, sometimes after several minutes of calling to a sleepy crew member for a flashlight or match by which to see it. On cloudy nights, when few or no stars are to be seen, the helmsman's job is much harder. Complicated by an often-unsteady helm, the helmsman is forced to check the compass every minute or so with a flashlight whose batteries are soon run down through constant use. By day the compass is generally observed more often regardless of the weather, although the sun, when low in the sky, is used as a reference.

Courses are committed to memory in terms of destinations and their required compass headings under various winds. That is, certain points of the compass are associated with certain destinations from various ports. For example, it is known that to sail from Balobaloang to Bima during the east monsoon, one must head due south, while during the west monsoon one heads south-southwest to southwest, depending on the strength of the wind and current. Likewise, to reach Makassar from the island during the east monsoon one travels somewhat east of north, while during the west monsoon a heading to the north-northwest is preferred. This difference, as navigators are quick to point out, takes into account drift from wind and currents, while true directions are also known. Practiced navigators have many of these bearings committed to memory and will refer to the experience of others as well as to charts and maps when they wish to travel to new or infrequent destinations.

On the author's initial voyage aboard a Bugis ship, the route traveled was well known to the seafarers of Balobaloang: Makassar to Bima via the island, a distance of about 212 nautical miles. Over the course of four days and five nights at sea without an auxiliary engine – and on later voyages after an engine had been installed – only occasionally were the helmsman or captain seen referring to the compass, and rarely at night or when in sight of land. When asked about this, both agreed that the compass could be used through the night, but to do so one would have to light the flashlight "so why not just use the stars?" Even if the compass were thrown overboard, we were assured the navigator could find his way.

Summary and Conclusion

This article has presented several examples of indigenous Indonesian calendrical and navigational systems and describes the celestial observations upon which they are based. It has also attempted to provide categories, drawn from international scientific astronomy, into which these observations may be placed.

With regard to the study of indigenous astronomical systems worldwide, there appear in regional agricultural calendars two types of celestial observations that may be unique to this cultural region. They are (1) observations of "cosmical" and "acronical" culminations – meridian transits at last and first gleam – of groups of stars and (2) observations of the lunar month for a limited number of months each year, creating discontinuous sidereal-lunar calendars. The use of stars by the Bugis navigators of South Sulawesi likewise appears represent a system that, along with its transformations used by Oceanic mariners, appears to be unique to the Austronesian world.

Implicit in the discussion of agricultural calendrical and navigation systems is the understanding that celestial observations do not stand alone. That is, many other environmental markers – changes in wind and weather and the appearances of flora and fauna also inform agricultural and navigational decision-making. It is suggested that by noting more carefully these and other signs in nature to which members of non-Western societies attend, we may gain a deeper appreciation of the true richness of human knowledge across cultures.

Astronomy in the Islamic World

DAVID A. KING

From the ninth to the fifteenth century, Muslim scholars excelled in every branch of scientific knowledge; their contributions in astronomy and mathematics are particularly impressive. Even though there are an estimated 10,000 Islamic astronomical manuscripts and close to 1,000 Islamic astronomical instruments preserved in libraries and museums, and even if all of them were properly catalogued and indexed, the picture that we could reconstruct of Islamic astronomy, especially for the eighth, ninth, and tenth centuries, would still be quite deficient. Most of the available manuscripts and instruments date from the later period of Islamic astronomy, i.e., from the fifteenth to the nineteenth century, and although some of these are based or modeled on earlier works, many of the early works are extant in unique copies and others have been lost almost without trace; i.e., we know only of their titles. The thirteenth century Syrian scientific biographer Ibn al-Qifṭī relates that the eleventh century Egyptian astronomer Ibn al-Sanbadī heard that the manuscripts in the library in Cairo were being catalogued and so he went to have a look at the works relating to his field. He found 6,500 manuscripts relating to astronomy, mathematics, and philosophy. Not one of these survives amongst the 2,500 scientific manuscripts preserved in Cairo today.

The surviving manuscripts thus constitute but a small fraction of those that were actually copied; nevertheless they preserve a substantial part of the Islamic scientific heritage, certainly enough of it for us to judge its level of sophistication. Only in the past few decades has the scope of the activity and achievements of Muslim scientists become apparent, and the days are long past when they were regarded merely as transmitters of superior ancient knowledge to ignorant but eager Europeans. Islamic astronomy is to be viewed on its own terms. The fact that only a small part of the available material, mainly Greek and Indian material in Arabic garb, was indeed transmitted to Europe is to be viewed as an accident of Islamic history. There is no need to apologize for using the expression "Islamic astronomy." Within a few decades of the death of the Prophet Muḥammad in the year 632, the Muslims had established a commonwealth stretching from Spain to Central Asia and India. They brought with them their own folk astronomy, which was then mingled with local traditions, and they discovered the mathematical traditions of the Indians, Persians, and Greeks, which they mastered and adapted to their needs. Early Islamic astronomy was thus a pot-pourri of pre-Islamic Arabian starlore and Indian, Persian, and Hellenistic astronomy, but by the tenth century Islamic astronomy had acquired very distinctive characteristics of its own. Sabra (1987) labels this process "appropriation and naturalization."

Astronomy flourished in Islamic society on two different levels: folk astronomy, devoid of theory and based solely on what one could see in the sky, and mathematical astronomy, involving systematic observations and mathematical calculations and predictions. Folk astronomy was favored by the scholars of the sacred law (*fuqahā*ʾ), not least because of various religious obligations that demanded a basic knowledge of the subject; these legal scholars generally had no time (or need) for mathematical astronomy. That discipline was fostered by a select group of scholars, most of whose activities and pronouncements were, except in the case of astrological predictions, of little interest to society at large.

The astronomers also played their part in applying their discipline to certain aspects of Islamic religious practice. It was not Islam that encouraged the development of astronomy but the richness of Islamic society, a highly literate, tolerant, multiracial society with a predominant cultural language, Arabic: but neither did Islam, the religion, stand in the way of scientific progress. The Prophet had said: "Seek knowledge, even as far as China." To be sure, overzealous orthodox rulers occasionally pursued, killed, or otherwise attacked "scientists" or destroyed or burnt their libraries, but these were exceptions. The scholars of the religious law, who saw themselves as the representatives of Islam, generally ignored the pronouncements of the scientists, even on matters relating to religious practice. Astronomy was the most important of the Islamic sciences, as we can judge by the volume of the associated textual tradition, but a discussion of it in the broader context of the various branches of knowledge, which has been attempted several times elsewhere, is beyond the scope of this essay.

Arab Starlore

The Arabs of the Arabian peninsula before Islam possessed a simple yet developed astronomical folklore of a practical nature. This involved a knowledge of the risings and settings of the stars, associated in particular with the acronychal settings of groups of stars and simultaneous heliacal risings of others, which marked the beginning of periods called *nawʾ*, plural *anwāʾ*. These *anwāʾ* eventually became associated with the 28 lunar mansions, a concept apparently of Indian origin. A knowledge of the passage of the sun through the 12 signs of the zodiac, associated meteorological and agricultural phenomena, the phases of the moon, as well as simple time-reckoning using shadows by day and the lunar mansions by night, formed the basis of later Islamic folk astronomy.

More than 20 compilations on the pre-Islamic Arabian knowledge of celestial and meteorological phenomena as found in the earliest Arabic sources of folklore, poetry, and literature are known to have been compiled during the first four centuries of Islam. The best known is that of Ibn Qutayba, written in Baghdad about the year 860. Almanacs enumerating agricultural, meteorological, and astronomical events of significance to local farmers were also compiled; several examples of these survive from the medieval Islamic period, one such being for Cordoba in the year 961. The Yemen possessed a particularly rich tradition of folk astronomy, and numerous almanacs were compiled there.

Since the sun, moon, and stars are mentioned in the *Qurʾān*, an extensive literature dealing with what may well be labeled Islamic folk cosmology arose. This was inevitably unrelated to the more "scientific" Islamic tradition based first on Indian sources and then predominantly on Greek ones. Since it is also stated in the *Qurʾān* that man should use these celestial bodies to guide him, the scholars of the religious law occupied themselves with folk astronomy.

Persian and Indian Sources

The earliest astronomical texts in Arabic seem to have been written in Sind and Afghanistan, areas already conquered by the Muslims in the seventh century. Our knowledge of these early works is based entirely on citations from them in later works. They consisted of texts and tables and were labeled *zīj* after a Persian word meaning "cord" or "thread" and by extension "the warp of a fabric," which the tables vaguely resemble. The Sasanian *Shahriyārān Zīj* in the version of Yazdigird III was translated from Pahlavi into Arabic as the *Shāh Zīj*, and the astronomers of al-Manṣūr chose an auspicious moment to find his new capital Baghdad using probably an earlier Pahlavi version of this *zīj*. The various horoscopes computed by Māshāʾallāh (Baghdad, ca. 800) in his astrological world history are based on it.

Significant for the subsequent influence of Indian astronomy in the Islamic tradition was the arrival of an embassy sent to the court of the Caliph al-Manṣūr from Sind ca. 772. This embassy included an Indian well versed in astronomy and bearing a Sanskrit astronomical text apparently entitled the *Māhasiddhānta* and based partly on the *Brāhmasphuṭasiddhānta*. The Caliph ordered al-Fazārī to translate this text into Arabic with the help of the Indian. The resulting *Zīj al-Sindhind al-kabīr* was the basis of a series of *zījes* by such astronomers as al-Fazārī, Yaʿqūb ibn Ṭāriq, al-Khwārizmī, and others, all prepared in Iraq before the end of the tenth century. The *Sindhind* tradition flourished in Andalusia, mainly through the influence there of the *Zīj* of al-Khwārizmī (see below). As a result, the influence of Indian astronomy is attested from Morocco to England in the late Middle Ages.

Greek Sources

The *Almagest* of Ptolemy (Alexandria, ca. 125) was translated at least five times in the late eighth and ninth centuries. The first was a translation into Syriac and the others were into Arabic, the first two under al-Maʾmūn in the middle of the first half of the ninth century, and the other two (the second being an improvement of the first) towards the end of that century. All of these were still available in the twelfth century, when they were used by Ibn al-Ṣalāḥ for his critique of Ptolemy's star catalogue. The translations gave rise to a series of commentaries on the whole text or parts of it, many of them critical, and one, by Ibn al-Haytham (ca. 1025), actually entitled *al-Shukūk fī Baṭlamiyūs* (Doubts about Ptolemy). The most commonly used version in the later period was the recension of the late ninth century version by the polymath Naṣīr al-Dīn al-Ṭūsī in the mid-thirteenth century. Various other works by Ptolemy, notably the *Planetary Hypotheses* and the *Planisphaerium*, and other Greek works, including the short treatises by

Autolycos, Aristarchos, Hypsicles, and Theodosios, and works on the construction known as the analemma for reducing problems in three dimensions to a plane, were also translated into Arabic; most of these too were later edited by al-Ṭūsī. In this way Greek planetary models, uranometry, and mathematical methods came to the attention of the Muslims. Their redactions of the *Almagest* not only reformulated and paraphrased its contents, but also corrected, completed, criticized, and brought the contents up to date both theoretically and practically.

Theoretical Astronomy

The geometrical structure of the universe conceived by Muslim astronomers of the early Islamic period (ca. 800–1050) is more or less that expounded in Ptolemy's *Almagest*, with the system of eight spheres being regarded essentially as mathematical models. However, in Ptolemy's *Planetary Hypotheses* these models are already taken as representing physical reality; this text also became available in Arabic. Several early Muslim scholars wrote on the sizes and relative distances of the planets, and one who proposed a physical model for the universe was Ibn al-Haytham (fl. Cairo, ca. 1025). In order to separate the two motions of the eighth sphere, the motion of the fixed stars due to the precession of the equinoxes, and the motion of the fixed stars due to the apparent daily rotation, he proposed a ninth sphere to impress the apparent daily rotation on the others.

Of considerable historical interest are various Arabic treatises on the notion of the trepidation of the equinoxes. This theory, developed from Greek sources, found followers who believed that it corresponded better to the observed phenomena than a simple theory of uniform precession. The mathematical models proposed were complex and have only recently been studied properly (notably those of Pseudo-Thābit (date unknown) and Ibn al-Zarqāllu (Andalusia, ca. 1070), who seems to have relied on his predecessor Ṣāʿid al-Andalusī). The theory of trepidation continued to occupy certain Muslim scholars (in the late period mainly in the Maghrib), as it did European scholars well into the Renaissance.

Other significant Islamic modifications to Ptolemaic planetary models, devised to overcome the philosophical objections to the notion of an equant and the problem of the variation in lunar distance inherent in Ptolemy's lunar model, belong to the later period of Islamic astronomy. There were two main schools, one of which reached its fullest expression in Maragha in northwestern Iran in the thirteenth century (notably with al-Ṭūsī and his colleagues) and Damascus in the fourteenth (with Ibn al-Shāṭir), and the other developed in Andalusia in the late twelfth century (with al-Biṭrūjī). The latter tradition was doomed from the outset by a slavish adherence to (false) Aristotelian tenets and by mathematical incompetence. The former was based on sophisticated modifications to Ptolemy's models, partly inspired by new observations; Ptolemy himself would have been impressed by it, as have been modern investigators, for the tradition has been rediscovered and studied only in the latter half of this century. In the 1950s Kennedy discovered that the solar, lunar, and planetary models proposed by Ibn al-Shāṭir in his book *Nihāyat al-suʾl* (the Final Quest Concerning the Rectification of Principles) were different from those of Ptolemy; indeed they were mathematically identical to those of Copernicus some 150 years later. In this work Ibn al-Shāṭir laid down the details of what he considered to be a true theoretical formulation of a set of planetary models describing planetary motions, and actually intended as alternatives to the Ptolemaic models. He maintained the geocentric system, whereas Copernicus proposed a hypothesis, which he was unable to prove, that the sun was at the center of things. Nevertheless this important discovery raised the interesting question of whether Copernicus might have known of the works of the Damascene astronomer. Since the 1950s we have progressed to a new stage of inquiry: we now know that there was a succession of Muslim astronomers from the eleventh to the sixteenth century who concerned themselves with models different from those of Ptolemy, all designed to overcome what were seen as flaws in them. The question we may now ask is: was Copernicus influenced by any of these Muslim works? The answer is unsatisfactory, namely, that he must have been; definitive proof is, however, still lacking.

Mathematical Astronomy: The Tradition of the *Zījes*

The Islamic *zījes* constitute an important category of astronomical literature for the historian of science, by virtue of the diversity of the topics dealt with, and the information that can be obtained from the tables. Kennedy (1956) published a survey of about 125 Islamic *zījes*. We now know of close to 200, and material is available for a revised version of Kennedy's *zīj* survey. To be sure, many of these works are lost, and many of the extant ones are derived from other *zījes* by modification, borrowing, or outright plagiarism. Nevertheless, there are enough *zījes* available in manuscript form to reconstruct a reasonably accurate picture of Muslim activity in this field.

Most *zījes* consist of several hundred pages of text and tables; the treatment of the material presented may vary considerably from one *zīj* to another. The following topics are handled in a typical *zīj*:

1. Chronology
2. Trigonometry

3. Spherical astronomy
4. Solar, lunar, and planetary mean motions
5. Solar, lunar, and planetary equations
6. Lunar and planetary latitudes
7. Planetary stations
8. Parallax
9. Solar and lunar eclipses
10. Lunar and planetary visibility
11. Mathematical geography (lists of cities with geographical coordinates), determination of the direction of Mecca
12. Uranometry (tables of fixed stars with coordinates)
13. Mathematical astrology

As noted above, by the eighth century a number of Arabic *zījes* had been compiled in India and Afghanistan. These earliest examples, based on Indian and Sasanian works, are lost, as are the earliest examples compiled at Baghdad in the eighth century. With the *zījes* compiled in Baghdad and Damascus in the early ninth century under the patronage of the Caliph al-Maʾmūn, we are on somewhat firmer ground. These follow either the tradition of Ptolemy's *Almagest* and *Handy Tables* or the Indian tradition. Manuscripts exist of the *Mumtaḥan Zīj* of Yaḥyā ibn Abī Manṣūr and the Damascus *Zīj* of Ḥabash, each of which was based on essentially Ptolemaic theory rather than Indian. The *Zīj* of al-Khwārizmī, based mainly on the Persian and Indian traditions, has survived only in a Latin translation of an Andalusian recension. Amongst the most important and influential later works of this genre are: the *Ṣābīʾ Zīj* of al-Battānī of Raqqa, ca. 910; the *Ḥākimī Zīj* of Ibn Yūnus, compiled in Cairo at the end of the tenth century; the *zīj* called *al-Qānūn al-Masʿūdī* by al-Bīrunī, compiled in Ghazna about 1025; the *Zīj* of Ibn Isḥāq, compiled in Tunis, ca. 1195; the *I lkhānī Zīj* of Naṣīr al-Dīn al-Ṭūsī, prepared in Maragha in northwestern Persia in the mid-thirteenth century; and the *Sulṭānī Zīj* of Ulugh Beg from early fifteenth century Samarqand.

Although the *zījes* are amongst the most important sources for our knowledge of Islamic mathematical astronomy, it is important to observe that they generally contain extensive tables and explanatory text relating to mathematical astrology as well. Islamic astrological texts form an independent corpus of literature, mainly untouched by modern scholarship. Often highly sophisticated mathematical procedures are involved. It should also be pointed out that in spite of the fact that astrology was anathema to Muslim orthodoxy, it has always been (and still is) widely practiced in Islamic society.

All early Islamic astronomical tables have entries written in Arabic alphanumerical notation (*abjad*) and expressed sexagesimally, i.e., to base 60. A number written in letters equivalent to "23 30 17 seconds" (Ulugh Beg's value for the obliquity) stands for 23 + 30/60 + 17/3,600 degrees, i.e., 23°30′17″. In sexagesimal arithmetic, more so than in decimal arithmetic, it is useful to have a multiplication table at hand, and such tables, with 3,600 or even 216,000 entries, were available.

Already in the early ninth century Muslim astronomers had restyled the cumbersome Indian sine function using the Greek base 60 (which the Greeks had used for their even more cumbersome chord function). Likewise the Indian shadow functions, unknown in Greek astronomy, were adopted with different bases (12, 6, $6\frac{1}{2}$, and 7, and also 60, and occasionally 1). Most *zījes* contain tables of the sine and (co)tangent function for each whole, or half, or quarter degree of arc. Entries are generally given to three sexagesimal digits, corresponding roughly to five decimal digits. However, certain Muslim scholars compiled more extensive sets of trigonometric tables that were not included in *zījes*. In the early tenth century al-Samarqandī prepared a set of tables of the tangent function with entries to three sexagesimal digits for each minute of arc. Later in the same century Ibn Yūnus tabulated the sine function to five sexagesimal digits, equivalent to about nine decimal digits, for each minute of arc, also giving the differences for each second. He also tabulated the tangent function for each minute of arc, and the solar declination for each minute of solar longitude. His trigonometric tables were not sufficiently accurate to warrant this number of significant figures, and indeed over four centuries were to elapse before the compilation in Samarqand of the magnificent trigonometric tables in the *Sulṭānī Zīj* of Ulugh Beg, which display the values of the sine and tangent to five sexagesimal digits for each minute of argument and are generally accurate in the last digit.

Planetary Tables and Ephemerides

Given the Ptolemaic models and tables of the mean motion and equations of the sun, moon, and planets were available to Muslim astronomers in the *Almagest* and *Handy Tables*, or the corresponding tables based on Indian models that exemplify the *Sindhind* tradition, Muslim astronomers from the ninth to the sixteenth century sought to improve the numerical parameters on which these tables were based. Most of the leading Muslim astronomers of the early period made solar observations and computed new solar equation tables. Ibn Yūnus is the only astronomer from the first four centuries of Islam known to have compiled a new set of lunar equation tables. The majority of Islamic planetary equation tables are Ptolemaic, and where exceptions do occur, such as in the tables of Ibn al-Aʿlam and Ibn Yūnus for Mercury, we find that they are based on a Sasanian parameter rather than on any new observations.

Ptolemy used the same data as Hipparchus for his determination of the solar apogee and hence obtained the same result. The Muslims thus inherited the notion that the solar apogee is fixed with respect to the fixed stars (although the planetary apogees move with the motion of precession), and it is to their credit that their earliest observations established that the solar apogee had moved about 15° since the time of Hipparchus. Most early Muslim astronomers accepted the *Mumtaḥan* value of 1° in 66 Persian years (actually a parameter attested in earlier Persian sources) for both precession and the motion of the apogees. Ibn Yūnus possessed all the necessary data that could be used to demonstrate that the motion of the solar apogee is not the same as the motion due to precession, but he chose to use the same value for both, 1° in $70\frac{1}{4}$ Persian years, which happens to be remarkably close to the actual rate of precession. Al-Bīrūnī (Central Asia, ca. 1025) seems to have been the first to distinguish the proper motion of the solar apogee from the motion of precession (this discovery is sometimes erroneously attributed to al-Battānī). It was Ibn al-Zarqāllu (Andalusia, ca. 1070) who was the first to assign a numerical value to both motions, although he also subscribed to the theory of trepidation.

All Islamic *zījes* contained tables of mean motions and equations for computing solar, lunar, and planetary positions for a given time. Some of the equation tables are arranged in a form more convenient for the user (so that one simply has to enter the mean motions, and calculations are avoided). Auxiliary tables were sometimes available for generating ephemerides without the tedious computation of daily positions from mean-motion and equation tables. From the ninth to the nineteenth centuries Muslim astronomers compiled ephemerides displaying solar, lunar, and planetary positions of each day of the year, as well as information on the new moons and astrological predictions resulting from the position of the moon relative to the planets. Al-Bīrūnī described in detail how to compile ephemerides in his astronomical and astrological handbook *al-Tafhīm fī ṣināʿat al-tanjīm* (Instruction in the Art of Astrology). Manuscripts of ephemerides had a high rate of attrition since the tables could be dispensed with at the end of the year: the earliest complete extant examples are from fourteenth century Yemen, discovered in Cairo in the 1970s and still unpublished; on the other hand, literally hundreds of ephemerides survive from the late Ottoman period.

Stellar Coordinates and Uranography

Most *zījes* contain lists of stellar coordinates in either the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course) or the equatorial systems, or occasionally in both. A survey of the stellar coordinates in Islamic *zījes* would be a valuable contribution to the history of Islamic astronomy, and could help to determine the extent to which original observations were made by Muslim astronomers. An impressive amount of research on Arabic star names and their later influence in Europe has been conducted in the last few years by Paul Kunitzsch.

In his *Ṣuwar al-kawākib* (Book of Constellation Figures) the tenth century Shiraz astronomer al-Ṣūfī presented lists of stellar coordinates as well as illustrations of the constellation figures from the Hellenistic tradition and also information on the lunar mansions following the Arab tradition. Later Islamic works on uranography are mostly restricted to Persian and Turkish translations of al-Ṣūfī, although some astrological works also contain illustrations of the constellations that have recently attracted the attention of historians of Islamic art.

Spherical Astronomy and Spherical Trigonometry

Most *zījes* contain, in their introductory text, the solutions of the standard problems of spherical astronomy, such as, to give only one example, the determination of time from solar and stellar altitude. Rarely any explanation given of how the formulae outlined in words in the text were derived. There were two main traditions. In the first, the problems relating to the celestial sphere are reduced to geometric or trigonometric problems on a plane. The construction known as the analemma was a singularly powerful tool for solutions of this kind. In the second, the problems are solved by applications of rules of spherical trigonometry. Both techniques are ultimately of Greek origin, and Muslim scholars made substantial contributions to each.

There is some confusion about these contributions in the modern literature. It has been assumed by modern writers that when a medieval writer used a medieval formula that is mathematically equivalent to the modern formula derived by a specific rule of spherical trigonometry, the medieval scholar must have known the equivalent of the modern rule of spherical trigonometry. In fact, however, the medieval formula may have been derived without using spherical trigonometry at all. The first known Islamic treatise dealing with spherical trigonometry independently of astronomy is by the eleventh century Andalusian Ibn Muʿādh. The contributions to spherical astronomy by scholars such as Thābit ibn Qurra, al-Nayrīzī, Abu'l-Wafāʾ al-Būzajānī, al-Khujandī, Kūshyār ibn Labbān, al-Sijzī, and Abū Naṣr are outlined in the recently rediscovered *Maqālīd fī ʿilm al-hayʾa* (Keys to Astronomy) of al-Bīrūnī, also from the eleventh century.

Already in the work of Ḥabash in the mid-ninth century we find a Muslim astronomer at ease with both spherical trigonometrical methods and analemma constructions for solving problems of spherical astronomy. In the *Zījes* of scholars of the caliber of Ibn Yūnus and al-Bīrūnī we find various methods for solving each of the standard problems of medieval spherical astronomy.

The auxiliary trigonometric tables compiled by such scholars as Ḥabash, Abū Naṣr (Khwārizm, ca. 1000), and al-Khalīlī (Damascus, ca. 1360) for solving all of the problems of spherical astronomy for any latitude are a remarkable testimony to their mastery of the subject.

Observation Programs and Regional Schools of Astronomy: Al-Maʾmūn's Circle

In the early ninth century the Abbasid Caliph al-Maʾmūn patronized observations first in Baghdad and then in Damascus, gathering the best available astronomers to conduct observations of the sun and moon. Some of the results were incorporated into a *zīj* called *al-Mumtaḥan*, "tested," although the details of the activities at the two observation posts are somewhat confusing. The *Mumtaḥan Zīj* was apparently compiled in Baghdad by Yaḥyā ibn Abī Manṣūr, but upon his death, according to Ḥabash, the Caliph ordered his colleague Khālid al-Marwarrūdhī to prepare some new instruments and conduct a 1-year program of solar and lunar observations in Damascus in order to compile a new *zīj*. According to Ḥabash this was done, but no such *zīj* is otherwise known to have been prepared before Ḥabash's own *Damascus Zīj*. Also simultaneous observations of a lunar eclipse were conducted at Baghdad and Mecca, and the longitude difference used together with the newly measured latitudes of the two localities to find the *qibla* at Baghdad.

These observations, like later ones, were mainly directed towards determining the local latitude and current value of the obliquity, and towards deriving improved parameters for the Ptolemaic planetary models and more accurate star positions. The armillary sphere, the meridian quadrant, and the parallactic ruler were known to the Muslims from the *Almagest*, and they added new scales and other modifications, often building larger instruments even when smaller ones would have sufficed. Our knowledge of the instruments used by al-Maʾmūn's astronomers is meager. An armillary sphere used by Yaḥyā in Baghdad was said to display markings for each 10 min of arc, but even contemporary astronomers were not impressed by the precision of the results obtained using it. A mural quadrant made of marble with a radius of about 5 m was used in Damascus, as well as a vertical gnomon made of iron standing about 5 m high. Al-Maʾmūn also patronized measurements of the longitude difference between Baghdad and Mecca in order to establish the *qibla* at Baghdad properly, as well as measurements of the length of one degree of terrestrial latitude.

Other Observational Programs

Besides the officially sponsored observations conducted in Baghdad and Damascus in the early ninth century, there are numerous instances of other series of observations conducted in different parts of the Muslim world.

The two brothers called Banū Mūsā made observations in their own house in Baghdad and also in nearby Samarra about 30 years after the *Mumtaḥan* observations. They also arranged for simultaneous observations of a lunar eclipse in Samarra and Nishapur in order to determine the difference in longitude between the two cities. In view of their proficiency in mathematics, it is most unfortunate that neither of the two *zījes* compiled by them has survived.

Al-Battānī carried out observations during the period 887–918 in Raqqa in northern Syria. He appears to have financed his observational activity himself, and although we have no description of the site where he made his observations, the instruments mentioned in the *zīj* based on his observations include an armillary sphere and mural quadrant, as well as a parallactic ruler, an astrolabe, a gnomon, and a horizontal sundial.

The observational activities of the Baghdad family known as the Banū Amājūr were almost contemporaneous with those of al-Battānī in Raqqa. Father and two sons, and also a freed family slave, all made observations and each compiled a *zīj*, none of which survives. In the accounts of their eclipse observations recorded by Ibn Yūnus it appears that the place where they conducted their observations had some kind of a balcony fitted with slits for observation, but the details are obscure. A particularly interesting account of a solar eclipse in the year 928 that they observed by reflection in water includes a remark that the altitude of the sun was measured on an instrument marked for each third of a degree.

A large mural quadrant was erected at Rayy (near modern Tehran) about the year 950, but we have information only on its use to establish the local latitude and obliquity of the ecliptic. In Shiraz not long thereafter, al-Ṣūfī used an armillary sphere with a diameter of about 5 m to derive the same parameters and to "observe" equinoxes and solstices. Al-Ṣūfī is best known for his work on the fixed stars, but it seems that this was based more on "observation," looking at the heavens with the naked eye, than on "measurement," looking at the heavens with precision instruments and making estimates of positions. Another contemporary astronomer who conducted observations on which we have no information other than the main parameters of his *zīj* was Ibn al-Aʿlam.

In the late tenth century the distinguished mathematician and astronomer Abuʾl-Wafāʾ al-Būzajānī made observations in Baghdad. Most of these appear to have been directed towards the determination of the solar parameters, and the obliquity of the ecliptic and the latitude of Baghdad, although Abuʾl-Wafāʾ also collaborated with al-Bīrūnī in Khwārizm (modern Khiva in Turkmenistan) on the simultaneous observation of a lunar eclipse in the year 997. We have no information on the nature of the site where Abu'l-Wafāʾ made his observations, other than its location in a specific quarter of Baghdad.

Contemporaneous with the activity of Abu'l-Wafāʾ was the establishment in 988 of an observatory in the garden of the Baghdad residence of the Buwayhid ruler Sharaf al-Dawla. The organization of a building and program of observations was entrusted to Abū Sahl al-Qūhī, a mathematician of considerable standing. We know from contemporary historical records that a special building was erected for the observations, which in turn were witnessed by "judges, scientists and scholars of note, astronomers, and engineers." In view of the favorable conditions under which this observatory was established, and the competence of its director, it is somewhat surprising that the two recorded "observations" that were witnessed by so many dignitaries were the entry of the sun into Cancer and Libra in the year 988. Al-Bīrūnī describes the main instrument that was constructed as a hemisphere of radius 12.5 m on which the solar image was projected through an aperture at the center of the hemisphere. Activity at the observatory stopped in 989 with the death of Sharaf al-Dawla, so that the institution lasted not much more than a year.

In 994 Abū Maḥmūd al-Khujandī made a measurement of the obliquity using a meridian sextant of about 20 m radius. This instrument was erected in Rayy, but al-Khujandī confessed to al-Bīrūnī that it was so large that the center of the sextant had become displaced from its intended position.

The Egyptian astronomer Ibn Yūnus made a series of observations of eclipses, conjunctions, and occultations, as well as equinoctial and solstitial observations. We are extremely fortunate to have not only his reports of these observations, but also his citations of earlier observations of the same kind made by individuals such as Ḥabash and the Banū Amājūr. Ibn Yūnus' purposed in making these observations and recording them in the introduction to his *Zīj* is somewhat obscured by the fact that he does not list those observations or present those calculations with which he derived his new solar, lunar, and planetary parameters. Neither does he mention any locations for his observations other than his grandfather's house in Fustat and a nearby mosque in al-Qarāfa. The popular association of Ibn Yūnus with an observatory on the Muqaṭṭam Hills outside Cairo is, as Aydm Sayili has shown, a myth. Nevertheless, Ibn Yūnus mentions at least one instrument, probably a meridian ring, that was provided by the Fatimid Caliphs al-ʿAzīz and al-Ḥākim. In a later medieval Egyptian source Ibn Yūnus is reported to have received 100 dinars a day from al-Ḥākim, and it may be that such extremely high payments were made to Ibn Yūnus when he was making satisfactory astrological predictions for the Caliph. Al-Ḥākim made an abortive attempt to find an observatory in Cairo, but this was after the death of Ibn Yūnus in 1009. At some time during his reign there was an armillary sphere in Cairo with nine rings, each large enough that a man could ride through them on horseback.

The observations of al-Bīrūnī were conducted between 990 and ca. 1025 in several localities between Khwārizm and Kabul. His recorded observations include determinations of equinoxes and solstices, eclipses, and determinations of the obliquity and local latitude.

The corpus of tables known as the *Toledan Tables* was compiled in the eleventh century, based on observations directed by Ṣāʿid al-Andalusī and continued by Ibn al-Zarqāllu. Only the mean motion tables in this corpus of tables are original; most of the remains were lifted from the *zījes* of al-Khwārizmī and al-Battānī.

In the thirteenth century there was a substantial observational program at Maragha. The results are impressive only in so far as theoretical astronomy is concerned. Otherwise the trigonometric and planetary tables in the major production of the Maragha astronomers were modified or lifted in toto from earlier sources. This is not a happy outcome for a generously endowed observatory fitted with the latest observational instruments, known to us from texts. In the early fifteenth century the scene had moved to Samarqand in Central Asia: there, a group of astronomers, directed by the astronomer-prince Ulugh Beg, did impressive work. Only the 40-m meridian sextant survives from the observatory. These men produced a set of tables which it would be foolish to judge before they have been properly studied. The same is true for the short-lived observatory in Istanbul under the direction of Taqiʾl-Dīn (1577).

Regional Schools of Astronomy

After the tenth century they developed regional schools of astronomy in the Islamic world, with different interests and concentrations. They also had different authorities (for example, in the furthest East al-Bīrūnī and al-Ṭūsī, and in Egypt Ibn Yūnus). The main regions were Iraq, Iran and Central Asia, Muslim Spain, Egypt and Syria, the Yemen, the Maghrib, and later also the Ottoman lands. Only recently have the complex tradition of Muslim Spain (tenth to fourteenth centuries), the colorful tradition of Mamluk Egypt and Syria (thirteenth to early sixteenth centuries), the distinctive tradition of Rasulid Yemen (thirteenth to sixteenth centuries), and the staid tradition of the Maghrib (twelfth to nineteenth centuries) has been studied. The traditions of Ottoman Turkey and Mogul India are currently being researched.

Transmission to Europe

The Europeans learned of Islamic astronomy mainly through Spain, a region where, because of political problems and the difficulty of communications, the most up-to-date writings were not always available. This explains, for example, how it came to pass that the Europeans came across two major works of Muslim astronomers from the East, al-Khwārizmī and al-Battānī, at a time when these works were no longer widely used in the Islamic East. It also explains why so few Eastern Islamic works became known in Europe. None of the Eastern Islamic developments to Ptolemy's planetary theory was known in Andalusia or in medieval Europe. Al-Biṭrūjī's unhappy attempt to develop planetary models confused Europeans for several centuries; he must be worth reading, they naïvely thought, because he was trying to reconcile Ptolemy with Aristotle. As far as astronomical timekeeping was concerned, this does not seem to have been of much concern to the Muslims in Spain; hence nothing of consequence was transmitted.

On the other hand, some early Eastern Islamic contributions, later forgotten in the Islamic East, were transmitted to Spain and thence to Europe; they have been considered European developments because evidence to the contrary has seemed to be lacking. A good example is the horary quadrant with movable cursor (the so-called *quadrans vetus*), which was invented in Baghdad in the ninth century and (at least in the version with the cursor) virtually forgotten in the Islamic East thereafter; it came to be the favorite quadrant in medieval Europe. What, if any, astronomical knowledge was transmitted through Islamic Sicily remains a mystery, and nothing of consequence is known to have been learned about the subject by the Crusaders.

In the European Renaissance there was no access to the latest Islamic works. So the Europeans contented themselves with new editions of the ancient Greek works, with occasional, almost nostalgic, references to Albategnius (al-Battānī), Azarquiel (al-Zarqāllu), Alpetragius (al-Biṭrūjī), and the like. A few technical terms derived from the Arabic, such as alidade, azimuth, almucantar, nadir, saphea, and zenith, and a few star names such as Aldebaran, Algol, Al-tair, and Vega, survived. When the Europeans did come to learn of some of the major Islamic works and to try to come to terms with them it was as orientalists and historians of astronomy, for by this time the Islamic materials other than observation accounts were of historical rather than scientific interest. Thanks to orientalists like the Sédillots in Paris, works that had been completely unknown to Europeans and mainly forgotten by Muslims were published, translated, and analyzed. Islamic astronomy was highly respected by such scholars and others, like the historian of astronomy Delambre, who, innocent of Arabic, took the trouble to read what his colleagues had written about the subject. However, Islamic astronomy, indeed Islamic science in general, received a blow below the belt from Duhem, a physicist and philosopher ignorant of Arabic who simply ignored what scholars like the Sédillots had written. His thesis, that the Arabs were incapable of scientific thought and that whatever merits their science may have had were due to the intellectually superior Greeks, still has many followers, but only amongst those ignorant of the research of the past 150 years.

In the period after ca. 1500 Islamic astronomy declined. All of the problems had been solved, some many times over. Much of the innovative activity had led into a cul-de-sac, from which it would not emerge until modern times, thanks to investigations of manuscripts and instruments. Not that interest in astronomy died out. From Morocco to India the same old texts were copied and studied, recopied, and restudied, usually different texts in each of the main regions, but there was no new input or output of any consequence. Astronomy continued to be used as the handmaiden of astrology, and for the regulation of the calendar and the prayer times. Where there was innovation – such as, for example, in the remarkable device made in Isfahan ca. 1700 that correctly displays the direction and distance of Mecca for any locality – one must suspect the existence of an earlier tradition. However, the old traditions died hard, and Muslim astronomers for several centuries spent more time copying old treatises and tables than compiling new ones.

During the millennium beginning ca. 750 and especially in the period up to ca. 1050, although also in the period up to ca. 1500, Muslim astronomers did first-rate work, most of which was not known in medieval Europe at all. Those few Islamic works from the early period that were transmitted, notably the *zījes* of al-Khwārizmī and al-Battānī (especially through the *Toledan Tables*) and the banal summary of the *Almagest* by al-Farghānī, convey only an impression of classical astronomy in Arabic garb. However, they were in no way representative of contemporary Islamic astronomy in the East, and whilst the Europeans labored for centuries to come to terms with them, Muslim astronomers were making substantial contributions to their subject that have only been revealed by modern scholarship.

There is a wealth of material relating to this subject that remains untouched. Very few Islamic astronomical works have been published or have received the attention they merit. Three out of close to 200 Islamic *zījes* have been published in the optimum way (text, translation, and commentary). We have no published edition of the Arabic versions of the *Almagest* (except for the star catalogue), or of any Arabic recensions or commentaries. Many of the published Arabic scientific texts were printed in Hyderabad, most with no critical apparatus. Likewise most of the historically important Islamic astronomical instruments are still unpublished, although the catalogue currently in preparation in Frankfurt promises to make them better known.

In 1845 Sédillot, whose privilege it was to have access to the rich collection of Arabic and Persian scientific manuscripts in the Bibliothèque Nationale in Paris, wrote: "Each day brings some new discovery and illustrates the extreme importance of a thorough study of the manuscripts of the East." Sédillot also realized the importance of Islamic astronomical instruments. Given the vast number of manuscripts and instruments now available in libraries and museums elsewhere in Europe, the United States, and the Near East, and the rather small number of people currently working in this field, Sédillot's statement is no less true today than it was a century and a half ago.

Astronomy in Japan: A Cultural History

Steven L. Renshaw, Saori Ihara

Japan's astronomical heritage, like so much of the culture's history, is one of enigma. Navigationally remote in ancient times and perhaps somewhat still socially remote amidst modern urbanization, it is easy for native and foreigner alike to perceive that there must be something unique and mysterious about what is "Japanese." Yet, this island country is a mixture of eastern and western imports, and the social, political, and pragmatic processes related to such importation have origins dating back at least two millennia. One who actually visits the country may be somewhat overwhelmed by a large number of temples, shrines, and other architectural landmarks, some dating back many centuries, all reflecting an interaction of native sociocultural systems with those derived from the Asian continent. The visitor may also be somewhat disappointed to find much of the nation's heritage engulfed by high-rise buildings and accompanying elements of industrialization, a factor which is also very much a part of modern Japan. Illumination from such industrialization is a thorn to every lover of the stars, from amateur to professional. Perhaps it is indeed the mixture of foreign imports with indigenous belief systems, a mixture more subtle than that of cultures such as the United States whose multiethnicity is so pronounced, that indeed proves to be the most unique aspect of Japan. In order to understand the deeper significance of Japan's heritage with the sky, one must often look beneath what appears on the surface.

For many in the West, astronomy in Japan is generally connected to Japanese names attached to comets, asteroids and supernova discovered by one of her many amateur astronomers, to astronauts accompanying NASA missions, to space probes launched from Tanegashima Island, or to the building of a huge telescope on Mauna Kea sporting the name of one of the most prominent asterisms of Japanese star lore, *Subaru*. A complete review of issues related to this heritage is far beyond the bounds of a single article. We will concentrate primarily on the cultural relations with the stars that have developed over the centuries in Japan. To provide an overview as well as a basis for understanding what astronomy means to this land, we will concern ourselves with (1) the development (or perhaps nondevelopment) of astronomy as a science in Japan, and (2) the significance of historical, social, and political purposes and their relation to star lore, mythology, and other aspects of cultural astronomy.

Astronomy as Science in Japan: Chinese and Western Influences

Many professional and amateur astronomers in Japan have asked, "Were ancient Japanese people not interested in the stars?" (see for example Yokoo 1997). Such a question reflects the fact that compared with Western traditions, it is quite difficult to find early star mythology and records of scientific or prescientific development that compare with many other ancient cultures. Though the exact date is uncertain, writing was introduced relatively late to the Japanese islands (the system was based on Chinese characters), and thus there is very little written record of ancient views of astronomy earlier than the seventh or eighth century.

In looking at Japan's development of astronomy, Aveni's (1989) allusion to a kind of ethnocentrism inherent in viewing *History of Astronomy* only through the eyes of the modern West and its evolved science is echoed in reverse. The Meiji Reformation (1867–1868) with a "deemphasis" of Buddhist traditions followed by post-World War II rejection of the most meaningful aspects of indigenous Japanese mythology left many in this country with a sense that there is and always has been little which can be considered original in astronomy emerging from Japan. On the other hand, the reader needs only to pick up any professional journal of astronomy to quickly find the names of Japanese authors who are conducting research in the science of astronomy using Western methodologies. Thus, to look at modern astronomy in Japan is not to look at any real cultural difference but instead to find an industrial country which is producing an increasing number of eminent scientists trained in Western methodologies. The importance of understanding cultural context relative to astronomical "knowledge" has been recently revived, and one cannot help but sense a certain "lack of self-esteem" among Japanese researchers who wish to pursue it.

In his *History of Japanese Astronomy*, Nakayama (1969) gives a very thorough account of the ways in which Chinese and later Western influences were imported into Japan throughout its history. Japanese astronomy was greatly conditioned and restricted by geographical, historical, and cultural barriers, and its early phases were dominated by Chinese influence and later by Western ideas. It is doubtful that any "scientific" expansion of Japanese astronomy occurred prior to close contact with China or with China via Korea. Further, while the primary purpose of calendrical study in both the West and in China was to develop precise means of time reckoning, calendar development in Japan generally focused on divination and securing the position of rulers rather than trying to develop precise theory, cosmology, or observation methods designed to explain the workings of the universe.

Nakayama's work is written in English and parallels the two-volume work on the *History of Astronomy* in Japan written in Japanese by the esteemed scientist and historian Watanabe (1986, 1987). A view of most Western discussions of the subject will lead the reader to conclude that little has changed in perception relative to Nakayama's assessment (see for example Sugimoto and Swain 1989; Pannekoek 1961; North 1995; Ronan 1996; Hashimoto 1997). While Aveni (1993) does emphasize more ethnographic and less ethnocentric viewpoints, he also tends to place Japan within the broader context of the "rich Chinese heritage," and does not really deal with Japan's cultural astronomical heritage.

When the English scholar, Chamberlain (1971), was assessing the general state of affairs in Japan in his *Japanese Things*, he indicated that even apart from any scientific originality, one would never find much creative lore composed in Japan relative to the stars. Viewing astronomy in Japan from only these perspectives, it is easy to get the impression that early and perhaps even later inhabitants of Japan never "looked up" were never inspired by much in the sky, patiently and/or eagerly waited for (or perhaps at times were even antagonistic toward) enlightenment from the Asian continent or later from the West, but nevertheless developed keen observational skills once such imports were implanted.

It is certainly true that almost everything which can be viewed as scientific astronomy was imported from the Asian continent or from the West in more modern times, and if only that side is viewed, discussion of the *History of Astronomy* in Japan can basically stop here. However, to discard the culture's relations with the sky by judging it only by its origination or development of scientific concepts dismisses what is perhaps one of the most unique case studies in how indigenous native beliefs (and accompanying views of the heavens) were integrated, seldom by forceful means (at least from the importer's side), with belief systems of other cultures (and their consequent views of the heavens). Such a pattern of coexistence has been paradoxical if not downright baffling to most Western eyes. By neglecting the socio-cultural side of Japanese history, one misses the complexity of the manner in which ancient Japanese (not only rulers, astrologers, and calendar scholars, but average farmers, fishermen, and other common citizens) incorporated astronomy into an extant system of belief and purpose, such providing culturally based reasons for the way astronomy did or did not develop in these islands.

Although we discuss many other examples of Japanese adaptation and development in the next section, it is worth noting particular historical events that we have explicated elsewhere (Renshaw and Ihara 1999). Consider the large influx of Chinese learning in the Asuka (late sixth to early eighth centuries AD) and Nara (710–784 AD) periods.[1] Certainly, palaces and Buddhist temples were being laid out using Chinese derived geomantic principles, and Chinese methods of calendar reckoning were adopted (Nakayama 1969). However, each aspect of Chinese learning that was incorporated had to find juxtaposition with a set of beliefs or purposes that sometimes stood in direct contradiction. Juxtaposing the descendancy of the emperor as a child of the sun goddess Amaterasu with the Chinese perception of imperial rule centered on the north celestial pole required some compromise. Buddhist temples aligned in North–South directions had to fit within a terrain that had Shinto shrines aligned in less celestial fashion but more along the flow of natural sites such as prominent sacred mountains, forests, waterfalls, or distinguished outcroppings of rocks. Apart from the necessary attendant "blessing" of a particular Shinto Deity on a Buddhist Temple, said deity often had a shrine built directly within the precincts of the temple grounds and was even given a form of "Buddhahood." Compromises also included such practices as substituting Shinto ritual objects for bones of the Buddha in the treasures buried beneath pagodas (see Matsumae 1993; Sonoda 1993; Brown 1993c).

The picture we see from reading Krupp's (1983, 1989) substantive accounts of temple layout and practice of seasonally based ritual in ancient Chinese capitals were only partially incorporated within the layouts and attendant rituals of ancient Japanese palaces and their imperial owners. Certainly, as will be seen in the review of social consciousness and purpose in the next section, rituals such as human sacrifice found no place in a belief system based on ritual purification and abhorrence of death. It is also significant to note that while China underwent several dynastic changes, some accompanied with revisions in cosmology and astronomical perception, Japan retained virtually one dynastic descendancy reaching well into the twentieth century, thus often seeing no need for "advances" taking place on the continent (Brown 1993a, c).

When cultural perspectives are included, it seems clear that the history of Japanese astronomy is not simply the history of Chinese astronomy or even, for better or worse, a direct mirror of such. While it may be impossible to distinguish anything as having been uniquely Japanese, cultural practices from earliest to modern times bear distinct marks of a social

---

[1] An exhaustive account of these periods and the influence of continental imports is far beyond the scope of this article. The reader may find articles from Volume I of *The Cambridge History of Japan* series including Brown (1993a, b, c), Kidder (1993), Inoue (1993), Naoki (1993), Matsumae (1993), and Sonoda (1993) to be particularly relevant to a deeper understanding of these processes.

consciousness and purpose inherent in Japan's cultural development. Too, while Chinese astronomy may not have been given its due in modern scholarship, it is also evident that all Asian cultures cannot be "lumped together" with China in order to gain a full understanding of the relation of astronomy and culture in any particular one.

Socio-Political Purposes and Their Impact on Development and Adaptation of Star Lore and Mythology

Ruggles and Saunders (1993) ask, "What do people see when they look at the sky?" and further state that "the answer is as much a cultural as an astronomical one." Their perception is especially relevant to unraveling the enigma of Japan's heritage with the sky. A growing database of archaeological evidence, renewed postwar and nonreactive scholarship with regard to historical texts, and the development of interdisciplinary approaches reveal Japan as a culture that has always been guided by an indigenous social consciousness and for most of its history a rather consistent set of social and political purposes (Brown 1993a). Such was certainly a factor in how Japanese developed myth, legend, and lore related to the stars, and it is in this area that we can find the rich sources of cultural astronomy in Japan.[2]

The ancient sense of social consciousness and purpose may best be understood by using the analogy of a lake fed by two springs. The lake represents the historical and modern socio-cultural milieu of Japan, and the springs feeding it are the sources from which that milieu has been formed. The first and nearest spring is composed of a native social consciousness and a specific set of socio-political purposes that we detail later. The second spring (better viewed as many secondary springs) consists of the infusion of ideas, concepts, technologies, philosophies, and religions including a virtually continuous input from the Asian continent and in later centuries large contributions from the West.

It is important to realize that the primary spring has always been fed by the second. The flow may have been slow or even imperceptible at times, but it has always been there (Oguma 1995). On the other hand, this primary spring (regardless of its diverse historic origins) has always been deep and has formed an archetypal base through which everything must be filtered to become "Japanese." At least within the last 1,600–1,800 years, the secondary spring has probably never had a direct route to Japan's archetypal lake; such flow has almost always passed through the primary spring.

Brown (1993c), Kidder (1993), and Matsumae (1993) have provided a cogent paradigm through which Japanese social consciousness and attendant Shinto beliefs and practices may be understood as well as socio-political purposes that guided the early formation of Japan as a unified country. From this paradigm, three primary aspects of early Japanese consciousness emerge: "linealism," "vitalism," and "optimism." Linealism emphasizes ancestral descendancy with filial duty to parents, siblings, friends, nation, etc. Vitalism emphasizes life along with the abhorrence of anything that has to do with death and stresses ritualistic (not moralistic) purity. Optimism places emphasis on being concerned, not so much with the distant past or future, but rather with moving forward through seasons and cycles of life, regardless of circumstances. The socio-political purposes which played a role in Japan's early development as a nation may perhaps be best paraphrased as follows: (1) unification of often warring petty "kingdoms" (along with their local myth, legend, and lore) through (2) cooperative efforts of common people in various ways such as cultivating rice (using celestial signs and allegories for seasonal determination of planting and harvesting as well as agriculturally based festivals) in order to (3) establish a singular lineal order of imperial rule (resulting in perhaps one of the greatest national Japanese myths that of the sun goddess Amaterasu and her place as ancestral head of the imperial line).[3] It can easily be argued, given political developments of the twentieth century, that while some commodities have

[2] A good chronology in English of Japan's general history may be found in Torao and Brown's (1991) *Chronology of Japan*. The most exhaustive history of Japan in English is the recently released Cambridge series (Hall et al. 1993). For shorter and perhaps more approachable views of Japanese history written in English, the following may be of value: Sansom's (1974) prewar but still viable 3 – volume *A History of Japan* and his (1973) *Japan: A Short Cultural History*; Hall (1971) *Japan From Prehistory to Modern Times*; Mason and Caiger (1973) *A History of Japan*; and Morton (1995) *Japan: Its History and Culture*.

[3] From our earlier discussion, the reader should have a good idea of the kinds of conflicts many imported ideas created for early Japanese. Other brief examples will further clarify the point: while the infusion of Confucianism reinforced many aspects of "lineality," especially with regard to the development of bureaucratic governmental practices, the Confucian idea of a cyclical rise and fall of dynasties was never really accepted in Japan and stood directly against the idea of a singular imperial line. The fourth and fifth century infusions of Buddhism with beliefs, which emphasized a better life in death than in the present, directly contradicted the concept of vitalism and optimism. In addition, the Buddhistic idea of eventual decay as well as the Confucian idea of a "glorious past" were incongruent with virtually all aspects of Japanese consciousness and purpose.

changed and political power has not always been imperial based, these fundamental aspects of Japanese consciousness and purpose still form a prime keystone of the culture's psyche.[4]

One of the few writers in English to deal with Japan's cultural star lore and myth is Krupp (1991, 1997). Readers may be familiar with the several accounts he provides of the fundamental Japanese myth of Amaterasu and its relation to the Japanese political history. However, while this myth, itself closely tied with the political purpose of unification, is a prime example of lore that reflects Japanese sense of consciousness and purpose, there are many other aspects of Japanese traditions and bodies of star lore which show the complex relation between indigenous native belief, pragmatic social need and purpose, and the kinds of celestial ascription's that developed therefrom. Little of this material has found its way into English sources, and in the remainder of this article, we discuss some of many examples of relations between Japanese values and social purpose and the stars. Specifically, we will look at (1) values applied to particular star groupings such as Oyaninai Boshi, (2) cooperative efforts such as planting, harvesting and fishing reflected in star lore closely tied to such asterisms as Subaru and the belt stars of Orion, (3) ancient Japanese purposes as seen in star paintings of archaeological sites such as the tombs of Takamatsu Zuka and *Kitora Kofun*, (4) mixtures of Shinto belief and values seen in adaptations of continental legend and ritual such as that of the legend of Orihime and Kengyuu and its relation to the festival of Tanabata, and (5) the pre-eminent holiday of the year for Japanese, New Years Day, in which the values of linealism, vitalism, and optimism come together in a celestial greeting of new beginnings.

Oyaninai Boshi: Linealism, Vitalism, and Optimism in the Stars

There are a number of celestial symbols which concern various groupings of three stars; Oyaninai Boshi including Orion's belt stars (Nojiri 1973), three stars of the fifth moon station of the Azure Dragon of Spring which includes Alpha Scorpio flanked by Sigma and Tau, and three stars discerned in the constellation Aquila including Alpha flanked by Beta and Gamma Aquila (Uchida 1973).[5] All have to do with seeing the image of two parents standing or being supported on either side by their child in the middle. Such symbols of filial duty are numerous in Japanese star lore and reflect the strong sense of lineality later reinforced by Confucian ethics. Further, particular attention is placed on this value relative not only to parents but to friends as well. An example of a sense of Japanese identity is seen in Kenji Miyazawa's more modern "lore," *The Milky-Way Railroad* (Sigrist and Stroud trans. 1995).[6]

Another legend incorporating the aforementioned sense of Japanese consciousness includes the belt stars and M42 region of Orion. According to Uchida (1973), one day two sisters were walking down the road, the younger dutifully following her older sister and shouldering a tub of water. Being chased by an ogre, they found a rope leading to the heavens and began to climb. Though the sisters escaped the ogre, the younger sister sadly had her foot bitten off. These days, we see the bamboo pole (the three belt stars called Take no Fushi in this story) with which she continues to carry water as she follows her sister (the moon) around the sky. Her remaining foot (M42 region) peeks from the folds of her kimono. Western readers may find the end of this legend disturbing or even somewhat cruel. However, all the fundamental values of Japanese consciousness are found in this story: linealism in the form of filial duty, vitalism in strength and courage, and optimism in a will to "go on" within ones present condition to an immediate brighter future.

The anecdotal nature of such star lore and legend takes on a completely different meaning when viewed within the context of ancient Japanese social consciousness and purpose. Again, while it would be futile to argue that such lore developed independent of external sources, it is also clear that its Japanese development reflects a unique cultural identity.

Cooperative Activity: Pragmatic Signs in the Stars

As in many cultures, the three belt stars of Orion (called *Mitsu Boshi*), the Hyades (*Ame Furi Boshi* or Rain Stars), and the Pleiades (*Subaru*) played a prime role as symbols of fertility and time pieces relative to seasonal

[4] It is easy for the reader to get full insight into the significance of these ideas by reading the many excerpts of manuscripts from periods throughout Japan's history which are accompanied by commentary in the excellent *Sources of Japanese Tradition* compiled by Tsunoda et al. (1964). The sense of Shinto consciousness and its pervasiveness in modern Japanese life is also discussed by Shigemitsu (1996).

[5] Here and in later sections, we discuss the Chinese derived *Sei Shuku* or "moon stations" along with the animals of cardinal directions. Though used extensively in Japan from earliest Chinese infusions, a discussion of their complexity is more appropriate in a work on Chinese astronomy. The reader is urged to look at sources such as Needham (1959), Ho (1985), or Nivison (1989).

[6] *Douwa Shu; Ginga Tetsudou no Yoru*. (A Collection of Tales; Night of the Milky-Way Railroad) was originally started in 1924, adapted for some years, and finally published posthumously in 1951. It remains one of the most popular stories in Japan, loved by children and adults.

change, specifically planting and harvesting during the rice cultivation period (Hirose 1972; Uchida 1973; Nojiri 1973, 1982). Their earlier and later heliacal setting in Spring as well as heliacal and later rising in Fall encapsulate that season and in more ancient times provided symbols related to festivals such as Spring *Higan* and *Ura Bon*. Spring Higan is celebrated within a period of 7 days surrounding the Spring Equinox. At this time, as any casual observer in latitudes similar to Japan will note, the Pleiades, Hyades, and Orion, all begin to set earlier and earlier each evening. For early Japanese, this setting was allegorical to planting of rice seedlings (Subaru or the Pleiades appearing as united seedlings), the rainy season (Hyades or Ame Furi Boshi seen as rain stars), and cultivation (one of the earliest symbols seen in the three belt stars of Orion was that of *Karasuki* or plow). Ura Bon is celebrated in the Fall when ancestral *kami* (deity) visit and are sent on their way in thanks for bountiful harvests. In more ancient times, when this festival was celebrated on the lunar calendar based 14th–16th days of the 7th month (late August or early September in the Gregorian calendar), these three prominent star patterns were indeed seen to transit the zenith as the full moon set and dawn arrived, a signal that ancestral spirits had indeed departed for yet another "season" (Miyata 1996). The appearance of Subaru rising in the evening at this time of year seems to have had significance not only in its relation to the end of the rice harvest but to the coming of winter.

The mythology found in the *Kojiki* (Records of Ancient Matters; see Chamberlain trans. 1981; Philippi trans. 1968) and the *Nihongi* (Chronicles of Japan; see Aston trans. 1972) places much importance on the deity (sun goddess) Amaterasu, who "conquered" lesser deities (local states) and was considered the progenitor of the imperial line. Interestingly, one of the earliest and most significant aspects of Subaru was related to the myth of Amaterasu. Apparently taken from the phrase *mi Sumaru no Tama*, the name *Sumaru* was used to describe this asterism referring to the string of the august jewels known to have been hung on the *sakaki* tree while deities danced to lure Amaterasu from the cave (Nojiri 1973). Allegorically, just as the sun (Amaterasu) was seen to depart for the winter, jewels (Subaru or Sumaru) were seen to appear in the sky, jewels which could be seen throughout the winter months and serve as a reminder for early Japanese that at some time the sun would indeed return with her Spring warmth, and another planting season could begin.

Lore related to Subaru is extensive, but its prime importance can be seen in the fact that it not only played a role in what would become a central myth for unification of the country, but also a time piece for the pragmatic need of farmers and fishermen who played a role in such unification efforts. For common people, struggle for unification was of secondary importance. What was of prime concern was that they know good and bad times for planting, harvesting, or setting lines for fishing. While the three star patterns we have mentioned were of significance because of their heliacal rising and setting, the three belt stars of Orion, due to their prominence, apparent equal spacing, and perceived change in position as they traced their way across the winter sky, were of particular pragmatic use to early and later Japanese citizens.

When viewed in early evening, the perceived angle of the three belt stars seen rising in the East, moving across the sky, and setting in the West at different times of the year, provided the base for particularly interesting lore in which farmers used Orion as an agricultural symbol (Uchida 1973; Hara 1975; Nojiri 1988). The three belt stars are variously called *Awainya Boshi* (Millet Stars), *Komeinya Boshi* (Rice Stars), or *Awaine Boshi* (Millet and Rice Stars). All these names relate to seeing *Mitsu Boshi* as a fulcrum, balancing the yield of rice or millet crops as they move across the heavens. The star *Alnilam* (*Epsilon Ori*) is seen as the center of this fulcrum. *Mintaka*'s (*Delta Ori*) being higher or lower than the center indicates the yield of millet; *Almitak* (*Zeta Ori*) represents the yield of rice. In latitudes of Japan, *Mitsu Boshi* rises in an apparent vertical position. As the three stars move across the sky in the fall, they appear at an angle that gives rice a strong weight on the balance; this is the time to harvest rice and plant millet. As this constellation is seen setting in the West in late Spring, Zeta Ori begins to dip lower and lower; this is the time to harvest millet and plant rice.

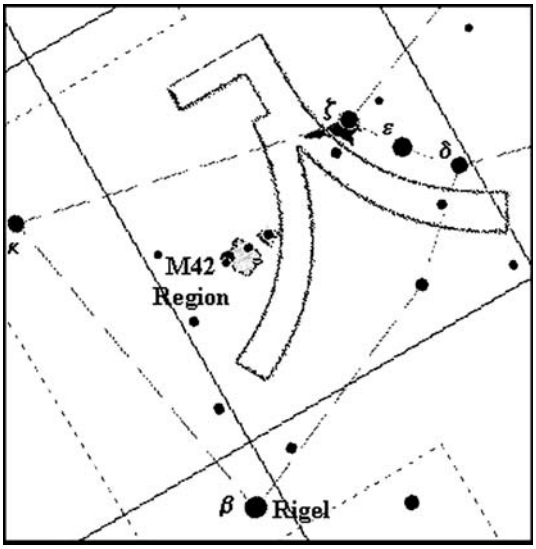
Especially in the cultivation of rice, several symbols of agriculture have been seen in the relation of the three belt stars to the M42 region. One of the oldest object references associated with this configuration uses the term *Karasuki* to describe the three belt stars as prongs of a plow with the M42 region being the handle used to pull it in the field. As mentioned earlier, this symbol is especially meaningful related to the evening appearance of the three stars in the time of early spring.

As a further example of adaptation of imports to suit unique and indigenous Japanese needs, it is interesting to look at some of the Chinese interpretations of star groupings such as Subaru or the three stars of Orion's belt and the differences in names applied by each culture. By the seventh century (perhaps earlier), the Chinese "cosmology" which gave rise to the concepts of 28 *Sei Shuku* or lunar stations encircling the celestial globe had found its place in Japan (Nakayama 1969; Watanabe 1987). The constellation of Orion contains two such *Sei Shuku*: the 20th which includes the small *Meissa* (*Lamda*, *Phi Ori*) and the 21st which embodies a much larger section of Orion and is most distinguished by the belt stars (*Mitsu Boshi*). Chinese characters were used by later Japanese writers to represent these configurations; however, the original Chinese term for the 21st *Sei Shuku* was simply *Shin* (three) while earliest records of Japanese nomenclature use *Karasuki* or plow (Ozaki et al. 1993; Shinmura 1994). Early Japanese gave little significance to the 20th station. Though continental influence can certainly not be dismissed as a major factor in Japan's agricultural development especially with regard to tools, it would appear that seeing this agricultural symbol in Orion may indeed have been in use before introduction of writing and other imports of more advanced Chinese culture into Japan.

Following massive infusions of culture from China and Korea, Japanese emperors practiced the custom of "plowing the first furrow" around the lunar New Year. However, Japanese lore associating the three stars with a plow seems to have preceded and perhaps only been augmented by the introduction of this Chinese based ritual.[7] "Astronomy" as practiced in China during Japan's early formation as a nation had depended for some time on somewhat more precise estimates of a lunar calendar for fixing dates (Nakayama 1969; Ho 1985). Because of its pragmatic use as an agricultural sign (though nonprecise), especially its prominent evening setting at what later was called Spring *Doyou* (the period of 18 days prior to the sectional term "Summer Begins," the official time for preparation to begin planting rice), *Karasuki* may have been original with early Japanese farmers. At any rate, its setting has certainly survived as a symbol of planting in most rice producing parts of Japan.

Another symbol for planting indeed reflects Chinese influence, and this is clearly seen in the incorporation of *Kanji* or Chinese characters. This symbol, again related to the setting of Orion in the West during the beginning of the rice cultivation season, was yet another reinforcement for use of the belt stars and M42 region as a sign for planting. Uchida (1973) indicates that Japanese in some agricultural areas see the Kanji for "entry" in the configuration and call it *Hoshi no Iri* (Entry of Stars). As fishermen saw stars set into the sea, Japanese farmers saw stars set into the western landscape. This symbol of Iri was merely another sign that it was time to plant (enter) rice seeds into the earth (Fig. 1).

Agricultural associations discussed so far have generally been related to the setting of *Mitsu Boshi* during early stages of annual rice cultivation. As mentioned, the rising of the three belt stars in the East was also an agricultural symbol and was allied with the end of the period of rice cultivation. Hara (1975) records



Astronomy in Japan: A Cultural History. Fig. 1 The *Kanji* for *Iri* or Entry superimposed on the belt stars and M42 region of Orion (computer graphic by Steven L. Renshaw).

that in many rice farming areas, the stars were called *Haza no Ma*, a term that refers to a three pole stand that is used in the field to dry rice. In the early phases of autumn, when Orion is no longer seen at sunset but rather rising earlier and earlier each night, farmers looked to the belt stars and saw them as a symbol that "only *Hasa* are left in the field," the harvest of rice being over.

While the combination of a lunar calendar and later adoption of a Gregorian calendar in post-Meiji era Japan led to more precise methods for determining times for planting and harvesting, many old farmers in rural agrarian areas still use methods that are centuries if not millennia old. According to Uchida (1973), the following timepiece is still recited in such areas: "When *Mitsu Boshi* are one fathom high, it's time to go to bed; when *Mitsu Boshi* are in the middle, it's the middle of winter; and when *Mitsu Boshi* lay, it's time to wake up." This refers to the vertical alignment of the three belt stars as they rise in early Fall, the angular position in the middle of the Southern sky in Winter, and the horizontal visual alignment in the West in Spring. These metaphors are related to, respectively, Fall harvest, Winter rest, and Spring planting.

Star lore related to fishing is somewhat more rare than that which is related to crop cultivation. It was primarily through cooperation of local farmers along with their local ancestral *kami* in the production of rice that early Japanese rulers were able to fulfill their purpose of unifying the country. Still, incorporating the legends of families of fishermen was an important part of this unification, and a mix of agrarian and fishing lore is found (see Nojiri 1982, 1987).

[7] See Krupp (1983, 1989) for a description in English of this and other cultivation related ceremonies that were practiced by the emperor in China. As they were recognized in Japan, some became part of the imperial ceremony, but many never found a place either because they did not fit within the imperial 'purposes' mentioned earlier or because they were in direct conflict with native *Shinto* belief (ritual sacrifice, for example).

In some fishing areas, the three belt stars are called *Kanatsuki*, which is a name given to a spear with three prongs used in fishing (Nojiri 1973; Uchida 1973). We can note some similarity in pronunciation of *Karasuki* (plow) and *Kanatsuki*. As a sign, *Kanatsuki* was used as a timepiece for favorable catches. When prospects for such seemed to be particularly good in the Fall, old fishermen were often heard to say "Let's wait for *Kanatsuki*" before going out for the evening's catch.

Perhaps one of the most significant relations to "fishing" found with *Mitsu Boshi* relates to their designation by some fishermen as Sumiyoshi Boshi. Sumiyoshi were the three deities mentioned in the *Kojiki* as being created from the ocean and being particularly favorable to seafarers (Nojiri 1988). Incorporation of these deities in the *Kojiki* and *Nihongi* was no doubt designed to find favorable reaction from the *be* or local families of fishermen. However, their use in legends which also included allusions to agricultural symbols make them a significant aspect of the way in which Japanese developed celestial allegories.

Obviously, ancient Japanese were not blankly "staring at their rice fields" while the heavens "revolved" overhead. Creative and pragmatic use of star patterns played a central role in the day to day life of common citizens. Using the example of the belt stars of Orion, we have briefly discussed some of the more significant associations used in cooperative activity.

Adaptation of Asian Cosmology for Power and Centrality: *Takamatsu Zuka* and *Kitora Kofun*

Some archaeological sites may provide cogent information relative to the early interaction of Japanese values and purpose with imported cosmology. One of the major archaeological discoveries was made in the early 1970s (Hirose 1972) in Asuka village, Nara prefecture. From an Edo Era painting showing this mound with a tall pine tree atop, this tomb was called *Takamatsu Zuka Kofun* (Tall Pine Burial Tomb) (Fig. 2).

Dating indicates that the tomb was built in the latter part of the seventh or early part of the eighth century. As was and is the case with most burials in China, Korea, and Japan, the tomb was aligned with celestial north. Paintings of animals related to the four cardinal directions were found on the walls, and careful inspection of the ceiling revealed a chart including the 28 *Sei Shuku* (lunar stations). Only a few scholars knew of the tomb's existence in the Edo era (1603–1867) and most believed it was that of the emperor Monmu (emperor from 697 to 707). Modern excavation revealed no inscription, and Monmu's tomb was later determined to be to the East. Similar tombs have been found in both China and Korea, and the construction period was also one in which scholars from Korea had been invited to the imperial court.

Astronomy in Japan: A Cultural History. Fig. 2 *Takamatsu Zuka Kofun* is aligned with celestial north. This view from due south shows the bamboo covered mound of the tomb. The doors are to chambers of relatively recent origin; inside are housed temperature maintenance and dehumidifying equipment used to protect the small tomb's delicate paintings. The tomb is not opened to the public (photo by Steven L. Renshaw).

What is significant about *Takamatsu Zuka Kofun* is the fact that it clearly shows the influence of Chinese and Korean cosmology on Japan in the Asuka Era (late sixth to early eighth centuries). In 1998, another such tomb, located about 1 km to the South of *Takamatsu Zuka Kofun* on Mount Abe and named *Kitora Kofun* (after the Kitaura area of Asuka village) was explored. The tomb was not actually entered but probed with subminiature cameras. Preliminary dating placed its construction within the same Asuka period as *Takamatsu Zuka Kofun*. While there are some remarkable similarities, there are also some anomalous differences in the paintings of the two tombs.

In *Kitora Kofun*, the paintings of the animals of cardinal directions appear to be in somewhat better condition than those of *Takamatsu Zuka Kofun* (in which some paintings appear to have been defaced in ancient times). The animals do seem to have been painted in a freer style than those that are found in the tomb to the north. There also appear to be more stars in the Kitora tomb paintings of the *Sei Shuku*. Unlike *Takamatsu Zuka Kofun*, the celestial equator and ecliptic as well as "the heavenly river" or Milky-Way appear distinct. Like *Takamatsu Zuka Kofun*, the tomb appears to have been plundered of any "treasure" it may have held. The south wall of *Takamatsu Zuka Kofun* was obliterated by entry in ancient times thus eliminating the painting of the Red Bird of Summer.

With regard to astronomical content, there are other significant differences. First, the paintings of *Sei Shuku* in *Kitora Kofun* appear to be based on Chinese/Korean charts of a much earlier period than that of *Takamatsu*

Zuka Kofun. Second, the point of the crossing of the ecliptic with the celestial equator can be seen in *Kitora Kofun* and appears to be near a point in Aries closer to Taurus and corresponding with a position several centuries earlier than the Asuka era or the tomb's construction (the vernal equinox was shifting into Pisces by the end of the seventh century). Third, since enough stars are seen in *Kitora Kofun* to determine just which ones could and could not be seen on the horizon, a relatively good estimate of observer latitude can be made. Fourth, the painting of the "White Tiger of the West" is reversed from that of *Takamatsu Zuka Kofun* and tombs with similar paintings found in China. In *Kitora Kofun*, the tiger is painted facing north. This point is especially interesting. When looking at the west wall of *Takamatsu Zuka Kofun* (note the photograph of the White Tiger in the Chinese tomb of similar dating in Krupp's *Echoes of the Ancient Skies* 1983: 112), the tiger is seen to face south, and this indeed corresponds with the placement of the figure of this animal among the stars. (Editor's note: see a detailed discussion of *Kitora Kofun* in this encyclopedia.)

These tombs provide us with a view of how Chinese/Korean astronomical thought found its way to Japan, and how such thought was incorporated into the social purposes of Japan's rulers. It seems evident that it is not the accuracy of the cosmology reflected in the tombs' paintings but rather the almost wholesale adoption of Chinese perceptions to further strengthen the centrality of imperial rule that was most important, especially in the case of *Kitora Kofun*. Japanese rulers wished to give themselves the same legitimacy that Chinese rulers had; incorporation of symbols and astronomical methods in order to accomplish this did not necessitate complete awareness of the underlying principles, but rather their mere presence. As mentioned earlier, such was the case with the introduction of Buddhism as well as other aspects of Chinese thinking. One can still see this kind of use of foreign import without substantive understanding in the almost playful use of foreign language in what sometimes appears to be gibberish in slogans and advertising of modern Japan. Use of foreign icons brings esteem, regardless of whether or not they are understood. Again, it must be stated that the central beliefs, ritual ceremonies, and social purposes of Japan appear to have remained and do remain somewhat constant regardless of import, such imports merely being incorporated within this larger "spring."

Adapting Chinese Lore to Native Beliefs and Purposes: Orihime, Kengyuu, and Tanabata

When we look at the adaptation of myth and legend imported from other cultures, we also find the obvious sense of indigenous Japanese values and socio-political purposes infused over time. Perhaps one of the best examples of this is the legend of Orihime and Kengyuu (Nojiri 1973). This story and associated festival were probably imported from China in the Heian Era (794–1185). The story involves the stars of Vega and Altair, and the reader should consult Krupp (1991) for an explanation of the story in its Chinese form. Essentially the same in character, there are some noticeable adaptations made based on the unique social and pragmatic needs of Japanese culture. In Japan, the star Vega is often called Orihime Boshi (Weaving Princess Star), and Altair is often called Kengyuu Boshi or Hiko Boshi (Puller of Cows Star). To give the reader one Japanese version of the legend, we will paraphrase Hara (1975).

One day, the emperor's daughter, Orihime, was sitting beside the Milky-Way. She had been weaving because her father, the emperor, "wished it" (he loved the beautiful clothes that she made). On this day, she was very sad because she realized that she had been so busy that she didn't have time to fall in love. Her father, Tentei, the ruler of the heavens, felt sorry for her and arranged a marriage with Kengyuu (who lived across the river, the Milky-Way). Their marriage was one of sweetness and happiness from the start; and everyday thereafter they grew happier and happier. But Tentei became very angry, because in spending so much time in her happy marriage, Orihime was neglecting her weaving. Tentei decided to separate the couple, so he placed them back in their original places, separated by the Milky-Way. On only one night of the year would he allow them to meet, the 7th day of the 7th month. Every year on that day, from the mouth of the river (the Milky-Way), the boatman (of the moon) comes to ferry Orihime over to her beloved Kengyuu. But if Orihime has not done her weaving to the best of her skills and ability, Tentei may make it rain. When it rains, the boatman will not come (because the river is flooded). However, in such a case, *Kasasagi* (a group of magpies) may still fly to the Milky-Way to make a bridge for Orihime to cross.

Related to this legend, ancient Japanese celebrated the festival of *Tanabata* on the 7th day of the 7th month each year (lunar calendar). The 7th day of the 7th month generally falls in August or September in the Gregorian calendar. At this time of year the constellations of Lyra and Aquila are prominent in the evening sky with their major stars (Vega and Altair) separated by the Milky-Way. The 7th day of the 7th month also finds a waxing crescent moon (boat) reaching its first quarter. If it is not raining, both *Orihime Boshi* (Vega) and *Kengyuu* (Altair) are quite conspicuous at the time of the *Tanabata* festival.

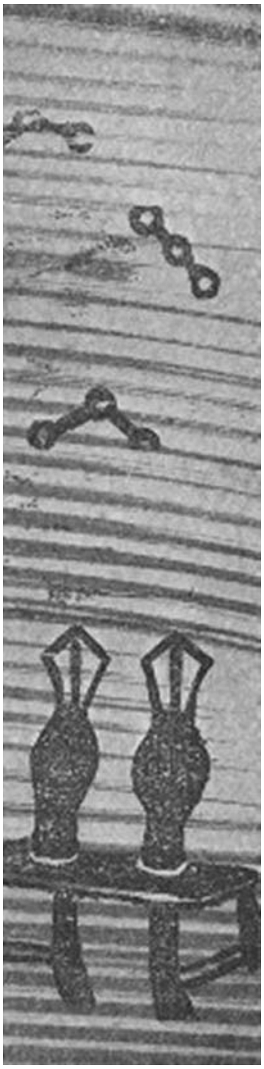
Tanabata may be translated as "weaving with the loom (*bata*) placed on the shelf (*tana*)," and the festival celebrates improvement of technical skill and ability. As in China, ancient Japanese added specific values to their wishes that Orihime hone her skills and work hard so that she could meet Kengyuu. In modern celebrations of *Tanabata*, people throughout Japan write wishes (generally for themselves or relatives) to the *kami* Orihime on colorful strips of paper. On the evening of Tanabata, they tie these paper wishes to freshly cut bamboo. Wishes may be for increased skills in work or school but may also be for anything that reflects a person's dreams and hopes for the future. Summer vegetables such as eggplant and cucumbers are prepared, and horse or cow figures made out of straw and water oats are decorated.

While the myth probably held seasonal significance in its Chinese origins, specifically the celebration of the end of the rainy season (reflected in a desire that it not rain), it found a variety of interpretations related to seasonality in its Japanese form. Particularly in relation to agricultural development in Japan, "wishes" related to celebrations of *Tanabata* ranged from desire for dry weather to desire for wet weather depending on the particular geographic region and whether a crop was to be planted or harvested at this time.

Following Shinto practice and ancient values, the concept of purification (generally including use of water) before the Bon festival (centered on the 15th day of the 7th month) was also added to the *Tanabata* festival. Before the legend was brought from China, a ritualistic festival had been held to welcome the water kami at this time of year; infusion of the legend of Orihime and Kengyuu added a motif of the ritual celebration of the marriage of a weaving lady and the water god (Okada and Akune 1993). In eastern parts of Japan, an associated ritual called Nebuta was celebrated. On the early morning of Tanabata, bamboo would be set afloat in the river, and people would brush their bodies with leaves from "silk" trees. By doing so, they were said to take their sleepiness (*nebuta*) away, another form of purification and preparation for Bon (Yoshinari 1996). The close relation of Tanabata to the indigenous Bon Festival has obviously led to a number of adaptations of the imported Chinese mythology. In short, one makes the coming of the Bon festival sacred by excluding impure spirits from the body at the first quarter moon, thus being pure for the coming of Bon at full moon. It is interesting that in some regions of Japan, *Tanabata* is accompanied by a taboo forbidding swimming or bathing in a river. Noting the relation with the celestial "river" or Milky-Way, the taboo is based on the idea that a *Kappa* or water deity resides in the river, and one should not make the pure water dirty by entering the water deity's home.

When it was first imported, *Tanabata* was celebrated only by imperial court officials. It was considered a graceful event, full of the simple elegance so associated with the Heian era of Japan. Lanterns were lighted, and poems were written on mulberry leaves still holding their dew (Nojiri 1973). Of course, as the custom spread to local areas, towns became covered with bamboo at *Tanabata*, and the festival took on more of the values inherent in Japanese consciousness and purpose (Fig. 3).

The process of adapting this imported legend and developing indigenous practices evolved in complex ways over the centuries, and we have touched on but a bit of this complexity. In modern times, the festival is generally celebrated on a solar July 7th, a date that is generally still within the rainy season. Sadly, the festival has lost much of its seasonal significance with modern industrialization. Of course, the vitalistic ethic of improved work and skill is still valued, regardless of



Astronomy in Japan: A Cultural History. Fig. 3 Decorated strip of *Tanabata* bamboo from the *Tottori* region of Japan. Note the representation of *Hiko Boshi* (Altair and two-flanked stars in Aquila) at the top and *Orihime Boshi* (Vega flanked by two stars in Lyra) near the middle (From Nojiri, Houei Nihon Seimei Jiten of Star Names in Japan, 1973, p. 60. Used with Kind permission of the publisher).

whether or not the day of celebration is attuned astronomically.

Prevalence of the Sun: Akemashite Omedetou Gozaimasu

No discussion of Japan's heritage with the sky can avoid the prime significance of the sun. Symbolism related to the sun is heavily incorporated in Japanese myth and is still seen in its flag. Being the most eastern of East Asian nations and indeed being seen as the land which the sun first greets in the morning, the phrase "land of the rising sun" developed special meaning for Japanese from ancient times. Along with the significance of Amaterasu as sun goddess, there are other ways in which the sun has become a central part of Japanese consciousness. The celebration of the New Year represents yet another way in which indigenous values are mixed with Chinese imports to provide a unique cultural perspective on the significance of vitalism and optimism.

While Christmas is celebrated in Japan to some degree, it is not considered a national holiday, and the attendant Western religious aspects of that day are certainly missing. New Year's Day is by far the more significant holiday. Before the Meiji Restoration, the New Year was celebrated according to the Chinese lunar calendar. In modern times, though the lunar calendar still has influence on scheduling of festivals and celebrations, the Gregorian calendar change is celebrated by most people as the "official" New Year.

In the days before the New Year begins, people busily prepare by cleaning house and cooking food to welcome the kami of new life. At this time, the Post Office is flooded by New Year's cards which each person sends to friends, relatives, and associates. Rail and air terminals are jammed with people trying to get back to their hometowns to spend the New Year's "night" and "daybreak" with family members.

Japanese express wishes for the New Year by saying "Akemashite Omedetou Gozaimasu." Only one Kanji (Chinese character) is found in this phrase (within the first word). This Kanji is a combination of the characters for sun and moon, and among other meanings, entails the sun and the moon getting together and becoming "bright." It represents "changing" and "opening," in a sense, "dawning" (Fig. 4).

In ancient lore (under the lunar calendar), the New Year was seen in relation to change in both the sun and moon as well as the symbol of their luminance. The meaning of the phrase "Akemashite Omedetou Gozaimasu" reflects the values of linealism, vitalism, and optimism. Perhaps it is expressed in English most appropriately as follows: "The year is changing; darkness gives way to light; new life begins; Congratulations!" Following tradition, many Japanese on New Year's morning brave the cold to find places with

Astronomy in Japan: A Cultural History. Fig. 4 The *Kanji* for *Ake*. Symbols for the sun and moon are placed together in this character to represent "bright" or "beginning" (computer graphic by Steven L. Renshaw).

unobstructed views of the Eastern Horizon and eagerly await the rising sun, the break of day, the symbol of new life. Incorporating the ideas of much ancient mythology, the sun is seen to be making its journey back to the North, and the Vernal Equinox is eagerly awaited.

As in other aspects of Japanese astronomy that we have discussed, Chinese imports and traditions were incorporated from early times. The New Year of 1996 was special in that it began another 12-year cycle of the Chinese calendar (based on positions of Jupiter with its 12-year orbit and consequent position about the ecliptic; Uchida 1981). The tradition of using Chinese based animal names for the 12 directions and associated years is popularly maintained in Japan. In 1996, things turned around once more to the direction of *ne* (mouse), the North, to the direction of the star Polaris, sometimes called *Ne no Hoshi* (mouse star) but also called *Shin Boshi*, the "Heart" star, the "soul of the Heavens." 1996 began the clockwise cycle again which from ancient Chinese geomancy means moving from N to NNE (1997, *ushi* or cow), to ENE (1998, *tora* or tiger), to E (1999, *u* or rabbit) and so forth.

The mixture of Chinese geomancy and symbolism with indigenous social values is clearly seen in the Japanese celebration of the New Year. Yet the quiet tolling of temple bells on New Year's Eve brings a certain calm and solitude unseen in most any other culture. It is in this very symbolic act that centuries of Japanese history and tradition, for better or worse, can be seen and truly appreciated.

Hopes for the Future Built on a Rich But Hidden Past

Most of Japan's recorded history reflects a culture continually influenced by imports, even when on the surface, the country appeared to be isolated. At the same time, a cultural consciousness combined with quite distinct social and political purposes has always been a source through which most any idea, foreign or domestic, had to be filtered.

Though we can still see much of the ancient heritage of Japanese astronomy in layouts, structures, mythology, and ethnographic lore, it is often difficult to find too many Japanese citizens aware of this sphere which incorporates a complex interaction of ancient values and purposes with celestial symbols. Feeling that the culture has adopted almost every modern concept that East or West has to offer, many Japanese themselves are unaware of the richness of their ethnoastronomic heritage. As in the West, many young Japanese are more likely to know the name of Pleiades rather than Subaru and associate the latter with an automobile company rather than the celestial symbol which meant so much to their ancestors. While Tanabata is still observed, and the legend of Orihime and Kengyuu still finds its way into modern songs and prose, few people are concerned about the festival's shift away from its seasonal association. In many ways, however, Japan's embracing of the West and virtual denigration of its past reflects a process which has been a part of the culture's way of handling infusion from its earliest times. Still, when the "face" is lifted, one still finds an enduring set of values and purposes that appear to predate written history.

Aveni (1989) alludes to the modern inclination to disassociate science from the social and historical context in which it was developed. He points out how such isolation lacks the notion of process or change and says that in a sense, we "seek ourselves in the tattered walls of others cultures." Aveni further mentions the danger of relying solely on written records and emphasizes using additional evidence in the form of archaeology and architectural icons to understand a nation's cultural astronomy. In taking a narrow view of astronomy as it developed into modern Western science, Aveni contends that we pursue what is interesting to us instead of what was important to the people we study.

The specific irony of Aveni's observations relative to the study of astronomy in Japan may rest in the view taken by many Japanese themselves. In a sense, the view is that we (Japanese) seek others' selves (Western science in particular) within the tattered walls of our own culture and come up sadly lacking. To further paraphrase, we (Japanese) tend to pursue what is of modern interest (to the West in particular) instead of what was actually important to our own ancestors throughout history. These perhaps enigmatic Japanese views are the result of a long and complex history involving interaction of native belief and consciousness with a perception that while unique, the native culture is somehow inferior to those imports it filters. Such lack of "cultural self-esteem" has led to a number of enigmatic events in Japanese history, not merely the denigration of its own astronomic heritage.

In looking at the overall influence of Japanese value, past and present, it may be worth noting that modern astronomical practice, while totally within the rubric of Western science, reflects a long heritage of curiosity combined with concern for future generations. A good example of this may be found in the diary of a young Kochi resident rediscovered in the 1980s. In 1664, while astronomers in Europe were trying to learn more about the motion and nature of comets, Matasaburou, a young boy of 12, began to observe what would later be known as Comet C/1664 W1. Encouraged by his teacher, Jian, he diligently observed the comet for over 4 months, wrote his impressions, and drew the changing shape of the comet in his diary. Despite the lack of astronomical knowledge, Matasaburou showed remarkable curiosity about the true nature of the *houki boshi* (brush star) and an abundant skepticism of the prevailing view among townspeople that the comet signaled doom. While his drawings do not have the flamboyance of those of Hevelius and others observing the comet in Europe, his diary shows every attempt to precisely plot the location and shape of the comet as it crossed the celestial sphere nightly. Matasaburou passed on to his own pupils the joy of discovery, and it is no doubt due to this that copies of his diary have survived the centuries. Such diligence is still seen in the work of amateur and professional astronomer alike. One cannot help but be reminded of the tireless efforts of professionals and amateurs who venture out on every clear night to observe and try to discover yet another celestial wonder.

Future astronomers, archaeoastronomers, and ethnoastronomers in Japan will no doubt come from an increasing number of young Japanese who have grown up in the intellectually free environment of modern Japan. Those not raised within the culture may find the door to Japan's astronomical past opening wider if there is a will to engage in exploration of consciousness and purpose still so evident beneath the surface of Japan's modern society. However, much work lies ahead in uncovering the vast richness of Japanese astronomy in history, and the future is probably most "optimistic" for those young Japanese scholars who find the riches of their heritage and culture inspiration and justification enough to seek knowledge about their nation's long pilgrimage with the sky.

Astronomy in Mainland Southeast Asia

Yukio Ōhashi

Southeast Asia is divided into two parts, mainland Southeast Asia and insular Southeast Asia (also called the Indo-Malay Archipelago). Mainland Southeast Asia is further divided into two parts. One is Vietnam, where Chinese influence is greater than Indian influence, and the other includes Burma, Cambodia, Laos, and Thailand, where Indian influence is greater. The Malay Peninsula is a part of mainland Southeast Asia geographically, but is culturally closer to insular Southeast Asia.

Astronomy in Burma, Cambodia, Laos, Thailand, and Yunnan

Traditional Calendars in Burma, Cambodia, Laos, Thailand, and Yunnan[1]

The traditional calendars of Burma, Cambodia, Laos, and Thailand in Southeast Asia, and those of the Tai (or Dai in the Pinyin system of Chinese transliteration) people in Sipsong-panna (or Xishuang-banna in Pinyin) in the Yunnan province of China have similar characteristics. They are basically based on the Indian (Hindu) calendrical system, which is a luni-solar calendar, with certain simplifications. The Indian influence is seen, for example, in the fact that the length of a year used in most of these calendars is 365.25875 days. This is similar to the sidereal year (not tropical year) of the Ārdharātrika school, one of the schools of Hindu astronomy. Dikshit, an authority on Hindu astronomy in the second half of the nineteenth century, pointed out that the length of a year used in an astronomical work procured by a French envoy from the Ayutthaya dynasty of Siam (present Thailand) is the same as that of the *Sūrya-siddhānta* quoted in the *Pañca-siddhāntikā* of Varāhamihira (sixth century AD) (Dikshit 1981: 378). This *Sūrya-siddhānta* belongs to the Ārdharātrika school.

Besides the Indian influence, there is also Chinese influence in this area, notably the animal names of the 12-year cycle.

The main differences between Indian (Hindu) traditional astronomy and the calendars in mainland Southeast Asia (except for Vietnam) are as follows. (The traditional calendar of Vietnam is based on the Chinese system, which I shall discuss in the next section.)

1. In the Hindu traditional calendar, an intercalary month is inserted when two successive new moons occur during which the sun remains in the same zodiacal sign. In mainland Southeast Asian calendars, the 19-year cycle is usually used for intercalation during which seven intercalary months, which consist of 30 days, are inserted after the fixed month of a year. Actually, the 19-year cycle is not harmonious with the sidereal year which is used in Hindu and mainland Southeast Asian calendars, and I suspect that this 19-year cycle might have been introduced from China.
2. In the Hindu traditional calendar, one month is divided into 30 *tithi*s, which are the periods during which the longitudinal difference between the sun and moon changes by 12°, and the number of the *tithi* at the beginning of a day (usually sunrise) becomes the name of the day. So, the number of days in a month is automatically determined. In mainland Southeast Asian calendars, 29-day months and 30-day months are usually distributed alternately at definite months of a year, and 11 intercalary days are distributed in 57 years at the fixed month of a year. Actually this method is slightly inexact.

One thing may be added here. Among Tai (or Thai) people, lunar months are named by serial number, and there are some variations of this method. This method is similar to the Chinese method, but is absent in the Hindu traditional calendar. The method used by Dai people in Sipsong-panna in Yunnan province (in China) is quite similar to an ancient variation of a Chinese method.

I suggest the following tentative hypothesis. The 19-year cycle intercalation and the method of month reckoning using serial numbers were introduced from

[1] For the calendars in mainland Southeast Asia, except for Vietnam, see Eade 1989 and 1995. For the Burmese calendar, see Irwin 1909, Silva 1914, and Htoon-Chan 1918. For the Cambodian calendar, see Faraut 1910. For the Lao calendar, see Phetsarath 1940 and Dupertuis 1981. And also, for the Dai calendar in Yunnan in China, Zhang and Chen (1981) may be consulted. It may also be mentioned here that Casparis (1978) may be consulted for calendars in insular Southeast Asia.

China, and were modified after the introduction of the Indian calendar (Ārdharātrika school). (For details, see Ōhashi 2002.) It may also be mentioned here that the calendar used in the inscriptions of Champa, which was a kingdom that existed in present central and south Vietnam until the seventeenth century AD, was also based on the Indian calendar.

Controversy Regarding the Dai calendar in Yunnan, China

There was a controversy between Dong Yantang and Zhang Yong, both of whom are Chinese scholars, in the first half of the twentieth century regarding the origin of the Dai peoples' calendar in the Yunnan province of China. In 1938, Dong Yantang published a paper on the origin of the Dai calendar (Dong 1938). In this paper, Dong Yantang argued that the Dai calendar was based on the Qin calendar of ancient China.

In 1939, Zhang Yong wrote a paper on the Dai calendar (Zhang 1939). Zhang Yong criticized Dong Yantang's paper, and concluded that the Dai calendar was based on the Indian calendar. Zhang Yong pointed out some reasons. For example, the Dai calendar uses half months just like the Indian calendar, and the Dai calendar divides a year into three seasons just like the Indian calendar. These reasons are justified. Zhang Yong mentioned other reasons also, and tried to show that the Dai calendar was completely based on Indian calendar without Chinese influence.

I think that the Dai calendar is basically based on Indian calendars, but there may be some Chinese influence also, as I mentioned in the previous section.

Historical Development of the Traditional Calendars in Yunnan and Burma

According to Zhang Gongjin and Chen Jiujin (Zhang and Chen 1981), the texts entitled *Suding* and *Suliya* were followed by the Dai people for making calendars before AD 1931, but the text entitled *Xitan* has been followed since AD 1931 or so. Zhang and Chen also say that the *Suding* and *Suliya* do not follow the 19-year cycle of intercalation strictly, but the *Xitan* follows the 19-year cycle of intercalation. The calendrical luni-solar year of the *Xitan* practically keeps pace with the tropical year, although the solar new year's day is calculated by the sidereal year as before. I compared their astronomical constants with Indian constants, and found that the *Suding* and *Suliya* follow the Ārdharātrika school, while the *Xitan* follows the Saura school (Ōhashi 2002).

According to Irwin (1909), the *Makaranta* (there are two methods of epoch: AD 638 and AD 1436), which probably follows the "original *Surya Siddhanta*" (i.e., Ārdharātrika school), was followed in Burma originally. Afterwards the *Thandeikta* (epoch: AD 1738), which chiefly follows the "present *Surya Siddhanta*" (i.e., Saura school), was used. Irwin writes that the *Thandeikta* is said to have been composed in about AD 1738 or AD 1838, and that the present *Sūryasiddhānta* was introduced into Amarapura, Burma, in AD 1786, and translated into Burmese after about 50 years. Irwin also states that the 19-year cycle of intercalation was followed in the *Makaranta*, but was not strictly followed in the *Thandeikta*. We should note that the Burmese *Makaranta* is probably different from the well-known Indian Sanskrit astronomical table *Makarandasāraṇī* (AD 1478) of Makaranda, which follows the Saura school.

Here, the treatment of the 19-year cycle of intercalation is just the opposite of the Dai calendar (Yunnan, China) and Burmese calendar. More detail about the calendar reform in these regions should be investigated.

Traditional Astronomy and Modern Astronomy in Thailand

In the mid-fourteenth century AD, Lithai (King Ruang) of the Sukhothai dynasty wrote the *Traiphum* (Three Worlds) (Reynolds and Reynolds 1982). This is a celebrated text of traditional Thai cosmology, which is based on Buddhist cosmology. Some information about traditional astronomy and the calendar is also found there.

In 1685, King Narai of the Ayutthaya dynasty observed a lunar eclipse with a telescope with the Jesuits sent by the French King (See Tachard 1688/1981: 230–246, and Choisy 1993: 215). King Narai requested mathematicians from France, and planned to build observatories at Louvo (now Lop Buri) and Siam (now Ayutthaya). This event may be considered the beginning of modern astronomy in Thailand.

In 1687, a French envoy, Simon de la Loubère, visited the Ayutthaya dynasty and procured an astronomical work entitled *Souriat*. This work was later analysed by a celebrated astronomer, Jean Dominique Cassini (See Loubère 1693/1969: 64–67 and 186–199, and Bailly 1787: 3–30.). This is the earliest information of India-based astronomy reaching Europe. Dikshit pointed out that the length of a year used there is the same as that of the *Sūryasiddhānta* quoted in the *Pañcasiddhāntikā* of Varāhamihira (sixth century AD) (Dikshit 1981: 378).

In the nineteenth century, King Mongkut (Rama IV) (r. 1851–68) studied European astronomy as well as Thai traditional astronomy. He ordered his own observatory near Phetburi. He predicted the total solar eclipse of 1868. According to the *Dynastic Chronicle*, the King calculated the eclipse "by using the old astrological texts of Siamese and Mon, as well as many old American and English texts." According to Thongchai, the Mon text used by the King is the *Saram*, one of the two Mon treatises for planetary calculation known in Siam; the other text more conventionally used by astrologers at that time was *Suriyayat*. (See Thiphaakorawong, vol. 2 1966 of 1965–1974: 532–539, Cook 1992, and Thongchai 1994, chapter 2.) This was a symbolic event in the course of the introduction of modern astronomy into Thailand.

There are several inscriptions with calendrical data in Thailand, which are also important sources of Thai astronomy (Eade 1996). There was an independent kingdom, Lanna, in North Thailand from the end of the thirteenth century to the beginning of the twentieth century. The people of Lanna had their own astronomy, which was based on Indian astronomy. (See Soonthornthum 1998; for the Northern Thai calendar, see Davis 1976.)

Burmese Constellations

Burma has a special system of constellations, and there are three beautiful star maps drawn on the ceilings of corridors of the Kyauktawgyi Pagoda at Amarapura (near Mandalay, Burma) (Figs. 1a–d are the star maps photographed by the author in 1984).

King Pagan (r. 1846–1852) built the Kyauktawgyi Pagoda in 1847 on the model of the Ananda Temple at Pagan (U Lu Pe Win 1960: 5). There is a pioneer study of Burmese constellations by Francis Buchanan (1799) (also see Nishiyama 1997). Although Burmese constellations include Indian constellations, there are many Burmese unique constellations, which are very important for investigating the original Burmese contribution.

Astronomy in Vietnam

There are four main countries where Classical Chinese was used as the official language of traditional learning: China, Korea, Japan, and Vietnam. In this section, I will discuss some aspects of Vietnamese astronomy based on the sources I consulted. When a Vietnamese or East Asian person is referred to in this section, the surname is written first as is the custom in these regions, unless commented upon otherwise.

Previous Researches

In 1934, Mikami Yoshio, a pioneer of the study of the history of Eastern mathematics in Japan, wrote a paper on a mathematical work of Vietnam. This is a study of a Vietnamese mathematical work entitled *Chi-minh toan-phap*, written in classical Chinese, which was brought to Japan by Matsumoto Nobuhiro, an authority on Vietnamese study in Japan.

In 1940, Yung Chang (as transliterated in his own paper where Chang is the surname, or Zhang Yong in modern Pinyin transliteration) (1911–1939), a Chinese scholar, wrote a paper on the Vietnamese calendar. This is a pioneer study of the Vietnamese calendar, and I was much impressed by this work. In the 1960's, Huard and Durand wrote popular articles on the history of Vietnamese science (Huard and Durand 1961/1965; Durand and Huard 1964/1966). In 1964, Ho Peng-Yoke wrote a paper on the records of natural phenomena, including astronomical phenomena, recorded in a historical work of Vietnam. It is necessary to continue this kind of work, comparing the records with other East Asian records, and checking them with modern calculations.

In 1979, a monograph on the history of science in Vietnam was published in Vietnamese in Hanoi (Vien Su hoc 1979). This book includes 12 papers, including a paper on the history of Vietnamese mathematics written by Ta Ngoc Lien. As far as I know, this book is the most detailed work on the history of science and technology in Vietnam. In 1991, Han Qi, a Chinese scholar, wrote an overview of the history of astronomy and mathematics in Vietnam (Han 1991). [Ed. note: See Han Qi's article on Jesuits and Knowledge Exchange in China in this volume.]

In 1999, the ninth International Conference on the History of Science in East Asia was held at Singapore. In this conference, there was a session on "New Topics in the History of Science in East Asia-Preliminary Research on Vietnamese Scientific Tradition." In this session, Chu Tuyet Lan and Nguyen Xuan Dien from the Institute of Sino-Nom Studies, Hanoi, introduced Vietnamese works on science, medicine and technology (Nguyen 2002), and Alexei Volkov read a paper on the *Toan-phap dai-thanh* of Luong The Vinh, a Vietnamese mathematical work. I think that this conference marked a kind of breakthrough for the study of the history of Vietnamese astronomy and mathematics.

In 2000, I visited the Institute of Sino-Nom Studies in Hanoi, and consulted some Vietnamese astronomical works with the help of Ms. Chu Tuyet Lan and Mr. Nguyen Xuan Dien. When I visited Vietnam, I found a small book on 13 Vietnamese scientists, both premodern and modern, written in Vietnamese (Le 1999). This is a popular book for youths.

In 2002, Alexei Volkov published a paper on the *Toan-phap dai-thanh*. I think that this is a monumental paper on the history of mathematics in Vietnam. Also in 2002, a convenient bibliography of classical literature of Vietnam was published in Taiwan. Several astronomical and mathematical works are listed there (Liu, Wang, and Chen 2002, part 1: 452–459).

Vietnamese Astronomy

Rough History of Vietnamese Calendars

1. Acceptance of Chinese calendars, notably the *Shoushi* calendar

The *Yuanshi*, the official history of the Yuan dynasty of China, says that a Chinese calendar was given to the Vietnamese king (Tran dynasty) in 1265 (*Yuanshi*,

a

b

c

d

Astronomy in Mainland Southeast Asia. Fig. 1 Star maps drawn on the ceilings of corridors of the Kyauktawgyi Pagoda at Amarapura.

vol. 209, Annan, the second year of Zhiyuan). At that time, the *Shoushi* calendar, the celebrated calendar of the Yuan dynasty, had not been made, and the *Daming* calendar of the previous Jin dynasty was still used in China.

The *Dai-Viet su-ky toan-thu*, an official history of Vietnam written in Classical Chinese, says that the *Shoushi* calendar was given to a Vietnamese king (Tran dynasty) from the Chinese Emperor in 1324. (*Dai Viet Su Ky Toan Thu*: 220, vol.6, 42 b in the original block print). From the above sources, we can suppose that Chinese calendars were accepted in Vietnam until the early fourteenth century.

2. *Hiep-ky* calendar

The *Dai-Viet su-ky toan-thu* states that the *Shoushi* calendar was changed into the *Hiep-ky* calendar in 1339 (Tran dynasty) (*Dai-Viet su-ky toan-thu*: 229, vol. 7, 9 b-10 a in the original block print). This record possibly means that the name of the calendar was changed, and does not necessarily mean that the method of calculation was changed. The *Mingshi*, the official history of the Ming dynasty of China, says that the *Datong* calendar of China was given to the Vietnamese king (Tran dynasty) in 1369, the next year of the establishment of the Ming dynasty (*Mingshi*, vol. 321, Annan, the second year of Hongwu). It may be that the *Datong* calendar, which is a revised version of the *Shoushi* calendar, was accepted in Vietnam at that time.

3. *Thuan-thien* calendar

The *Dai-Viet su-ky toan-thu* tells that the *Hiep-ky* calendar was abolished, and the *Thuan-thien* calendar was adopted in 1401 (Ho dynasty) (*Dai-Viet su-ky toan-thu*: 267, (vol. 8, 39a in the original block print). The difference between these two calendars is not recorded.

4. Acceptance of the Chinese *Datong* calendar

Vietnam was directly ruled by the Ming dynasty of China from 1413 to 1428, and the *Datong* calendar must have been used. The Le dynasty was founded in 1428 in Vietnam, but there is no record that the calendar was changed.

The *Mingshi* states that the *Datong* calendar was given to the Mac, who ruled Vietnam for certain period, in 1540 (*Mingshi*, vol. 321, Annan, the 19th year of Jiajing). In 1829, Nguyen Huu-than wrote in his *Y-trai toan-phap nhat-dac-luc* that the *Datong* calendar had been used until the *Hiep-ky* calendar (Vietnamese adoption of the Chinese *Shixian* calendar) was adopted in 1813 (Zhang 1940: 34.).

5. *Hiep-ky* calendar (=*Shixian* calendar)

According to Nguyen Huu-than, as we have seen above, the *Shixian* calendar of the Qing dynasty of China was adopted in Vietnam as the *Hiep-ky* calendar in 1813 (Nguyen dynasty). This *Hiep-ky* calendar should not be confused with its previous namesake. Zhang Yong compared Vietnamese chronological tables with Chinese calendar, and pointed out that the *Shixian* calendar was actually used in Vietnam from 1813 to 1840.

6. Consideration of the longitudinal difference

Zhang Yong pointed out that the Vietnamese *Hiep-ky* calendar has differed from the Chinese *Shixian* calendar since 1841. This must be due to the consideration of the longitudinal difference between Vietnam and China.

Calendar Reformation Under Minh-manh

In order to reform the calendar, astronomical observations were made under the emperor Minh-manh (r. 1820–1840) of the Nguyen dynasty. There are some source materials about this reformation.

The *Dai-Nam hoi-dien su-le* (1855) is a comprehensive official record of the system of government of the Nguyen dynasty. It has a section on the Kham-thien-giam (National Astronomical Observatory). According to this section, it was declared in 1837 that the prime meridian for Vietnam passed through its capital (Hue), whose latitude was determined to be 16°22′30″, and longitude measured from the Western prime meridian to be 105° (*Dai-Nam hoi-dien su-le*, vol. 259, 13a–b). The actual position of Hue is 16°27′N, and 107°33′E (from Greenwich). So, the above-mentioned Western prime meridian must be Paris (2°20′E from Greenwich).

There is another interesting work entitled *Thien-van-khao* (Study of Astronomy), which is volume 1 of the *Su-hoc bi-khao* of Dang Van-phu. This text records longitude and latitude (from Hue) of several places determined in 1837. According to this text, the longitude seems to have been determined by the observation of lunar eclipses using local time. From the above sources, we know that Vietnamese astronomers made efforts to make the calendar more suitable for Vietnam.

Another interesting work is the *Quoc-trieu thien-van-chi*. This is a chronological compilation of the records of heavenly phenomena from 1569 to 1888.

The traditional astronomies in several regions of mainland Southeast Asia are very interesting, but their detailed study is our future task. Several original sources are still in manuscript form or extremely rare. Fortunately, some people are now going to study this subject, and I hope that more results can be reported in the near future.

In the case of Vietnamese astronomy, it is necessary to compare it with Chinese astronomy, and in the case of Burmese, Cambodian, Lao, and Thai astronomies, it is necessary to compare them with Indian astronomy. Thorough study of the regional differences and their relationships with regional cultures are needed. I hope some readers of this article contribute to this subject in the future.

Astronomy in Mesoamerica

Martha J. Macri

Mesoamerica extends from northern central Mexico into Nicaragua. The region contains dozens of distinctive ethnic groups. Shared linguistic features, ceremonies, and mythic traditions show that these diverse peoples have been in intimate contact with one another for thousands of years. One of their shared intellectual achievements is their understanding of the cosmos. A long history of observing and recording astronomical phenomena has allowed them to establish amazingly precise measurements of the cycles of the earth, sun, moon, and the visible planets. Much of the indigenous knowledge in this region did not survive the initial years of violence and disease, which were followed by centuries of less dramatic, but equally destructive political and economic oppression. Nevertheless, among specialists in many contemporary indigenous communities (day-keepers, calendar priests, community scholars), fragments of the ancient knowledge are retained today. Further evidence comes from ethnographic and historical descriptions, measurements of ancient architectural features (site alignments and building plans), ritual books, and historical records of political events associated with astronomical phenomena.

Mesoamerican astronomy differs from that of Greece, Mesopotamia, China, and most of Egypt, in that it developed within the tropics (Aveni 1981). There, the stars of the night sky rise and fall in a more or less straight trajectory, while the stars of the northern sky trace circular patterns around the North Star. Also in the tropics, the annual solar cycle is measured, not just by the summer and winter solstices, but additionally, by the twice-annual passage of the solar zenith.

The set of twenty day names combined with the numbers from 1 to 13 (creating a 260 day calendar), and the year of 18 months of 20 days with five added days (resulting in a calendar of 365 days) were common throughout the region. The two calendars combine to form a cycle of 52 years, known to such linguistic groups as the Nahuatl, Maya, Mixe-Zoque, Zapotec, and Mixtec. These cultures shared ceremonies, mythic traditions, and a common system of knowledge that included the prediction of expected solar and lunar eclipses (Fig. 1), observation of the seasonal rising and setting of the Pleiades, and awareness of the periods of Venus, Mars, Jupiter, and Saturn. Dates of significant conjunctions of planets, the moon, bright stars, and constellations were recorded on carved stone monuments from at least as early as CE 156.

The movement of the sun, moon, stars, and planets seems to have been measured in part by observing the important points of rising or setting on the horizon and noting the alignment with hills, mountains, and buildings. Unusual shaped structures such as Building J at Monte Alban and the Caracol at Chichen Itza (Fig. 2) may have had astronomical observation as their primary function. The year sign found in Mixtec and Mexican codices was thought by some to represent an instrument used to measure the movement of the sun. Some modern Maya day keepers have calendar boards on which they mark the passing of days. The ancient peoples of Mesoamerica also produced mirrors, which may have been employed in observation, though such use has not been substantiated.

Astronomy in Mesoamerica. Fig. 2 The Caracol at Chichen Itza. Photo by author.

The degree of precision required to note astronomical phenomena varies greatly depending upon the event. Daily changes in the phases of the moon are easily observed. Solar events such as equinoxes and solstices are measurable within a range of several days. First perceptible movement of the outer planets (Mars, Jupiter, and Saturn) from stationary points (the location marking the change from forward to retrograde motion and vice versa) may not occur for a week or more. Some planetary conjunctions may be visually notable for weeks, but conjunctions involving the moon and the visible planets last for only a day or two and occur frequently. Heliacal risings and eclipses are measured by hours. An awareness of these variations is necessary to evaluate supposed records of such events.

Scattered throughout Mesoamerica are structures oriented so that solstices and equinoxes could be observed by persons stationed on their summits or sighting them through their doors. These include Group E at Uaxactun, buildings from the Puuc region in the northern Yucatan peninsula, the Templo Mayor in Mexico City, and Alta Vista near Zacatecas located directly on the Tropic of Cancer. Temple 22 at Copan, Honduras, the Governor's Palace at Uxmal, and the Caracol at Chichen Itza were built with architectural features marking the rising and setting points of Venus. At Yaxchilan summer ceremonial activities recorded in hieroglyphic texts on stelae and lintels coincided with the summer solstice.

Cycles composed of fractions of days were counted in multiples of the cycle in order to preserve whole numbers. For example, the lunar sidereal period (the time required for the moon to return to the same position against the background of the stars) were counted in sets of three. This cycle is observed today by the K'iche' Maya of Momostenango as an 82 day period equal to three sidereal periods of 27.3 days (Tedlock 1992). This same 82-day cycle, and multiples of it, were recorded by the Classic Period Maya in inscriptions at Palenque and Calakmul. The synodic period of the moon (the time required for the moon to return to the same position relative to the sun), 29.53 days, was frequently recorded in Classic Maya inscriptions in what is called the lunar series, part of the initial series dates that introduce a majority of Classic monumental texts. The lunar data recorded the number of days since the first visible crescent, the number of the current lunation within a set of six months, the name, or patron of the month, and whether the current month contained 29 or 30 days—another example of how the Maya dealt with fractions.

Although debated since the turn of the century, it now seems certain that the ancient Mesoamerican recognized 13 zodiacal constellations. Animals and other figures representing the constellations have been identified in the murals of Bonampak, in the sky band on Las Monjas at Chichen, in the Acanceh mural in Yucatan, in the three Maya fan-fold books, the Dresden, Paris, and Madrid codices (Fig. 3), and in the Mexican Borgia, Cospi, and Vaticanus codices, as well in as the colonial Florentine Codex by Sahagún.

The changing position of the Pleiades throughout the year continues to be important in Mesoamerica. Modern peoples tend to know the names of a few individual stars—undoubtedly, many were named in the past. Barbara and Dennis Tedlock, for example, have recorded that Alnitak, Rigel, and Saiph in the constellation Orion are known as the "three hearth stones" to modern K'iche'.

Today the K'iche' call the undivided segment of the Milky Way the "white road." The half of the Milky Way that contains the divided segment is referred to as the "road of the underworld." Linda Schele associates various ancient iconographic representations with the changing position of the Milky Way in the night sky. She suggests that when it crosses the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course), it represents the place of creation, when it rims the horizon the portal to the underworld is then overhead, in its east–west direction it becomes the cosmic monster, and when it "sinks" from a horizontal to a vertical position relative to the ecliptic is depicted as a canoe.

Obsidian is thought to be the result of meteors hitting the earth. Throughout Mesoamerica, meteorites are called the excrement of the stars. Several Maya groups refer to meteorites as the cigar butts of the gods. As in the Old World, comets are generally considered bad omens. Both meteors and comets are illustrated repeatedly in the codices of central Mexico.

The planet Mercury has been associated with the Venus Almanac in the Dresden Codex, and with a passage in the Codex Fejérváry-Mayer of the Borgia group of codices. Mercury was in a line with Jupiter and Venus near the Pleiades in the western sky at

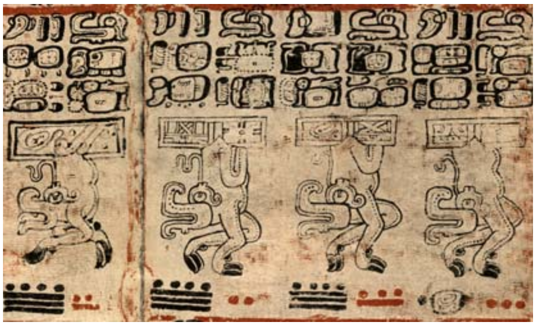
twilight in CE 162, the Initial Series date on the Tuxtla Statuette. Twelve days later Mercury had reached maximum elongation and was heading downward toward the horizon, and Jupiter and Venus, still near the Pleiades, were less than 1.3° apart. If the 4 and 8 shown in the text of that inscription signify days, they may have recorded Mercury's maximum elongation.

Venus remains perhaps the most important planet throughout Mesoamerica (Fig. 4). Five sidereal periods are equivalent to eight of earth's solar years, a ratio shown by the five pages of calculations and images from the Dresden Codex (Fig. 5). Maximum elongation of Venus as evening and as morning star is recorded on the two Long Count dates on La Mojarra Stela 1 from Veracruz (CE 143 and CE 156). The Venus almanac in the Dresden Codex follows Venus through 65 synodical revolutions of 584 days. Heliacal rising after inferior conjunction is repeatedly recorded with war events in Maya texts from the Classic Period (Fig. 6).

The second date on La Mojarra Stela 1 is the day of the first rising of Mars in the east at sunset. At Palenque during the reign of Kan B'alam, a conjunction of Mars, Jupiter, Saturn, and the moon was recorded on CE July 19, 690. The Dresden Codex contains a 780-day Mars almanac. Page 43 shows calculations of multiples of the 780-day period (Fig. 7). The Maya depicted Mars as a hoofed beast suspended from the sky band (Fig. 8).

The two Long Count dates on the La Mojarra stela both record first stationary points of Jupiter. Conjunctions of Saturn and Jupiter of less than two degrees



Astronomy in Mesoamerica. Fig. 8 Mars Beast Suspended from Skyband in the Dresden Codex. Photograph taken by Ernst Förstemann in 1880. Courtesy of Dumbarton Oaks Research Library and Collection.

separation occur regularly at slightly less than 20 years (also only slightly less than a *k'atun* of 20 periods of 360 days). These conjunctions and attendant rituals are recorded at Palenque and Yaxchilan. Jupiter is specifically associated with several Maya rulers.

In ancient Mesoamerica astronomical knowledge was maintained by priest scholars an office distinct from political rulers. Astronomical knowledge was used, however, by political leaders to reinforce and to legitimize their authority. Written records include descriptions of the sky on dates that are significant because they are births or period endings. Dates for other events, such as accessions, wars, and heir designations, seem to have been chosen to coincide with planetary, lunar, and solar phenomena. A few dates seem to have been recorded specifically to commemorate an eclipse or some dramatic planetary conjunction.

In other parts of the world, the invention and spread of writing is associated with the necessity of keeping records of commercial transactions. In Mesoamerica, however, writing was stimulated by, if not invented for, the recording and prediction of astronomical phenomena. Even with the loss of literacy, astronomical knowledge has endured through oral traditions, and through persistent ceremonial practices.

Each of the sources listed below contains extensive bibliographies on Mesoamerican astronomy. Some websites provide introductory information, others, articles on specific findings. Web searches on Mesoamerican astronomy and related topics will yield a number sites showing that the desire to use the stars to understand current events did not die with the ancient sky watchers. Some of those sites also contain useful scientific information and informative charts and images.

Astronomy in Native North America

E. C. Krupp

The astronomical activities and traditions of the American Indians north of Mexico were based upon practical observation of the sky but were not supported by a written language. For that reason, our knowledge of North American Indian astronomy relies upon the archaeological data, ethnohistoric reports from early encounters between Europeans and the indigenous peoples, and ethnographic information collected more recently by anthropologists. Although this material is distorted and incomplete, it enables us to outline the general character of North American Indian astronomy and to understand some of it in detail. All of these sources confirm that North American Indians farmed, hunted, and gathered by the sky. They developed calendric techniques to order the sacred and ordinary dimensions of their lives. They timed ceremonies by the sky. They extracted symbols from the sky. They told stories about the sky. Throughout all of the cultural territories, physical environments, and linguistic traditions of North America, celestial phenomena were incorporated into ritual, iconography, myth, shamanic activity, and worldview.

North American Indians were familiar, of course, with the fundamental cycle of day and night, the daytime path of the sun, and the unmoving pole of the night sky. Cardinal directions, which emerge from the daily rotation of the sky and the circular parade in which the stars march at night, were important to many groups. The moon's phases were monitored, and each monthly cycle was often associated with a seasonal change on earth. The seasonal shift of sunrise, sunset, and the sun's daily path was known. Solstices were recognized, and the rising and setting points of the summer and winter solstice sun sometimes established an alternate directional scheme. Seasonal appearances and disappearances of stars were noted. Constellations were contrived from conspicuous and useful stars. In the historic era, unusual events like eclipses, bright comets, fireballs, and meteor showers attracted notice and sometimes provoked ritual response. Planets were recognized by at least some groups, but explicit evidence of detailed indigenous knowledge of their cyclical behavior has not survived.

Like traditional peoples everywhere, the Indians of North America saw the sky as a realm of power. Access to that power required knowledge of the sky. They acquired that knowledge through careful observation and used that knowledge to order and stabilize their lives. This practical understanding of the sky – the sun, the moon, and the stars – is not the same thing as modern scientific astronomy, for it did not attempt to test and abandon metaphors of nature in the same way science does today. It did, however, help integrate human behavior with nature and consolidate social cohesion. Celestial objects were not just convenient metronomes. They were powerful, supernatural beings, and they revealed the basic structure – the fundamental order of the world. Because cosmic order is, in part, what is meant by the sacred, the Indians' interaction with the sky was an encounter with the sacred.

The earliest account of North American Indian astronomy was reported in 1524 by the Italian explorer Giovanni di Verrazano. He encountered the Narragansett Indians of Rhode Island and mentioned that their seeding and cultivation of legumes were guided by the moon and the rising of the Pleiades. The Pleiades comprise a distinctive cluster of stars. Its value as a signal of seasonal change was recognized throughout the continent. In California, for example, there is explicit evidence of Pleiades lore in all but 12 of the 58 native cultural territories. Those 12 actually correspond to a very small fraction of the entire area and population of the state, and their lack of Pleiades tradition is primarily due to linguistic and cultural extinction. Despite the extraordinary linguistic diversity represented by the 75 mutually unintelligible California Indian languages and 300 different dialects, names for the Pleiades, myths about the Pleiades, and seasonal references to the Pleiades are documented in all five major families of indigenous California languages.

Studies of North American Indian astronomy have emphasized the prehistoric Southwest and the historic Pueblos. This is due to the survival of prehistoric Pueblo architectural monuments and rock art and to the preservation of some information about historic Pueblo astronomical techniques and celestial lore in ethnological reports. Close to the end of the last century, Stephen described in detail the horizon calendar used by the Hopi Sun Chief to establish key dates in the ceremonial and agricultural cycles of the village of Walpi. More recently, historian of science McCluskey demonstrated that Hopi observations of the sun were accurate to 4 arcmin. This is, however, an average error, and it is difficult to do much better than 30 arcmin in any single horizon event. McCluskey verifed that the Hopi actually allowed themselves a few days' leeway in scheduling the winter solstice ceremony.

If Stephen had not seen the Sun Chief perform his duties, we would not know where his sunwatching station was located. Nothing marks the point out at the end of a mesa or on the roof of the highest house. Other references to North American horizon observatories suggest that many were just as subtly blended into the community landscape, and that makes the identification of prehistoric observatories a challenge. Symbolic astronomy was, however, often incorporated into monumental architecture and rock art. By analyzing alignments and iconography, it is sometimes possible to spot the hand of the ancient skywatcher. For example, Pueblo Bonito, an 800-room, five-story, D-shaped apartment-town in Chaco Canyon, New Mexico, makes good use of passive solar heating to stabilize room temperatures in summer and winter. It was completed in the twelfth century AD, and its east–west front wall is oriented cardinally with an accuracy of 8 arcmin. Such accuracy is achievable with simple surveying techniques that rely upon the unaided eye, but it is nevertheless respectable. In addition, archaeologist Jonathan Reyman interpreted corner windows in two rooms as winter solstice sunrise apertures.

The Anasazi built large subterranean community ceremonial chambers known as Great Kivas. Most of these, like Chaco Canyon's Casa Rinconada, possess cardinal orientation, and the plan of a Great Kiva is thought to mirror the Pueblo concept of the cosmos.

There are many pictographs and petroglyphs in Chaco Canyon, and the star and crescent on a panel near the Penasco Blanco ruin have been promoted by some as a representation of the AD 1054 Crab supernova explosion. Prehistoric Indians in the American Southwest very likely saw that spectacular event, but there is no way to verify that the Penasco Blanco pictographs are an eyewitness record of it. The supernova interpretation of star/crescent elements in Southwest rock art was first offered in 1955 as an explanation for two sites in northern Arizona. Since then, the number of reported star/crescent groupings has multiplied, but opinion on the supernova is divided. Reyman argues thoughtfully that the Penasco Blanco site is actually a sunwatcher's shrine and implies that the Crab supernova has nothing to do with these star/crescent designs. Even if they do depict the supernova rising with the waning crescent moon on the morning of 5 July 1054, they tell us nothing substantive about prehistoric Pueblo astronomy. In 1990, Robbins and Westmoreland revived the argument all over again with an analysis of numerical symbolism on prehistoric Mimbres ceramics. One of these has a rabbit in the shape of a crescent moon accompanied by a “star” with 23 rays. This detail is argued to be consistent with the Chinese historical account of the Crab supernova, for the Chinese reported it was visible in the daytime for 23 days.

A spiral petroglyph on Fajada Butte, the most conspicuous landmark in Chaco Canyon, interacts with “daggers” of midday sunlight at the solstices and the equinoxes. These light-and-shadow effects, first reported by Sofaer et al. received a great deal of international attention and inspired considerable controversy. Initially, the “Anasazi Sun Dagger” was interpreted as a “precise solar marker”, but it may be more correct to regard it as a symbolic seasonal display.

One of the best candidates for a sunwatcher’s observing platform is also located in Chaco Canyon, on an upper ledge on a rincon (a square-cut recess or hollow in a cliff) near Wijiji ruin. Rock art on the ledge includes elements as old as the Anasazi and as recent as the Navajo. A line-of-sight to the southeast coincides with a natural rock chimney on the other side of the rincon, and this feature dramatically marks the winter solstice sunrise.

Astronomer Zeilik has emphasized the importance of “anticipatory” observations of the solstices and other astronomical events. The Sun Chief must know ahead of time, with accuracy, when the solstice is due in order to mobilize the community for the ceremonial activity that culminates in the solstice. This is exactly what Walpi’s Sun Chief did, and Wijiji has the ability to deliver advance information and confirmation of the solstice. The site is interpreted, then, by extending significant information from the historic period back into the prehistoric context.

Astronomical components have been identified at many other sites in the Southwest, including Hovenweep, Yellow Jacket, Chimney Rock, Casa Grande, and Mesa Verde. Celestial rock art elements are present throughout the Southwest. Few of these involve accurate mapping of constellations, but several seem to invoke magical power attributed to the stars. Chamberlain has studied Navajo star ceilings in Canyon de Chelly and concluded that most of them are connected with symbolic protection or other celestial magic. Schaafsma interprets war and star imagery in the petroglyphs of New Mexico’s Galisteo Basin as part of a tradition of Southern Tewa celestial war magic.

Nine years after astronomer Hawkins rekindled interest in ancient and prehistoric astronomy in 1963, with his studies of solar and lunar astronomical alignments in Stonehenge, another astronomer, Eddy, identified celestial sightlines in the Bighorn Medicine Wheel, a North American antiquity *Time* magazine headlined as “Stonehenge USA.” The Bighorn Medicine Wheel is located at an elevation of 9,600 ft, above the timberline on Wyoming’s Medicine Mountain. It is a ring, 87 ft in diameter, drawn in small rocks. Originally, the Wheel had 27 or 28 spokes of stones that converged on the main cairn at the center. Five other cairns were constructed on the Wheel’s rim, and the one spoke that extends beyond the rim ends in its own cairn. The ring is actually a flattened circle. Its axis of symmetry coincides with the spoke that reaches from the outside cairn, southwest of the rim, to the cairn at the center. Eddy demonstrated that this line also continues to the northeast horizon and the point of summer solstice sunrise. He associated other lines between cairns with the sequential risings of three bright stars in the predawn sky in summer. Although the age of the Bighorn Medicine Wheel is uncertain, a radiocarbon date for a piece of wood retrieved from the central cairn associates it with the seventeenth century. Eddy thought that the Bighorn Medicine Wheel might have been used at that time by historic Plains Indians to make astronomical observations.

It seems likely, however, that the Bighorn Medicine Wheel is much older. It resembles other similar structures, especially in southern Canada, that are known to be thousands of years old. Who built the Bighorn Medicine Wheel and when it was built are still not known with certainty. There is reason to be skeptical about the practical value and validity of the stellar alignments, but the summer solstice sunrise line is congruent with the design. If the solstice alignment were part of the original plan, it may have had as much to do with vision quests and shamanic retreat as with calendric observation.

In the historic era, Plains Indians incorporated the sky into symbols and ritual. The well-known Sun Dance was intended to inspire prayer and visions through self-infliction of pain, fasting, and thirst. Gazing at the sun while suspended from a pole with ropes looped through the flesh of the chest was thought to purify and spiritually strengthen the participant. Although not all Plains tribes practiced this demanding regimen in the Sun Dance, acquisition of sacred power was a common theme. The enclosure in which the ceremony took place is called a Sun Dance Lodge, and it is sometimes built with 28 posts said to represent the days of the lunar month. Originally, the ritual was performed at the time of the summer full moon nearest to the time of the bison hunt.

Another Plains group, the Skidi band of the Pawnee, is known to have possessed a rich and detailed tradition of star lore. This knowledge has been reviewed and analyzed by Chamberlain in *When the Stars Came Down to Earth.* The Skidi Pawnee Morning Star sacrifice was timed by the movements of planets, especially Mars and Venus, and mythologically, the planets were key players in the Skidi Pawnee Creation myth.

In Nebraska, the Omaha devised a symbol of social cohesion and tribal stability out of the Sacred Pole that was erected ceremonially at tribal gatherings. Omaha myth and ritual allow us to deduce that the Sacred Pole was oriented on the north celestial pole. Its power was linked to the stabilizing character of the hub of the sky.

It is a curious fact that so much public interest in ancient North American Indian astronomy has been directed toward the prehistoric Southwest and the Bighorn Medicine Wheel. Although these sites are valid targets of study, they belong to relatively unpopulated parts of the continent. Even the well-documented traditions of the Plains Sun Dance, the Skidi Pawnee Morning Star Sacrifice, and polar axis symbolism of the Omaha Sacred Pole must be considered marginal traditions of North America.

The mainstream, on the other hand, belongs to the most populated zones of North America. To understand, then, the true character of North American Indian astronomy, it is necessary to look at the Mississippi Valley and California. Nowhere north of Mesoamerica had a comparable population density.

Unfortunately, we know relatively little about the astronomical traditions of the ancient Mississippi Valley. In 1961, however, archaeologist Wittry excavated a feature he called the Sun Circle at Cahokia, a great population center and powerhouse of regional trade in central Illinois between AD 700 and 1200. Cahokia is best known for its large mounds, some of which supported temples and residences. Others hosted burials. Monks Mound, the largest prehistoric earthen construction in the world, is the centerpiece of what was the Chicago of the prehistoric Midwest.

Originally, the Sun Circle was a 410-foot-diameter ring of 48 tall posts (perhaps 30 ft high), with a pole in the middle of the circle but offset apparently intentionally 5 ft from the true center. Three of the posts that once occupied the holes that now remain combined with the center pole to deliver alignments to the rising sun at summer solstice, winter solstice, and the equinoxes. Wittry believed that the Sun Circle's purpose was calendric. It is difficult to understand, however, why a complete ring of posts would be needed and why the posts were so tall. On the other hand, the intentional displacement of the central post makes the astronomical alignments possible.

Despite the ambiguity that persists with Cahokia's Sun Circle, archaeologist Fowler verified the ancient Cahokians' interest in cardinal directions. The city's limits were established by a particular type of earthen mound, and these mounds also defined the primary, and cardinal, axes of the site. In 1994, Fowler described another post circle on the main north–south axis of Cahokia. Its design, size, and astronomical potential mimic the Sun Circle.

The Incinerator Site, a smaller stockaded Mississippian village near Dayton, Ohio, included an arrangement of posts also thought to have astronomical meaning. The largest post, 2 ft in diameter, was located in a plaza, and it formed a line with a post inside a nearby building. This line pointed to the sunrise on April 24th and August 20th. Both dates potentially have agricultural significance. The April date could mark the end of the frost and the beginning of planting. The August date is linked to the Green Corn Ritual, performed in the historic era when the corn filled the husk but was not yet ripe. Cardinally oriented logs were kindled at this time into the New Fire, which also had solar associations.

European explorers encountered the descendants of the Mississippian mound builders in the southeast United States. The chief of the Natchez was known as the Great Sun. He claimed to be the brother of the sun and greeted the sun each morning, when it first appeared from the top of his residence mound. We also know the Natchez subdivided the daylight hours into four periods based upon the position of the sun. They measured the year in months based on the observed phases of the moon and named each lunation for an appropriate seasonal phenomenon.

In the Far West, before Columbus, California competed respectably with the Mississippi Valley for the distinction of being the most populous and densely populated zone north of Mesoamerica. Some indigenous astronomical traditions persisted in California until quite late, and valuable information was collected by ethnographers, especially Harrington. The revival of interest in California Indian astronomy was largely initiated by Hudson and Underhay, whose book, *Crystals in the Sky*, reconstructed the sky lore of southern California's Chumash Indians. Explicit references to horizon observations of the solstice sun and solstice rituals have been collected from the entire state. The moon's phases were counted, and the lunar months were named by most California groups. They recognized familiar patterns of stars, including the Big Dipper and the Belt of Orion. They named many other stars and used them as seasonal signals. They saw the Milky Way as a route to the sky followed by the souls of the deceased. Elaborate Milky Way ceremonialism is known among the Luiseño, who incorporated it into ritual initiation of the youth, mourning songs for the dead, sacred myth, and rock art.

California possesses many rock art sites and some of the most complex rock art in the world. Some of these sites have been associated with solstitial light-and-shadow events that interact with the rock art. Often, particularly at winter solstice, the light develops into a pointed, knifelike shape that pierces a carved or painted element. These effects appear to be symbolic, for they do not generally pinpoint the solstice with high accuracy. Rather, they "work" over a solstice "season" perhaps two to four weeks long. Although there is no explicit evidence that links solstice effects with California rock art, we do know the names of two Chumash shamans who went into the mountains at the time of winter solstice to paint on the rocks.

In detailed application, Native American astronomy was richly varied in North America, but its purpose and basic character were broadly the same throughout the continent. For that reason, we can rely upon Francisco Patencio, Chief of the Palm Springs Indians of southern California, for words that could apply to nearly all Indians:

> When the sun swung to the north and the moon showed quartered by day overhead, or west, they knew by the signs of the sun and the moon when the seeds of certain plants were ripe, and they got ready to go away and gather the harvest. Every plant that grew, the nesting time of all birds, the time of the young eagles, everything they learned by the signs of the sun and the moon. *Stories and Legends of the Palm Springs Indians* (Los Angeles: Times Mirror, 1943).

Astronomy in Sub-Saharan Africa

Keith Snedegar

At the turn of a new millennium the study of astronomical practices in precolonial African societies remains an open field. Major sources of evidence have yet to be fully scrutinized – astronomical texts in Arabic, Ge'ez, Hausa, Malagasy and Swahili, celestial iconography in the African arts, and perhaps most importantly, astronomical knowledge encoded in the vast reservoir of oral tradition. It should be no surprise that Muusa Galaal's groundbreaking monograph on Somali ethnoastronomy derives wholly from oral literature (Galaal 1992). As for the built environment, a few African architectural structures have been surveyed for astronomically meaningful features with interesting if not definitive results; further archaeoastronomical research would doubtless reveal more about the cosmologies behind African material culture. Nonetheless, scholars from various disciplines have already demonstrated that African time reckoning, divination systems, performance art and literature utilized the sky as a cultural resource. Jarita Holbrook of the University of Arizona is a leader of a new generation of scholars exploring African cultural astronomy (Holbrook 2004, 2005). At a popular level the documentary film *Cosmic Africa* (2003), featuring the South African astronomer Thebe Medupe, has done much to introduce the subject to wider audiences.

Sahara Region

Ancient astronomically aligned structures have been discovered in a megalithic complex in the southern Egyptian desert at Nabta, where nomadic pastoralists made their summer camps by a playa, or seasonal lake, between 6,500 and 5,300 years ago. The Nabta site probably served as a ceremonial center. It comprises several oval clusters of stones and isolated megaliths, and numerous tumuli containing cattle and sheep burials. The burials are analogous with ritual practices of modern African pastoralists who slaughter animals to mark socially important occasions. Archaeoastronomer McKim Malville used theodolite and GPS measurements to map the site. He found three lines of megaliths radiating from the largest structure. A nearby stone circle containing four sets of upright slabs, which may have been used to fix positions along the horizon, exhibits two line-of-sight "windows," along a north–south axis and at an azimuth of 62°; the rising mid-summer sun would have been visible through the second line of sight circa 6,000 years ago. Malville has theorized that the geometry of the standing stones reifies a conceptual system integrating death, water, seasonal fertility, and the motion of the sun (Malville et al. 1998). Presumably, the ancient Nabtans correlated solstice observations with the onset of summer monsoon rains. It is intriguing that the megaliths, located in the playa deposits, would have stood in the shallow lake water. The rising and falling water level marked against the stones could have been a powerful indicator of seasonality. With climatic change bringing hyperaridity and desertification to the Sahara region around 4,800 years ago, the seasonal occupation of Nabta came to an end. The Nabtan pastoralists may have migrated to the Nile Valley, contributing their practice of solar observation as well as their reverence for cattle to the cultural development of predynastic Egypt (Wendorf and Schild 2001).

While Nabta is the earliest Saharan site thought to have astronomical alignments, surveys of pre-Islamic tombs in the Tassili N'Ajjer region of Algeria and parts of southern Morroco have also indicated structural orientations suggestive of some calendrical purpose (Belmonte et al. 1999, 2002). In the historic period the nomadic Tuareg people have practiced celestial navigation in their travels across the great desert. When traveling north the Tuareg oriented themselves according to the mother camel constellation *Taləmt* (Ursa Major), and when traveling south they watched the gazelle stars *Ineren* (α and β Centauri). *Əmanar*, "The Guide" (Orion) and Tələzdak, the date palm (Scorpius) are other important asterisms in the Tuareg sky (Donaint 1975).

West Africa

By the first millennium AD the trade between West Africa and Mediterranean North Africa was functioning as an important mechanism for cultural exchange. The transmission of Islam to West Africa would engender formal academic traditions based on written texts in Arabic. From the fifteenth century onward a number of scholars in Timbuktu and other Islamic centers studied astronomy as an adjunct to the Quranic sciences. The corpus of Arabic scientific writings of West African provenance has yet to be analyzed in any detail, but a number of manuscripts preserve meteorological observations, particularly floodings of the Niger River, and details of solar and lunar calendars (Saad 1983). Rebstock (1990) located numerous mathematical, astronomical and astrological texts in Mauretania, 13 of them having to do with the Islamic calendar. Results of a study by the Al Furqan Foundation suggest that roughly one percent of Arabic manuscripts in West Africa contain astronomical material (Hunwick 1997). There are probably several hundred texts yet to be identified and analyzed. A Library of Congress exhibit of manuscripts from Timbuktu afforded a glimpse of this raw material, including tracts entitled *The Important Stars among the Multitude of the Heavens* and *The Rise and Setting of Auspicious Stars* (Library of Congress 2003).

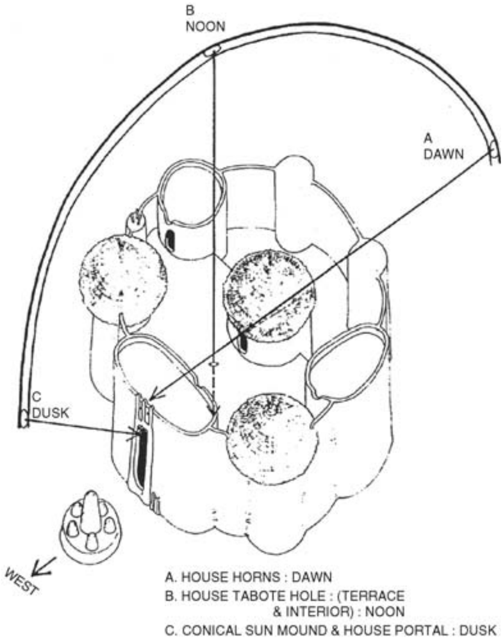
The existence of these texts indicates that at least some West African scholars engaged Arabic mathematical astronomy at rather advanced level. However, the reputed fascination of Aḥmad Bābā al-Tinbuki (1556–1627) and al-Ḥājj Muḥammad al-'Iraqi (fl. 1650) with esoteric astrology likely typifies the chief matter of interest. Many West African literati dabbled in celestial divination; others considered astrological prediction spiritually dangerous. The great Fulani scholar Muḥammad al-Wali (d.1688) wrote a diatribe against astrology and its practitioners. Ironically, his pupil Muḥammad ibn Muḥammad gained fame with an astrological opus, *al-Durr al-Manzūm* (Strung Pearls). It was not an original work. Its chief source was the *Secret Concerning the Dialogue with the Stars* of the Persian sage, Fakhr al-Dīn al-Rāzī (Ullmann 1972). The lack of any coherent school of astronomy or astrology in West Africa is perhaps attested by Muḥammad Bello of Sokoto, who recorded his observations of a bright comet in 1825. Several people asked him to explain the phenomenon so he wrote a treatise on it. Unable to find any scientific writings on comets, he was reduced to quoting theological opinions to assure his readers that the object did not signify the end of the world (Ogunbiyi 1991–1992) (Fig. 1).

The science of the stars did not remain solely in the Arabic language. Savants in the city of Kano translated Arabic star lore into Hausa. The anonymous pedagogical text, *Hisabi ʻAssawwakai*, gives an elementary account of Islamic astronomy, and is still circulating in northern Nigeria (Kani 1992). The Hausa took up astrology with enthusiasm, astrological verse becoming a prominent genre of vernacular literature. A Hausa poem attributed to Abdullah ibn Muḥammad describes the 28 *anwā'*, 12 signs of the Zodiac, and planetary rulership of parts of the sky, according to the foreign practice. Ibn Muḥammad apparently learned his astrological theory from the writings of Moroccan practitioners such as ʻAbd al-Hāqq, whose *Kitāb al-falak* (Book of the Planets), was widely read in Northern Nigeria. While the Ibn Muḥammad text largely retains Arabic terminology, other Hausa works apply indigenous epithets for the stars which were not derivations from the Arabic but reflect local tradition (Hiskett 1967, 1975).

Astronomy in Sub-Saharan Africa. Fig. 1 A page from *Kashf al-Ghummah fi Nafa al-Ummah* (The Important Stars Among the Multitude of the Heavens). Mamma Haidara Commemorative Library, Timbuktu, Mali (Library of Congress 2003).

As for the built environment in West Africa, studies by Drucker-Brown (1984) and Blier (1987) have shown that certain vernacular architectures perform a symbolic as well as a functional purpose; home design not only manages light and heat resources but incorporates visual metaphors of directional affiliation and spatial organization alluding to the sun's diurnal and annual motion. Among the Mamprusi of northern Ghana the *zonga* or entranceway of one's home faces west so that the rays of the setting sun are directed into an area where family elders sit. It is here where in the late afternoon the position of light falling onto a wall is judged as an indication of the agricultural seasons. Elaborating on this theme, the Batammaliba people of Togo and Benin believe that the home should be representative of the solar deity, Kuiye. When a house is constructed, the builders perform a ritual in hour of Kuiye. It occurs at local noon when the sun is on the meridian, the "center" of the sky, and involves the placement of cooked cereal on the *tabote* stone in the center of the homestead. The home itself is aligned on an east–west axis, with its portal and family shrines facing west. This allows the rays of the setting sun to strike the shrines of the family's deceased elders; it is believed that when such shrines are illuminated, Kuiye communicates with the ancestors about the affairs of living family members. Batammaliba granaries are also identified with Kuiye's domain, being divided into three sections, each associated with a different crop harvested in accordance with the three seasons delimited by tradition (Fig. 2).

Unfortunately, while West African astronomical traditions have not as a whole attracted much attention, an inordinate amount of publicity has surrounded exaggerated claims for an advanced state of knowledge on the part of the Dogon people of Mali. Based on their fieldwork conducted in the 1930s, Griaule and Dieterlen (1950, 1965) reported that the Dogon were aware of Sirius B, a small star invisible to the unaided eye. Such was the fuel for Temple (1975), among others, who claimed for the Dogon a heliocentric model of the solar system and independent knowledge of the satellites of Jupiter and the rings of Saturn. Thanks to television series such as "In Search of…" (1979) the Dogon have entered the popular imagination. Penetrating criticism by respected scientists and a field evaluation of Griaule's reportage, determining many elements, including the astronomical portions, to be either misconstrued or altogether unsupported by ethnographic evidence, have done little to stay the proliferation of misinformation on Dogon cosmology (Van Beek 1991).



Astronomy in Sub-Saharan Africa. Fig. 2 The sun's path and corresponding parts of a Batammaliba homestead (Blier 1987).

East Africa and Madagascar

By the shores of Lake Turkana a megalithic site designated Namoratunga II, comprising 19 basalt pillars and at least one grave marked by upright slabs, has been surveyed for possible astronomical alignments (Lynch and Robbins 1978). Although there is no proof positive that the Namoratunga stones were erected with an observational purpose in mind, they appear to be nonrandomly aligned in directions corresponding with the rising positions of seven conspicuous stars and asterisms – Bellatrix, Orion's Belt (δ, ε, ζ Orionis), Saiph, Sirius, the Pleiades, Aldebaran, and Triangulum – on the local horizon ca. 300 BCE. These stars may have served as calendrical markers for the ancient Cushitic people who erected Namoratunga. However, efforts to elucidate a cultural linkage between the purported Namoratunga tradition and calendrical practices of the Borana people in the historical period have met with doubtful results (Soper 1982; Doyle and Wilcox 1986). Most scholars have identified the Borana asterism *Lami* as the constellation Triangulum, but when Tablino (1994) asked Borana time-reckoning experts to identify *Lami* they invariably pointed out α and β Arietis. The Triangulum alignment at Namoratunga, at least, looks to be questionable.

Christian Ethiopia has a tradition of skywatching documented in manuscripts dated back to the Middle Ages. Neugebauer (1979, 1981) found that Ethiopian astronomical knowledge applied almost exclusively in religious contexts. The astronomical chapters of the Ethiopic *Book of Enoch* contain simple arithmetical schemes for the motion of the sun and moon. The origins of this treatment are obscure, but they are more likely to derive from the rudimentary astronomical traditions of Egyptian Judeo-Christian communities than from early Babylonian schemes. Other texts and Easter tables of the Ethiopian Church reflect the computus of Alexandrian Christianity. A thirteenth-century computus of Abu Shaker of Alexandria, for reckoning Easter and other movable feasts, is extant in a number of Ethiopic manuscripts dating from the sixteenth century. Ethiopian chronicles record comets, eclipses, and other astronomical events from the fifteenth century onward.

The folk astronomy of Islamic Somalia appears to be directly influenced by the practices of south Arabia. Nomadic Somali herders know Polaris as *Hhiddigo*, the Prayer Star; by noting its direction after establishing an evening camp, they can orient themselves toward Mecca for their five daily prayers. Somalis have also adopted the 7 day week, and the folk practice of *taawil*, or assigning a good or evil value to each day. The most telling indicator of Arabic influence, however, is the recognition of lunar stations (Arabic: *anwā'*), 28 stars or asterisms, noted for their risings and settings over the year. Although the camel and sheep herding peoples of Somali used the *anwā'* (called *god* in Somali dialects) as a framework for a seasonal calendar, they viewed lunar stations primarily as divinatory signifiers. It is still held by many Somalis that the Moon's passage through the stations releases favorable or unfavorable celestial influence. *Dirir* (Spica) which means "good omen" is the most important station, as it is believed to govern the summer rains. Traditional Somali weather experts judge the quantity of future rain when *Dirir* is in conjunction with the Moon; a majority consider the Moon and *Dirir* rising in conjunction to be an auspicious sign. However, if the Moon passes north of *Dirir* a drought is expected. A child born on the night of a conjunction is thought to possess *buruud*, the ability to inspire respect among the people. A *Dirir* child will also have good fortune in owning camels and horses. At all events, a considerable body of Somali proverbs, songs and folktales has grown around the import of lunar stations (Galaal 1992).

Peoples of the East African coast have for centuries engaged in long distance trade with the Middle East and South Asia. The fifteenth-century master seafarer Aḥmad ibn Mājid left behind an Arabic memoir on Indian Ocean navigation techniques which relied heavily on stellar observation. He noted that navigators of Mombasa, Sofala, and Madagascar sailed by the stars of Ursa Major, which they called *al-Hīrāb* (Tibbetts 1981). Swahili manuscripts at the University of Dar es Salaam also attest to celestial navigation on the part of East Africans. The Arabic element was considerable nonetheless: a majority of the 105 Swahili star names collected by Knappert (1993) are derived from Arabic, and Kiswahili lunar station vocabulary preserves the Arabic terminology essentially unaltered. Moreover, the adoption of Islam by Swahili-speaking peoples brought with it the Islamic lunar calendar and the practice of orienting mosques in the direction of Mecca. Nonetheless, the Swahili lived in an environment of parallel time-reckoning systems. The indigenous Bantu tradition of the Pleiades or *Kilimia* remained distinct from the *anwā'* system and continued to be used for the regulation of agricultural work. In Swahili the Pleiades are *Kilimia*, the Ploughing Stars. Referring to the *vuli* and *masika* monsoon periods, and their respective planting seasons, a proverb runs: "If the Ploughing Stars set in sunny weather they rise in rain, if they set in rain they rise in sunny weather." As viewed in the evenings from equatorial Africa the Pleiades disappear in the Sun's glare, they "set" about early May, reemerging in the morning sky just as June's *vuli* rains begin. Observed in the predawn sky *Kilimia* are seen to set at the end of the *masika* rains in November; when they are glimpsed rising in the evening twilight they herald a dry or "sunny" period. Alongside the Islamic lunar calendar Swahili-speaking peoples kept a 365-day year subdivided into 36 and a half "decades" of 10 days each. This solar year, which begins with the *Nairuzi* festival, appears to be of Persian origin (Gray 1955).

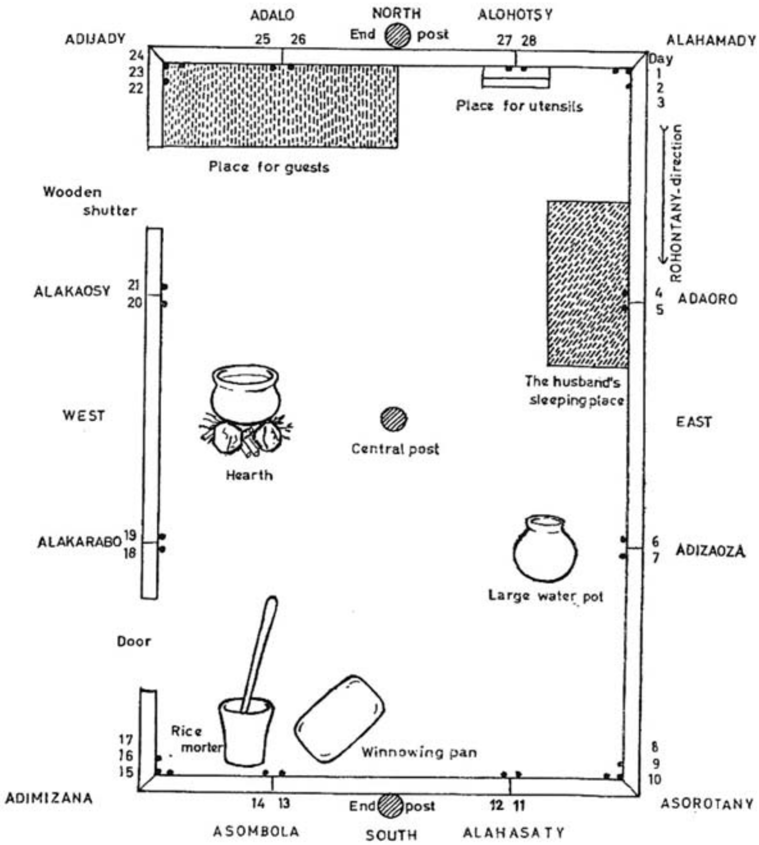
On the island of Madagascar the highly syncretic *Mpandandro* astrological system appears to integrate Arabic and South Asian practices with indigenous culture. Writing in a modified Arabic script, scholars among Antaimoro and Antambahaoka peoples of southeastern Madagascar compile *Sorabe*, or "great books" containing history, medicine, geomancy and astrology. Malagasy astrologers utilize lunar stations and assign favorable/unfavorable values to days within a 7-day week. The temporal scheme is represented spatially in the orientation and lay out of the traditional rectangular house (Verin and Rajaonarimanana 1991) (Fig. 3).

Central and Southern Africa

The African states centered on Great Zimbabwe and Mapungubwe between the twelfth and fifteenth centuries presumably developed temporal and spatial ideologies involving the sky. Even so, there is no conclusive evidence for intentional astronomical alignments at Great Zimbabwe, despite the recent conjectures of independent archaeologist Richard Wade (Campbell 2002). Other southern African sites have not been surveyed specifically for their archaeoastronomical potential, but the features of an Iron Age village called Ntsuanatsatsi are very suggestive. Situated a kilometer west of a prominent hill in the grassy highveld of the Orange Free State, South Africa, the stone-walled ruins face eastward. The place name, Ntsuatsatsatsi, attested to as early as the 1830s, means "sunrise" in the Sesotho language. For local Sotho clans the hill is reputed to have been where the first ancestors rose from the earth. In former times, Bafokeng chiefs held their councils on top of the ridge across from the hill. Their ability to gauge the annual motion of the sun by the sunrise locations on Ntsuanatsatsi hill may have contributed to the prominence of these early Sotho leaders (Maggs 1976).

The ritual initiation of adolescents into full membership of the community is an important aspect of African society. A "morning star," usually identified in the literature as the planet Venus, traditionally had strong associations with male rites of passage in Central and Southern Africa. The Mbunda people looked for an object they called *gongonosi*; the Tsonga of Mozambique used the cognate term *ngongomela* "towering in strength." Victor Turner noted the visibility of such a morning star on the last morning of the Ndembu ceremonies he witnessed; he further recorded that the initiation title of the third boy to be circumcised was *kaselantanda*, "he of the morning star" (Turner 1967). According to Junod (1927), Tsonga initiation schools were synchronized with the appearance of Venus in the morning sky during a winter month (June–September in the southern hemisphere). One of Junod's informants, the Tsonga elder Shinangana, chronicled a few of the schools in the last half of the nineteenth century: they occurred in 1862, 1873, 1881, 1887, and 1893. Venus was indeed a morning star in the first three years, but not in 1887 or 1893, although in the later year Jupiter was located in the morning sky and could have served as *ngongomela*. Hence, it would be rash to assert any correlation between periods of the morning visibility of Venus and the age-sets of Tsonga initiates. In a praise poem which inspired the young Nelson Mandela, Krune Mqayi sang of counting the years of manhood by the rising "Morning Star." For the Xhosa of South Africa this object was unquestionably the Pleiades, the dawn rising of which occurs late in June. It is said that the month of the Pleiades, *Eyesilimela*, symbolized new life; the coming-out ceremony of the *abakwtha* circumcision school was synchronized with the appearance of the star cluster (Snedegar 1997). The morning star, however imprecise its own identity, was recognized across central and southern Africa as a key identifier of the male child's passage into the daylight of adulthood.

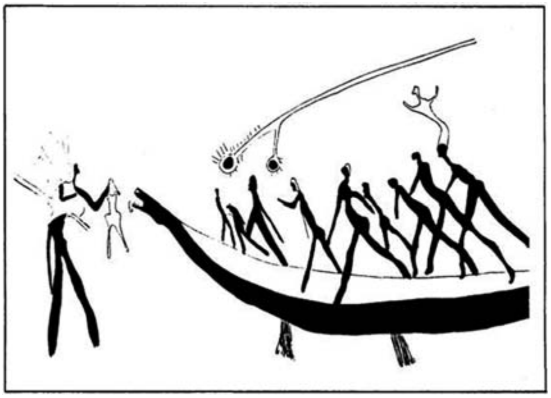
The night figures prominently in the cognitive universe of the Khoisan peoples, who articulate their knowledge in oral traditions which have been transmitted across generations. The evening campfire traditionally served as the venue for sky stories. Appropriately, many San groups recognize a "Fire Finisher" star whose



Astronomy in Sub-Saharan Africa. Fig. 3 Plan of a Malagasy house indicating directional associations with 12 months and 28 lunar stations (Ruud 1960).

position above the horizon indicates the time on cold winter nights. Fire Finisher is said to rise in the evening and set before dawn, about the time the night's fire has burned to embers. By all accounts, Fire Finisher is a brilliant star which seems to be alone in the sky. Three stars fit the profile and are in fact identified as Fire Finisher by different San groups: Antares (by the Nharo), Arcturus (!Xo), and Regulus (G/wi). Like Fire Finisher, all stars are associated with fire. In the Ju/'huoan dialect the act of stoking a fire, causing sparks to fly into the air, is described with the same words as a shooting star. One of the most famous myths concerns a girl of the "early race" who created the Milky Way by throwing ashes from her campfire into the sky. For many San, however, the Milky Way is the Backbone of the Night. There may be a connection with the moon. A nineteenth-century explanation of the Moon's waning phases claims that the Sun chases the Moon; as it catches up, the Sun slices away pieces of the Moon until nothing remains. But before the Moon is altogether devoured, it says, "Oh Sun! Leave for the children the backbone!" (Bleek and Lloyd 1911). Sirius is often identified as the Hip Star or Thigh Star. In her fieldwork, Marshall (1986) discovered that the !Kung San see Canopus and Capella as "horns of *tshxum*," an identity, perhaps a magical rain bull, centered on the Pleiades. Predawn observation of *tshxum* and its horns indicated the coming of spring rains.

In Khoisan mythology human ancestor spirits inhabit the night. They are accompanied by spirits of terrestrial animals including lions, elands, gemboks, hartebeests, steenboks, porcupines, hedgehogs, and giraffes. The starry sky becomes a great canvas for hunting stories, of which ≠Gao N!a, or G≠kao N!a'an, is often the leading man. According to a story collected by Marshall (1986), ≠Gao stood on the Large Magellanic Cloud one evening looking for game to hunt. He spotted three zebras, the three stars in Orion's Belt, and shot an arrow at the middle one. The arrow fell short; it is represented by the stars just south of the zebras. After his unsuccessful shot, ≠Gao decided to send the zebras down to earth for the San to hunt. Nineteenth-century Khoikhoi told a similar tale. Their rendition identified the hunter with the star Aldebaran, spurred on by his wives, the Pleiades. Having failed in his hunt, Aldebaran cannot return to his family, and is fixed in his place in the sky. Another story independently documented by Marshall and Biesele (1996), involves the sons of ≠Gao, !Xuma and Kha//'an,



Astronomy in Sub-Saharan Africa. Fig. 4 San rock painting of bolide-like object near Bethlehem, South Africa (Thackeray 1988).

identified with α and γ Crucis, who went out hunting an eland but themselves were pursued and killed by two lions "the keepers of the west," α and β Centauri. ≠Gao suspected the lions. He hid a pair of magic horns in a tree, and invited the lions to dance under its branches. The horns fell onto the celebrating lions, killing them. ≠Gao then resurrected his sons. Celestial players reenact the story on October evenings when the stars of Crux, representing the two boys, set or "die" on the southwestern horizon; they are followed by α and β Centauri, the lions tricked into death. As viewed from San locations in the Kalahari Desert, where Crux is not quite circumpolar, α and γ Crucis rise again later in the night; the boys are visually resurrected.

Meteors have an important place in Khoisan folklore. These "shooting stars" are interpreted in various ways, but they are generally considered to signify creatures having supernatural powers. Some say meteors are antlions falling to earth in search of food; for others they are porcupines or hedgehogs. Hence a porcupine-skin bag is called a star skin, and hedgehog fat is a chief ingredient for amulets worn in curing dances (Traill 1994). Through dance a shaman enters a trance state in which, it is believed, he is able to traverse the sky as a meteor, obtaining supernatural potency from the ancestors. Such potency is supposed to give him the mastery over disease as well as control of game animals and the spring rains. The meteoric trance experience is very probably illustrated in rock art. Although only a few rock art images suggestive of meteoric trance have been recorded, the territory in which these images have been found stretches from Zambia to Lesotho (Thackeray 1988). One extraordinary rock painting in South Africa portrays a shamanistic dance; a bolide-like object appears to zoom over the dancers' heads and burst into two fragments (Fig. 4).

Astronomy in Tibet

YUKIO ŌHASHI

Tibetan astronomy is a living form of traditional astronomy, and is the basis of the Tibetan calendar which is used in Tibet and in Tibetan communities in India, and other places in the world.

There are four branches of Tibetan astronomical science (*rtsis*). The most important branch is *skar-rtsis* (star calculation) which is based on the *Kālacakra* astronomy of India. Another branch is *dbyaṅs-'char* which is based on Indian divination, *svarodaya.* Another is *nag-rtsis* (black calculation), based on Chinese astrology and natural philosophy, and the last branch is *rgya-rtsis* (Chinese calculation), based on the Shixian calendar of China.

Indo–Tibetan Astronomy

The Tibetan *Tripitaka* is a collection of Tibetan translations of Buddhist works, some of which include astronomical information. There is a Tibetan translation of the *Śārdūlakarṇa-avadāna*, which is a Buddhist work in which early Indian astronomy and astrology of the Vedāṅga period, the post-Vedic period before Greek influence, are mentioned. There is also a Tibetan translation of an early Indian astrological text ascribed to Sage Garga. Astronomical knowledge in these texts is from an early period, and not of *skar-rtsis.* The most important texts from an astronomical point of view are the Tibetan translation of the *Kālacakra-tantra* and its commentary, *Vimalaprabhā.*

Kālacakra-yāna Buddhism is the last stage of Esoteric Buddhism in India. Its most fundamental text is the *Kālacakra-tantra.* It is not known when and where it was composed. Some people say it was introduced into Tibet in AD 1027, and was introduced into India from Central Asia 60 years before. I believe that it was composed in the eleventh century, because the year 1027 is used as the beginning of the 60-year cycle (*bṛhaspaticakra*) in the text itself. I also believe that it was composed in India, because it adopts the Hindu system of astronomy without any apparent influence of Chinese or other astronomy.

According to the commentary *Vimalaprabhā*, there was the original text or *Mūla-tantra*, where the *Siddhānta* system of astronomy was explained, and the text on which it comments is the abridged text or *Laghu-tantra*, where the *Karaṇa* system of astronomy is explained. The *Mūla-tantra* is not extant, and it is difficult to say whether it actually existed as a whole or not, but some fragments are quoted in the *Vimalaprabhā.* The *Siddhānta* system of astronomy is called *grub-rtsis* in Tibetan, and the *Karaṇa* system is called *byed-rtsis.* In Tibetan astronomy, these two systems are basically the same, and only the length of a year and a month are different. In the *Siddhānta* system, one sidereal year = 365.270645 days and one synodic month = 29.530587 days. In the *Karaṇa* system, a sidereal year = 365.258675 days, while a synodic month = 29.530556 days.

In the Tibetan calendar, there are two intercalary months for 65 ordinary months. This is harmonious with the *Siddhānta* system, but not with the *Karaṇa* system. The *grub-rtsis* is usually followed now.

Since about the twelfth century, the *Kālacakra* calendar has been followed in Tibet. In the fourteenth century, a comprehensive treatise of *Kālacakra* astronomy entitled *mKhas-pa-dga'-byed* (AD 1326) was composed by an encyclopaedic scholar Bu-ston Rin-chen-grub (1290–1364). After Bu-ston, lHun-grub-rgya-mtsho wrote the *Pad-dkar-źal-luṅ* (AD 1447), and his system was developed as the Phug school. The most famous work of this school is the *Vaiḍūrya dkar-po* (AD 1683) written by Saṅs-rgyas-rgya-mtsho, who was the regent of the fifth Dalai Lama. Another famous work is the *Ñin-byed-snaṅ-ba* (AD 1714) of Dharmaśrī.

There is another school, mTshur-phu, whose fundamental text is the *Ñer-mkho-bum-bzan* (AD 1732) written by Karma Ṅes-legs-bstan-'dzin.

Let us use astronomical calculation in the *mKhas-pa-dga'-byed* as a case study. It is one of the earliest treatises of the *skar-rtsis* branch of Tibetan astronomy and will give a general idea of *skar-rtsis.* As *skar-rtsis* is based on *Kālacakra* astronomy, it is similar to Hindu astronomy. First, mean motions of the planets are calculated, and then the equation of the center and the epicyclic correction are applied. The operation of the equation of the center (Sanskrit: *manda-karman*) is called *dal-ba'i-las* in Tibetan, and the operation of the epicyclic correction (Sanskrit: *śīghra-karman*) is called *myur-ba'i-las.*

Three kinds of days are used. They are *ñin-źag* (Sanskrit: *sāvana-dina*), *tshes-źag* (Sanskrit: *tithi*), and *khyim-źag* (Sanskrit: *saura-dina*). A *ñin-źag* is a civil day measured from sunrise to sunrise. A mean *tshes-źag* is a 13th part of a synodic month. The equation of the center of the sun and moon are applied so as to make a *tshes-źag* correspond to the change of 12° of the longitudinal difference between the sun and moon. A mean *khyim-źag* is a 360th part of 1 year.

The ecliptic is divided into 12 *khyim* (Sanskrit: *rāśi*) or zodiacal signs, and also into 27 *rgyu-skar* (Sanskrit: *nakṣatra*) or lunar mansions. Each day as well as *rgyu-skar* is divided into 60 *chu-tshod* (Sanskrit: *nāḍī*). One *chu-tshod* is further divided into 60 *chu-sraṅ* (Sanskrit: *vināḍī*). One *chu-sraṅ* is divided into six *dbugs* (Sanskrit: *prāṇa*).

The mean motion of the sun and moon is calculated from the following simple formulae, which correspond to the *grub-rtsis* system:

Length of a *khyim-źag* = length of a *tshes-źag* × $\left(1+\frac{2}{65}\right)$

Length of a *tshes-źag* = length of a *ñin-źag* × $\left(1-\frac{1+\frac{1}{707}}{64}\right)$

The equation of the center of the sun is given for each zodiacal sign. Twelve zodiacal signs are divided into four quadrants. Then 6/135, 4/135, and 1/135 of the mean daily motion of the sun are subtracted from or added to the mean daily motion of the sun in each sign. The variables 6, 4, and 1 are called *dal-rkaṅ* (slow step). The ecliptic is divided into the first half (*rim-pa*) and the second half (*rim-min*). The first as well as the second half is further divided into the first part (*sṅa-rkaṅ*) and the second part (*phyi-rkaṅ*). So, one part consists of three signs. The first point of the first half is the apogee.

This *dal-rkaṅ* is, in fact, the difference between the mean motion and the true motion of the sun during one zodiacal sign's movement of the mean sun in terms of *chu-tshod.* Hence, the maximum equation is the total of the variables, that is 11 *chu-tshod* or 2°26′40″. The solar apogee is located at the first point of Cancer in this system.

One anomalistic month is roughly considered as 28 *tshes-źag*, and a correction is applied to the length of each *tshes-źag.* This correction is called *zla-ba'i-myur-rkaṅ* (fast step of the moon). The word *myur* (fast) shows that it was considered to be the epicyclic correction rather than the equation of center. Since the period of 28 *tshes-źag* is a little longer than the actual anomalistic month, a special correction is also applied so as to diminish the period of 28 *tshes-źag* at the rate of one *tshes-źag* per 3,780 *tshes-zag.* So, one anomalistic month becomes about 27.55459 civil days.

One anomalistic month is divided into four quadrants, each of which consists of seven *tshes-źag.* Then 5, 5, 5, 4, 3, 2, and 1 *chu-tshod* are added to or subtracted from the length of each *tshes-źag*. These values were probably originally meant to be the difference between the mean motion and the true motion of the moon during one *tshes-źag* in terms of *chu-tshod*. Since the time interval during which the moon moves the arc of one *chu-tshod* is about 1.01 *chu-tshod*, this was considered to be one *chu-tshod*, and the same value was used for the correction of the length of a *tshes-źag*. The maximum equation is the total of the variables, that is 25 *chu-tshod* or 5°23′20″.

Five planets are divided into *źi-ba'i-gza'* which corresponds to inner planets, and *drag-gza'* which corresponds to outer planets. The sidereal period (*dkyil-'khor*) of each planet is given as follows:

Mercury (*lhag-pa*): 87 days 58 *chu-tshod* 12 *chu-sraṅ*

Venus (*pa-saṅs*): 224 days 42 *chu-tshod*

Mars (*mig-dmar*): 687 days

Jupiter (*phur-bu*): 4332 days

Saturn (*spen-pa*): 10766 days

Just as in the case of the sun, *dal-rkaṅ* (slow step) for each zodiacal sign is given for each planet. The mean daily motion of each planet in the case of outer planets, or of the sun in the case of inner planets, is corrected as follows.

Corrected daily motion = $A \mp A(d/135)$, where A is the mean daily motion, and d is *dal-rkaṅ*. The value of *dal-rkaṅ* for each planet is:

Mars: 25, 18, and 7

Mercury: 10, 7, and 3

Jupiter: 11, 9, and 3

Venus: 5, 4, and 1

Saturn: 22, 15, and 6

The total of the value of *dal-rkaṅ* is the maximum equation in terms of *chu-tshod*. The maximum equation of each planet is:

Mars: 50 *chu-tshod* or 11°6′40″

Mercury: 20 *chu-tshod* or 4°26′40″

Jupiter: 23 *chu-tshod* or 5°6′40″

Venus: 10 *chu-tshod* or 2°13′20″

Saturn: 43 *chu-tshod* or 9°33′20″

The longitude of the apogee of each planet in this system is Mars: 126°40′, Mercury: 220°, Jupiter: 160°, Venus: 80°, and Saturn: 240°.

The "parameter of step" (*rkaṅ-'dzin*) is used to count steps of epicyclic correction. The period of 60 *chu-tshod*'s change of the "parameter of step" is considered one step. Sixty *chu-tshod* correspond to one lunar mansion, and there are 27 lunar mansions, so one cycle consists of 1,620 *chu-tshod*. One cycle is divided into two halves, and each consists of 14 steps. The 14 step of the first half and the first step of the second half consist of 30 *chu-tshod* only.

In the case of the outer planets, daily motion of the "parameter of step" is the mean daily motion of the sun minus the daily motion of the planet which has been corrected by its equation of center. In the case of the inner planets, the daily motion of the "parameter of step" is the daily motion of "parameter of fast step" (*myur-rkaṅ-'dzin*) minus the true daily motion of the sun. The "parameter of fast step" is, in fact, the daily motion of the planet's revolution, because it is defined as the quotient of 1,620 *chu-tshod* divided by the planet's sidereal period. The variable of the epicycle correction is given as *myur-rkaṅ* (fast step) for each step.

The method of the correction is as follows: let M be the true daily motion of the planet, D the daily motion of the planet in the case of an outer planet and the daily motion of the sun in the case of an inner planet, both of which have been corrected by the equation of center of the planet itself, K the daily motion of the "parameter of step," and m the *myur-rkaṅ*. Then, for the steps from the first step to the 13 step of the first half and from the second step to the 14 step of the second half, the following equation gives the true daily motion of the planet

$$M = D \pm K\frac{m}{60}.$$

For the 14 step of the first half and the first step of the second half, the following equation is used

$$M = D \pm K\frac{m}{30}.$$

The first half (*rim-pa*) as well as the second half (*rim-min*) are further divided into the first part (*sṅa-rkaṅ*) and the second part (*phyi-rkaṅ*). The correction is plus in the first part of the first half and the second part of the second half, and minus in the second part of the first half and the first part of the second half.

The values of *myur-rkaṅ* for each planet are shown in Table 1. The values are arranged for the first half. In the second half, the same value is used in reverse order.

Astronomy in Tibet. Table 1 The values of *myur-rkaṅ* for each planet

Planet	First part	Second part
Mars	24, 23, 23, 23, 21, 21, 18, 15, 11, and 3	11, 38, 80, and 53
Mercury	16, 16, 15, 14, 13, 11, 7, 5, and 0	4, 11, 20, 28, and 34
Jupiter	10, 10, 9, 8, 6, 6, 2, and 1	3, 6, 9, 11, 16, and 7
Venus	25, 25, 25, 24, 24, 22, 22, 18, 15, and 8	6, 30, 99, and 73
Saturn	6, 5, 5, 4, 4, 2, 2, and 0	2, 4, 5, 6, 8, and 3

The total of the value of *myur-rkaṅ* in one part is the maximum epicyclic correction in terms of *chu-tshod.* The maximum correction of each planet is:

Mars: 182 *chu-tshod* or 40°26′40″
Mercury: 97 *chu-tshod* or 21°33′20″
Jupiter: 52 *chu-tshod* or 11°33′20″
Venus: 208 *chu-tshod* or 46°13′20″
Saturn: 28 *chu-tshod* or 6°13′20″

In a paper written in 1986, I compared the astronomical constants used by Bu-ston with those of some schools of Hindu astronomy, and pointed out that they are close to those of the Ārdharātrika school of Hindu astronomy.

Sino–Tibetan Astronomical Science

The *nag-rtsis* is said to have been introduced into Tibet from China in the seventh century. It is based on Chinese astrology and natural philosophy. According to the *Zla-ba'i-'od-zer* (AD 1684) of Dharmaśrī, a popular work of *nag-rtsis*, the most fundamental elements of the *nag-rtsis* are as follows.

1. *Khams* (also called*'byuṅ-ba*), which are the five elements of Chinese natural philosophy: wood, fire, earth, metal, and water.
2. *Lo-'gros*, which are 12 animals used to name each year of a 12-year cycle: rat, ox, tiger, rabbit, dragon, snake, horse, sheep, monkey, bird, dog, and boar. This 12-year system is the Chinese system, which is widely used in East Asia. The combination of the *khams* and *lo-'gros* is used to name each year of a 60-year cycle. This is also the Chinese system.
3. *Sme-ba*, which is the Chinese "nine stars" used for astrological purposes.
4. *sPar-kha*, which is eight symbols of Chinese natural philosophy, of which the most fundamental text is the famous *Yijing* (I Ching, Book of Changes).
5. *Zla-ba*, which is 12 months for each of which 12 animals are attributed. The first month of spring is a tiger, and so on.
6. *Tshes*, which is the date of the month.
7. *Dus-tshod*, which is a 12th part of a day, for each of which 12 animals are attributed. The midnight is rat, and so on.
8. *gZa'*, which is eight planets: the sun, moon, five planets, and *rāhu*. The *rāhu* (dragon's head, or the ascending node of the lunar orbit) is not Chinese, but of Indian origin.
9. *sKar-ma*, which is the Chinese 28 lunar mansions or lodges.

The *rgya-rtsis* is based on the Tibetan version (AD 1725) of the Mongolian translation (AD 1711) of the Chinese astronomical work *Xiyang xinfa suanshu* (AD 1669) compiled in the Qing dynasty, which is the theoretical text on the Shixian calendar. The Shixian calendar is the last luni-solar calendar in China.

The traditional Tibetan calendar, which is based on the Phug school of *skar-rtsis*, is still used by Tibetan people. Also, several Tibetan astronomical texts are extant, and the process of astronomical calculation is explained in detail in these texts. More extensive study of Tibetan astronomy by historians of astronomy will be fruitful. In 1987, Chinese scholars Huang Mingxin and Chen Jiujin published a *skar-rtsis* text of epoch AD 1827, the *Rigs-ldan-sñiṅ-thig* of Phyag-mdzod gsuṅ-rab, with Chinese translation and astronomical commentary. This is a good introduction to Tibetan astronomy.

Atomism in Islamic Thought

Alnoor Dhanani

Atomism, the view that there are discrete irreducible elements of finite spatial or temporal space, played a significant role in Islamic intellectual history. It was upheld by most practitioners of the uniquely Islamic discipline of *kalām*. However, some practitioners of *kalām* (i.e., *mutakallimūn*) as well as all but one of the practitioners of *falsafa* (i.e., *falāsifa* – those engaged in the Neoplatonized Peripatetic philosophy of medieval Islam) were antiatomists. There was thus a lively debate between atomists and antiatomists, regarding not only matter theory, but also other areas of natural philosophy and cosmology, particularly theories of space, time, void, motion, and causality.

Kalām has no counterpart in the Western tradition. Even though primarily theological in orientation, it is not equivalent to theology. The subject matter of *kalām* includes not only theological topics, e.g., the nature and attributes of God, prophecy, and revelation, but also philosophical problems of cosmology, logic, anthropology, psychology, etc. The origins of *kalām* are obscure and a subject of debate. Suffice it to say that *kalām* arose in the mid-eighth century, and that during the later half of that century, questions about the nature and attributes of objects were being discussed. In their discussion of such questions among themselves and with others from the various religious and intellectual traditions of the Hellenized Near East, the *mutakallimūn* had access to views and theories propounded by the intellectual, doctrinal, and sectarian movements of Late Antiquity: Neoplatonism, Stoicism, Manicheanism, Dualism, Bārdaiṣānism, etc. Little is known about the *mutakallimūn*'s manner of access to these views. It was probably oral and through personal contact. Such a transmission is in sharp contrast with the large-scale translation of Greek philosophical and scientific texts during the late eighth and ninth centuries which gave rise to *falsafa*.

The *mutakallimūn* of the late eighth century held three theories of matter and its attributes. In the first, bodies are the only constituents of the world. All secondary qualities like sound, taste, color, etc. are thus corporeal. It follows that perceptible objects consist of several interpenetrating bodies. This view, whose origins are Stoic, was held by some Dualists. Its early *kalām* subscribers were Ḥishām ibn al-Ḥakam (d. ca. 795), and al-Aṣamm (d. 815). Later, the antiatomist Ibrāhīm ibn Sayyār al-Naẓẓām (d. 835–845) advocated it, albeit holding that motion was the sole accident.

In the second theory, unextended accidents are the only constituents of the world. Extended bodies result from a combination of accidents, namely, color, taste, hot/cold, rough/smooth. The origins of this view lie in Neoplatonism and Christian theology. Its *kalām* subscribers were Ḍirār ibn ʿAmr (d. 815), Ḥafṣ al-Fard (fl. 810), and Ḥusayn al-Najjār (d. ca. 835–845).

The third theory holds that accidents and bodies constitute the world, and that bodies are constituted from atoms. This view had its partisans among the Dualists and the Bārdaiṣānites. It was appropriated into *kalām* by Abū al-Hudhayl al-ʿAllāf (d. 841) of the Basrian Muʿtazilī school of *kalām*; the Baghdadī Muʿtazilī Bishr ibn al-Muʿtamir (d. 825–840); and Muʿammar ibn ʿAbbād al-Sulamī (d. 830). Towards the mid-ninth century, the atomic theory displaced its rivals to become the dominant physical theory of *kalām*. Atomism was upheld by the Ashʿarī *kalām* school formed in the tenth century in opposition to Muʿtazilīs, particularly regarding questions of man's free will and God's absolute power. However, atomism was attacked by the *falāsifa* who upheld Aristotelian arguments. In the eleventh century, the Basrian Muʿtazilī Abū al-Ḥusayn al-Baṣrī (d. 1044) embraced *falsafa* physical theory and abandoned atomism. Atomism declined further in the twelfth and later centuries with the growing influence of Ibn Sīnā's (d. 1037) philosophy. Even though atomism was never actually abandoned, it was no longer central to post-twelfth century *kalām*.

As none of the writings on physical theory of the eighth and ninth century *mutakallimūn* has survived, their theories must be reconstructed from extant fragments. The principal source has been the doxography, *Maqālāt al-islāmīyīn* (The Doctrines of Muslims) by the former Muʿtazilī and founder of Ashʿarī *kalām*, Abū al-Ḥasan al-Ashʿarī (d. 935). The following account of early atomism may be drawn: early *kalām* atomists distinguished between the atom (denoted by *jawhar* (atom), *juz'* (part), *al-juzʾalladhī lā yatajazzaʾ* (the indivisible part)) and the body. The body has length, breadth, and depth, while the atom lacks these dimensions (however al-Ṣāliḥī [fl. end of ninth/early tenth century] held that the atom was a body). Rather, they believed that dimensions are produced by combinations of atoms. Hence, a minimal length arises when two atoms combine (or, in the formulation of the *mutakallimūn*, a line is formed by the combination of two atoms). There were different views on the minimal number of atoms which constitute a body having length, breadth, and depth: Abū al-Hudhayl held that it was six; Muʿammar held that eight were required; and Abū al-Qāsim al-Balkhī (d. 931) held that four sufficed.

There are obvious parallels between *kalām* and Greek atomism regarding proofs for the existence of atoms, as well as terms which denote the atom. Yet the concept of dimensionless atoms combining to form bodies with dimension is unique to *kalām*. New light has been shed on this puzzling view, and on *kalām* physical theory in general, by the rediscovery of eleventh century sources. Of particular importance are the Basrian Muʿtazilī texts of Ibn Mattawayh and Abū Rashīd al-Nīsābūrī (both fl. first half of eleventh century), as well as Ashʿarī texts by Abū al-Maʿalī al-Juwaynī (d. 1085) and Ibn Fūrak (d. 1015). These sources reveal that, in his reformulation of *kalām*, the Basrian Muʿtazilī Abū Hāshim al-Jubbā'ī (d. 933) had redefined the atom as "that which occupies space (*mutaḥayyiz*)," a designation which was also applied to the body. From this designation, as well as arguments advanced in support of the theses that the atom has magnitude (*miṣāḥa*) and its shape resembles a cube, it is clear that the atom must somehow be extended (the Ashʿarī *mutakallim* Abū Bakr al-Fūrakī (d. 1085) states: the atom is the smallest of what is small with respect to volume). Paradoxically, these *mutakallimūn* insisted that despite its magnitude the atom lacked length, breadth, and depth. Like their earlier colleagues, they continued to hold that dimensions were produced by combinations of atoms. Moreover, they considered any difference between their view of the atom and the earlier view as marginal; it was partially conceptual but partially a result of the manner of expression.

These texts suggest the interpretation that a geometry of discrete space underlies *kalām* atomism (as in Epicurean atomism). In ancient and medieval thought, any distinction between geometrical and physical space was inconceivable. If physical space was continuous, then so was geometrical space. Likewise, discrete physical space meant discrete geometrical space. Hence, *kalām* formulations of "indivisible," "dimension," "magnitude," and "body" need to be analyzed within discrete geometry. Here, a point, which is defined as that which has no parts, is equivalent to the indivisible magnitude (i.e., atom). Next, a line, which is terminated by two end points, must consist of at least two indivisibles. It follows that two indivisibles constitute the least line and are the least to constitute the dimension of length. The *kalām* atom cannot, thus, have length, breadth, or depth, but it has magnitude for it is an indivisible of discrete (and not continuous) geometry. The combination of atoms to form linear dimensions is no longer problematical; unlike points of continuous geometry which lack both dimension and magnitude, atoms/indivisibles of discrete geometry have minimal magnitude yet lack dimension. Such atoms combine to form objects with larger magnitudes and dimension. In a discrete geometry whose indivisibles are square-shaped (as seen from a continuous geometry, for the *mutakallimūn* state that the atom *resembles* a square; having no dimensions it cannot be a square!), one may configure minimal bodies from four, six, or eight atoms.

In his critique of atomism, Aristotle argued that atomism entails indivisible parts of space, time, and motion. Accordingly, most eighth and ninth century atomist *mutakallimūn*, and many later *mutakallimūn* upheld the minimal parts of space, time, and motion. In the tenth century, Abū Hāshim al-Jubbā'ī abandoned the minimal parts of space (and consequently minimal parts of time and motion) in response to difficulties raised by antiatomists. His successors did not all adopt this view; some continued to say that space, time, motion, and matter were constituted out of indivisibles. We may also note that the atomist *mutakallimūn* upheld the existence of void spaces.

Atomism posed several conceptual and geometrical difficulties, some of which are traceable to Aristotelian arguments against atomism. It may be relevant to mention some Islamic contributions. One argument formulated by Abū al-Hudhayl, which is based on Zeno's dichotomy paradox, was the ant and sandal argument. Imagine an ant creeping over a sandal. In order to traverse the sandal, the ant must first traverse half the sandal; but to traverse half, the ant must first traverse half of this, and so on. Hence the traversal cannot commence unless the division terminates at an indivisible (i.e., atom). Abū al-Hudhayl's student, the antiatomist al-Naẓẓām, responded with his theory of leap (*ṭafra*), saying the ant does not traverse through all points on the path of traversal, but it traverses through some and leaps over others. Hence, al-Naẓẓām claimed, one may traverse from one location to another without traversing all intervening points. The theory of leaps played an important role in discussions of physical theory, if only to illustrate the absurdity of the actually infinite division of matter which was attributed to al-Naẓẓām. Al-Naẓẓām also formulated a clever argument against atomism. Imagine a rotating millstone. Since both an inner circle and the millstone's circumference must complete a rotation in equal time, when an inner circle is ten atoms in length, and the circumference is a hundred atoms, for each unit of space traversed by an atom on the inner circle, an atom on the circumference would have to traverse ten units. Explaining this, al-Naẓẓām resorted to his theory of leaps: when an atom on the inner circle moves one unit, an atom on the circumference moves one unit and leaps nine units. Abū al-Hudhayl, however, responded that the atom on the inner circle moves for one time unit and rests for nine units, while the atom on the circumference moves for all ten units. Al-Naẓẓām objected that this entails that particles of a solid body cannot adhere to each other but must be set loose to allow for such moments of motion and rest. Hence, a rotating solid body must disintegrate (*tafakkuk*) and its internal configuration of atoms be modified. The atomist *mutakallimūn*, unable to answer al-Naẓẓām's challenge, accepted the internal disintegration of a rotating body. However, they considered it to be analogous to a salt shaker where salt particles move freely within the confines of the shaker.

Why did the *mutakallimūn* embrace atomism? This question has puzzled researchers, particularly given the difficulties atomism raised. The thesis that atomism was theologically more acceptable than the continuously divisible matter theory of the *falāsifa* has been widely accepted. Continuous divisibility raises problems of infinity, and the *mutakallimūn* were mindful of the relationship between ending infinite regress in the argument for the temporal creation of the world and the argument for the divisibility of matter. Yet the question still remains as to why three theories of matter were considered theologically sound in early *kalām*, and why early atomists did not claim that their theory was, theologically, the most sound. The assertion that antiatomists were heretics is only found after the tenth century when atomism had triumphed. The question of the affinity of atomism to occasionalism has also been raised, but this needs to be reexamined in the light of new sources.

Atomism was also upheld by the famous physician and *faylasūf* Abū Bakr Muḥammad ibn Zakariyāʾ al-Rāzī (d. 925). However, surviving accounts are scanty. We only know that his atoms were extended (like Democritus' atoms). Atomism is part of al-Rāzī's cosmology of the five eternals: God, Soul, Space, Time, and Matter upheld by the Ṣābians of Ḥarrān. Some of al-Rāzī's views may derive from Irānshahrī (fl. late ninth century) about whom very little is known.

Ātreya

Guy Mazars

Ātreya or Punarvasu Ātreya was probably the physician of an ancient king of Gāndhāra. The name Ātreya implies that he was either a descendant or a disciple of Atri, a sage mentioned in the *Veda*. The date of Ātreya may be fixed before the grammarian Pāṇini (seventh century BCE) and after the *Atharvaveda* (1200 BCE), ca. 1000 BCE.

On the basis of his teachings, six of his disciples composed medical treatises. One of them, Agniveśa, wrote the *Agniveśatantra* or 'System of Agniveśa', which became known as the *Carakasaṃhitā* after its revision by Caraka. Another disciple, Bhela, wrote the *Bhelasaṃhitā*, which has fragmentarily been preserved in a single manuscript. Unfortunately, the text is mutilated and full of scribe's errors. Some scholars are of the opinion that the *Bhelasaṃhitā* may be older than the *Carakasaṃhitā*. The *Hārītasaṃhitā* is ascribed to a third disciple, also called *Ātreyasaṃhitā*. But the text that has come down to us is regarded as a relatively late work of an apocryphal nature, though parts of it might be old.

As to the treatises composed by the other three disciples of Ātreya, they have not been preserved. But quotations from their works occur in many commentaries. Two other Ātreya, Kṛṣṇātreya and Bhikṣu Ātreya, are mentioned in the *Carakasaṃhitā*. According to the *Mahābhārata*, the 'Great Epic of India', Kṛṣṇātreya was the founder of a medical school. There is mention of another Ātreya connected with the Buddhist University of Takṣaśilā. He was the teacher of a contemporary of Buddha (fifth century BCE), the famous surgeon Jīvaka to whom tradition attributes extraordinary operations.

Aztec Science

Frances F. Berdan

The name Aztec most commonly refers to a group of people who dominated the Valley of Mexico, and indeed much of central and southern Mexico, in the fifteenth and early sixteenth centuries. These people, who called themselves Mexica, settled their city of Tenochtitlan (today Mexico City) in the mid-1300s, in the midst of a large number of already-settled cities. The Mexica, as hunter and gatherer immigrants from the northern deserts, were latecomers to the Valley of Mexico and combined their nomadic-style culture with the ways of life of long-settled villagers and urban dwellers. In the fifteenth and early sixteenth centuries numerous different ethnic groups coexisted in the Valley of Mexico; these groups were politically organized in city–states and exhibited emblems of their specific cultural identities (such as patron gods, clothing styles, and distinctive dialects). Three of these groups, the Mexica of Tenochtitlan, the Acolhua of Texcoco, and the Tepaneca of Tlacopan, joined in a military alliance which conquered much of Mexico and created the Aztec empire.

Mexica society was hierarchical and highly specialized. In general, pronounced distinctions between nobles and commoners and between members of different ethnic groups also meant differences in access to certain scientific knowledge and specialized training. Noble boys were educated in priestly schools where the curriculum included literacy skills, astronomically based calendrics, and the learning of histories, orations, and songs. Some highly placed individuals, such as the sixteenth-century Acolhua king of Texcoco, Nezahualpilli, actively pursued scientific knowledge and were renowned as philosophers. This particular king spent endless nocturnal hours on his palace roof studying the movements of heavenly bodies, and consulted extensively with other learned individuals, undoubtedly priestly specialists. Medicinal knowledge and skills were in the hands of highly trained physicians, who appear in the documents as men or women skilled in herbal remedies and treatments of injuries and afflictions. Specific forms of scientific knowledge, embedded in industrial arts such as stone or feather-working, were generally the special province of defined ethnic groups, who passed on their craft from parent to child. Engineering and architecture (manifest, for instance, in the creation of buildings, dikes, and the development of elaborate irrigation works) would have required special training, perhaps in an apprentice-style setting. However, the documents are silent on this. Much knowledge of agronomics, as in genetic engineering of food crops, was probably developed by farmers themselves, who slowly but persistently developed increasingly productive strains of maize and other crops. While documentary evidence is scanty, it can be concluded that some scientific knowledge was developed and passed on in a formal, literary context while other knowledge (such as seed selection and midwifery) was maintained in a more informal "folk" realm.

The Mexica were the last of a long succession of complex states and civilizations in central Mexico. As such, they inherited many cultural traditions from prior civilizations, which included a great deal of scientific knowledge. Urban planning had a long history in Mesoamerica, and several cities in central Mexico display a consistency in their alignment since at least Teotihuacan times (ca. AD 1–750). While still a controversial subject, alignments of cities and specific structures within those cities were probably linked to astronomical phenomena. The Mexica were devout admirers of their predecessors the Toltecs (ca. AD 960–1160), to whom they attributed much of their scientific knowledge. This included medicine, geology and mining, astronomy and calendrics, architecture, and fine technical arts (especially featherworking, metal-working, and stoneworking). While the Mexica honored the Toltecs with these inventions, most of these skills and surely much of this knowledge clearly predated the rise of the Toltec civilization in central Mexico.

Mexica scientific knowledge was empirically based, but also closely linked to religious beliefs. To the Mexica and their neighbors, the natural and supernatural worlds shaded into one another, and their practical, scientific inquiries cannot be understood apart from their religious concepts and cultural symbolism. So empirical astronomy was intertwined with astrology; the involved system of calendrics was largely based on prolonged astronomical observations, but the calendars themselves were applied to ritual as well as practical ends. Medicine combined pragmatic remedies with shamanism, divination, and magical cures. Glyphic writing, sculpture, architecture, and the luxury crafts of stone-, feather-, and metal-working all relied on sophisticated and well-honed practical technologies; the resulting works served secular goals and/or displayed a complex religious symbolism. Animals and plants resided in the everyday, visible natural world, but also carried a heavy load of abstract meaning in the less tangible world of mythology and religious symbolism. To the Mexica and their neighbors, then, an empirical, scientific realm of understanding and inquiry was not readily separable from a more abstract, religious realm.

Mexica scientific concepts and knowledge are understood only imperfectly today, mainly due to the paucity of primary source materials on the subject. The ancient peoples of central Mexico, including the Mexica, maintained extensive libraries of pictorial books (codices), but virtually all of these were destroyed during or shortly after the Spanish conquest in 1521. Some of the information contained in these books was reconstructed following the Conquest and set down in written and/or pictorial form, usually under the supervision of Spanish friars. The most famous of these, and one which includes considerable information on astronomical knowledge, natural history, and medicinal practices is *Historia general de las cosas de Nueva España* [The General History of the Things of New Spain (Florentine Codex)], derived from native informants and compiled in the Narhuatl (Aztec) language by the Franciscan friar Bernardino de Sahagūn. Codices based on native glyphic writing traditions were also produced in early colonial times. Some of these contain interesting scientific details, such as images of plants and animals in place name glyphs and a star-gazing priest in the Codex Mendoza; or herbal remedies pictured and described in the Badianus Herbal. Also available, and providing variable enlightenment on native scientific concepts, are Spanish-language histories and descriptions of the Mexica and their neighbors by Spanish secular and religious officials. Among the most revealing of these are the natural histories of Francisco Hernández and Gonzalo Fernandez de Oviedo y Valdés, although the latter focuses primarily on areas to the south and east of the Aztec imperial domain. These post-Conquest sources blend native concepts and information with European understandings and conventions, and must be read in that light. Written sources are augmented by the material remains of the people themselves, discovered and interpreted archaeologically. The remains of structures provide clues to architectural and engineering skills; urban layouts suggest detailed understandings of the movements of celestial bodies; artifacts in metal, stone, and feathers (and the tools that produced them) reveal sophisticated industrial technologies; and ancient food remnants, such as corn cobs, demonstrate a steady enhancement of crop productivity through hybridization and selective breeding.

To illustrate the extent and goals of Mexica scientific inquiry, a closer look at astronomy, natural history, and medicine is presented below.

Cosmology, Astronomy, and Astrology

Like their forebears and contemporary neighbors, the Mexica were sophisticated observers of astronomical phenomena. Systematic celestial observations and studies were reportedly the domain of the elite. Imperial rulers such as Motecuhzoma (r. Mexica 1502–1520) had duties which included observing star groups in the night sky, as well as carefully following the morning star, Venus. Nezahualpilli, sixteenth-century ruler of neighboring Texcoco, could observe and record (and probably measure) the movements of celestial bodies from the roof of his royal palace. This “observatory” was structured so a man could just lie down and contemplate the night sky through small perforations through which were placed lances with cotton spheres atop. While this description of observing techniques is vague and not entirely clear, it does indicate that careful, rigorous, naked-eye techniques were employed to follow changes in the celestial realm. While rulers may have spent some of their nocturnal hours studying the heavens, this activity was more commonly performed by priests, who spent many waking hours at night. The Codex Mendoza shows one such priest engaged in observing the heavens for the purpose of marking the passage of time. Some temples may have served as “sighting stations” or observatories, from which pairs of crossed sticks could have been aligned to gain accurate lines-of-sight to celestial phenomena.

Lines-of-sight were also established between temples and recognizable points on the horizon, and between specific urban structures. The passage of the sun through the seasons could be readily charted in this fashion, with solstices and equinoxes especially marked. For instance, solar equinox sightings in Tenochtitlan were made from the Temple of Quetzalcoatl through an opening between the twin temples of the Great Temple. These various devices and techniques also allowed the ancient Mexicans to track the phases of the moon, record the arrangements of star groups (constellations), follow the movements of the Pleiades, calculate the rotation of Venus, and predict eclipses.

The Mexica conception of the universe and its heavenly bodies was a combination of scientific observations and ideological constructs. Celestial and terrestrial space was united in a hierarchical scheme, with 13 heavenly layers and nine layers of the underworld. Heavens and underworld were linked by earth, which was counted in each. The world above the earth combined visible phenomena with invisible gods and goddesses; for instance, the moon occupied the layer above the earth, followed by the clouds in the next tier, then the sun, Venus, and the Fire Sticks constellation (perhaps the belt and sword of Orion) in successive levels. It should be kept in mind that certain celestial bodies, especially the sun, moon, and Venus, were not only visible phenomena but were also accorded divine status. Heavenly layers also contained invisible deities, with the male/female creator god at the apex. This whole arrangement is quite different from the heliocentric (sun-centered) and geocentric (earth-centered) concepts developed in the Eastern Hemisphere.

The movements of the sun, stars, moon, and planets had important practical and ritual applications for the Mexica and their neighbors. They were especially concerned with the passage of time, and developed complex and accurate calendars. These included a calendar of 365 days (based on the sun's passage) and a ritual calendar of 260 days (of uncertain derivation). The former was especially used in seasonal agricultural planning, while the latter was the basis for divination and astrological determinations. Combined, these two calendars yielded a 52-year cycle which carried a heavy load of ritual and symbolism. To the Mexica, time was cyclical and repetitive, and much as the individual seasons and years came and went with marked similarity, so also did the 52-year "centuries." However, the fate-oriented Mexica also saw cycles in the creation and destruction of the universe; legends told of four prior worlds and their destructions, the Mexica living in the "fifth sun." A great deal of ritual and sacrifice was required of the central Mexicans to assure the continuance of this world, which could end at the closing of each 52-year unit. Thus a great deal of cultural interpretation was lent to the systematic visual astronomical observations of priests and rulers.

Similarly, ancient Mexicans frequently oriented entire cities along astronomical lines, especially 15–20 east of north. The basis for this common spatial arrangement is still unclear, although it may relate to the movements of the Pleiades. Still, in orienting their centers along consistent, meaningful lines, the earthly, sacred, and scientific were meshed into a single cultural realm.

Natural History and Ecology

Like the celestial bodies above the earth, the natural phenomena on and in the earth were viewed both scientifically and symbolically. In this close perceived link between natural and supernatural, the creatures of the earth performed a variety of functions in both visible and invisible cultural realms. Birds and beasts, for instance, were valued as providers of food, fur, and feathers, but were also frequent subjects of metaphors and players in myths and legends. However, the roles that creatures played in myths, the meanings they carried in the ritual calendar, or the messages they conveyed in metaphors were based on empirical observations of behavior, life cycles, and anatomy. For example, a human fugitive was likened to a fleet deer, the patting of tortillas compared to the flapping wings of a butterfly, and an eavesdropper described as the little mouse which inhabited every nook and cranny of a house. Close, systematic observations also led to an understanding of the transformations of the hummingbird, which seemingly died during nighttime or winter periods and came to life in the warmth of day or springtime.

Much of the study of wild creatures undoubtedly took place in the animals' natural habitat, so that, for instance, the wiley hunting techniques of the bobcat or the nesting of certain birds in "inaccessible places" are recorded. However, the Mexica also maintained a large zoo and aviary in the city of Tenochtitlan, and such a setting would have provided ample opportunity for observation and study. This was particularly significant for understanding birds and beasts from distant parts of the empire; these were especially valued for their fine feathers or precious pelts.

Habitats of various creatures were meticulously recorded, surely from direct attention to nature: the grey fox was a cave-dweller, the tadpole lived in fresh water among algae and waterlilies, the raccoon preferred forests and crags, and so on. The many parts of nature were understood as interconnected: the American Bittern's enthusiastic nighttime singing predicted heavy rains and abundant lacustrine fish; the Ruddy Duck's evening antics signaled rain at dawn; the song of another bird heralded the onset of frost.

Relationships among the various creatures themselves, including humans, were readily understood by the Mexica, whose hunter-gatherer experience was combined with knowledge acquired in agrarian and urban contexts. Human involvement in ecological dynamics at times had significant consequences. The Mexica were aware of the rarity of certain creatures, such as the wood ibis or certain serpents; indeed, they considered it a bad omen to catch the wood ibis, a cultural constraint which would have served to preserve this rare avian. In another example, the ruler Ahuitzotl (1486–1502) was reportedly responsible for bringing Great-tailed Grackles to Tenochtitlan from eastern lands and ordering their protection. However, these birds thrived to such an extent that they became an ecological burden and lost their popularity. In these contexts, the Mexica were active participants in the continuous ecological drama, engineering changes with often-unexpected consequences.

Medicine and Health

The Mexica were scientific and empirical in their discovery and use of medical cures for a large number of illnesses and injuries. The specialized doctor, or *ticitl*, used practical approaches to his/her profession, examining and diagnosing physical problems and prescribing appropriate cures. Physicians could call on a large pharmacopoeia derived from herbs, roots, animals, and minerals to relieve symptoms, heal injuries, and restore health. They were skilled in soothing burns, setting broken bones, and suturing lacerations, many of these latter injuries undoubtedly suffered in the frequent battles fought in this militaristic society.

Procedures could be multistaged and quite complicated. Broken bones, for instance, were first set, then splinted with poultices of specified ground roots or herbs. There was some variety in these usages, as the curative ground roots or herbs could be spread on the injury, drunk with pulque, or enjoyed in a bath. A bitten tongue was first subjected to a mixture of chile cooked with salt, followed by a more comforting application of bee or maguey honey. The Mexica considered at least 132 herbs to have curative properties, and these were applied to at least 40 ailments other than injuries. Curable ailments included nosebleed, pimples, headache, diarrhea, fatigue, coughs, chest pains, nausea, and many fevers and infections. Some infirmities could be served by a variety of cures – for instance, 45 different herbs could be used to relieve fevers and 18 could be applied to festered skin. On the other hand, some remedies had multiple uses – one herb, for instance, could reportedly slow bleeding, inhibit vomiting, relieve side and chest pains, and in general restore a person's strength.

Medicinal aids were often mixed into complex curative potions. Additionally, cures were at times combined with other types of remedies. One of the most popular of these was the sweatbath, often recommended as helpful in childbirth problems, skin festering, and traumas. Practical remedies were also at times joined with divinatory and magical cures; magic and divination were used in both diagnosis and curing of certain illnesses. The Mexica believed that some illnesses could have supernatural causes; these included soul loss and the intrusion of unpleasant supernatural substances.

In another vein, some illnesses required adherence to strict taboos: a patient with a fever was not to eat hot tortillas or chiles, and one with a head wound was to refrain from eating fish or meat. A preventative element is also evident in Mexica medicine. For instance, one designated herb was said to aid digestion and prevent fevers, a nursing mother could prevent diarrhea in her infant by shunning avocados, and stammering or lisping could be avoided by weaning children at a young age. Thus medicine and the maintenance of health in Mexica society were complex matters, relying on a blending of practical, scientific knowledge, and strong religious beliefs.

Applications of Mexica Science

What did the Mexica do with the vast amount of knowledge they and their forebears had acquired about the world around them? What was the purpose of the many systematic and rigorous studies they made of the heavens and the earth?

While some priests and rulers may have enjoyed the process of discovery for its own sake, it is clear that scientific knowledge among the Mexica was preeminently geared toward practical and religious applications. Long-term, rigorous observations of the heavens, and the recording of celestial movements, furnished the Mexica with temporal order. These scientific inquiries provided the basis for a sophisticated calendrical system, the ability to make appropriate seasonal preparations, and the capacity to predict and prepare for extraordinary and sometimes fearful events (such as eclipses).

The Mexica were hunter-gatherers long before they entered the Valley of Mexico and there adopted a well-developed agrarian lifestyle. Bolstered by both of these traditions, the Mexica were keen observers of nature and its processes. They understood the anatomy, behavior, life cycles, and ecology of wild plants and animals. They also had a sophisticated knowledge of cultigens, and drew on a long agrarian tradition of seed selection, agricultural technology, and even the ability to predict certain pertinent weather conditions from animal behavior. They applied this extensive and varied knowledge first and foremost to increase and protect their food supply. However, natural resources also enhanced their life conditions by providing fibers, furs, and feathers for clothing and adornment; building materials for domestic and godly shelter; and precious stones and metals for a show of status.

Nature also provided a wealth of medicinal cures, discovered, combined, and applied successfully by specialized physicians. Administering the proper remedy to the specific ailment undoubtedly required considerable experimentation, but unfortunately the documents are silent on this process.

We therefore have quite a bit of information on the Mexica's scientific results, but little understanding of their methods. Those methods, such as rigorous naked-eye astronomy, repeated observations of earthly phenomena, and centuries-long seed selection, yielded a significant body of sophisticated scientific knowledge, applied by the Mexica to cultural ends. The Mexica consistently linked the scientific realm to the religious and utilized empirical discoveries to enhance and embellish their everyday lives.

Bakhshālī Manuscript

Takao Hayashi

The Bakhshālī Manuscript is the name given to the oldest extant manuscript in Indian mathematics. It is so called because it was discovered by a peasant in 1881 at a small village called Bakhshālī, about 80 km northeast of Peshawar (now in Pakistan). It is preserved in the Bodleian Library at Oxford University.

The extant portion of the manuscript consists of 70 fragmentary leaves of birchbark. The original size of a leaf is estimated to be about 17 cm wide and 13.5 cm high. The original order of the leaves can only be conjectured on the bases of rather unsound criteria, such as the logical sequence of contents, the order of the leaves in which they reached A. F. R. Hoernle, who did the first research on the manuscript, physical appearance such as the size, shape, degree of damage, and knots, and the partially preserved serial numbers of mathematical rules (9–11, 13–29, and 50–58).

The script is the earlier type of the Śāradā script, which was in use in the northwestern part of India, namely in Kashmir and the neighboring districts, from the eighth to the twelfth centuries. G. R. Kaye, who succeeded Hoernle, has shown that the writing of the manuscript can be classified into at least two styles, one of which covers about one-fifth of the work. There is, however, no definitive reason to think that the present manuscript consists of two different works.

The information contained in the manuscript, the title of which is not known, is a loose compilation of mathematical rules and examples collected from different works. It consists of versified rules, examples, most of which are versified, and prose commentaries on the examples. A rule is followed by an example or examples, and under each one the commentary gives a "statement," "computation," and a "verification" or verifications. The statement is a tabular presentation of the numerical information given in the example, and the computation works out the problem by following, and often citing, the rule step by step.

Thus, the most typical pattern of exposition in the Bakhshālī Manuscript is:

1. Rule (*sūtra*)
2. Example (*udāharaṇa*)
   - Statement (*nyāsa*/*sthāpanā*)
   - Computation (*karaṇa*)
   - Verification(s) (*pratyaya*/*pratyānayana*)

A decimal place-value notation of numerals with zero (expressed by a dot) is employed in the Bakhshālī Manuscript. The terms for mathematical operations are often abbreviated, especially in tabular presentations of computations. Thus we have *yu* for *yuta* (increased), *gu* for *guṇa* or *guṇita* (multiplied), *bhā* for *bhājita* (divided) or *bhāgahāra* (divisor or division), *che* for *cheda* (divisor), and *mū* for *mūla* (square root). For subtraction, the Bakhshālī Manuscript puts the symbol, + (similar to the modern symbol for addition), next (right) to the number to be affected. It was originally the initial letter of the word *ṛṇa*, meaning a debt or a negative quantity in the Kuṣāṇa or the Gupta script (employed in the second to the sixth centuries). The same symbol is also used in an old anonymous commentary on Śrīdhara's *Pāṭīgaṇita*, which is uniquely written in the later type of the Śāradā script (after the thirteenth century). Most works on mathematics, on the other hand, put a dot above a negative number.

The problems treated in the extant portion of the Bakhshālī work involve five kinds of equations, namely (1) simple equations with one unknown (15 types of problems), (2) systems of linear equations with more than one unknown (14 types), (3) quadratic equations (two types, both of which involve an arithmetical progression), (4) indeterminate systems of linear equations (three types, including the so-called "Hundred Fowls Problem," in which somebody is to buy 100 fowls for 100 monetary units of several kinds), and (5) indeterminate equations of the second degree (two types: $\sqrt{x+a} = u$ and $\sqrt{x-b} = v$, where u and v are rational numbers; and $xy = ax + by$).

The rules of the Bakhshālī work may be classified as follows:

1. Fundamental operations, such as addition and subtraction of negative quantities, addition, multiplication, and division of fractions, reduction of measures, and a root-approximation formula,

$$\sqrt{a^2+r} \approx a + \frac{r}{2a} - \frac{(r/2a)^2}{2(a+r/2a)}.$$

2. General rules applicable to different kinds of problems: *regula falsi*, rule of inversion, rule of three, proportional distribution, and partial addition and subtraction.
3. Rules for purely numerical problems: simple equations with one unknown, systems of linear equations with more than one unknown, indeterminate equations, and period of an arithmetical progression.
4. Rules for problems of money: equations of properties, wages, earnings, donations, etc., consumption of income and savings, buying and selling, purchase in proportion, purchase of the same number of articles, price of a jewel, prices of living creatures, mutual exchange of commodities, installments, a sales tax paid both in cash and in kind, and a bill of exchange.
5. Rules for problems of travelers: equations of journeys, meeting of two travelers, and a chariot and horses.
6. Rules for problems of impurities of gold.
7. Rules for geometrical problems: volume of an irregular solid and proportionate division of a triangle.

All the rules of the first category, namely the fundamental operations, occur only as quotations in the computations of examples. Many of the other rules could belong to either *miśraka-vyavahāra* (on mixture) or *śreḍhī* (of series) in a book of *pāṭī* (algorithms) such as Śrīdhara's *Pāṭīgaṇita* and *Triśatikā* (eighth century), etc., but they have not been arranged according to the ordinary categories of *vyavahāra*.

We apparently owe the present manuscript to four types of persons: the authors of the original rules and examples, the compiler, the commentator, and the scribe. Possibly, however, the commentator was the compiler himself, and "the son of Chajaka" (his name is unknown), by whom the Bakhshālī Manuscript, or at least part of it, was "written," was the commentator, or one of the commentators. The colophon to the section that deals exclusively with the *trairāśika* (rule of three) reads:

> This has been written by the son of Chajaka, a brāhmaṇa and king of mathematicians, for the sake of Hasika, son of Vasiṣṭha, in order that it may be used (also) by his descendents.

Immediately before this statement occurs a fragmentary word *rtikāvati*, which is probably the same as the country of Mārtikāvata mentioned by Varāhamihira (ca. AD 550) among other localities of northwestern India such as Takṣaśilā (Taxila), Gandhāra, etc. (*Bṛhatsaṃhitā* 16.25). It may be the place where the Bakhshālī work was composed.

A style of exposition similar to that of the Bakhshālī work ("statement," etc.) is found in Bhāskara I's commentary (AD 629) on the second chapter called *gaṇita* (mathematics) of the *Āryabhaṭīya* (AD 499). Both Bhāskara I's commentary and the Bakhshālī work attach much importance to the verification; it became obsolete in later times. The unusual word *yāva* (*yāvakaraṇa* in Bhāskara I's commentary) meaning the square power, and the apparently contradictory meanings of the word *karaṇī*, the square number and the square root, occur in both works.

Bhāskara I does not use the symbol *yā* (the initial letter of *yāvattāvat* or "as much as") for unknown numbers in algebraic equations even when it is naturally expected, while he employs the original word *yāvattāvat* itself in the sense of unknown quantities (in his commentary on *Āryabhaṭīya* 2.30). This probably implies that he did not know the symbol. The symbol is, on the other hand, utilized once in the Bakhshālī work in order to reduce the conditions given in an example to a form to which the prescribed rule is easily applicable; after the reduction, the symbol is discarded and the rule is, so to speak, applied mechanically (fol. 54^{v}). This restricted usage of the symbol seems to indicate that the work belongs to a period when the symbol was already invented, but not very popular yet.

There has been quite a bit of dispute over the dates of the manuscript. Hoernle assigned the work to the third or the fourth century AD, Kaye to the twelfth century, Datta to "the early centuries of the Christian era," and Ayyangar and Pingree to the eighth or the ninth century. The above points suggest that the Bakhshālī work (commentary) was composed not much later than Bhāskara I (the seventh century).

Balkhī School of Arab Geographers

GERALD R. TIBBETTS

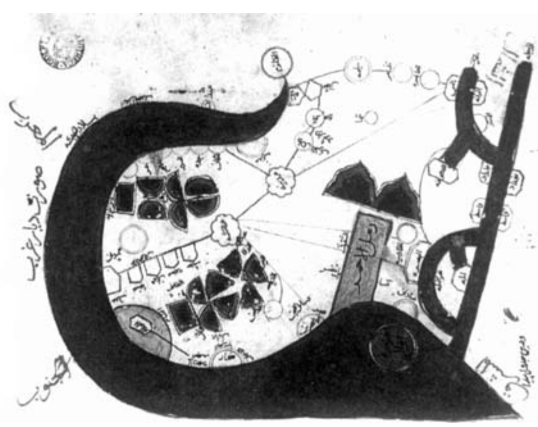
The Balkhī School refers to a group of four authors who recognize the fact that their geographic work is interlinked. It is also known to scholars as the Classical School of Arab Geography or the Islamatlas. Abū Zaid Aḥmad ibn Sahl al-Balkhī (d. 322/834), who wrote *Ṣuwar al-aqālīm*, is the earliest of them and presumably the originator. The other three authors are Abū Isḥāq Ibrāhīm ibn Muḥammad al-Iṣṭakhrī (ca. AD 950) (*Al-masālik wa'l-mamālik*), Muḥammad ibn Ḥawqal (d. between 350/861 and 360/972) (*Ṣūrat al-arḍ*) and Abu ᶜAbdallāh Muḥammad ibn Ahmad al-Muqaddasī (d. ca. 390/1000) (*Aḥsān al-taqāsim*).

Their work is based on a series of maps covering the Islamic Empire together with a text which consists mainly of notes on the maps. Many copies of these works survive; the earliest surviving manuscript being a version by Ibn Ḥawqal dated AH 479/AD 1086. This is the earliest Arabic manuscript to contain a map. Yet, copies of al-Iṣṭakhrī's book were still being produced as recently as the middle of the nineteenth century AD. There is so much material available that scholars have identified two separate editions 3ns of al- Iṣṭakhrī, three of Ibn Ḥawqal and two of al-Muqaddasī, although one of the versions of Ibn Ḥawqal does not contain maps. These different texts can be associated with similar sets of maps, and these maps can be compared and relationships established which enable us to trace the development of "Balkhī" cartography. The standard set of maps consists of a world map, two oceans (Indian and Mediterranean), four Roman provinces (i.e., areas which were originally Byzantine) and 14 Persian provinces (Fig. 1).

It is obvious that the maps are conceived as a set covering the Muslim Empire with reasonable detail, and there is no attempt to cover non-Islamic areas in the same way. It has been suggested that this policy of including only Islamic regions is deliberate. Each map is given a page or so of textual description, and each of these descriptions is planned in such a way that lists of routes, towns, mountains, rivers, etc., are given for each province. Thus they bear a certain resemblance to the work of Ibn Khurdādhbih, although the latter's work was not accompanied by maps nor did he limit himself only to the Dar al-Islam. There is a likelihood that the Balkhī School material and the work of Ibn Khurdādhbih are based on Persian (Sassanid) materials which survived the Islamicization of the Persian home areas.

The Balkhi maps cannot be connected together like the sectional maps of al-Idrīsī to form one large map of the known world. Al-Iṣṭakhrī and Ibn Ḥawqal show no interest in projection, scale, or mathematical geography and do not mention latitudes and longitudes at all. The only form of measurement given is that of days, journeys (*marḥala*). The maps are very geometrical in design. Lines are straight or arced, rivers are parallel lines, lakes often perfect circles. Towns can be circles, squares, four pointed stars or something similar. Stopping places on routes resemble small tents or caravanserais.

al-Muqaddasī's text is based on the same principles but is a considerable improvement over that of his predecessors. He also includes a section on astronomical geography and geodesy including a note on the Greek system of climates. Both Ibn Ḥawqal and al-Muqaddasī are more up-to-date and are more at home in Europe and North Africa, having a preference for the western part of the Empire rather than the Persian speaking areas. al-Muqaddasī's maps however have a closer affinity with those of al-Iṣṭakhrī, whereas we would expect,



Balkhī School of Arab Geographers. Fig. 1 Map of Arabia from al-Iṣṭakhrī's *Ṣuwar al-buldān*. From the from the nature of his text, something much more advanced. He has however a different selection of maps, there being no world map nor one of the Caspian Sea and a completely new map of the Arabian desert.

The works of these authors were reproduced continually throughout the centuries not only in Arabic but also in Persian or Turkish translation. Other writers occasionally borrow a selection of the maps or an individual map. Some of the later versions are very corrupt and hardly recognizable. A world map derived from this school appears regularly in the works of Ibn al-Wardī and often in texts of al-Qazwīnī's cosmography showing how popular these maps were in the Muslim world.

Bamboo

DAVID TURNBULL

Few other plants or materials have been so pleasing to the eye, have inspired so many artists, poets, and philosophers, or have contributed so materially to the development of civilization as have bamboos. Bamboo (*Arundinaria*) is a grass that grows with great rapidity in a wide range of climates with over 1,500 species around the world. It is both immensely strong and very light. It is easily worked with simple tools and is strikingly beautiful both in the economy of its natural form and in its finished state. Yet not only has its key role in the development of science and technology been largely overlooked by Western historians of science, but its contemporary uses tend to be contemptuously undervalued as simple and traditional. It was dismissed as "poor man's timber."

The reality is that bamboo has been one of the prime nutrients of Asian culture and may yet turn out to have a significant role to play in civilizations around the world. The applications and powers of bamboo are almost limitless from the purely aesthetic to merely practical. The earliest boats were made of bamboo. Through inspiring poetry, metaphysics, painting, and geometry while simultaneously being the material for its production, bamboo has both created and preserved knowledge, wisdom and art. Bamboo has not only sustained life by providing housing, food, and medicine, it has been used to make a profusion of tools and domestic and industrial essentials from baskets to scaffolding, cables, and steel reinforcing, from musical instruments to windmills, bridges, and airplanes.

It was a raw material for papermaking that bamboo made its greatest contribution in the past, while also having the capacity to revolutionize paper production in the future. Bamboo is a super producer yielding two to six times more cellulose per acre than pine and can be cropped annually, but its capacity to provide paper pulp has gone largely unrecognized outside India, China, Thailand, and Brazil. Fifty percent of the world's timber is used to make paper, while in India two-thirds of the paper is made from bamboo with more than 40 factories making 600,000 tons of paper annually. If this use of bamboo were extended worldwide, the saving of old growth forest currently used in wood chip production would be greatly reduced.

In Colombia and Costa Rica, bamboo, when coated with concrete in a form of lath and plaster construction, has proved to be a cheap and effective way of building earthquake-proof housing. Similar techniques are under development in the Philippines and Hawaii to use bamboo in cyclone-proof buildings. Bamboo has proved extremely effective in stabilizing soil and preventing erosion. As a "mop crop" it also has a great capacity to extract nitrates and phosphates from effluent. These characteristics make it an ideal plant for handling two of the world's most significant problems, soil degradation and water quality. It is the ultimate renewable resource and if it is employed in either or both these ways it can become a cheap and sustainable feed stock for making paper, houses, furniture, flooring, a profusion of decorative items as well as food and medicine.

However, it is in this transition from being virtually a free good to being a valued resource that potential problems lie. Demand is already exceeding supply in India, and while government economists in Delhi argue that bamboo can become a cash crop that will improve the lot of the poor, it is possible that the landless peasants will end up being unable to afford even poor man's timber. As Western civilization gradually overtakes the developing world, research on the more industrial uses has begun, and it is being widely used in making parquet flooring and laminated beams. It is to be hoped that, as it becomes a first world resource, it does not become just another opportunity for exploitation. If the developing economies leave the knowledge of its uses and the control of production in the hands of the local people, bamboo has the capacity to benefit all of us.

Banū Mūsā

Donald R. Hill

The Banū Mūsā were three brothers, Muḥammad, Aḥmad, and al-Ḥasan, who were amongst the most important figures in the intellectual life of Baghdad in the ninth century. We do not know their dates of birth, but Muḥammad died in 873 and could hardly then have been less than 70-years old, because the youngest brother al-Ḥasan was already a brilliant geometrician in the reign of al-Maʾmūn (813–833). Their father, Mūsā ibn Shākir, was a noted astronomer and a close companion of al-Maʾmūn when the latter was residing at Marw in Khurasan before he became caliph. When Mūsā died, al-Maʾmūn became the guardian of his sons, who were given a good education in Baghdad, becoming skilled in geometry, mechanics, music, mathematics, and astronomy.

Under the successors of al-Maʾmūn, the brothers became rich and influential. They devoted much of their wealth and energy to the quest for the works of their predecessors, especially in Greek and Syriac, and sent missions to the lands of the Byzantine Empire to seek out manuscripts and bring them to Baghdad. Muḥammad is said to have made a journey to Byzantium in person. The brothers acted as sponsors to a group of scientists and translators, to whom they paid about 500 *dinars* a month. The most outstanding of these scholars were Thābit ibn Qurra and Hunayn ibn Isḥāq, who rendered numerous works, many of which would otherwise have been lost, from Greek and Syriac into Arabic. Muḥammad was on friendly terms with this group of scholars, particularly with Huṇayn, who translated and composed books at the request of his patron. The brothers therefore played a leading role in the transmission of Greek works into Arabic, and in the foundation of the long and important contribution of the Islamic world to the sciences. Some 20 works are attributed to the Banū Mūsā, of which three have survived. The best-known and most important of the brothers, books, which were largely the work of Aḥmad, is their *Kitāb al-ḥiyal* (Book of Ingenious Devices). The work comprises descriptions of some 100 small machines, including alternating fountains, self-filling and self-trimming lamps, and a clamshell grab. About 80 of the devices, however, are trick vessels of various kinds that exhibit an astonishing mastery of automatic controls. The inspiration for Aḥmad's work is undoubtedly to be found in the machine treatises of the Hellenistic writers, particularly the *Pneumatics* of Philo of Byzantium (mid-third century BCE) and the *Pneumatics* of Hero of Alexandria (fl. ca. AD 60). The *Kitāb al-ḥiyal*, although some of the devices in it come directly from Philo or Hero, goes well beyond its Greek predecessors, particularly in the use of small pressure variations and conical valves and other components in automatic controls. Indeed, the work of the Banū Mūsā in the variety and ingenuity of their control systems was unsurpassed until quite recent times. There may have been some didactic intention in their writing, but most of their constructions are quite trivial to our eyes. Nevertheless, many of the ideas, techniques, and components that they used were to be of considerable importance in the development of machine technology.

Basketry in Ancient Egypt

Willeke Wendrich

The oldest basketry found in Egypt dates to the Neolithic period (ca. 5900–4000 BCE). In the Fayum Oasis, about 100 km (60 miles) southwest of Cairo, grain storage pits were excavated in the desert floor, lined with coarse straw basketry (Fig. 1).

First discovered in 1926 (Caton-Thompson and Gardner) and examined in detail for the first time in 2005 after recent excavations (Wendrich and Cappers 2005), these baskets represent a coiling technique. This entails a bundle of straw fastened into a coil with a number of stems pulled out of the straw bundle at regular intervals. This particular type of coiling went out of use and was replaced by a variation of the coiling technique, which existed simultaneously. This type of coiling makes use of different materials for the bundle and the winders (Fig. 2).

Near the Neolithic grain storage pits part of an extremely finely coiled basket was found, dated to about 4200 BCE, made of separate bundle and winder materials and decorated with darker winders along the rim (Fig. 3).

These two examples from the Egyptian Neolithic demonstrate that basketry technology was well advanced by that time and must have known a long period of development for which we have no other evidence.

The oldest and most frequently used techniques in ancient Egypt were coiling, twining and mat weaving. Coiling was used to produce sturdy baskets, varying in size from 3 to 60 cm in diameter. In Ancient Egypt wood was scarce. Basketry, therefore, had an important function, replacing cupboards as containers for clothing, food, and many other items. The tomb of Tutankhamun contained over 120 baskets (Reeves 1990: 204; Malek). Even coffins and sandals were made in the coiled technique.

Twining has been attested from the Predynastic period onward. The twining technique consisted of a (passive) warp and a weft of two active strands. These were twisted around the passive warp elements, and each other, in either S or Z orientation. The twining technique was extremely versatile, depending on the materials used and the distance between the weft and warp elements. Fig. 4 shows some of the variety.

Matting was used widely as awnings, windbreaks and doors, but also as mattresses for sleeping and covers to wrap the dead. Egyptian architecture was characterized by many references to the use of mats in the original shrines and temples. The “drum” that was

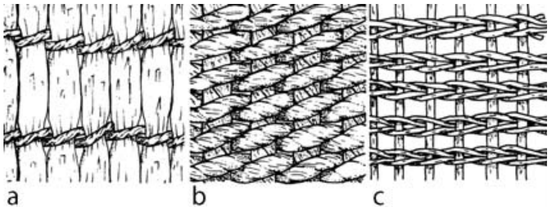
Basketry in Ancient Egypt. Fig. 3 The Fayum Neolithic produced very fine decorated coiled basketry. This 6,000 year old fragment was found only a few centimeters under the surface. Photograph UCLA/RUG Fayum Project.



Basketry in Ancient Egypt. Fig. 4 Three examples of the many variations used to produce twined basketry: (a) a mat made of bundles of grass, fastened into a fabric with widely spaced rows of twining; (b) a sturdy mat made of narrowly spaced twined string, and (c) a sieve grid made of open twined strips of palm leaf.

part of the so-called false door represented a rolled up mat, and decorative motifs on tomb and temple walls, such as pillars carved to resemble tied reed bundles, a stylized motif representing the tied off bundles of grass matting (the *kheker* motive) and other decorative patterns, also referred to mats. The Djoser complex in Sakkara, for instance, displayed many references to the perishable predecessors of its stone architecture (Lehner 1997: 84–93; Verner 2002: 108–140).

For mat weaving a simple horizontal ground loom was used, consisting of four wooden pegs in the ground, to which two crossbeams were tied. The warp was kept taut by tightening the strings tying the two beams to the ground pegs. A third beam, with evenly spaced holes, guaranteed the regular spacing of the warp string (in more delicate loom types this part would be called the *reed*). It had a double function, because by slamming the beam into the woven part of the mat, it also served as a beater, creating a tight weave. The mats were mostly made with a warp of grass string, spaced 3–4 cm apart, and a weft of single grass stems, or small bundles of grass. For sleeping mats the grass was laid in with the thicker base side of the stem, while the tip was left to stick out from the warp, forming a more comfortable thick fibrous pad underneath the mat. An early depiction of a mat weaver is found in the tomb of Khety in Beni Hassan and dates to the early Middle Kingdom (ca. 1900 BCE, see Fig. 5).

From approximately the fourth century BCE onward the plaiting technique became increasingly popular in Egypt. Sandals were no longer made of many parallel rows of coiling, but rather plaited with palm leaf. The equivalent of our flip-flop was plaited with eight strips of doam palm leaf, each approximately 4 cm wide. More elaborate sandals had several padded layers, of fine and coarse plaiting with different materials: coarse plaits from palm fiber for the outer sole, fine plaited palm leaf fabric for the inner sole. Fans were made of extremely fine plaited matting, using strands of palm leaf of only 2 mm wide. For both mats and baskets a completely new technique was introduced into Egypt,

Basketry in Ancient Egypt. Fig. 5 Tomb painting of a mat weaver (detail), dating to the Middle Kingdom (approximately 1600 BCE). From the tomb of Khety in Beni Hassan, Middle Egypt.

consisting of plaited strips sewn together to form a seemingly ongoing plaited fabric. Depending on the pattern, only twill strips plaited with a particular number of strands (9, 13, 17, 21, etc.) could be used, which created broad edges, with a particular orientation. The edges were pulled inside each other, thus completely hiding the sewing strand. The most commonly used materials for basketry changed slightly over time. In the prehistoric and Predynastic periods the materials attested are papyrus (*Cyperus papyrus*), the stems of the composite *Ceruana pratensis* and wheat or barley straw. In the Pharaonic period tall tough grasses (*Desmostachya bipinnata* and *Imperata cylindrica*) were used for twined and woven matting, as well as for the bundles of coiled basketry. The coils were fastened with winders of papyrus rind or doam palm leaf (*Hyphaene thebaica*). Date palm leaf (*Phoenix dactylifera*) occurred rarely in the Pharaonic period, but became widely used toward the Late Period and the Greco-Roman period, taking over the significance of both papyrus and doam palm leaf. This probably had an environmental reason; a slight climatic change caused the doam palm to retreat south and at present this species occurs only sparsely south of Luxor and is common only in Sudan. The date palm, on the other hand, was cultivated increasingly in all of Egypt. Similarly, papyrus plants, cultivated for writing material and basketry, withdrew to the south and at present do not occur in a natural habitat in Egypt.

The variety of ancient Egyptian basketry techniques, shapes, and materials reflect the widespread use and functionality of these objects. The tomb paintings and reliefs from all periods of Egyptian history corroborate the information from the archaeological material. Bearers of offerings were shown carrying baskets full of produce and goods, farmers were depicted sowing from twined baskets, loading the harvest in enormous carrying nets and carrying the threshed grain in baskets to the granaries. Perhaps the most telling was the fact that in many of the ostraka (pot sherds and lime stone chips used as scrap paper) from the village of Deir el Medina baskets (of grain) were listed as the standard size for paying wages.

Baudhāyana

R. C. Gupta

India's most ancient written works are the four *Vedas*, namely *Ṛgveda, Yajur-veda, Sāma-veda*, and the *Atharva-veda*. There are different schools which are represented by various *Saṃhitās* or recensions of the *Vedas*. To assist their proper study, there are six *Vedāngas* (limbs or part of the *Veda)*, namely *Śikṣā* (phonetics), *Kalpa* (ritualistics). *Vyākaraṇa* (grammar), *Nirukta* (etymology), *Chandas* (prosody and metrics), and *Jyotiṣa* (astronomy, including mathematics and astrology). These auxiliary Vedic works (except the last) are written in *sūtra* or aphoristic style.

The *Kalpa Sūtras* deal with the rules and methods for performing Vedic rituals, sacrifices, and ceremonies, and are divided into three categories: *Śrauta, Gṛhya,* and *Dharma*. The *Śrauta Sūtras* are more specifically concerned with the sacrificial ritual and allied ecclesiastical matters. They often include tracts which give rules concerning the measurements and constructions of *agnis* (fireplaces), *citis* (mounds or altars), and *vedis* (sacrificial grounds). Such tracts are also found as separate works and are called *Śūlba Sūtras* or *Śulbas*. They are the oldest geometrical treatises which represent in coded form the much older and traditional Indian mathematics. The root *śulb* (or *śulv*) means "to measure" or "to mete out".

The names of about a dozen *Śulba Sūtras* are known. The oldest of them is the *Baudhāyana Śulba Sūtra*. It belongs to the *Taittirīya Samhitā* of the *Black Yajurveda* and is the 13 *Praśna* or chapter of the *Baudhāyana Śrauta Sūtra*. The title *Baudhāyana Śulba Sūtra* shows that its author or compiler was Baudhāyana, or perhaps more correctly, it belonged to the school of Baudhāyana. Other Vedic works bearing the same name are known. It is more proper to consider these works as belonging to the Baudhāyana school than to regard them as authored by the same person.

Here we are concerned with Baudhāyana the *śulbakāra* that is, the author of the *Baudhāyana Śūlba Sūtra*) or the *sulbavid* (expert in *sulba* mathematics and constructions). We do not know his biographical details. Georg Bühler believed that he hailed from the Andhra region, but a recent study by Ram Gopal shows that he probably came from northern India. His dates are also uncertain, being any time between 800 and 400 BCE. Taking into account the views of A. B. Keith, W. Caland, David Pingree, and Ram Gopal, he may be placed about 500 BCE or earlier. However, it must be noted that much of the material in *Baudhāyana Śulba Sūtra* is traditional and, thus, still older than its date of compilation and coding.

The *Baudhāyana Śulba Sūtra* is not only the earliest but also the most extensive among the *Śulbas*. The subject matter is presented in a systematic and logical manner. Of course, the language is somewhat archaic, and due to the aphoristic style, the rules are highly condensed. The *Baudhāyana Śulba Sūtra* was commented on by Dvārakānātha Yajva (ca. seventeenth century). His Sanskrit commentary called the *Śulbadīpīkā* was published more than a century ago by Thibaut (1848–1914) in his edition of the *Baudhāyana Śulba Sūtra*. A recent edition (Varanasi 1979) of the *Baudhāyana Śulba Sūtra* also contains the above commentary as well as another called *Bodhāyana śulbamīmāṁāṁsā*, which was written by Vyaṇkateśvara (or Veṅkateśvara) Dīkṣita who lived during the Vijaya-nagaram kingdom (ca. 1600).

The text of the *Baudhāyana Śulba Sūtra* is divided into three chapters which comprise a total of 272 passages or 519 aphorisms. The main subject is the measurement, construction, and transformation of various altars and fireplaces. The forms of the three obligatory *agnis* (whose tradition was older than even the *Ṛgveda*) were square, circle, and semicircle, but those of optional *citis* involved all sorts of plane figures, including the above three and also the rectangle, rhombus, triangle, trapezium, pentagon, and some complicated shapes.

Some mathematical topics covered in the *Baudhāyana Śulba Sūtra* are a fine approximation for the square root of two and the so-called Pythagorean theorem. In the latter, the sides of a right-angled triangle obey the rule $a^2 + b^2 = c^2$.

The *Baudhāyana Śulba Sūtra* also contains formulas for circling a square and squaring a circle, and provides rules for basic simple geometric constructions, such as drawing a perpendicular on a given line or drawing the right bisection of a line. Some other elementary plane figures such as the isosceles triangle, trapezium, and rhombus are also covered for construction.

The *Baudhāyana Śulba Sūtra* deals with the measurements and constructions of a large number of fire-altars (*Kāmya agnis*). These were needed as part of rituals performed to attain certain desired objects according to the religious beliefs of the Vedic people. It was essential that the shape, size, area, and orientation of the relevant altar be according to the prescribed instructions. Otherwise, there was a risk of divine wrath.

The standard forms of some of the optional altars were those which resembled certain birds. The most significant and perhaps the oldest of such altars was the *śyenaciti* (falcon-shaped altar). It was to be constructed when one desired heaven (after death) because "the falcon is the best flyer among the birds." The spatial dimensions, the number of bricks (of prescribed shapes and sizes), the number of layers, etc., are all given. It is interesting to note that the archaeological remains of this most striking and complicated *śyenaciti* reported to be built in Kausambi in the second century BCE, still survive.

Early Indian geometry developed because of the need for accurate altar constructions and transformations which often required quite advanced mathematical knowledge.

Beads

Robert G. Bednarik

Of the Palaeolithic forms of possible symbolic products, beads and pendants seem to tell us the most about the cognition and technology of their users. First, there are the purely technological aspects. To make a bead one has to be able to drill through an object (or enlarge a natural perforation), thread a string through the hole and fasten the ends of the string, presumably by knots (Warner and Bednarik 1996). To persist with such a process of manufacture, one must have a mental construct of the end product, and a desire to acquire what is clearly a non-utilitarian artefact. While the bead is such an artefact, the string is not, being utilitarian. It is merely a means of permitting the bead to fulfil its non-utilitarian role. Hence this is a combination not only of diverse (composite) and interactive artefacts, but also a hierarchy of diverse concepts of relating to them. The primary imperative, presumably, is to display the bead to its best advantage; the secondary intent is to find a means of doing so. A piece of, say, ostrich eggshell can be worn on a string without first drilling a hole through it, so why bother with this additional work? It is through such considerations that beads are imbued with the potential of meaning and significance.

Whether they are sewn on apparel or worn on strings, beads and pendants have symbolic meanings that are far removed from the empiricism of the interpreting Western anthropologist. For instance, they may be protective, warding off evil spirits or spells, or they can be good luck charms. They can signify status (e.g. availability for marriage, political status, and state of mourning), and convey complex social, economic, emblemic, cultural, ideological, religious or ethnic meanings, or any subtle combinations of them. Their emic meanings can be public or private, but they may be difficult to convey to an alien researcher, and they could never be deduced reliably through archaeology.

Beads have no possible utilitarian function that is not attributable to purely symbolic purposes. Describing them as decorative, for instance, does not amount to any clarification, because it does not tell us why they are 'decorative'. All communicative functions of beads are culturally negotiated; the abstract values they communicate to the initiated beholder are crucial to their existence, yet for the early periods of humanity they are entirely inaccessible to the researcher. The outstanding technical perfection of some particularly early specimens has prompted the proposition that these objects expressed concepts of perfection and it has been demonstrated, via replicative experiments, that such perfection was achieved through a great investment of labour and carefully applied skills (Bednarik 1997). The intentionality of perfection as well as the various layers of intended cultural meanings of such objects would have been all impossible without the use of a 'reflective' communication system of a complexity that does not seem achievable without consciously modulated speech. Hence beads and pendants constitute key evidence in the quest to clarify the cognitive evolution of humans – not just because they demonstrate the use of symbolisms, but because they demand social, cultural and cognitive systems of an adequate sophistication to support the complex aggregate of mental abstractions without which such objects simply cannot exist. We have many other indicators of language use several hundred thousand years ago, during the Lower and Middle Palaeolithic (e.g. other forms of symbolism, or seafaring), but the use of beads and pendants during these earliest phases of human culture provides one of the most crucial forms of such evidence.

Middle and Lower Palaeolithic finds with both artificial and natural perforations are quite common, and many hundreds have been found since the mid-nineteenth century. They demonstrate considerable complexity of human cognition and social structures up to perhaps half a million years ago. The earliest mention of possible beads of the Lower Palaeolithic relates to the first Palaeolithic tools ever reported, from the very type-site of the Acheulian (Boucher de Perthes 1846). Prestwich (1859: 52), who recognized the authenticity of the St Acheul stone tools Jacques Boucher de Perthes had been collecting for many years, noted that the holes in some of the *Porosphaera globularis* beads he himself collected at French sites had been artificially enlarged. Similarly, many of the 200 Acheulian beads Smith (1894: 272–276) discovered at Bedford, England, showed artificial enlargement of the natural orifice. These, too, were of *Porosphaera globularis* fossil casts, but Smith was not aware of the earlier French finds. His opinion that the globular fossils had been used as beads was confirmed by Keeley (1980: 164) who examined some of the Bedford specimens. However, these important finds remained largely ignored until Bednarik, interested in resolving the issue of the earliest beads, conducted a detailed microscopic study of 325 *Porosphaera globularis* specimens held in the Pitt Rivers Museum at Oxford University (Bednarik 2005). They had all been collected before the early twentieth century, most in England, some in France. In focusing on the best-provenanced part of the collection, the Acheulian finds from the Biddenham quarry at Bedford, he found that many specimens bore distinctive artificial flaking around the narrow end of the natural central tunnel. Moreover, many were observed to bear distinctive wear facets around both tunnel openings, which leaves no doubt about their use as beads. They must have been permanently arranged with their tunnels in alignment to acquire this wear – in other words, they must have been on a string and worn in that way for considerable periods, often for years (Fig. 1).

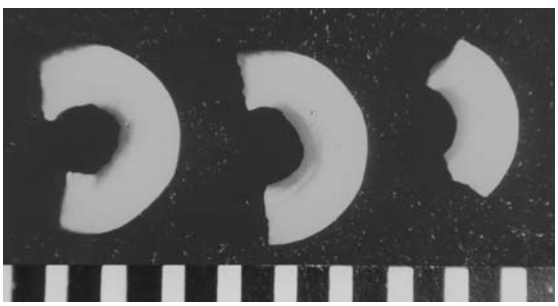
Circular, disc-like fossil casts have also been found at Acheulian sites, such as the crinoid columnar segments (*Millericrinus* sp.) from Gesher Benot Ya'aqov, Israel (Goren-Inbar et al. 1991), and in France columnar crinoid segments from a site on the Loire and from Soissons, near Aisne, Picardie (Bednarik 2005). Several disc beads made from ostrich eggshell have been excavated from substantial Acheulian layers in Libya (Bednarik 1997). They are from the El Greifa site complex at Wadi el Adjal, near Ubari. The site is located on what was a peninsula of the huge Fezzan Lake in the Pleistocene, which then occupied a large part of southwestern Libya. The U/Th isotopes of the calcareous sediments dated the ostrich eggshell beads from the Late Acheulian of El Greifa site E as being in the order of 200,000-years old. The near-perfect rounded circumference and central perforation of these beads demonstrate that hominins of the Acheulian possessed the technology of working this fragile medium with confidence and skill. These perfectly

Beads. Fig. 1 Some of the Acheulian stone beads from Bedford, England (photo by author).

made artefacts also imply the existence of the social structures necessary to provide an ideological context for the production and use of body 'decoration' (Fig. 2).

Among the earliest objects with human-made perforations we know of are the two perforated pendants from the Repolust Cave in Styria, Austria. One is a wolf incisor, very expertly drilled near its root; the second is a flaked bone point, roughly triangular and perforated near one corner (Bednarik 1997). Both objects have received little attention since they were first reported (Mottl 1951). They were excavated with a lithic industry variously described as Levalloisian, Tayacian and Clactonian, which is in fact an undifferentiated Lower Palaeolithic assemblage, clearly free of Mousterian elements. There is no reliable dating evidence available, the currently favoured age estimate of around 300,000 years is based on the accompanying faunal remains, especially the phylogeny of the bear remains (Fig. 3).

In addition to these Lower Palaeolithic beads from three continents, there are numerous perforated objects also from the Middle Palaeolithic, and many of them may have served as beads or pendants. The Micoquian has yielded an artificially perforated wolf metapodium



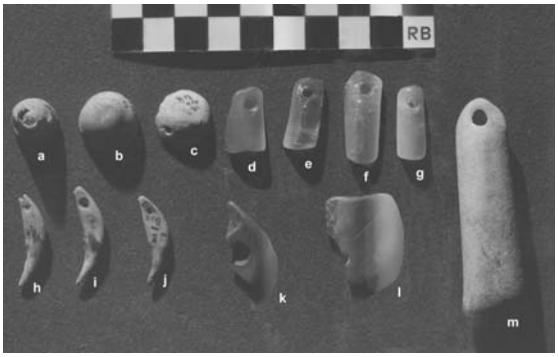
Beads. Fig. 2 The technical perfection of ostrich eggshell beads, such as the El Greifa specimens, illustrates the cultural complexity of the Acheulian period (photo by author).

Beads. Fig. 3 Perforated wolf incisor, Repolust Cave, Austria, probably of the Lower Palaeolithic (photo by author).

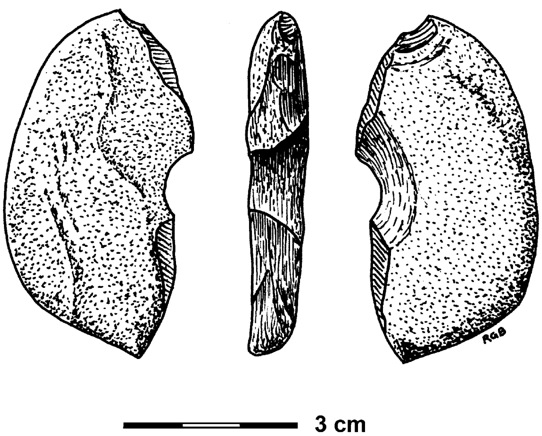
as well as a wolf vertebra from the Bocksteinschmiede, Germany (Marshack 1991; Narr 1951), while the Micoquian of Prolom 2, Crimea, produced no less than 111 perforated animal phalanges, besides four engraved palaeoart objects (Stepanchuk 1993). The Mousterian of France has yielded a partly perforated fox canine and a perforated reindeer phalange from La Quina (Marshack 1991; Martin 1907–1910), another perforated bone fragment from Pech de l'Azé (Bordes 1969), and a probable crinoid[1] fossil from Fontmaure (van der Made 2002). Two perforated canines from Bacho Kiro, Bulgaria, too, are of the Middle Palaeolithic (Marshack 1991). The Middle Stone Age of Blombos Cave, South Africa, produced 41 perforated snail shells that are about 75,000-years old. Two slightly older perforated seashells come from Border Cave, also in South Africa (Beaumont et al. 1992), as does a centrally perforated ostrich eggshell fragment from the same site, about 76,000-years old (Grün and Beaumont 2001). Other African finds of the general period are a perforated shell from Oued Djebanna, Algeria; four deliberately drilled quartzite flakes from Debenath, Nigeria; and a bone pendant from Grotte Zouhra, Morocco (McBrearty and Brooks 2000). Towards the end of this technological phase, beads and pendants became increasingly common, and materials of stone began to be drilled, first appearing in Russia and China. Thirteen such specimens from the lower occupation layer of Kostenki 17, found below a volcanic horizon thought to be about 40,000-years old (from the Campanian Ignimbrite eruption in Italy), include not only polar fox canines (Fig. 4) and gastropod shells with perforations, but also stone and fossil cast objects (Bednarik 1995). From an intermediate Middle to Upper Palaeolithic site in China, wenhua Shiyu, comes a broken stone pendant (Bednarik and Yuzhu 1991; Fig. 5). The oldest beads found in Australia, from Mandu Mandu Creek rockshelter, are about 32,000-years old and of a stone tool industry of Middle Palaeolithic technology (Morse 1993).

With the advent of the Upper Palaeolithic in Eurasia, beads became more numerous in various regions. This includes specimens made by the Neanderthals of the Châtelperronian of the French Upper Palaeolithic, among them again a crinoid fossil segment (Leroi-Gourhan 1965; Fig. 6). Just three graves at the Russian site Sungir' – with a stone tool technology that is transitional between Middle and Upper Palaeolithic implement types, the Streletsian – contained more beads than have been found in the entire Pleistocene sites of the rest of the world (Bednarik 1995). They yielded 13,113 small ivory beads and over 250 perforated canine teeth

[1] A crinoid is a type of primitive marine invertebrate animal (echinoderm) with a cup-shaped body and five feathery radiating arms.



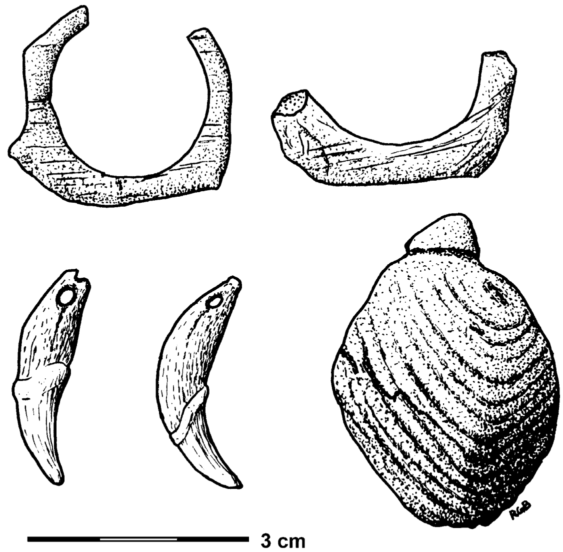
Beads. Fig. 4 Beads and pendants from Kostenki 17, Russia, >40,000-years old. (a–c) are snail shells; (d–g) are silicified, semi-translucent fossils; (h–j) are fox canines; and (k–m) are stone pendants (photo by author).



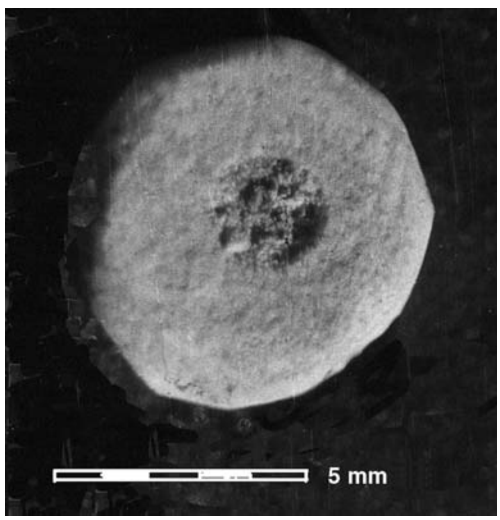
Beads. Fig. 5 Fragment of drilled stone pendant, about 28,000-years old, from wenhua Shiyu, China (drawn by author).

of the polar fox. By this time, perhaps 28,000 years ago, the art of bead making had reached an extraordinary level, in which the results of thousands of hours of labour were lavished on just three burials. In India we have only a few specimens from the entire Palaeolithic: two from Bhimbetka, south of Bhopal, and three from Patne, Maharashtra (Fig. 7). Two of the latter are not perforated, although one is centrally scored (Bednarik 1997). Other Asian regions producing ostrich eggshell beads include Siberia (Krasnyi Yar, Trans-Baykal), Inner Mongolia (Hutouliang) and the Gobi desert in northern China and Mongolia. The ostrich, now extinct in Asia, was widely distributed to the end of the Pleistocene, occurring in the Arabian Peninsula until well into historical times.

Both southern and northern Africa have yielded countless finds of worked ostrich eggshell (Baur-Röger 1987, 1988; Camps-Fabrer 1962, 1966, 1975; Cziesla 1986; Goodwin 1929; Marmier and Trecolle 1979;



Beads. Fig. 6 Two ivory ring fragments, two perforated animal canines and a fossil shell with an artificial groove for attachment, made by Neanderthals. Grotte du Renne, Arcy-sur-Cure, France (drawn by author).



Beads. Fig. 7 Ostrich eggshell bead, early Upper Palaeolithic, from Bhimbetka, Madhya Pradesh, India (photo by author).

Marshall 1976; Sandelowsky 1971; Woodhouse 1997). In the far north of Africa the Capsian, belonging already to the first half of the Holocene, yielded not only numerous figurative and non-figurative engravings on ostrich eggshell fragments, but also beads of snail shells, teeth and small stones, besides those of ostrich eggshell. The southern African sites providing such finds date from the Middle Stone Age right up to recent periods. Ostrich eggshell beads from Bushman Shelter near Ohrigstad, Transvaal, have been suggested to date from somewhere between 12,000 and

47,000 years ago. Beads of this material span a vast age spectrum, still occurring in recent periods in southern Africa. For instance, they are found in the Smithfield B, a tool complex of the subcontinent's interior regions of the fourteenth to seventeenth centuries AD. Indeed, ostrich eggshell beads are among the most enduring symbolic artefacts in human history. Much the same can be said about other forms of beads. For instance, a publication about Palestinian jewellery of the most recent ethnographic past features a photograph of a bead described as a 'fossilized sea urchin' (Helmecke 1990: Pl. 13f), depicting in fact a crinoid fossil cast that closely resembles the crinoids recovered from the Acheulian site Gesher Benot Ya'aqov in the same region, on the River Jordan (Goren-Inbar et al. 1991). Although separated by hundreds of millennia in time, the same materials were used for the same class of symbolic artefacts over an enormous time span – a poignant reminder that in terms of their humanness, our distant ancestors were a great deal closer to us than many archaeologists are willing to concede.

Ben Cao Gang Mu

Liao Yuqun

The application of herbal, mineral, animal, and man-made substances in medical therapy has been recorded in China since antiquity. These pharmaceutical compilations are called *Ben Cao*.

In the Ming dynasty, a masterpiece, *Ben Cao Gang Mu* (Compendium of Materia Medica), was published in AD 1590. In China, as well as in other parts of the world, this work is the best known and most respected description of traditional pharmaceutics. The value of this enormous achievement, written by one person, goes far beyond the scope of a pharmaceutical-medical drug work. In fact, it constitutes an extensive encyclopedia of knowledge concerning nature and the technology required for the medicinal use of nature.

The compilation of *Ben Cao Gang Mu* was based on the *Zheng Lei Ben Cao* (Classified Materia Medica, compiled at the end of the eleventh century AD). Li Shizhen, the author, took from it 1,479 drugs. He supplemented these with 39 drugs that had been included in the drug compendia of the Jin Yuan period, as well as with 374 drugs that he himself described for the first time, so that the *Ben Cao Gang Mu* contained a total of 1,892 drugs. This number is confirmed by the table of contents; the actual number should be 1,898. To continue the statistics: the number of drug illustrations is 1,160 and that of the recorded prescriptions is 1,196, of which Li Shizhen collected or newly compiled 161 himself.

The entire work was divided into two chapters of illustrations and another 52 chapters containing the texts. The first four text chapters are of a general nature; chapters five through 52 contain the monographs. The total number of drugs was divided into 16 groups, and then 60 subgroups. Thus, for example, the group of herbs was divided into the subgroups of mountain herbs, aromatic herbs, swamp herbs, poisonous herbs, convolvulous herbs, water herbs, stone herbs, moss and lichen herbs, and finally, various herbs.

For each drug the following ten items were discussed. As they were used only when the information was necessary, not all are contained in each monograph:

1. Information concerning a previously false classification of the drug
2. Information on secondary names of the drug, including the sources of these names
3. Collected explanations
4. The pharmaceutical-technological preparation of the drug
5. Explanation of doubtful points
6. Correction of mistakes
7. Information on the thermo-influence and taste of the drug
8. Enumeration of the main indications of the drug
9. Explanations concerning the effects of the drug
10. Enumeration of prescriptions in which the drug is used

As for the author, Li Shizhen was born into a medical practitioner's family. When he was unable to pass the official career exams after three attempts, he was determined to devote himself to the study of medicine. Through 30 years' clinical practice and learning from many experts, he, after innumerable hardships, completed the manuscript in 1578, but the first edition was not finished until after his death.

Bhāskara I

Agathe Keller

Bhāskara I was a 7th century astronomer, probably from the region that is between the border of modern day Mahārashtra, Gujarat, and Madhya Pradesh in India.

He wrote two treatises in the line of Āryabhaṭa I's astronomy, the *Mahābhāskarīya* (Shukla 1960) and the *Laghubhāskarīya* (Shukla 1963). Bhāskara did not just restate in an explicit way Āryabhaṭa I's astronomy; he also provided explanations and interpretations of this astronomer's reasoning. Bhāskara I is also the author of a commentary on the *Āryabhaṭīya* (see the entry on Āryabhaṭa). This is the oldest known Sanskrit commentary on this treatise. It is also the oldest known commentary for the whole mathematical and astronomical tradition in Sanskrit. The commentary is called the *Āryabhaṭīyabhāṣya* (Shukla 1976; Keller 2006). Bhāskara I himself dates the writing of this text to 628 AD. He is thus a contemporary of Brahmagupta.

This commentary, not being written in compact *sūtra* verses, can help us reconstruct what astronomy and mathematics were for a 7th century astronomer. It gives us precious insights into how mathematical and astronomical concepts were derived and discussed. Bhāskara, for instance, discusses the relation of mathematics to astronomy, giving several definitions of mathematics in the opening part of his commentary. His idea of *gaṇita* (computation, mathematics) seems to be quite malleable and open. Indeed, if the discipline called *gaṇita* is understood as a set of procedures, general (*samānya*) or specified (*viśeṣa*), then it encompasses astronomy (*jyotiṣa*). But it can also be seen as a set of specialized subjects. In this case, it is quite separate from astronomy. Bhāskara provides us with different proposals as to how one can classify the subjects related to mathematics. He thus states for the first time the classification of mathematics into eight *vyavahāra*s, which were used after him in arithmetical texts (see the entry on arithmetic in India). He also alludes to equations (*bija*) as a way of classifying mathematical subjects, an idea that had a certain posterity in the algebraic tradition in India (see the entry on algebra in India). For Bhāskara I all computations belonged both to arithmetic (*rāśigaṇita*) and to geometry (*kṣetragaṇita*). Thus series (*średdhi*) are seen as both sums of numbers (belonging thus to arithmetic) and piles of objects (belonging thus to geometry).

Bhāskara's commentary also testifies to how astronomy and mathematics were practiced in those times. For instance, Bhāskara gives details on the constructions of gnomons (sundials), describing various shapes, styles and schools for this instrument. He also sometimes explains how a mathematician (*gaṇaka*) uses a working surface (probably just the bare ground or a slate) on which numbers are disposed and diagrams drawn. These were then used when solving problems, which involve moving quantities, or seeing a proof in a drawn figure (Keller 2005).

Bhāskara's commentary on the *Āryabhaṭīya* is an important landmark in understanding the beginning of sine trigonometry. His work shows us that the fundamental diagram of sine trigonometry is a bow field (*dhanuḥkṣetra*). A bow field is composed of a back (*pṛṣṭha*), a chord (*jyā*) and an arrow (*śara*). This is illustrated in Fig. 1.

By the time Bhāskara wrote his commentary, it was fairly common to consider something that can be a bit confusing at first, the half-chord of the half-arc. That is, in Fig. 2, the segment AO is the half-chord of $a/2$, and not the half-chord of a. This segment is what we call the sine of arc $a/2$, when in a circle of radius 1. In Bhāskara's mathematics, however, circles are seldom with a unit radius, and so he deals in fact with R sines, e.g., R times the sine. This segment is called *ardhajyā* (lit. half-chord), but slowly as it became a technical term in itself, the word half (*ardha*) was sometimes dropped, until the segment itself was called *jyā*. The innovation constituted by the sine over the chord becomes clear if we look at Fig. 2 again. Indeed, by using this segment, computations using the Pythagorean theorem become possible enabling one to derive lengths of segments quite easily. To explain how to derive tables of sine differences, Bhāskara prescribed the construction of a diagram, which is shown in Fig. 3 (Hayashi, Yano 1991). It can be seen as an ancestor of our trigonometric circle.

As a mathematician, Bhāskara did not restrict himself to trigonometry but provided his insights on a great range of subjects. For instance he gave a detailed version of different problems solved by a pulverizer (e.g., a method to solve Pell equations, Bag 1979), all sorts of variations on the Pythagorean theorem, reflections on the concept of quadratic irrationals (Chemla, Keller 2002 and Datta 1980), and many others (Rao 2006). As a scholar, he often staged intellectual debates and took positions on them, thus letting us have a feel for the oppositions existing between different schools of mathematicians and authors that existed at the time, something that Brahmagupta's work also testifies to.

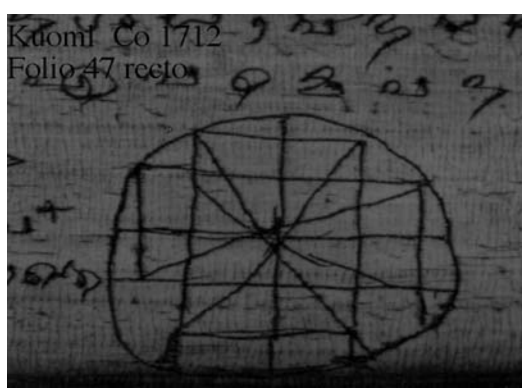
Bhāskara I. Fig. 2 The half-chord of the half-arc. Drawing by the author.



Bhāskara I. Fig. 3 Bhāskara's diagram for deriving sines.

Bhāskara's legacy has been especially felt in Kerala. If you judge the popularity of an author as being measured by the number of commentaries it has given rise to, we can note that in Kerala, his works were commented upon by Govindasvāmin (ca. 825), Śaṅkaranārāyaṇa (ca. 869) and Parameśvara (ca. 1430). After first being confused with his namesake Bhāskara II by early 19th century scholars (Datta 1930), his work was slowly brought to light in the early twentieth century (Datta and Singh 1938). Finally K. S. Shukla took the time to edit his texts and translate his treatises in the 1960s and 1970s.

Bhāskara II

R. C. Gupta

Undoubtedly, the greatest name in the history of ancient and medieval Indian astronomy and mathematics is that of Bhāskarācārya (b. AD 1114). His *Līlāvatī* is the most popular book of traditional Indian mathematics. He is usually designated as Bhāskara II in order to differentiate him from his earlier namesake who flourished in the early part of the seventh century.

According to Bhāskara's own statement towards the end of his *Golādhyāya,* he was born in Śaka AD 1036 or AD 1114. He also adds that he came from Vijjaḍaviḍa near the Sahya mountain. This place is usually identified with the modern Bijapur in Mysore. S.B. Dikshit is of the opinion that Bhāskara's original home was Pāṭaṇa (in Khandesh), where a relevant inscription was discovered by Bhau Daji in 1865. According to the inscription, Manoratha, Maheśvara, Lakṣmīdhara, and Caṇgadeva were the names of the grandfather, father, son, and grandson, respectively, of Bhāskara. Caṇgadeva was the chief astronomer in the court of the king Siṅghaṇa and had established in AD 1207 a *maṭha* (residential institution) for the study of the works of his grandfather. Bhāskara's father, Maheśvara, was also his teacher.

Bhāskara's *Līlāvatī* (The Beautiful) is a standard work of Hindu mathematics. It belongs to the class of works called *pāṭī* or *pāṭīgaṇita*; that is, elementary mathematics covering arithmetic, algebra, geometry, and mensuration. Its popularity is shown by the fact that it is still used as a textbook in the Sanskrit medium institutions throughout India. It provides the basic mathematics necessary for the study of almost all practical problems, including astronomy. The subject matter is presented through rules and examples in the form of about 270 verses which can be easily remembered. There is a story that the author named the work to console his daughter Līlāvatī, who could not be married due to some unfortunate circumstances; but the truth of the story cannot be ascertained. Bhāskara addressed the problems to a charming female Līlāvatī, who, according to some scholars was his wife (and not his daughter).

The great popularity of *Līlāvatī* is illustrated by the large number of commentaries written on it since it was composed about AD 1150. Some of the Sanskrit commentators were: Parameśvara (about 1430), Ganeśa (1545), Munīśvara (about 1635), and Rāmakṛṣṇa (1687). Only a few of these have been published. Gaḍeśa's gives a good exposition of the text with a demonstration of the rules. However, the best traditional commentary is the *Kriyākramakarī* (ca. 1534), which is a joint work of Śaṅkara Vāriyar and Mahiṣamaṅgala Nārāyaṇa (who completed it after the demise of Śaṅkara).

There are a number of commentaries and versions in regional Indian languages. Quite a few modern scholars have edited, commented on, and translated *Līlāvatī*. At least three Persian translations are known, the earliest being by Abū al-Fayḍ Fayḍī (AD 1587). The English translation by Colebrooke (1817) was based on the original Sanskrit text and commentaries.

Bhāskara's *Bījagaṇita* (Algebra) is a standard treatise on Hindu algebra. It served as a textbook for Sanskrit medium courses in higher mathematics. In it the author included an exposition of the subject based on earlier works. Among the sources named were the algebraic works of Śrīdhara and Padmanābha. Besides operations with various types of numbers (positive, negative, zero, and surds), it deals with algebraic, simultaneous, and indeterminate equations. There is a separate chapter on the Indian cyclic method called *cakravāla*. He attributes the method to earlier teachers but does not specify any name. Due to the difficult nature of some of the topics, the *Bījagaṇita* was not as popular as the *Līlāvatī.*

Bhāskara's *Siddhānta-śiromaṇi* (AD 1150) is an equally standard textbook on Hindu astronomy. It has two sections: *Grahaṇita* (Planetary Mathematics) and the *Golādhyāya* (Spherics). Often these two sections appear as independent works. There is a lucid commentary on the whole work by the author himself. It is called *Mitākṣarā* or *Vāsanābhaṣya*. Other commentators include Lakṣmīdāsa, Nṛsiṁha, Munīśvara (1638/1645), and Rāmakṛṣṇa. The 14th chapter of the *Golādhyāya* is the *Jyotpatti*, which may be regarded as a small tract on Hindu trigonometry.

Usually it is customary to regard Līlāvatī, Bījagaṇita, Grahaṇita, and the Golādhyāya as the four parts of the *Siddhānta Siromaṇi* which make it a comprehensive treatise of Bhāskarācārya's Hindu mathematical sciences. His two other works are the *Karaṇa-kutūhala* (whose epoch is 1183), a handbook of astronomy, and a commentary on Lalla's *Śiṣyadhīvṛddhida-tantra* (eighth century AD). Some other works have also been attributed to him, but his authorship of *Bījopanaya* is questionable.

Bhāskara introduced a simple concept of arithmetical infinity through what he calls a *khahara*, which is defined by a positive quantity divided by zero, e.g., 3/0. His arithmetical and algebraic works are full of recreational problems to provide interesting pedagogical examples.

Perhaps the most important part of Bhāskara's *Algebra* is his exposition of the Indian cyclic method. We now know that the method was already known to Jayadeva (eleventh century AD or earlier). A modern expert, the late Selenius, praised it by remarking that "no European performance in the whole field of algebra at a time much later than Bhāskara II, nay nearly up to our times, equaled the marvelous complexity and ingenuity of cakravāla method." Fermat proposed the equation $61x^2 + 1 = y^2$ in 1657 to Frénicle as a challenge problem. However, by applying the above method, Bhāskara had already solved the problem five centuries earlier. Bhāskara's solution (which he got just in a few lines) in its smallest integers was $x = 226{,}153{,}980$, $y = 1{,}766{,}319{,}049$.

The feat was possible not only due to the technique but also because of a well-developed symbolic notation. Colebrook remarks

> Had an earlier translation of Hindu mathematical treatises been made and given to the public, especially to the early mathematicians in Europe, the progress of mathematics would have been much more rapid, since algebraic symbolism would have reached its perfection long before the days of Descartes, Pascal, and Newton.

Another gem from Bhāskara's *Algebra* is a very short proof of the so-called Pythagorean theorem.

The geometrical portion of *Līlavatī* covers mensuration regarding triangles, quadrilaterals, circles, and spheres. A special rule gives the numerical lengths of the sides of regular polygons (from three to nine sides) in a circle of radius 60,000. The last chapter entitled *Aṅka-pāśa* is devoted to combinatorics.

Bhāskara's *Jyopatti* contains many trigonometrical novelties which appear in India first in this tract.

Although an equivalent of the differential calculus formula

$$\Delta \sin \theta = \cos \theta \, \Delta\theta$$

already appeared in Munñjla's *Laghumānasa* (AD 932), Bhāskara II gave its geometrical demonstration. He knew that when a variable attains an extremum, its differential vanishes. A crude method of infinitesimal integration is implied in his derivation of the formula for the surface of a sphere. This he gave in the *Vāsanābhāsya* on the *Golādhyāya* (Chap. III).

Bhāskara's *Siddhānta-śiromaṇi* is one of the most celebrated works of Hindu astronomy. It is a comprehensive work of *Brahma-pakṣa*. He praised Brahmagupta, who belonged to the same school, but his own astronomical work became more famous.

Although based on the works of predecessors, rather than on any fresh astronomical observations, the *Siddhānta-śiromaṇi* served as an excellent textbook. Systematic presentation of the subject matter, lucidity of style, and simple rationales of the formulas made it quite popular. It also contained some improved methods and new examples. For instance, he gave a very ingenious method of finding the altitude of the Sun in any desired direction in his *Golādhyāya* (III, 46). His professional expertise and all-round knowledge made him a truly great and revered *ācārya* (professor) of Hindu astronomy and mathematics for generations.

Bian Que

Liao Yuqun

Bian Que, one of the most famous medical men in ancient China, lived during the time of the Zhou dynasty, between 500 and 600 BCE. He was good at various subjects in medicine and skilled in diagnosis and treatment, especially in pulse-taking and acupuncture.

Sima Qian (about 145–96 BCE), a well-known historian, wrote a biography of Bian Que in his work *Shi Ji* (Historical Record). In it, he discussed Bian Que's practicing medicine, wandering from town to town and effecting miraculous cures, even bringing the dying back to life. In the end Bian Que was killed by a jealous commissioner of the Imperial Academy of Medicine. Sima Qian says: "Bian Que expounded medicine as the guiding principle of (medical) technique; the later generations followed it and could not change any more." He was regarded as the founder of traditional Chinese medicine, but according to the historical materials in the biography, Bian Que lived and flourished for hundreds of years. That is because its author confused him with another famous medical man, Qin Yueren. Probably Qin Yueren was a follower of Bian Que's teachings.

In the earliest bibliography, *Qi Lue*, written in the first century BCE, Bian Que was assumed to be the author of some medical works such as *Bian Que Nei Jing* (The Internal Classic of Bian Que) and *Bian Que Wai Jing* (The External Classic of Bian Que). Although all of them have been lost, the contents can be partly found in other extant medical works, which reflect what he contributed to traditional Chinese medicine.

Bian Que said that the blood and *qi* (vital energy) move along the channels of the body, making 50 circuits per day. Some medical historians consider this the first intimation of the circulatory system of the blood; others are more skeptical. This view was constructed on the principle of cyclicism, a very common mode of thought for the Chinese.

It was he, too, who founded the extremely complicated old Chinese system of pulse-taking, according to which a doctor was supposed to be able to diagnose an illness solely by the condition of the pulse. It was not just a question of whether the beat was strong or weak, regular or uneven. Pulses could also be distinguished as "sounding like a sickle, first exuberant then dying away"; "flowing along quietly like flying hair or feathers"; "beating deep and strong like a thrown stone"; "sounding delicate like the string of an instrument"; or "slipping along like a fish or a piece of wood on the waves". From the above selection of possible pulse beats, it is easy to see with what extraordinarily sharpened sensitivity the Chinese doctor examined his patient. Bian Que also discussed how to diagnose illness by the condition of the complexion. For example, a yellow complexion and nails were an indication of jaundice; red dealt with the heart; and white was always due to the lungs.

As for therapy, Bian Que used the traditional techniques such as acupuncture, moxibustion, and drugs to cure various diseases. We do not know who invented those treatments; however, all of them were improved owing to Bian Que's practice and teaching. Indeed, these are still followed in clinical practice and diagnosis today.

Bitumen in China

Hans Ulrich Vogel

Reports of bitumen seepages and production concentrate on four provinces: northern Shaanxi and eastern Gansu from the Han period onward, Sichuan from the Ming onward, and Xinjiang which has records of bitumen seepages during the periods of the Northern Dynasties (386–581), the Tang, and the Qing. In addition, during the Ming and Qing periods, minor production sites existed in Guangdong, Taiwan, Zhejiang, Anhui, and Liaoning (Liaodung).

The earliest record of bitumen seepages refers to northern Shaanxi that is the oil fields of Yanchang and Yongping of today. The *Hanshu*, first century AD, states that in Gaonu district (modern-day Yan'an) "there is the Wei River; it can burn." This statement is elucidated by later sources, which say that on the water of the Wei River "fat" (*fei*) is floating which can burn and which can be taken for greasing cart axles or as fuel for lamps.

Sources from the Song onward provide more details on the locations of Shaanxi petroleum seepages and production methods. In his famous account of about 1070 on using petroleum carbon for ink, Shen Gua (1031–1095) mentions the production of "stone oil" (*shiyou*) in the two prefectures Fu and Yan and of "stone juice" (*shiye*) in Yanchuan. He wrote that stone oil grew in the sand and stones of the waterfront, was mixed with spring water, and, with a view to ink manufacture, was produced inexhaustibly within the earth, in contrast to the limited supply of pine wood. In spring, local people collected it with pheasant tail brushes and put it into pots. The method of collection described by Shen Gua is similar to that described in Agricola's *De re metallica* of the mid-sixteenth century.

Song and Yuan sources report that near Yan'an bitumen was used to make so-called "stone candles" (*shizhu*). Lu You (1125–1210) says in his *Laoxuean biji* of 1190 that they are solid like stone and give a very bright light. Moreover, "they also gutter like wax [candles]. Their smoke, however, is thick and may fumigate and defile curtains and clothes. This is why people in the western [part of the empire] do not esteem them." The stone cave supplying the raw material for the production of the stone candles was, however, closed in 1270 by government order.

Perhaps the first notion of a well intentionally dug for getting bitumen can be found in the *Da Yuan da yitongzhi*, the comprehensive administrative and geographical description of the Yuan period:

> South of Yanchang district, at Yinghe, there is a stone oil well which has been cut open. Its oil can burn and also cures itches and ringworms of the six domestic animals. Annually, 110 *jin* [pounds] are handed in. Moreover, in Yongping village, 80 *li* north-west of Yanchuan district, there is another well, which annually procures 400 *jin*. They are handed over to the [Shaanxi] Route (*lu*).

As in many other cases, the output of oil seepages was low. The record also shows that the government was heavily interested in this resource, probably because of its importance for warfare.

The use of bitumen in warfare from the Yumen oil field in western Gansu is reported by an eighth-century source, stating that, in 578, the Emperor Wu of the Northern Zhou, when being besieged by the Turks at Jinquan, took this "fat" and set it afire, thus burning the enemies' assault weapons. When brought into contact with water, it burnt even more, with the result that Jinquan was saved.

With the development of deep drilling, Sichuan became an important producer of bitumen, being a by-product of the search for brine and, later, natural gas. Sixteenth-century accounts report that the sources of the fire wells of Jiading and Qianwei are all "oily." Because of its odor, locals call the stone oil "realgar oil" (*xionghuangyou*) and "sulfur oil" (*liuhuangyou*). It was thought that the sources and veins of stone fat, realgar, and sulfur were interconnected. Officials filled bamboo tubes with oil and ignited it for lighting the way. Moreover, special iron lamps were constructed which fitted the use of bitumen as fuel. An indigenous terminology developed which was based on the colors of bitumen. White bitumen was called "rice-soup oil" (*mitangyou*), green "green-bean oil" (*lüdouyou*), yellow "gardenia-nut oil" (*zhiziyou*), and black "black-lacquer oil" (*moqiyou*). Petroleum occurred at depths of 180–220 m, ca. 360 m, and 950–990 m, and there were experts who knew exactly to which depths the hoisting buckets should be sent to have them filled with petroleum exclusively.

The most important application of bitumen in crude and distilled form was certainly in the military field, where it was used for incendiary weapons. The sources do not inform us about details of the processing and distilling methods, but this may be due to the fact that these were treated as military secrets. The second most important use of bitumen was for lighting purposes, for which numerous references, particularly for regions near bitumen seepages or wells, can be found. In Sichuan, bitumen appears to have served sometimes as fuel for the evaporation of brine. Bituminous products were also used for greasing cart axles and the bearings of water power trip-hammers, manufacturing ink, sealing leather wine sacks, covering floors, and tempering iron.

Moreover, bitumen was often applied for medical, pharmaceutical, and alchemical purposes. For instance, Li Shizhen's *Bencao gangmu*, published in 1596, states that it is smeared on ulcers, ringworms, worms, and scabies, and is used for drugs which heal flesh wounds caused by iron arrows. A source of the seventh century tells us that when swallowing the bitumen of Jiuzi in Xinjiang, fallen out teeth and hair can be induced to grow again. Later sources are less sanguine about internal application and sometimes stress that bitumen is poisonous.

Although, in China, bitumen seepages and deposits were discovered and used from an early period onward, the overall economic, technical, and scientific role of bitumen remained small and did not extend much beyond the limits of the small number of production areas. The only exemption was in the military field, where testimonies of fire and flame throwers using distilled petroleum are numerous. The revolutionary impact of the Drake Well in mid-nineteenth century Pennsylvania was not due to the depth reached in deep drilling, but to the fact that beforehand a thorough scientific investigation of the properties, refining methods, and possible applications of petroleum had taken place. It was this combination of scientific investigation, technical achievement, establishment of production plants, and creation of a huge demand that was responsible for the rise of the petroleum industry in the West.

Bone Technology in Africa

ALICE M. CHOYKE

Particular cellular structures in the hard tissues of animals provide potential raw materials for manufacturing tools and ornaments. Mammalian bones and teeth provide the bulk of the raw material not only because of their form but also because they were available in the refuse derived from the consumption of meat. Egg and mollusk shell (gastropods and bivalves) were also modified. It is possible that, like ivory in later periods, they might have been sought after for the sake of the shell raw material itself. In parallel, since osseous tissues come from living animals which often had important symbolic significance to the humans exploiting them, their bones may also have had a variety of special significances in traditional tool manufacture. At the beginning, bones were used rather than modified in regular ways, but quite early on humans used a variety of techniques (cutting, scraping, abrasion, and drilling) to produce standardized objects. Until the Late Bronze Age in the second millennium BC, flaked stone tools, rough stone surfaces, and polishing materials were used to manufacture quite sophisticated objects.

As it was the cradle of humankind, it is not surprising that Africa was the scene of the earliest bone working in the world and some of the latest as well, representing almost two million years of transforming the hard tissues of animals into tools and ornaments. Furthermore, African bone technology is also distinguished by the use of two special raw materials: ivory and ostrich eggshell. As elsewhere, however, animal bone lay at the heart of technological processes while antler, a staple material in Europe, was unknown. Shells, riverine or marine, were used as ornaments almost everywhere across the continent and from remarkably early times in the Middle Stone Age to the present.

Outside Africa, until quite recently, the earliest, securely dated worked bones, small split-based projectile points, came from the Central European Szeleta culture at around 35,000 BP, representing the earliest securely dated manufactured objects in Europe, coeval apparently with the arrival of anatomically modern humans in Europe. Worked wooden artifacts from the sites of Clacton and Lehringen as well as three wooden spears found at the 400,000-year old site of Schoeningen in Germany, however, show that Middle Pleistocene European hominids used wood. *Homo erectus* craftspeople could scrape and shave wood so handily that working bone should have presented few problems. There are also examples from this early time period in Europe of large mammalian phalanges, deer antler and diaphysis shaft fragments being used as retouchers for making stone tools. There is even one example from Italy of bifacial tools flaked from an elephant long bone (d'Errico and Backwell 2001; d'Errico 2003).

Some of the chronological and spatial gaps in the distribution of these early bone objects from Europe and Africa revolve around the survival of bone on archaeological sites. Very ancient sites are rare everywhere in the world. Furthermore, and importantly, preservation of organic, osseous materials was dependent on the way those objects were used, where they were discarded, and the natural conditions prevailing in those places. Acidic soils destroy bone while root action and animal gnawing can also modify surfaces and shapes. Osseous materials of any kind, compared with stone, will begin to erode and break apart when exposed for more than a month or two in the open air. Thus, both cultural behavior with regard to tool use, location(s) of that use, and traditions of discarding worked bone after they broke compound natural conditions to affect what objects can be found by excavating archaeologists. Bone tools have not often been systematically researched, perhaps because their study also requires such an intimate knowledge of the biology of the bones they derive from.

The Taphonomy[1] of Worked Osseous Materials

What particularly makes any discussion of African bone tool technologies a challenge is the size of the continent, especially relative to the amount of published research which has gone on there. This research has been quite localized in time and space. On the one hand, lands along the great Nile, from Nubia to Egypt have been intensively studied. However, the very grandeur of Egyptian civilization has meant that researchers have concentrated on the grand places, the palaces, temples, and burial monuments and emphasized ceramics and exquisite, special finds. Predynastic settlement has only recently begun to be investigated and even there the bone finds are rarely published in detail. Much less is known of the later prehistory and history of bone technology in the enormous territory of North Africa, best known archaeologically for the great Roman and Medieval Islamic cities whose ruins dot the shores of the continent.

On the other hand, because humankind is infinitely fascinated with its beginnings a great deal of attention has been paid to early hominid sites in South Africa, the Rift Valley and Congo. Over 50 years ago, Raymond Dart, the physical anthropologist famous for his discovery of the baby Australopithecine skull from Taung in South Africa (Dart 1925), later interpreted some of the bone finds from the South African site of Makapansgat as being among the first "natural" tools used by these early hominid populations (Dart 1949, 1962). Since then there has been debate concerning whether these artifacts were modified or simply used by these early hominids or were the result of nonhuman taphonomic processes such as erosion. However, such tools were never found, or rather they were not evident to the people working on these ancient sites and so the idea was rejected. It was almost inevitable, given the relatively well-funded research on early human sites, regularly ongoing in Africa, that new finds would emerge to revive Dart's ideas and even greatly expand them.

The First Humanly Modified Bones in the World—Termite Extraction Tools

Three of the most famous early hominid sites in the world, Swartkrans (Members 1-3, ca. 1.8–1.0 Mya) Sterkfontein (Member 5, 2.0–1.7 Mya), and Drimolen (2.0–1.5 Mya) are located in South Africa. These sites contain the first evidence for the systematic modification and use of long bone shaft fragments and horncores (the boney core within bovid horn sheaths) for tools (d'Errico and Backwell 2001, 2003). These 68 tools were originally interpreted through microscopic analysis as tools for digging up tubers and working skins (Brain and Shipman 1993). The bones from these three sites were later reexamined using a multidisciplinary approach that compared wear patterns on pseudobone tools created by known natural processes with the patterns on experimentally used bone tools and with the traces of wear found on the original objects (Backwell and d'Errico 2005; d'Errico and Backwell 2003).

It was immediately clear that the wear on the artifacts matched that neither on pseudotools nor on artifacts used for digging tubers or preparing hides. Wear traces on the working ends of tools used experimentally to excavate termite mounds most closely fit the wear traces found on these archaeological objects (Backwell and d'Errico 2001). The bones used as raw material all show signs of weathering prior to use in that they have weathered breakage patterns as opposed to spiral fractures. In addition, compared to other bone fragments found at these sites the 68 modified bone objects stand out as a group since they are made from longer, broader bone fragments showing that they were intentionally selected by these early hominids. The researchers were able to find robust horncores with tips that had been reshaped by grinding.

The presence of such relatively sophisticated shaping suggests that even at this early date, modern human behavior was beginning to emerge, together with

[1] Taphonomy is the study of the conditions and processes by which organisms become fossilized or are preserved.

the ability to preplan objects according to culturally determined patterns. Although the technology used was far less complex than the completely shaped bone tools found at Middle Stone Age sites such as Blombos cave in southwestern South Africa or regularly encountered in materials from the Late Stone Age to the present day, there is still evidence that the location and direction of the facets produced on the tips represent planned behavior. The makers and users of these termite extraction tools, probably the robust australopithecine, *Paranthropus robustus*, seem to have had a clear understanding of the relationship between the shape of the tip and how the tools were going to be used (D'Errico 2003; D'Errico et al. 2003). Such complex thinking was always previously associated with anatomically modern humans. The discovery and recognition of these tools have forced scientists dealing with human evolution to change their ideas about what defines modern human behavior.

The earliest specimens of anatomically modern *Homo sapiens* come conclusively from Africa at Omo Kibish in Ethiopia dating to 185,000 BP and Herto in Ethiopia dating to 165,000 BP. However, evidence for planned sophisticated tool making, especially complex techniques for modifying osseous materials for tools and ornaments or even symbolic expression, only appears, at the earliest, 50,000 years later. Students of the development of modern cognitive thought divide into two schools on this issue. One school, led by the scholar Richard Klein (2002), proposes a revolution in mental capabilities beginning around 40,000 years ago in Europe and some 5,000 to 10,000 years earlier in Africa. This can be seen for example, in the presence of ostrich shell disk beads at the site of Enkapune Ya Muto in Kenya dated to 45,000–50,000 BP. A smaller but growing group of researchers lead by Brooks and Henshilwood have argued that technological complexity developed slowly in a piecemeal way along with what may be called modern human behavior (McBrearty and Brooks 2000). Proofs of this development may be found in the single-row barbed harpoons from Katanda in the Congo, which have been controversially dated to 90,000 BP (Brooks and Smith 1987), and more securely in the well-dated finds from Blombos Cave dated to 77,000 BP.

Katanda and the Harpoon in Africa

Barbed harpoons have a special place in the history of bone technology of Africa (Yellen 1998), demonstrating continuity in their basic form if not in their actual use. At Middle Stone Age Katanda, single-row barbed harpoons were found with remains of giant Nile carp. New dates seem to reconfirm that Katanda was a very early site (McBeaty and Brooks 2000). The harpoons were dated using thermoluminesence techniques, and there is still debate whether the deposits where the harpoons and fish remains lay can be accurately dated using this method. It has also been suggested that the harpoons themselves may have been washed onto this terrace from later sites. The debate will probably only be resolved if more sites from this early date are found. The manufacturing technique used to produce the Katanda harpoons (D'Errico et al. 2003) was quite different from the technique worked out for the harpoons found at the Later Stone Age lakeshore site of Ishango in Zaire. Ishango is securely dated to around 25,000 BP (Brooks and Smith 1987). The bone harpoons found there have been interpreted as signs of a fishing industry (Van Noten 1982; Brooks and Smith 1987).

It no longer seems quite so unreasonable that objects of such sophistication could have been produced so early in the history of modern *Homo sapiens*. Such single- and double-row barbed objects have also been found widely distributed across Africa on sites younger than 10,000 BP (for example, Camps 1974, Camps-Fabrer 1961, Haaland 1992; Petite-Maire et al. 1983). Although the earliest harpoons from Katanda and Ishango in Central Africa are interpreted as having been used in fishing, there is ample ethnographic evidence showing that such barbed objects can also be used for hunting land mammals, especially in bush land where the prey may not be visible. Mesolithic (Haaland 1992) midden deposits at a lacustrian site from northern Mali dating to ca. 6900 BP contained 200 beautifully carved single- and double-row harpoons as well as fish hooks, long pins and a carved crocodile bone (Petite-Maire et al. 1983).

Single-row harpoons were found at the Sudanese site of Esh Shaheinab in the Nile Valley as well as another late single-sided harpoon made from elephant ivory (Choyke 1990) from the Middle Bronze Age site of Kerma (ca. 3500 BP), the capital of the Nubian Kingdom of Kush located on the Upper Nile in Sudan. Other, single-row barbed harpoons were discovered at two pre-Iron Age settlements (ca. 3000 BP) at Gajiganna on Lake Chad (Breurig et al. 1996). Later evidence, from a burial at the site of Daima I (around 2500 BP), also on the shore of Lake Chad, shows a double-row alternating barbed harpoon having been used as a weapon against humans (Connah 1981). All these complex, fine objects were produced using a variety of techniques depending on the time period and local traditions. Whether used for fish, hunting land mammals or as weapons in human conflict all such objects required a disproportionate amount of time to produce, beyond what would have been practically necessary. Thus, their form has other social implications related to display and identity within and between groups of people.

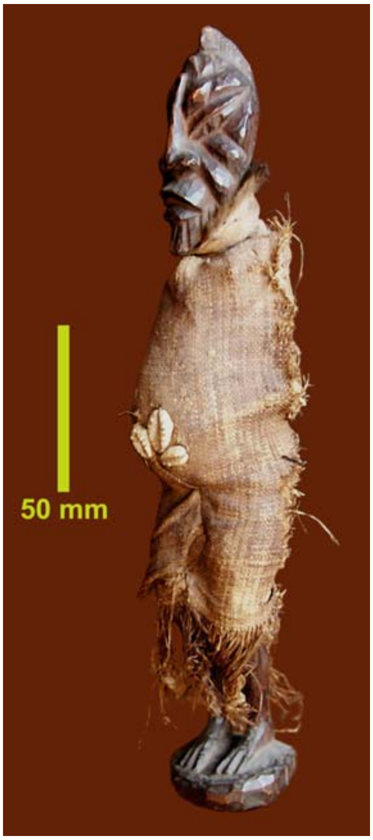
Ornamentation and Symbolic Reasoning

The well-published Middle Stone Age cave shelter of Blombos overlooking the Indian Ocean is securely dated by thermoluminesence to ca. 77,000 BP. It is notable for the 40 standardized bone tools found there including the three finely crafted spearheads and three projectile points. These points were formed by scraping and then polished to give them "added value" possibly in exchanges designed to facilitate relationships between neighboring groups of people. Other bone points at the same site were used in leather working (Hensilwood et al. 2003; D'Errico 2003:192). However, the site is also remarkable for a ruminant mandible fragment with 11 incisions grooved on it with a flint point (D'Errico et al. 2001). Together with pieces of ochre that were ground flat and incised with patterns this represents evidence of symbolic thinking.

Even more sophisticated symbolic thinking is evidenced by the much later incised long bone handle or rod dated to ca. 25,000 from Ishango Cave in Zaire. These repetitive regular groups of notches have been interpreted as representing some kind of mathematical thought (D'Errico 2003) or as a record of regular events, perhaps associated with female cycles such as menstruation (Brooks and Smith 1987). This question will probably never really be resolved.

Blombos cave excavations also revealed 19 tiny bivalve shells of *Nassurius kraussianus*, which had been artificially drilled, as evidenced by wear facets around the edges of the holes (D'Errico 2005). Engraved ostrich shell found at the site of Diepkopf on South Africa's Western Cape dates to 60,000 BP while ostrich shell beads dated to 70,000 BP came to light at Loiyangalani in Tanzania. Again, it has been argued that such sophisticated objects were designed not only for personal adornment but also for exchange, a social lubricant for acquiring social partners (Yellen and Brooks 1995, D'Errico 2003). Fish vertebrae drilled to be made into beads have been reported from Mesolithic sites in Central Sudan (Haaland 1992).

Beads made of bone and mollusk and bivalves and, in particular, ostrich shell, continue to be made even today. (Figs. 1 and 2) everywhere on the continent (Vialou and Vialou 1981; Breurig et al. 1996; Camps 1974; Camps-Fabrer 1966; Connah 1981; Choyke 1990; Van Noten 1982, Petit-Maire et al. 1983). Ostrich shell beads and engraved shells appear regularly on Neolithic sites across North Africa. Cowrie shells, often with their dorsal sides cut off so they lay flat on clothing or on the neck, were certainly used in North Africa by the Neolithic period. Since their form resembles the human vulva it is usually suggested that these shell beads are connected with fertility. In ancient Egypt, there are depictions of women wearing cowrie shells. As in many other places around the world, they



Bone Technology in Africa. Fig. 1

are often imitated in other raw materials like gold, bronze, and bone. All these kinds of bone and shell beads represent a technological tradition of fantastic antiquity which seems to grow sharply in complexity and become widespread about 6000–7000 years ago, in North Africa at least, with a variety of incised bones, decorative pins, and a variety of ornamental shapes produced in bone and shell. The Neolithic period in Africa also saw the advent of special tools and ornaments made from human teeth, long bones, and even crania—surely all with special, socially deeply embedded symbolic significance (Camps-Fabrer 1966).

The Use of Ivory

Although drilled and suspended animals' teeth, and in particular canine teeth, are found around the world, the earliest use of ivory still seems to have been at Olduvai Gorge in Tanzania, as reported by Mary Leakey in the Olduvai volume. This material has not been studied as it is difficult to differentiate true and pseudotools made on teeth, but Mary Leakey described them as tools. However, with the extinction of mammoths, African elephant and hippopotamus ivory use became restricted

Bone Technology in Africa. Fig. 2

Bone Technology in Africa. Fig. 3

to Africa and the Near East, certainly from the fifth millennium onwards, only reappearing in Celtic continental Europe at the end of the Iron Age and with the coming of the Romans.

In Africa, ivory was traded from Central Africa to the Nile Valley to make prestige goods and beautiful ornaments at least from the predynastic Middle Bronze Age (second millennium BCE). There is now evidence of this trade in the Iron Age from Botswana (Reid and Segobye 2000). Ivory as a raw material was exported out from Europe through Egypt around the Mediterranean. Roman sites in provincial Europe frequently have objects made from ivory, manufactured elsewhere in the empire.

Manufacturing of ivory seems to have become common rather late compared to other raw materials. From the Kushite site of Kerma comes a hippo ivory harpoon as well as elaborately carved inlays from elephant ivory (Choyke 1990). Dynastic Egypt sees an explosion in the use of ivory as decoration for furniture and as beads, buttons, and statuettes, perhaps related to the widespread use of metal in bone and ivory industrial manufacturing. This tradition of ivory working continued into medieval times (for example in Ghana, Stahl and Stahl 2004) and until recently in sub-Saharan Africa (Figs. 3 and 4).

Bone Tool Production in Later Prehistory

By the Neolithic period, bone working had developed into a multitude of variable industries using different combinations of techniques. Each group had their own standardized way of making tools and these were best made into pointed tools like awls and projectile points. Use was frequently made of ruminant metapodium bones, which can be grooved down the median line with a pointed flaked stone tool and then easily split. Using one of the epipheseal ends as a handle the diaphysis was sharpened through some combination of scraping with a flaked stone tool or abrasion with a rough-textured stone. This is an ancient technique, even preserved in a ritual form as a burial offering in the cemetery at Kerma where two new and identical mirror-image sheep metapodial awls from two different bones were deposited with the deceased (Choyke 1990). Awls were used in leather-working and coiled basket working. Stone tools were the tools of choice in bone working until the end of the second millennium BCE in Egypt when metal tools took over. Stone tools, however, were still important at Kasteelberg, an Iron Age site in South Africa where a combination of hammering off the epiphyseal ends, grooving, splitting, and fine grinding and polishing were used to create beautiful bone projectile points or link-shafts for arrows. These objects have parallels with objects used until recently by

Bone Technology in Africa. Fig. 4

San Bushmen (Smith and Poggenpoel 1988). Simple bone awls based on the spiral fracture of long bones were also common at Kasteelberg as elsewhere across Africa and the world. Otherwise, there are broad tendencies for bone to continue to be made into objects with beveled edges used as wedges, scrapers, and burnishers, especially for leather working and ceramic production.

It would be impossible here to go into all the different ways bone, ivory, ostrich-egg shell, and mollusk shell have been used in the last 6000 years in Africa. There is a general tendency for bone objects to be made for increasingly special purposes. Often they were made to be parts of composite objects as fittings, handles, closures, and ornaments. Hopefully, as archaeological work continues in Africa it will be possible to present a more integrated picture of the way this ancient technology developed there.
