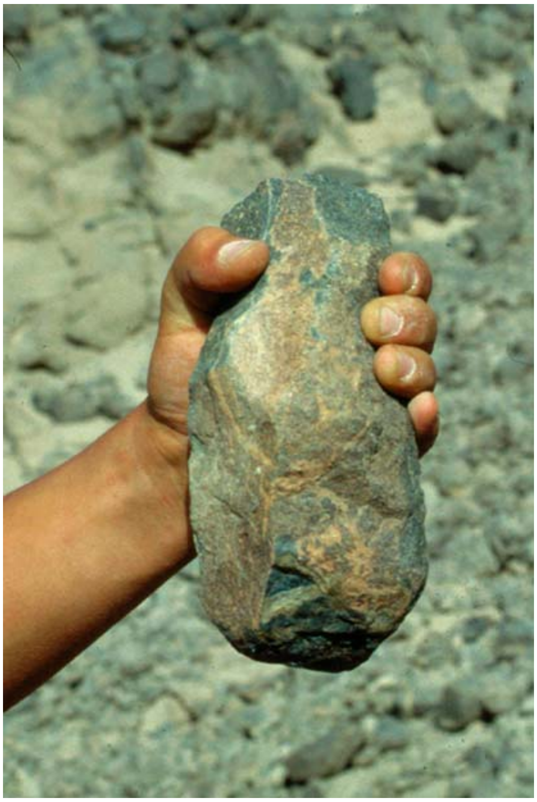
Gold mining in Ancient Egypt started in pre- and earlydynastic times with open pits and moderate underground activities (Fig. 5). During this early period, the gold-bearing quartz veins were crushed *in situ* to a fine powder fraction by huge calabash-shaped stone hammers of 6–10 kg weight, which must have been held with both hands (Fig. 6). In this way the gold slivers within the quartz were liberated for later processing. This mining method formed conspicuous smooth surfaces, both at the walls and the stopes (a step-like part of the mine where minerals are being extracted) of the underground operations.

Gold Production in Old and Middle Kingdom Times

During the Old (2700–2160 BCE) and Middle Kingdom (2119–1794 BCE) the previously described prospecting method of searching for malachite staining in the host rocks continued, but in addition hematite-enriched quartz veins (in places with barite) became important for exploration and, in the case of gold discovery, for subsequent mining targets.

Old Kingdom gold mining techniques continued with *in situ* crushing of the gold-bearing quartz vein systems, but two new basic types of stone hammers were developed: an oval stone axe of 2–5 kg weight (Fig. 7) with a chiselled notch for a forked wooden stick and a more or less cylindrical one-handed stone hammer with a ergonomically formed handle (Fig. 8). With these new mining implements, a more effective exploitation of the auriferous quartz veins was established.

During the Middle Kingdom this tool inventory continued, but additional stone mortars were introduced, allowing for the lumpy quartz ore to be crushed first to about pea-sized grains and then to a powder fraction. Again, no archaeological evidence for further gold recovery treatments during this period has been



Mining in Ancient Egypt and Nubia. Fig. 8 One-handed stone hammer from El Sid mine/Central Eastern Desert with a chiselled, ergonomically formed handle used in Old and Middle Kingdom gold mining sites.

discovered, but the remark of the nomarch (provincial ruler) Ameni, who is quoted in his Beni Hassan tomb as having said "I forced their (Nubian) chiefs to wash the gold" (Newberry 1893) gives a clear hint that hydro-metallurgical concentration processes were well established during these periods.

In Fig. 9, a few gold mining sites for both pre- and earlydynastic times and Old and Middle Kingdom periods are shown. However, quite a few of the early mining sites might have been so intensively overlaid by later operations that today no older surface remains are still visible.

Gold Production in New Kingdom Times

From the New Kingdom (1550–1070 BCE) onwards, gold mining operations concentrated more in the central Eastern Desert, predominantly south of the Qena-Safaga road, and were also spread over the eastern portion of the Red Sea hills (Fig. 10). Because of the conquest of Nubia, exploitation of the Wadi Allaqi area and sites deep into Northeast Sudan (Fig. 11) also became possible. Moreover, gold prospecting targets were significantly enlarged. Quartz vein systems free of hematite and green copper aureoles were also successfully prospected. More detailed studies of the quartz vein systems exploited during the New Kingdom indicate the profound knowledge of the ancient prospectors. They were clearly aware of the general structural control of gold-bearing veins. Furthermore, because of the systematic exploration of remote desert regions during the New Kingdom, granitic–granodioritic areas in the southern and eastern parts of the Eastern Desert became new and important prospecting and mining targets. These were extended to the Wadi Allaqi and even to Northeast Sudan.

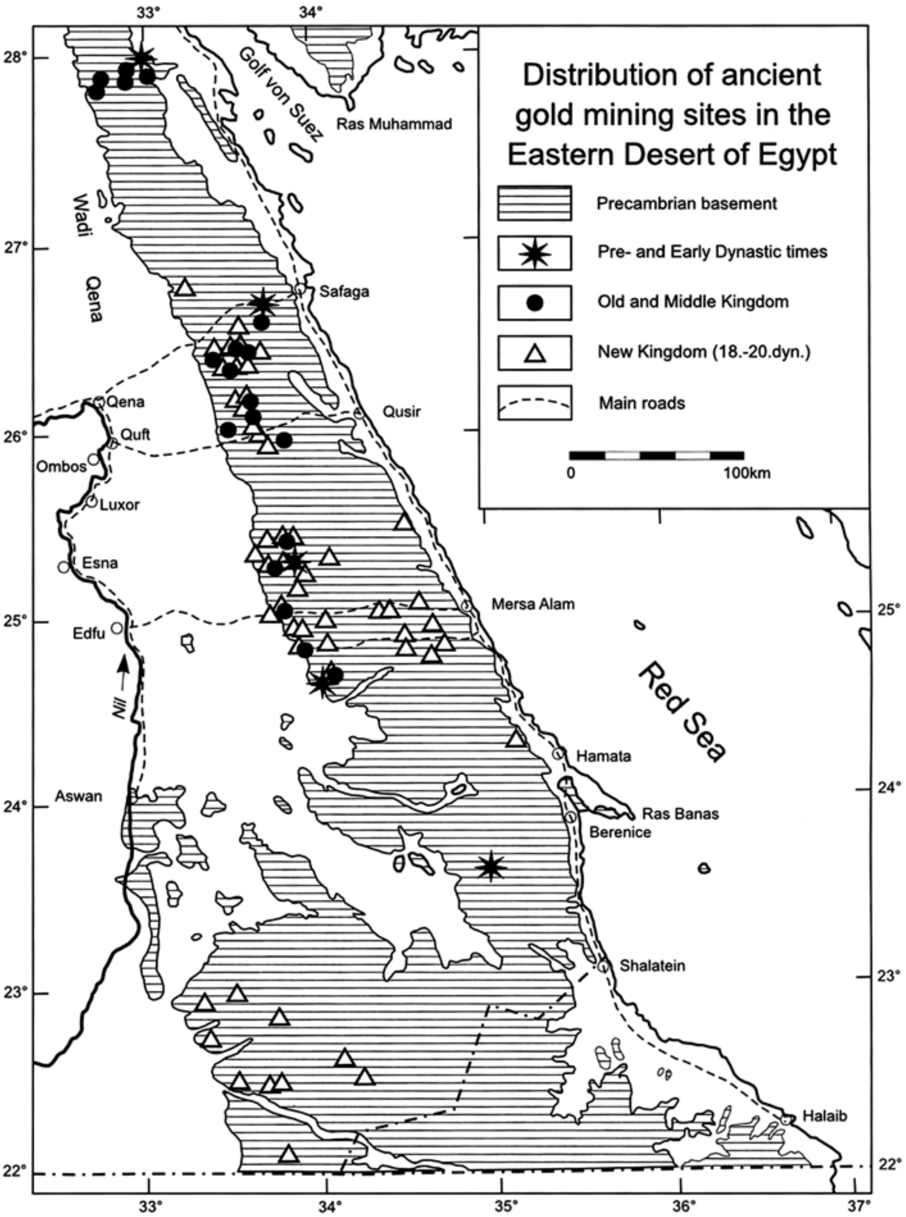
Intensive gold prospecting and processing were extended to include wadi-working operations, where gold-bearing quartz samples were systematically picked from the coarse grained fractions of the wadi sediments. At these sites, the employment of hundreds of workers was possible, in contrast to the limited number of miners in underground workings. This led to an enormous increase in gold production, documented by an increase of known gold artefacts.

A radically new milling technique also had a strong impact on gold production at the onset of the New Kingdom. Millstones up to 80 cm long and 30–50 cm wide, with a flat and oval-shaped grinding plane, and differently sized sets of millstones used with one or both hands (Fig. 12) were introduced. These stone mills are similar to the flour mills commonly used in the Nile valley since very early times (Roubet 1989). The introduction of these flour milling techniques into the gold ore processing industry indicate that only from the New Kingdom onwards were the majority of miners Egyptians from the Nile valley. This assumption is also confirmed by the predominant occurrence of typical New Kingdom pottery remains within mining sites in the Egyptian Eastern Desert, and also in Nubia.

Before milling, the initial lumpy ore was crushed down to about bean-sized particles with a double-sided stone anvil of about 30 × 30 cm and a rounded stone pestle of 0.5–2 kg weight. The separation of barren and gold-bearing quartz fragments exclusively by eye was perfected by the workers, as small and uncommon remaining mine dump heaps in the wadi grounds today contain only milky white and translucent barren quartz gravels (Fig. 13).

Separation of gold from the fine-milled quartz powder fraction was managed by washing as attested by preserved tailing dumps. At first view these tailings appear as mostly pink to reddish heaps of quartz sand, analogous to normal desert sand. Investigation with a simple hand lens, however, reveals both sharp-edged quartz grains which are artificial products as well as remaining gold concentrations of about 3–5 g/t. This rather high residual gold content unfortunately caused the destruction of many ancient gold production sites at the beginning of the twentieth century, when modern

M

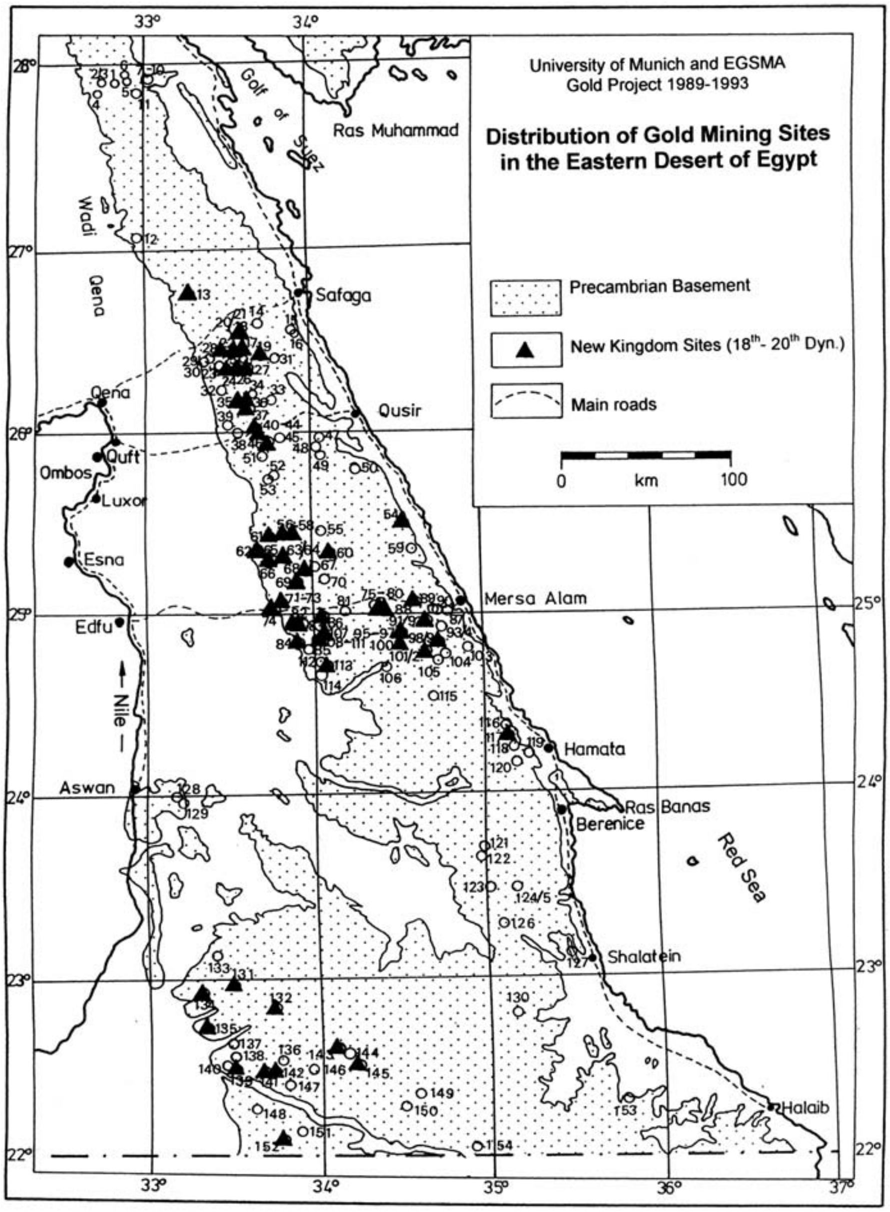


Mining in Ancient Egypt and Nubia. Fig. 9 Map of the gold mining sites in the Eastern Desert with the positions of both Pre- and Early dynastic times and Old and Middle Kingdom periods (after Klemm, et al. 2001).

gold production started with cyanide leaching of the old tailings, thus destroying most of the preserved and untouched original archaeological sites (Schweinfurth 1904).

At quite a few of the New Kingdom gold production sites, inclined gold washing tables constructed of stone fragments, consolidated by primitive clay/sand mortar and with a surface covered by a layer of the same material, can be observed. The lengths of these washing tables varies between 2.2 and 4 m, and they are 40–60 cm wide and 80–100 cm high, corresponding with an inclination angle of 15–20° (like Fig. 14, but in general much more ruined).

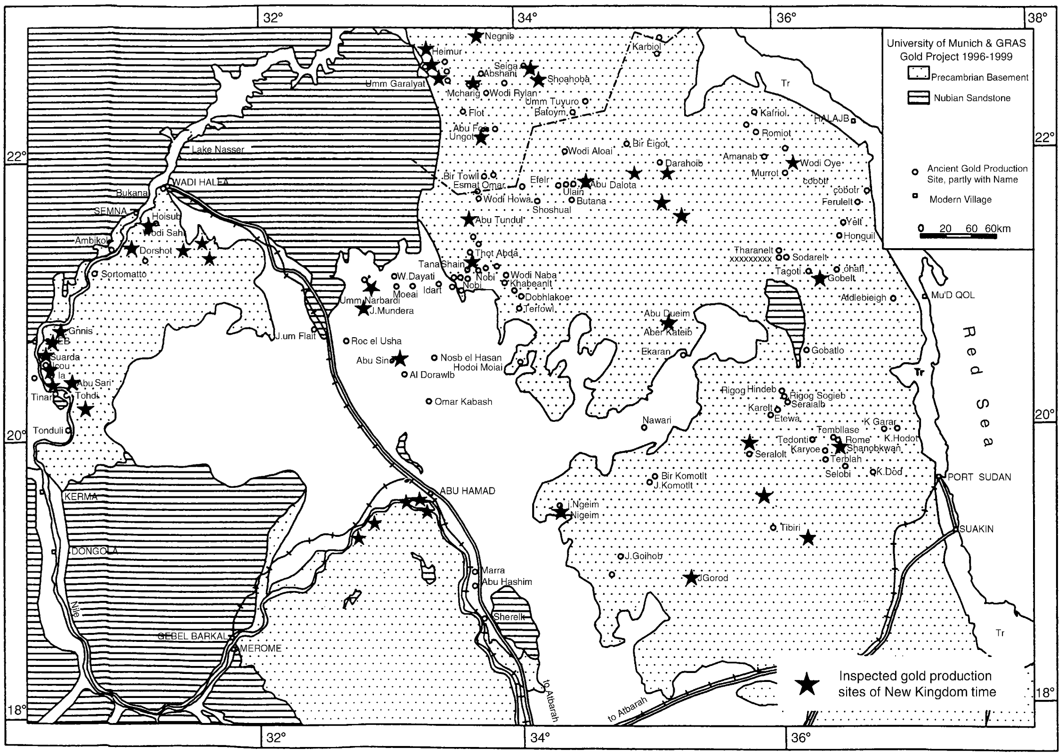
The question remains, however, as to how the planar surface of the inclined table was prepared, to separate the fine-grained gold particles liberated by the grinding process from the quartz ore. No direct archaeological evidence exists for this important step in ancient gold recovery. Because of the lack of any archaeological relics it might be assumed that the covers of these inclined tables were of organic materials. Two possibilities are likely – either a wooden grid or simply



Mining in Ancient Egypt and Nubia. Fig. 10 Distribution of the New Kingdom gold production sites in the Egyptian Eastern Desert. Note the wide activities all over the Desert regions especially within the very southernmost parts around Wadi Allaqi.

sheepskins, as both were commonly used in the more recent past for separation of gold slivers and quartz sand fractions. The sheepskin hypothesis is supported by the supposition that sheep were available at the mining sites as food, and further, both the lanolin grease and the washed fibres of the sheepskins would have trapped the sharp-edged gold particles whereas the barren quartz particles were carried off with the water suspension. The legend of the Golden Fleece, therefore, may have been of Egyptian origin and of far greater antiquity than the voyage of the Argonauts. Finally, burning the pelts containing the gold particles yields a raw gold product, but obviously no witness to this last possible step of the gold recovery procedure remains.

In the early New Kingdom, approximately between the reigns of Thutmosis I (1504–1492 BCE) and Amenophis IV (1351–1334 BCE), Nubia was conquered and incorporated into the Egyptian New Kingdom Empire. Most probably the name Nubia is taken from “nub”, the ancient Egyptian word for gold. Along the river Nile in Nubia, panning techniques most



Mining in Ancient Egypt and Nubia. Fig. 11 Distribution of the New Kingdom gold production sites in Northeast Sudan. Note the concentration of the sites along the river Nile, but also the widely scattered localities all over the vast distances of the Nubian Desert.

Mining in Ancient Egypt and Nubia. Fig. 12 New Kingdom millstones with a flat and oval-shaped grinding plane and differently sized sets of millstones used with one or both hands. These stone mills are similar to the flour mills commonly used in the Nile valley since very early times.

probably increased gold production in the New Kingdom (Vercoutter, 1959). As mentioned above, the Middle Kingdom nomarch Ameni forced the chiefs of the Nubians to perform gold washing. As alluvial river gold is still panned today in parts of Nubia, especially in the area around Shamkhiya, some 30 km west of Abu Hamed, this or a similar technique may have been known during Pharaonic times. Inscriptions on dedication lists at New Kingdom Egyptian temples like Medinet Habu, where "gold of the water" is registered (Hölscher 1957), support gold extraction from alluvial (wadi and river sediments) sources (Fig. 15).

The well-organized housing areas of the various gold-working sites of the New Kingdom are constructed mainly of 3–4 roomed houses, with dry stone walls about 30 cm wide and up to 1.5 m high and, in many

Mining in Ancient Egypt and Nubia. Fig. 14 Two inclined Arab period washing tables perpendicular to each other with a rim of light tailing from Heimur/Wadi Allaqi. This type of washing table has been archaeologically assigned to be in use from the New Kingdom on, but they might have been in use even earlier.

cases, with a front terrace (Fig. 16). The lack of any protective enclosing walls indicates that during this period the Eastern Desert of Egypt was peaceful and under the direct control of Pharaonic Egypt. In Nubia, starting from Wadi Allaqi, this peaceful situation became changed at places. At Umm Garaiyat the New Kingdom settlement is protected by a large enclosure wall, and at other sites the New Kingdom settlements are hidden in side wadis, such as at Duweishat and Abu Sari. Other New Kingdom gold production sites further to the south, like Sai Island, Shamkhiya, Tanta and Mograt Island seem to have been operated only within strongly fortified settlements.

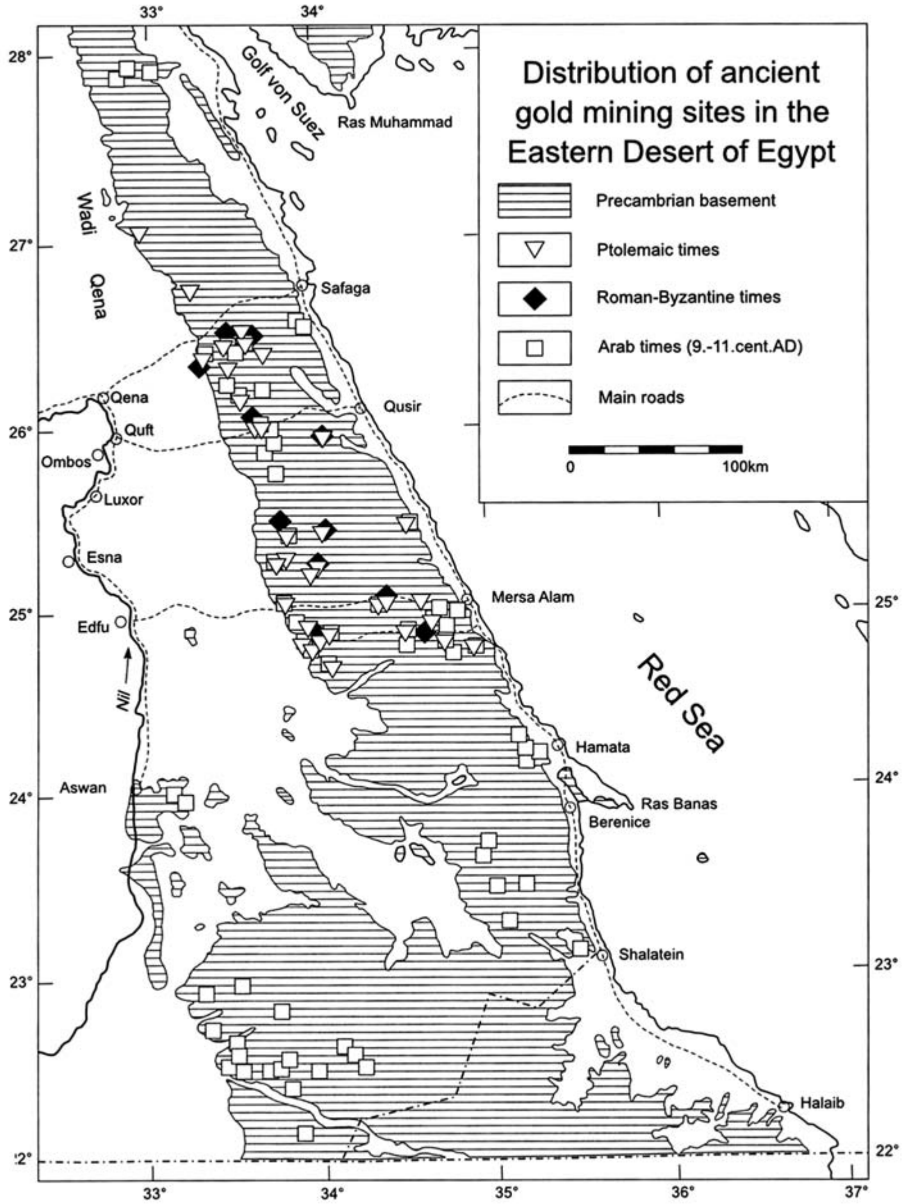
This latter assumption is based on the observation that almost all of the more southerly New Kingdom gold production sites today are only indirectly recognizable, as the typical New Kingdom stone mills and crusher stones are mainly incorporated into the walls of far later

Mining in Ancient Egypt and Nubia. Fig. 16 Remains of a many-roomed stone house from the New Kingdom settlement of Abu Sari gold mining site, Sudan.

medieval fortifications of the Christian kingdom of Makuria. The most probable interpretation is that these fortifications are nothing less than rebuilt earlier defensive installations from New Kingdom times. This assumption is supported by a site called Ras el-Gazira at the westernmost part of Mograt Island (near Abu Hamed in Sudan), where a relatively untouched New Kingdom gold production site is directly protected by an impressive stone fortification with an extended field of rock palisades towards the open eastern plain of the island. Here, as at the other sites, mostly only scanty ceramic remains are detectable as surface inventory, but a detailed archaeological excavation is urgently required.

Mining technique improved significantly in New Kingdom times, mainly with the introduction of bronze chisels, which allowed a much more selective separation of the gold-bearing quartz generations of a multiphase quartz vein from the barren parts of the host rocks. The miners selectively followed the most promising ore shoots, which resulted locally in a somewhat chaotic pattern of underground operations. Fortunately, in most mines supporting pillars ensured the safety of the ancient miners. During the New Kingdom no sophisticated ventilation of the underground operations was developed, limiting the maximum depth of operations to about 30 m, the maximum depth for maintaining a sufficient oxygen level by normal circulation for men and burning oil lamps.

In Figs. 10 and 11 the distribution of the many New Kingdom gold production sites in Egypt and NE Sudan shows the very extensive gold production operations carried out during these times. It should be emphasised that in Nubia these activities were restricted only to the rather limited period between the reign of Thutmosis III and Amenophis III. From the government of Amenophis IV onwards, throughout the Ramesside (about 1300–1100 BCE) period, no archaeological evidence for Pharaonic gold mining within the Nubian



Mining in Ancient Egypt and Nubia. Fig. 17 Distribution of Ptolemaic, Roman–Byzantine gold production sites in the Eastern Desert of Egypt. Note that only in the central parts of the Eastern Desert during Ptolemaic times did gold production activities take place. Note further the sparse Roman–Byzantine sites (after Klemm, et al. 2001).

Desert, south of Wadi Allaqi has been detected. In the Egyptian Eastern Desert, primary New Kingdom gold production started early in the 18th Dynasty and collapsed completely by the end of the Ramesside period; it seems to have been suspended throughout the entire Late Period, until early Ptolemaic times.

Gold Production in Ptolemaic (Greek) Times

It is very likely that in Ptolemaic and also in Roman times essentially no new prospecting strategies were developed and that only the ancient New Kingdom Pharaonic mining sites were reorganized and partly mined out. The mining was again limited by underground shaft termination at a final ventilation depth, approximately 30 m below surface. Only those mines which were located close to the desert roads (Murray 1925) were further exploited or re-established in Ptolemaic and Roman times (Fig. 17). Based on Agatharchides, reported by Diodor III, 12, gold mining took place in the southern part of Egypt, close to the “border of Ethiopia”. In spite of justified doubts about the authenticity of Agatharchides’ description (Woelk 1966) it is generally accepted that gold mining took place in the Wadi Allaqi district during Ptolemaic times, although the exact area is not mentioned literally. Recent investigations (Klemm, Klemm, and Murr 2001) within the Wadi Allaqi area, contrasting Castiglioni et al. (1995), did not confirm any Ptolemaic mining site, and it is most doubtful whether during that period any gold mining activity was feasible in this area, because of the aggressive desert tribes dominating the entire southern Eastern Desert and reaching deep into what is now Northeast Sudan (Updegraff 1982).

A dramatic improvement in milling technique and ore processing was introduced by the Ptolemaists. They used concave-shaped millstones of 70–80 cm length and 30– 40 cm width, with parallel incised, about 1 mm deep grooves on the milling plane. Semi-circular two-lugged millstones of 5–10 kg weight were moved by hand over the grinding plane, milling the pea-sized crushed quartz into a powder fraction and setting free the fine gold slivers (Fig. 18). With this swinging milling method the whole process was about five times more effective than earlier methods. For crushing, the old anvil and pestle system remained, but with an enlarged size of the crusher stone.

Most probably this new design of a concave-shaped milling stone is not an original Greek invention. It may have been derived from the Minoan island of Crete, where this mill type has been excavated in the Minoan cities of Gournia and Festos. Based on the Greek mining experience, Ptolemaic underground mining in Egyptian gold mines became significantly improved. Thus, in gently dipping gold quartz vein workings, dome-shaped mine ceilings allowed the reduction of supporting pillars to distances of 4–6 m, which increased the minable output.

Another important improvement was the adaptation of circular concentration washing plants from the Laurion mining district in Attica, as described in detail by Conophagos (1980). It became possible to process primary gold-bearing sulphidic ores with pyrite, chalcopyrite, galena, sphalerite and arsenopyrite, hitherto not extractable. Remains of such concentration plants (Fig. 19) are well preserved at Daghbag, Bokari and, in spite of recent destruction, also at Barramiya.

The reasons for the reduced Ptolemaic gold mining activities in only the Central Eastern Desert of Egypt are not reported in historical documents, but we know from Roman sources that large parts of the Eastern

Mining in Ancient Egypt and Nubia. Fig. 18 Concave-shaped Ptolemaic gold mill with a two-handled milling stone, together producing a swinging milling technique and thereby increasing the fineness of the quartz ore powder fraction. Gidami gold mining site, Eastern Desert, Egypt.

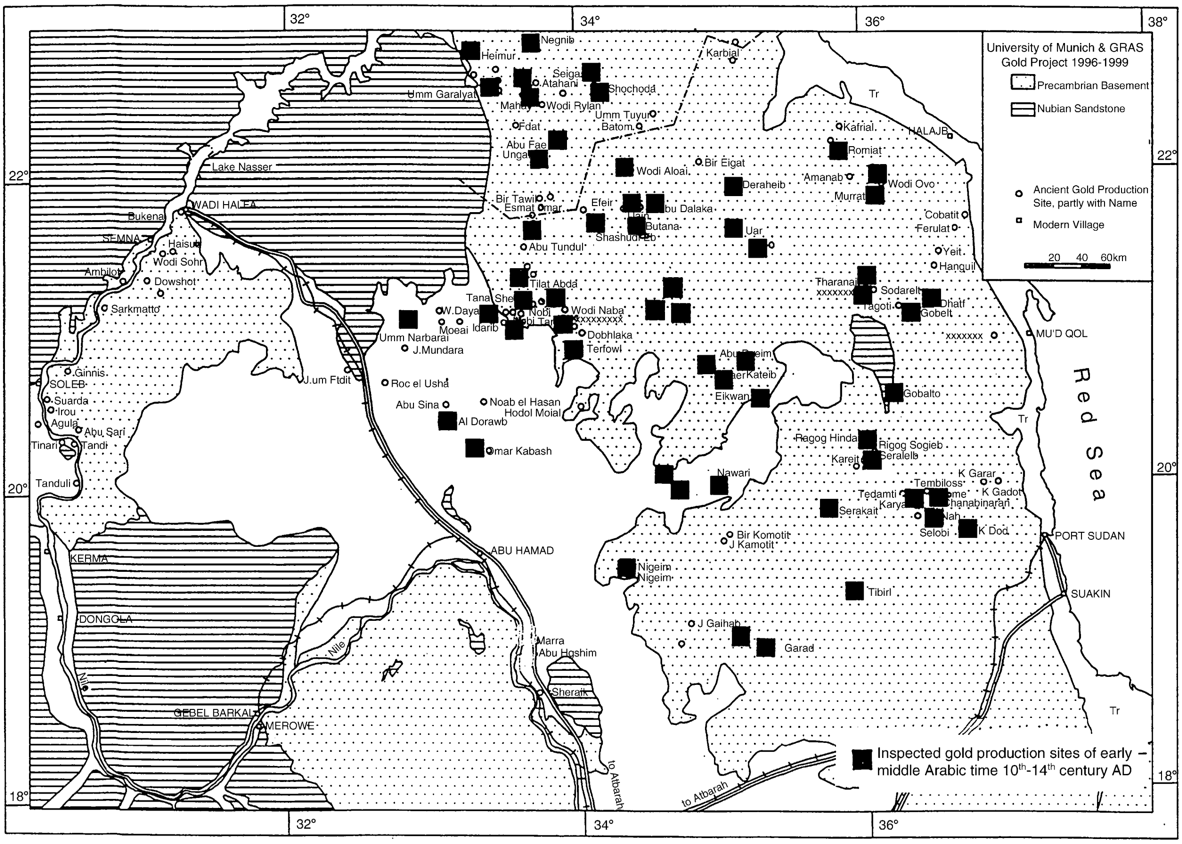
Desert and Nubia were difficult to subdue because of the aggressive attitudes of the local nomadic tribes (Sidebotham 1991), who the Romans called Blemmyes. The Bisharin tribes inhabiting this region today are regarded as their descendants, and still habitually carry dangerous swords and daggers.

Gold Production during Kushitic Times in Nubia

In Nubia quite a few New Kingdom gold mining sites became reworked later, reusing the older tools, especially the stone mills. At these sites one can observe that the typical, rather flat New Kingdom oval, trough-shaped stone mills bear a distinct deeper secondary concavity, indicating a different and later type of handling of the milling technique.

The most probable age for renewed mining of these sites was during the strong Kushitic Kingdom (about 800–400 BCE). Unfortunately, at these sites only local Nubian ceramics, hard to assign to a distinct period, have been found and more detailed excavations are needed to yield a better chronology. The relatively few sites where this reworked millstone variety, dating to the Kushitic period, was identified, might not have



Mining in Ancient Egypt and Nubia. Fig. 22 Distribution of the gold production sites in the northeastern Sudan (Nubian Desert) during early Arab times. Note that the Arab gold workings never reached the river Nile regions.

been the only gold source of this time, because washing of gold took place in Nubia at least since Middle Kingdom times.

Gold Production in Roman and Byzantine Times

During Roman and Byzantine times, gold production decreased dramatically because of continuous attacks by the desert tribes of the Blemmyes. The Roman presence in the Eastern Desert was restricted exclusively to well-protected desert roads, with fortifications spaced at about a day's walk. It became economically ineffective to protect the many gold mining sites scattered all over the desert. Only a few highly productive sites close to protected roads remained operable during Roman times. In spite of the highly evolved Roman prospecting experience, the gold mining activities in the Eastern Desert dropped nearly to zero in contrast to other regions of the Roman Empire.

The final improvement in the effectiveness of gold processing was the import of the Roman quern technology (Childe 1943), originally a Celtic invention (Cauuet 1991). This type of a round mill, of 30–45 cm in diameter, consists of a basal stone with a disc-shaped hollow in which a round convex upper turning stone was fitted that had a central axial hole and a lateral one for the handle stick (Fig. 20). The quern produced an even finer powder fraction with an improved gold recovery in about a third of the time required by the earlier method. The crushing stones are of characteristic small size (about 15 × 15 cm) and were used as both hammers and anvils. The same tools remained in use until Arab times and querns are still used today within rural areas as flourmills.

For Byzantine times, only very poor archaeological evidence for gold mining exists. Even for the settlement at Bir Umm el–Fawakhir which was inhabited during Byzantine times, and despite the assumption of Meyer and Heidorn (1998), we could find no unequivocal proof for gold ore dressing during an extended survey.

The Bedouin tribes, dominating the entire Eastern Desert of Egypt and the Nubian Desert, traditionally were not interested in mining. This is the same today (Fadl Hasan 1967), as they refuse any digging in the ground, including even simple agriculture in sufficiently watered wadi grounds.

Gold Production in Arab Times

For the early Arab times no field evidence for primary underground gold prospecting has been detected and only existing ancient mining sites became reactivated all over the entire Eastern Desert. In contrast, in Northeast Sudan away from areas close to the River Nile, extensive wadi working operations in secondary gold deposits were started at many new sites. It seems that the mining activities during this period became more concentrated in the southern parts of the Egyptian Eastern Desert including the Wadi Allaqi and especially in the Northeast Sudan. The abundant wadi works in secondary gold deposits formed part of huge fortified settlements, and inclined washing tables surrounded by tailings can be found. According to Floyer (1893), the peak of the early Arab mining activities took place from the 10th to 11th centuries AD, beginning under A. Ibn Tulun (about 990 AD) until the Fatimitic time in Egypt (Fig. 21), and until about 1350 AD in Northeast Sudan (Fig. 22). The rich and highly specialized ceramic finds at these sites indicate different ethnic populations.

We do not know why the Arab gold operations became paralyzed around 1350 AD. Most probably, the productive wadi grounds were worked out and the few underground mines reached their lowest ventilation levels. Around this time also the Christian Kingdoms in Nubia collapsed and their population converted to Islam. Whether this religio-political step has any connection to the cessation of gold production in the Nubian Desert must be left for further investigations.

Nevertheless, it might be taken into consideration that the conversion to Islam opened to the Arabs the possibility of immigration by systematic intermarriage with the local Nubian population. Their concomitant access to the fertile lands around the Nile valley offered a much better livelihood than the increasingly exhausted gold production sites of the unfavourable Nubian Desert.

Mirrors: Metal Mirrors from India

Sharada Srinivasan

Metal mirrors have a long antiquity in various parts of the Old World and Asia. Mirrors have had considerable magico-religious and aesthetic significance in parts of Asia, for example in China and India. The English word 'speculation' comes from the Roman words meaning magic for telling the future by looking in a mirror (speculum), and mirror divination is still taught in the Tibetan Buddhist tradition. The motif of the celestial maiden, deity or dancer admiring herself in a mirror is an enduring one in Indian sculpture, as exemplified by a Kushan sculpture of a Yakshi or tree nymph from Sanghol (first and second century CE).

Fine bronze mirrors with figurines on the 'tang' or the shank that fit onto their handles are found from ancient Egypt. Early flat, circular or tanged mirrors come from Harappan contexts in the northwest of the Indian subcontinent at Quetta and Harappa in Pakistan (ca. 2000 BCE) and Dholavira in Gujarat, India. These would have been made of bronze with a low-tin content (i.e. less than 10%).

Subsequently bronze mirrors of a higher tin content came into vogue in various parts of the ancient world. Low-tin bronze consists of the coppery-toned solid solution of tin in copper, known as the alpha phase, which enhances its strength. However, it has limited reflectivity, whereas cast bronze with higher amounts of tin has increasingly higher reflectivity. This is due to the formation upon cooling of higher tin bronze of an alpha plus delta eutectoid phase; i.e. a fine mixture of two solid components, the alpha phase and the delta phase which a silvery white intermetallic compound of copper and tin. However, since this delta phase component is also highly embrittling, as-cast higher tin bronze mirrors were usually leaded. Such examples of cast bronze mirrors with 20–25% tin and 5–10% lead are widely found from Han China and the Roman world from the Christian era (Meeks 1993). Bronze mirrors have been one of the most prolific and exotic of Chinese *objets d'art*. The addition of lead improves castability, but lead is an opaque material that is not soluble in copper and may have compromised the reflectivity.

At the village of Aranmula in Kerala in southern India, a unique mirror making tradition survives. Here, a cast high-tin bronze mirror of 33% tin of highly specular or reflective properties is made which is comparable to, if not better than, modern mercury glass coated mirrors (Fig. 1). This is done by optimising the presence of the brittle silvery-white delta phase of bronze while eschewing the use of lead. In an anthropological study, Mukherjee (1978) briefly mentioned the craft of making metal mirrors at Aranmula, while studies were also made by Thomas 1991, Srinivasan and Pillai et al. (1992). The author documented the making of metal mirrors from Aranmula in 1991, followed by detailed technical and micro-structural studies on equipment purchased in early 1992 by Dr. Ian Glover from mirror makers hailing from Malakkara, also in Kerala (Srinivasan and Glover 1995, 1997, 1998). These comprehensive metallurgical investigations on fragments of the mirror alloys established that uniquely, these were made of a binary alloy of copper with 33% tin. This may be described as a high-tin delta bronze due to its close match with the composition of the pure delta phase of bronze, an intermetallic compound ($Cu_{31}Sn_8$) of 32.6% tin and the rest copper. It is this composition, approximating to a pure delta phase, which yields properties ideally suited for a mirror, since it is a hard, stable and silvery compound, which can be polished with great reflectance. The entire mirror manufacturing process seems geared to optimising the presence of this delta phase, which the copper-tin phase diagram indicates forms only within a narrow composition range of bronze of 32–34% tin at non-equilibrium room temperatures (Scott 1991: 95). While this silvery metallic alloy shatters quite easily like glass, this brittleness is offset not by adding lead but by casting a very thin blank, no more than 3-mm thick, which would thus cool quickly with fewer heterogeneities. Then the

Mirrors: Metal Mirrors from India. Fig. 1 Traditional metal mirror of cast high-tin delta bronze (33% tin) made at Aranmula, Kerala.

Mirrors: Metal Mirrors from India. Fig. 2 Cast oval mirror blank of silvery delta bronze mounted on wooden polishing board.

Mirrors: Metal Mirrors from India. Fig. 3 Heating of crucible-cum-mould in a hearth fuelled by coconut husks.

blank is reinforced by mounting it with resin on a wooden mount for the polishing process (Fig. 2). A finished mirror from Aranmula consisted of 32.5% tin, approximating the composition of the pure delta compound of 32.6% tin. Thus, it is remarkable that merely by using traditional 'low-tech' methods and materials a rather sophisticated 'high-tech' metallurgical end product is achieved.

At the workshop of Janardhan Achari of Aranmula, a cleverly made jug-shaped crucible-cum-mould of clay is used for the casting process. The lower portion consists of a two-piece clay mould which is connected to the neck, consisting of a hollow cup wherein the metal pieces to be cast are placed and sealed with clay. Then this closed clay crucible-cum-mould is heated neck down on a hearth (Figs. 3 and 4), whereby the metal melts in the neck, and then the jug-shaped crucible-cum-mould is tipped over so that the molten metal flows into the narrow gap between the oval two-piece mould so that it solidifies into a thin 3 mm oval metal blank. The cast blank, which is retrieved by breaking the mould, is mounted onto a wooden handle and polished over several days with hessian and velvet

Mirrors: Metal Mirrors from India. Fig. 4 Heated inverted crucible-cum-mould being removed from hearth with the lower part containing the metal to be cast. When the jug-shaped crucible-cum-mould is tipped over the molten metal flows into a narrow hollow space for the blank created by two flat disc moulds.

Mirrors: Metal Mirrors from India. Fig. 5 Polishing of cast blank on hessian cloth using the powdered brittle mirror alloy itself for polishing.

cloth to get a mirror finish (Fig. 5). The hardness of the delta bronze alloy was found to be between 500–540 VPN, which is harder than normal steel, and thus the thin mirror blank could be polished almost entirely free of distortion. Ingeniously, the hard mirror alloy is itself used to give the mirror a final polish since it can be easily powdered, as it is highly brittle. This would usefully serve to smooth out and fill in any defects in the cast blank with the same alloy to give the best

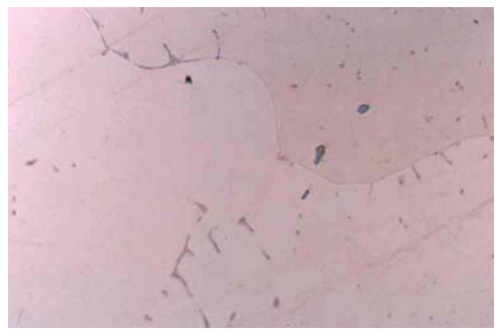
possible mirror finish. The microstructure of an as-cast mirror fragment recently made at Malakkara with 33.4% tin showed a structure consisting predominantly of a matrix of whitish delta phase interspersed with a bluish network of the alpha plus delta eutectoid (Fig. 6).

Such mirrors yield a precise point image, as they do not suffer from blurring due to refraction through glass encountered in standard glass mirrors. The colours seem to be reflected even more brilliantly. For many high-tech applications, the type of refraction that occurs through glass mirrors is unacceptable and 'front-facing mirrors' are used, such as those, which consist of a layer of softer reflective aluminium under a thin protective quartz material. However, as pointed out by T. Poston, the hard Aranmula mirror alloy has comparable reflectivity to these front-facing mirrors and does not scratch easily; unlike a layered surface, it can be repolished. Although the mirrors made these days have a blank which is no more than 7–10 cm along its oval length, in 1998 the elderly Janardhan Achari, perhaps one of the last of the meticulously traditional practitioners, showed a metal mirror with a 30-cm long blank made in his heyday. (Large modern front-facing mirrors are a major challenge to make by the deposition technology).

Fig. 7 shows an old metal mirror from Kerala with the insignia of the Travancore Royal family of Kerala, which may date to the seventeenth and eighteenth century. Metallurgical investigations on tiny fragments of the mirror undertaken by the author at the Department of Conservation and Scientific Research, Freer Gallery of Art, Smithsonian Institution in 1998 indicated that the mirror consisted of almost pure crystals of silvery white delta phase (32.6% tin bronze) (Fig. 8) with practically no eutectoid [as agreed by T. Chase, personal communication]. The absence of the eutectoid suggests that the blank may have been rapidly cooled. This indicates the high level of technological accomplishment in isolating the reflective intermetallic delta compound. This is no small feat even in modern metallurgical terms. The structure of the delta phase is that of gamma brass and contains



Mirrors: Metal Mirrors from India. Fig. 8 Microstructure of fragment of above old mirror showing that it consists almost of pure delta phase crystals with very little inter-granular bluish eutectoid phase (940 X).

icosahedral clusters; the icosahedron being the most symmetric of all objects (Srinivasan and Ranganathan in press). Metaphorically speaking, it is as if the inner beauty of the intermetallic compound mirror stares back at the onlooker gazing into it (Fig. 9). The shadowy whitish patterns in that image (Fig. 9) are in fact the crystals of the predominant delta phase.

This waning handicraft tradition of Aranmula has not only technological significance but also considerable sacred meaning. The Aranmula mirror (*valkannadi* in Tamil and Malayalam), was one of the eight auspicious articles or *ashtamangalyam* set that traditionally made up a bride's wedding trousseau from the Nair and Namburthri communities (Thurston and Rangachari 1909). A Kushan period Jain votive tablet (first and second century CE) (illustrated in Czuma 1985) depicts a mirror as part of the *ashtamangalyam* set. Fig. 10 shows a celebrated sculptural bracket figure of a *madanika* or temple dancer holding a mirror in the steatite temple of Belur, Karnataka of the Hoysala period (twelfth century), and such depictions are also found in the eleventh and twelfth centuries sandstone temples of Khajuraho. [Such mirrors uncannily resemble the thick

Mirrors: Metal Mirrors from India. Fig. 9 Srinivasan demonstrating image reflected in Aranmula mirror with whitish crystals of predominant delta phase being seen in the background.

Mirrors: Metal Mirrors from India. Fig. 10 Sculptural bracket figure from Belur, Karnataka showing *madanika* or dancer with mirror which resembles the Aranmula wooden mount for polishing mirror blanks.

wooden polishing board with a rear handle from Aranmula onto which the mirror blank is fixed with resin for polishing. Indeed, one might speculate that this could have itself been used as a finished mirror as an alternative to the current traditional practice of mounting the mirror blank into a tanged brass frame]. Metal mirrors are also worshipped in Kerala, where they are known as *kannadi bimba.* In a subsidiary shrine at a temple complex dedicated to the Goddess Bhagavati in Ernakulam, Kerala, an old large metal mirror is worshipped as a form of the goddess.

The manufacture of the Aranmula kannadi has been a zealously guarded secret of all but a handful of surviving master craftsmen known as *acharis.* Discussions with them indicate that they believe the craft has an indigenous origin. Local legends link the history of the Aranmula mirror to the Parthasarathy temple to Krishna at Aranmula, one of Kerala's five most sacred shrines. One lively story of the origins of the Aranmula metal mirror was reported in 1992 to Glover by mirror maker Janardhanan Achari (Srinivasan and Glover 1995). Some bronze craftsmen are said to have originally migrated from Tamil Nadu to make artefacts for the Parthasarathy temple. The Raja of Aranmula had threatened to evict, since they had grown fat and lazy. A widow, Parvati Ammal, came to their rescue as she dreamt that Lord Parthasarathy or Krishna had revealed the secret of making an unusual reflecting metal. In an interesting twist, not only was the king placated by the crown made of this material but he also exhorted the artisans to make mirrors for the auspicious *ashtamangalyam* wedding sets of brides-to-be from this alloy dreamt up by the widow.

As indicated before, the unleaded delta bronze mirrors of Aranmula are technologically distinct from mirrors elsewhere, such as the leaded specular bronze mirrors which were common in China. Rather, the Aranmula high-tin delta metal mirror seems to draw from longstanding Indian familiarity with making artefacts of unleaded binary high-tin bronze which had previously been little recognised. Metallurgical investigations were made by the author on vessels from Iron Age burials and megaliths such as from the Nilgiris and Adichanallur in Tamil Nadu, datable to the early to mid first millennium BCE (Srinivasan 1994; Srinivasan and Glover 1995, 1997) and one from Adichanallur by Paramasivan (1941). These were to be wrought and quenched high-tin beta bronze with around 23% tin, ranking amongst the earliest and most finely wrought and elegant examples known in the world, with some having rim thicknesses of no more than 0.2 mm and with a range of decorations from fluted or carinated (shaped like the keel or prow of a ship) shapes, or ringed and floral motifs. Due to the formation at high temperatures of a plastic beta intermetallic compound phase of a composition of 22.8% tin (and the rest copper), these specialised alloys can be hot forged considerably between 600–700°C. Thereafter, quenching in water results in the retention of the high-temperature beta phase in a rapid martensitic transformation, akin to that found in steel, which is characteristic by needle-like structures in the metallic microstructure as seen the quenched structure of an Iron age bowl from Adichanallur. This yields improved properties of golden lustre, musicality, toughness and corrosion resistance. Also, quenching prevents the formation of the low-temperature alpha plus delta eutectoid phase which due to its embrittling effect was undesirable in this case.

Vessels and cymbals of wrought and quenched high-tin beta bronze are still made in Kerala, bearing similarities in design to the megalithic vessels documented by the author in 1991 and with Glover in 1998. Mirrors were amongst the collections from the Nilgiri cairns (of about 40 vessels each in the British Museum and the Government Museum, Chennai) and Adichanallur burials from Tamil Nadu of the early to mid first millennium BCE. One such sample of unleaded 30% tin bronze was reported from the Nilgiri cairns by Breeks (1873: 63, 156). From Sonepur in eastern India an early historic period metallic specimen of 32.4% tin-bronze was reported (Biswas 1996: 187). Minor occurrences of tin have been reported in parts of India such as Hazaribagh in east-central India and in Karnataka in southern India, while the author reported old slags from co-smelting copper and tin ores from the Karnataka region (Srinivasan 1997) which might suggest that minor local tin reserves could have been exploited in southern antiquity. Indeed, Maloney (1975: 26) suggests that tin was one of the items of export from the Karnataka coast by Solomon's army along with peacocks, iron, ivory, apes, gold and silver. Two unleaded bronze samples of 22% and 26% tin were reported from the Indus Valley site of Mohenjodaro (ca. 2500 BCE) (Mackay 1938: 480–81), although without a metallographic study it is not possible to conclude if these were intentionally quenched beta bronzes. From the Bhir mound in Taxila in Pakistan, a binary high-tin bronze mirror of 25% tin was uncovered (Marshall 1951: 567–9). A vessel examined by the author from the Vidarbha megaliths of Maharashtra, carbon dated to about the eighth century BCE, was a quenched high-tin bronze with 21% tin, as was another with 24% tin from the Gandharan Grave Culture of Pakistan of the early first millennium BCE. Rich finds of high-tin beta bronze vessels and bracelets have been found from Ban Don Ta Thailand, fourth century BCE (Rajpitak and Seeley 1979; Bennett and Glover 1992). These show similarities with the Nilgiri and Adichanallur vessels in the ringed and knob-based decorations, although metallurgical comparisons indicate that the south Indian bowls were much more extensively hot forged prior to quenching. While trace element comparisons do not suggest common metal sources, it is possible that Indianised stylistic influences were common to southeast Asia together with other cultural influences such as Buddhism in the latter first millennium BCE. In the medieval Tamil text, *Arrichantira Puranam*, *kanjanam* is used to describe a shining mirror whilst this word is also used to describe cymbals (Tamil Lexicon), conveying the metallic lustre of high-tin bronzes. Thus, it is probable that the Aranmula mirror making process evolved out of longstanding metallurgical traditions prevalent in the Indian subcontinent for the use of bronzes of a high tin content. Significantly, in recent years this skilled and quaint mirror craft from Aranmula has been awarded a Geographical Indicator (GI) patent in India.

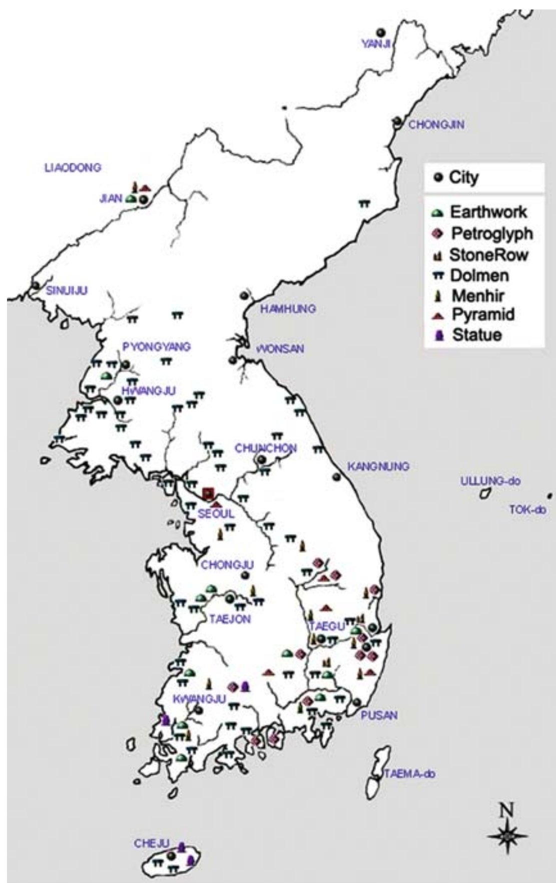
Monuments in Korea

SARAH MILLEDGE NELSON

Megaliths in Korea are either single standing stone slabs (menhirs) or arrangements of standing stones with a large capstone on top (dolmens). Korea has not only the largest number of dolmens in Asia, but the most imposing ones as well. They range in time from about 1500 BCE to the early centuries AD. Dolmens are found throughout the Korean peninsula, but are far more common in areas where rice agriculture was practiced (Fig. 1). Calling these large constructions dolmens is terminology borrowed from Europe, where similar megalithic monuments are found, especially in Western Europe. In Korea they are called *koindol*.

Dolmens are characterized by several standing stones propping up a capstone that covers and extends beyond the vertical stones. A single stone standing alone, without touching another stone, is called a menhir. Various typologies of Korean dolmens have been proposed, sometimes dividing dolmens into as many as seven different types. The simplest division, and the most obvious, is between the table type, which stands above the ground usually on four upright stone slabs with a larger capstone balanced upon them, and



Monuments in Korea. Fig. 1 This map of Korea is showing the ancient remains and the contemporary capital, main cities, rivers, islands around the korean peninsula. Ions of earthwork in the map mean mainly the enormous turf mounds (ancient king's tombs before A.D. 935).

the capstone-on-the-ground type, which covers a burial. The table type is more like the dolmens of Europe after which they are named, but it is clear that those that have only a large stone visible are a close relation. The table type is found mostly in the northern part of the Korean peninsula as well as in Liaoning Province in China, and the other capstone on the ground type is found more in the southern part of the peninsula, although there is no clear demarcation line between the two.

The stone slabs holding up the capstone of the northern type can be as much as two meters high, and the capstone usually weighs several tons. Most were probably burial chambers, although little has been left of their contents. Occasional sherds of red pottery, very rare polished stone daggers, and tubular beads, would place them in the Bronze Age. They appear to be related to cultures from the northeastern part of China that buried their dead in stone slab tombs. If so, then these are highly exaggerated slab graves. They tend to have been erected singly, on heights or in the middle of plains where they could be seen from afar. This meant that they were not difficult to locate, and very few of them escaped looting, in antiquity or later.

Southern style dolmens have a variety of types of graves underground beneath the capstone. They are hard to distinguish from erratic boulders, and therefore have not been plundered at the same rate as the northern ones. Stone cists are the most common form of grave under the ground-level megalithic stone. Some of these burial were untouched, and have yielded small red jars, polished stone daggers, and tubular bead necklaces, sometimes with a curved jade as a pendant. These curved jades are often known in the west by their Japanese named *magatama*, but in Korea they are called *gogok*. Other graves found under dolmens include large jar burials, simple pit burials, and burials topped by a "paving" of small stones. They may have similar grave goods.

In the south, dolmens tend to be found in groups, often in lines. One may be larger or higher than the others, or they may seem to be equal in size. They may be spread along a stream when related to medium sized habitation groups, but as part of larger villages or towns they are often found in one or more rows.

Some dolmens have round pits in them that are known as cup-marks. These could be formed naturally by pebbles being scoured round and round in the rain, but some of them appear to have a pattern and may be deliberately made by a human agency. They have been related in Korea to various myths which associate the birth of important people with eggs.

Menhirs are usually found singly or in pairs. They have been likened to the wooden *changsun* that used to be carved in pairs, one male and one female, leading into Korean villages until the 1970s. Menhirs are less common that dolmens. It is said that there are several fields with seven dolmens arranged in the shape of Ursa Major, or the Big Dipper. The *Chilsong*, the Seven Stars, are sacred to *mudang*, the women shamans of Korea.

Evidence that the southern style lasted into the Iron Age includes one with a cache of Chinese style daggers from the third century BCE. However, most dolmens seem to be associated with Bronze Age pottery and stone tools. It has been argued that rice agriculture brought social changes to Korea that are exemplified by the presence of dolmens. These large constructions would have required considerable labor, which would have had to be coordinated. Furthermore, they suggest permanent leaders, perhaps even chiefs, who had the ability to mobilize the labor of many people. Large villages and towns do not appear in Korea when the main crop consisted of millets; rather, they appear along with rice agriculture and larger settlements. The semi-lunar stone knife, sometimes found in dolmens and always associated with Mumun pottery and Red Burnished pottery, is argued to be a tool for harvesting rice. Nelson (1999) argues that rice agriculture appeared in Korea before dolmens, and that dolmens are related to the increasingly complex social structure that became possible with the cultivation of rice.

M

Moses Maimonides

Y. Tzvi Langermann

Moses Maimonides (1135–1204) is without a doubt the single most luminous figure in Jewish intellectual history since Talmudic times. He possessed professional expertise in most of the sciences of his day, most notably astronomy, mathematics, and medicine. Maimonides' early education in Spain, the country of his birth, seems to have stressed the exact sciences in particular. He refers in his writings to his studies with some students of Ibn Bājja. Furthermore, he edited and taught scientific texts written by two Andalusians, Jābir ibn Aflaḥ and al-Muʾtamir ibn Hūd.

In matters astronomical Maimonides' chief contributions concern problems of cosmology and the first visibility of the lunar crescent. As to the former, Maimonides devotes an entire chapter (II, 24) of his philosophical *chef d'oeuvre*, *The Guide of the Perplexed* (Arabic *Dalālat al-Ḥāʾirīn*; Hebrew *Moreh ha-Nevukhim*), to a discussion of the various ways in which the then-accepted models for planets violate certain basic principles of Aristotelian natural philosophy, namely that all heavenly motions be uniform, circular, and about a stationary center. (This problem, by the way, seems to have vexed Andalusian thinkers in particular.) Maimonides surveys the proposed solutions of Ibn Bājja and Thābit ibn Qurra, but he finds no way out of the quandary. It remains a matter of debate among scholars whether Maimonides considered the problem insoluble, since the true workings of the heavens are a matter for metaphysics and hence beyond full understanding, or whether he felt the problem had a solution, indeed, one which would yield a system not very unlike the Ptolemaic models which he criticizes.

In the closing chapters of the section of his law code (*Mishneh Torah*) devoted to the sanctification of the new moon, Maimonides develops a full, sophisticated method for computing whether or not the crescent will be visible on the eve of the thirtieth day of the lunar month. One calculates the "arc of vision," which is the sum of the difference in right ascension between the true positions of the two luminaries, and two-thirds the latitude of the moon. If this arc is greater than 14°, or the sum of the arc and the elongation (the difference in ecliptic longitude between the two luminaries) is greater than or equal to 22°, the moon will be visible. As Maimonides himself avers, the method draws upon written sources, but some of the procedures have been simplified without doing damage to their accuracy.

Maimonides forcefully repudiated astrology. Like nearly all of his contemporaries, he acknowledged a gross physical effect which the motions and luminescence of the heavenly bodies exercise upon terrestrial processes. However, he rejected the notion, central to the astrology of his day, that the stars emanate any noncorporeal force, and he passionately urged that neither individuals nor nations allow themselves to be guided by astrological forecasts.

Maimonides was both a practicing physician and a medical author. According to his account, he traveled daily to treat the sick at court, and upon his return he found his waiting-room full of patients. His medical writings include condensations of the important works of Galen, and a number of original books and monographs. The final section of his own *Aphorisms* (*Fuṣūl Mūsā*, *Pirqei Moshe*) consists of a scathing critique of Galen's views on medicine and philosophy. Maimonides' medical writings display erudition, clear and concise formulations, and insight; however, his place in the history of medicine, particularly against the background of his contemporaries, remains to be determined.

Maimonides held definite opinions concerning the history and philosophy of science. Scientific teachings must be founded upon solid logical demonstrations. True, observations are vital, but purely empirical claims – those whose authenticity rests solely upon repeated observations, but cannot be placed within any logical framework – are not scientific. This point is made forcefully in his treatise on asthma, and it is one of the underpinnings of his rejection of astrology. Moreover, Maimonides held the view that science progresses in a cumulative fashion, through the refinement of existing data and the absorption of new information; there are no revolutionary leaps. Thus he was able to have it both ways with regard to unsolved issues, e.g., the question of the structure of the heavens. He took tactical advantage of the problem, using the cosmological quandary to attack the doctrine of the eternity of the universe (which rested on astronomical arguments), yet at the same time he felt confident enough in his basic understanding of the workings of the heavens to make use of that knowledge as a steppingstone in the path to knowledge of the Creator.

The most lasting influence of Maimonides, at least as far as his Jewish readership is concerned, was not in the specific scientific knowledge that he disseminated. Rather, his momentous contribution was to elevate the study of the sciences within the context of the religious life. According to Maimonides, the ritual performances and ethical demands of the Jewish tradition have as their goal the preparation of the individual for knowledge of God (to the extent that this is humanly possible), and mastery of the sciences is an indispensable step in this process of religious fulfillment. The observant Jew who follows the lead of Maimonides will regard the study of the sciences as a primary religious obligation.

Mound Builders

Connie H. Rickenbaker

The subject of mound builders is a vast topic involving numerous groups throughout the Eastern United States. Earthen mounds, one of the visible traits of these cultures, are located from the Gulf of Mexico to the Great Lakes with concentrations in the Midwest along the Ohio and Mississippi River drainages. Numerous mound-building cultures were present across this area and through time, and the mounds served a variety of functions.

In some places conical mounds were built to inter the dead while flat-topped pyramidal mounds served as the foundations for important buildings, such as temples or chiefs' residences. Some of the better known mound sites are Cahokia, near St Louis, Missouri (cultural phases and occupation between AD 800–1200) of the Mississippian tradition (*Cahokia Mounds*), Moundville, Alabama (a dominant center from AD 1250–1500) (*Moundville*), and those associated with the Hopewell Culture (ca. 200 BCE–AD 400), centered in the Ohio Valley (*Hopewell*).

One of the most acrimonious debates of nineteenth century American archaeology concerned the origins of the mound builders of North America. The Europeans first noted the mounds in the late eighteenth century and quickly began arguments as to whether or not the Indians had constructed the structures. These continued until Cyrus Thomas' *Report of the Mound Explorations of the Bureau of Ethnology* (1894) demonstrated that Native Americans had built the mounds.

Styles and raw materials used by individuals varied between cultures based on location and time, but all of the people expressed their creativity and ingenuity through manufactured material artifacts. Indian technology included the actual mound construction, tool manufacture, pottery, and archaeoastronomy. A brief discussion of each technology follows.

Mound Construction

The types of soil and amount of material necessary for mound construction vary with each site whether they were built in prehistoric or historic time periods. The tons of material moved from the point of origin to a mound attest to the division of labor and orderliness of each culture. Individual basket loads denoting the means of transporting the raw material arc often visible at excavations. The number of mounds at a single site varies greatly from one or two to over 100 as evidenced at Cahokia. The number of mounds does not correspond with any particular time period. Watson Brake, the oldest known earthen works in North America, is composed of

M

11 mounds all connected by a human-made embankment (*Watson Brake*). One example of mound construction is the serpent mound from the Hopewellian culture which is nearly one-quarter of a mile long (*Serpent Mound*).

The people outlined the structure with small stones and lumps of clay and then dug up tons of yellow clay and then buried their markers. This mound was not a place of burial, but a deliberate religious effigy with the result of a "flawlessly modeled serpent, wriggling northward, mouth agape, trying to swallow a massive egg" (Ballantine 1993).

Tool Manufacture

People of the mound cultures made projectile points for hunting through the process known today as flintknapping. The knapper of a point used an antler hammer or stream cobble to remove flakes from the larger stone core. Smaller flakes were carefully removed as the work progressed on a single point flake. The final forms evident from some mound sites illustrate the meticulous work of highly skilled flintknappers across time and cultures. Changes in projectile point size probably reflect environmental changes that resulted in variations in prey species and probably also in hunting techniques.

For thousands of years prehistoric hunters used a spear or javelin with a point attached to kill their prey. Forms of points aid archaeologists in dating sites where some designs are similar across time, while others differentiate particular cultures. Eventually the *atlatl* or spear thrower was introduced, which increased the casting distance and power of the throws. The hunter held the *atlatl* which was shaped like a large crochet needle. The hooked end was inserted into a shallow socket in the end of the spear opposite the point and hurled with a smooth gliding motion. The *atlatl* was made from available wood while the *atlatl* point was bone or stone.

The technology of preparing meat after the kill also required specialized tools including knives, scrapers, and cutters. Although similarities in design exist across time, individual types are indicative of different cultures. The parent material tells much about a mound site and whether or not the people were involved in trading. Some prehistoric mound sites were cultural trading centers such as Poverty Point (1500 BCE) in northeastern Louisiana where numerous raw materials were used by the people for grafting material artifacts. Trade routes were known to have spanned multiple state areas as the material artifacts were made from copper, quartz, jasper, chert, and flint which were imported into the area (*Poverty Point*).

In addition to the technology for meat preparation, the people of the mound cultures prepared the animal skins for clothing and other utilitarian purposes. Construction of these items required technology for removing, preparing, and sewing the skins. A list of the tools used by people from the different mound cultures includes hammerstones, polishers, and whetstones. These tools required little if any modification of natural materials by the individual. However, once used, the alterations in shape and signs of wear indicate their uses. Other tools such as axes, drills, gouges, celts, and adzes had to be carefully shaped. Drills and gouges were used to make perforations in the skins, while celts and adzes were used for cutting.

Prehistoric technology also included the use of bone to manufacture different tools for the work around a community. The bone tools were made by breaking and grooving animal bones and then grinding the bone to shape the needed object. Fleshers, used to scrape the inside of fresh animal hides, were usually the lower leg bone of a large animal. Awls were used for perforating and sewing along with small hammers, and fish hooks were made from antlers or bone.

Pottery

The need to transport water and store food necessitated the use of containers for these purposes. Pottery making was an integral part of many of the later mound cultures. The earliest designs were simple and fewer vessels were made, but as time passed the designs and technology for pottery making resulted in works of great beauty and complexity. As with projectile points and other tools, the designs, shapes, and materials of the pottery crafted reveal specific information indicative of particular mound cultures.

In addition to everyday use, pottery was also part of ceremonial practices including burial. Whether a vessel or only a potsherd, the pottery yields valuable information about the technology of the cultures. Various tempering materials, including shell, bone, and sand, were mixed with the raw materials to strengthen it. In most mound cultures both decorated and undecorated pieces were crafted and the use of coloring slip was also part of the technology for some.

Decoration on the pottery, whether bowls, jars, or effigy pieces, was usually applied before the vessel was dried. A variety of methods were used which are significant because the individual expressions reflect change over time and culture. Decorations were often made by using the fingertip or a pointed stick or bone. Potters also used the cordwrapped technique which required wrapping a paddle or stick with a cord or woven material and then pressing it into the wet surface to create a pattern. Check-stamped decorating made use of carved bone or wood which was pressed or stamped into the object. As with the technologies of all the mound cultures, some individuals crafted pieces which are exquisite works of art illustrating the creativity and ingenuity of intelligent people from different mound cultures through centuries of time.

Archaeoastronomy

Native Americans are known for their close association with nature and the heavens. The lives of the people from the mound cultures were also intertwined with the cycle of celestial bodies as they observed eclipses and the solstices, devised calendars for ceremonies, and established planting times. They left messages of their science and wisdom in their artifacts and the earthen works which are the visible legacy of their makers.

Archaeologists have studied two research questions related to Mississippian cultures. They concern measurement and units of measurements used by the mound builders/community planners, and archaeoastronomy. Studies have been conducted at Cahokia near St Louis (list of websites provided) and in Arkansas at the Toltec Mound State Park (*Toltec Mound*) to investigate the utilization of both orientation to celestial bodies and preconstruction engineering by the mound builders.

Results from a preliminary study by Sherrod and Rollingson (1987) show that within the Arkansas community there is a predetermined spacing of mounds. The unit is termed the Toltec Module and is measured in increments divisible by 47.5 m. Alignments of the solstice, equinox, and stellar positions are evidence that the mound builders placed importance on the observation and knowledge of celestial phenomena and the mounds were positioned to mark these alignments permanently (*Alignments*).

Reconstruction planning of the community features including mound construction is evidenced by both standardized distance spacing and celestial alignment. "Interaction among many communities of the Mississippi River Valley may well have been widespread with the use of the Toltec Module a reflection of this interaction" (p. 81).

Questions go unanswered and debates continue concerning the mound builders. What do the mounds mean and why were they built? What were the mechanisms which powered the large exchange and trading systems within cultures such as Poverty Point? Also debated is the issue of size of actual populations at the large ceremonial sites. The study of archaeoastronomy and standardized measurements are still in early research stages and thus the extent of Indian technology and meaning are still open for further investigation (*Archeoastronomy*).

Recent research by Saunders et al. (1994) of four mound complexes in Louisiana which predate Poverty Point raises the question as to whether mound construction technology diffused from a single area or independently developed within several cultures. In relation to actual construction of the mounds anywhere, did their makers build one at a time or were multiple mounds under construction at the same time? See below for websites on Watson Brake.

A growing area of research which includes the mound builders is the archaeology of gender (Gero and Conkey 1991; Walde and Willows 1991). Interpretation of archaeological sites has been dominated by views in which women and children were underrepresented if present at all in much research. As the mound builders are studied from more equitable views, questions emerge on women's roles as tool makers and hunters. One theme which unifies the research is the theoretical outlook which views gender relationships as the fundamental structural component to social organization.

Peoples in other parts of the world also built mounds and earthen structures. They frequently consist of only one structure. Several examples are found in Ireland referenced as megalithic tombs and include Newgrange and Knowth (*Knowth*). Lennart S. Madsen discussed earthworks in Scandinavia in his presentation, "The Role of Earthworks in Establishing the Danish Kingdom – second to thirteenth Century AD." At the same Society for American Archaeology 2001 Conference, Maximilian O. Baldia presented "Monuments at the Crossroads: Comparative Archaeology of North American and European Monuments." Their abstracts can be accessed via the internet (*SAA Conference 2001*).

Moxibustion

Shigehisa Kuriyama

Moxibustion, also spelled moxabustion, is a traditional East Asian therapeutic technique involving the burning of tinder made from the artemisia plant. The technique has three major variants. In one, small cones of the artemisia are burned directly on the skin; in a second, some intermediary substance – commonly a thin slice of garlic or ginger, or a layer of soybean paste – separates the tinder cone from the skin; and in a third, smoldering sticks of artemisia, about a half inch in diameter, are held about an inch to three inches away from the skin. The last two methods fall under the rubric of "warming" or "traceless" moxibustion: both heat the treated sites, but unlike the first technique, they leave no scars. There is, in addition, a hybrid combination of acupuncture and moxibustion in which a clump of artemisia is burned at the protruding end of an implanted needle.

The word *moxa* comes from the Japanese term for the artemisia tinder, *mogusa*. Though the term may have made its way into Portuguese as early as the sixteenth century, printed Western language accounts of the technique began to appear only in the 1670s. For a brief while, it enjoyed a minor vogue in Europe, particularly as a treatment for the gout, but ultimately it did not take root. Still, occasional theses on moxibustion continued to be presented at European medical faculties into the nineteenth century.

The details of moxibustion's origins in China are uncertain. In the most ambitious review of the subject to date, Yamada shows that the therapy originally had magical implications: the aim of cauterization was to drive out alien, noxious spirits. He argues that by the early Han dynasty (206 BCE–AD 220), however, moxibustion had begun to assume a new, quite different identity. Gradually shedding its ties to demonic expulsion, it came to be conceived, instead, as a form of stimulus therapy. The purpose of burning now was to clear blockages in the flow of the body's own essences and rectify imbalances in the distribution of blood and vital breath (*qi*). Yamada's analysis of this change builds upon three theses (1) that the key to the transformation of moxibustion was the "discovery," in the third century BCE, of a series of *mo* – vessels thought to carry blood and vital breath throughout the body; (2) that the theory of the *mo* first arose in the context of moxibustion; and (3) that the practice of acupuncture followed, and was made possible by, the discovery of the *mo* in moxibustion.

Yamada's account may not cover the full story; some evidence suggests that the experience of bloodletting also contributed to the rise of acupuncture. But two points are indisputable. The first is that the earliest descriptions of the *mo* – those in the Mawangdui manuscripts (third century BCE) – concentrate exclusively on moxibustion, and do not mention needling. The second is that from the Han dynasty onward the histories of moxibustion and acupuncture were intimately intertwined. More often than not, acupuncture treatises were, at the same time, treatises on moxibustion. The titles of major traditional texts – from Huangfu Mi's *Zhenjiu jiayijing* (AD 282), through Wang Zhizhong's *Zhenjiu zisheng jing* (1220), to Gao Wu's *Zhenjiu jieyao* (1536) and Yang Jizhou's *Zhenjiu dacheng* (1601) – all evoke needling (*zhen*) and moxibustion (*jiu*) together in the same breath, as a compound, *zhenjiu*. The reason is clear: healing with moxa entailed burning artemisia along the same *mo*, and indeed on the same sites, needled in acupuncture.

Physicians did distinguish between the two therapies. For Yang Jizhow, in fact, the ability to discriminate between when and where to burn and not needle, and conversely, when and where to needle but not burn, marked the superior physician. Gao Wu's *Zhenjiu juying* (1537), for instance, names 45 "forbidden points" for moxibustion (sites where treatment was to be avoided or at least pursued with special caution), but for acupuncture names only 22. The two lists, moreover, have no points in common.

Between the seventh and thirteenth centuries, physicians also composed several treatises devoted to moxibustion alone. Cui Zhiti's *Guzhengbing jiufang* (640) discussed how to treat tubercular diseases with moxa and Wenren Qinian's *Beiji Jiufa* (1226) explained how to deploy moxibustion in emergencies; Zbuang Zhuo's *Gaohuang jiufa* (1128) detailed the special benefits of burning moxa on the so-called *gaohuang* points, whereas the *Mingtang jiujing* (seventh century) reviewed treatment sites more generally, identifying for each site the various ailments treatable by moxibustion.

By slight modifications in technique, moxibustion could be used either to tonify deficiencies in vital energy, or to disperse pathological excess. For example, to tonify, one simply allowed the moxa cone to burn down naturally; to disperse, the therapist blew gently upon the burning cone to make the heat more intense. Traditionally, however, the tendency was to deploy moxibustion primarily as a tonifying technique, and to favor it for treating chronic disorders.

People also turned to moxibustion to prevent illness. In his *Yaofang* (seventh century), Sun Simiao (Sun Simo) notes that officials going to the regions of Wu and Shu made sure always to keep several unhealed moxa spots on their bodies. This, they believed, protected them from a variety of epidemic diseases. More generally, it became proverbial wisdom that burning moxa regularly on special sites like the *sanli* points of the legs warded off sickness of all kinds, and promoted longevity.

Moxibustion's popularity as a prophylactic measure and as a treatment for chronic complaints drew theoretical support from the belief in its tonifying influence. But it also reflected a more basic fact: unlike needling, burning moxa did not require sophisticated technical skill. Once patients learned where to burn – whether guided by illustrated books, tradition, or doctors, then they could treat themselves, or be treated by family members. Thus, while acupuncture and moxibustion shared common historical origins and a common understanding of the body, the sociology of their practice diverged. Whereas acupuncture remained largely the preserve of specialists, moxibustion tended to become part of popular self-treatment. Professional acupuncturists in East Asia today still make use of moxibustion, but so do many patients who have never been needled.

Mummies in Egypt

Jehane Ragai, Gregg de Young

Mummification was practiced in ancient Egypt to ensure the continued existence of the deceased. At death, several spirits were believed to be released, the most important of which were the Ka, the Ba, and the Akh. A person's fate in the afterlife, in the form of these three spirits, was believed to be directly tied to the continued existence of the physical body.

The Ka, appearing at birth, resembled the human physical body in all aspects. After death, it remained in the tomb with the mummified body, acting as a protective spirit, and fed on the daily offerings presented at the tomb.

The Ba embodied the personality and individual characteristics of the person. It also appeared at birth, but after death was believed to fly off to heaven, returning regularly to visit the Ka and the body. It sometimes seems to serve as "spiritual link" between the two.

The Akh, after a silent or dormant existence during the person's life, separated from the body at death and embarked on a journey through the land of the dead, never to return. All three spiritual elements were essential for the continued existence of the individual and their continued survival depended on the existence of the human body.

Egyptians in the predynastic era, prior to 3100 BCE, buried their dead in shallow graves under the hot desert sands. This left the body prey to wild animals and desert thieves. From the first dynasty (ca. 3100–2900 BCE) on, the Egyptians built mud brick burial chambers, but these, too, proved unsatisfactory because the bodies gradually deteriorated under the action of moisture in these chambers.

By the end of the Old Kingdom (ca. 2600–2180 BCE), the Egyptians had begun to embalm their dead through desiccation by means of dry natron (a mixture of sodium carbonate and bicarbonate). The technique was later termed "mummification" from the Persian word *mummiya*, meaning bitumen or pitch. Corpses embalmed by the Egyptians took on a blackened color, and this effect was mistakenly attributed to bitumen.

By the Middle Kingdom (ca. 2150–1780 BCE), the process was perfect. After death, the body was taken to the "place of purification," where it was stripped and washed in a dilute natron solution. It was then moved to a special "embalming house" where it was placed on a large wooden board. The brain was broken into small pieces by a hooked utensil which was introduced through the nostrils and penetrated the cranial cavity by breaking through the ethmoid bone. The brain was then removed by a long delicate spoon and disposed of. The empty skull was filled with sawdust, resin, or resin-soaked linen.

An incision was then made on the left side of the abdomen and the liver, stomach and intestines removed. A puncture in the diaphragm also allowed for the removal of the lungs. The heart was left in situ as the center in which the good and evil deeds of the individual accumulated. (A light-weighted heart during the day of reckoning would ensure resurrection and an afterlife for the individual.)

The removed organs were washed with a natron solution, dried, and sealed in Canopic jars (often with a solution of natron). These jars were eventually placed in the tomb with the deceased. The empty cavities were washed with palm wine and packed with sand, straw, or sawdust mixed with resin or bags of natron. The body was then placed on a slanting board and covered with dry natron for 40 days to ensure total desiccation by osmosis (the skin acting as a semipermeable membrane).

Following the dehydration of the body came a ceremonial washing and an anointing with oil. The cranial and body cavities were repacked with linen soaked in resin, the abdominal incision was closed, linen balls were placed in the eye-sockets, and the cheeks were padded with linen. The body was then coated with molten resin and subsequently wrapped, beginning from the toes, in strips of linen arranged in intricate patterns. In some cases, the body would be adorned with jewelry, and amulets conferring special protection on the mummy would be enclosed in the linen wrappings.

The entire embalming process took 70 days, after which the ceremony of the "Opening of the Mouth" took place. A priest would symbolically open the mouth of the deceased. This would be followed by an elaborate succession of actions and prayers.

The practice of mummification, with some variations in the process of preparation and wrapping, continued in Egypt until the fourth century AD, when Christianity had become the principal religion. The practice then steadily declined.

Mummies in South America

Bernardo Arriaza, Vicki Cassman

The Atacama desert, along the west coast of Chile and Peru, is an area of extreme aridity which has provided for unique preservation of human remains and cultural materials from thousands of years ago. The incredible preservation, especially of human mummies, has furnished us with a glimpse at mortuary traditions and rites associated with the first settlers beginning at least 9,000 years ago, through to the arrival of the Spanish Conquistadors.

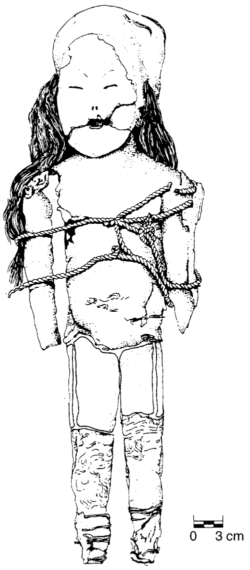
The Chinchorros fishermen, who lived from 7000 to about 1500 BCE, are of special interest because from 5000 to 1700 BCE, they practiced artificial mummification of their dead. The Chinchorro people lived in the Atacama from Ilo in Southern Peru to Antofagasta in Northern Chile, and occupied about 900 km of the Pacific coast of South America. The area surrounding the modern city of Arica, in northern Chile, was where Chinchorro artificial mortuary practices originated. From this area artificial mummification customs (or intentional interventionary preservation) spread north and south. The bodies were prepared for the journey to the afterlife in remarkable ways. For example, some bodies were completely disarticulated and then wholly reassembled and sculpted. Various styles were practiced through time, such as Black, Red, and Mud-Coated styles. All these styles have two things in common: human intervention in the preservation of the cadaver, and an extended body position for interment.

The Black Mummies were the oldest and most complex, beginning about 5000 BCE and lasting for about two millennia. To make the Black Mummies, the morticians completely cleaned and separated the deceased's bones and soft tissue. Subsequently, the skeletons were reconstructed, and the bodies rebuilt into statue-like rigid forms, using long sticks for internal reinforcement along the extremities and spine. Reed cords bound the bones and sticks together, and a light gray ash paste was applied to stuff and model the individual. The skin was often replaced, and sometimes pieces of sea lion skin were added when the person's own skin did not suffice after drying. Facial features and sexual organs were insinuated. A short wig of human hair was added to the head and secured with cords. Then the morticians painted the entire body with a black manganese paste, which was polished to a high sheen, hence the name Black Mummies.

In contrast, the Red Mummies often were made without disarticulation of the body. Instead incisions were made to remove organs. Long sharpened sticks were pushed under the skin of arms, legs, and the spine to add rigidity, and body cavities were stuffed. After suturing the incisions, the body was painted with red ocher, but the facial mask was often painted black. In a few cases the skin was replaced bandage style. A wig made of long black human hair was added to the head and secured with what looks like a red clay motorcycle helmet. This Red style appeared about 2000 BCE and lasted about 500 years (Fig. 1).

After the Red style, artificial mummification techniques were simplified. The bodies were not eviscerated; they were simply encased in a thick cement-like coating that prevented decomposition. This Mud-coated style lasted only a couple of centuries. After this period,

M



Mummies in South America. Fig. 1 Chinchorro child in the Red Mummy Style (drawing by Raul Rocha, used with permission of the author).

ca. 1700 BCE, the Chinchorro bodies were still buried in an extended position, but were preserved only through the desiccating forces of the environment; they were no longer artificially mummified.

Often the Chinchorro mummies were enshrouded in twined reed mats and buried in shallow pit graves in groups of about six bodies of various ages and both sexes. The cemeteries were located in the sandy coastal dunes beyond the reach of the tides. The few grave goods accompanying the dead were fishing lines, shellfish and cactus fishing hooks, harpoons, bone and stone tools, stone mortars, and gill nets. No individual had a substantially larger number of grave goods that would set him apart as socially above the others. The Chinchorros also received similar mummification and burial treatments regardless of age and sex. Even fetuses were mummified. Apparently everyone was treated equally, with the same mortuary treatment, as would be expected in an early egalitarian society.

Although Chinchorros were simple fisherfolk without knowledge of ceramics, agriculture, or loom weaving, their spiritual and religious life must have been highly sophisticated, as the mummies have demonstrated. The sophistication of the mortuary treatment, the repair of the mummies, and the millennial duration of their practices, all indicate that mummification was central to the social lives of Chinchorro people. It appeared they venerated the mummified bodies of their ancestors by placing them on display for an extended period before burial. Perhaps they petitioned the mummies for blessings during their daily lives. Later South American cultures like the Incas revered their desiccated ancestor mummies (natural mummification). For the Inca the dried bodies of their ancestors were considered *Huacas* or deities that had the power to provide fertility, good crops, and happiness. The Inca brought food and drink to the dead and included the mummies in their religious celebrations. For the Incas and the Chinchorros, the mummies linked the real world with the spiritual world.

The Chinchorros did not vanish after their artificial mummification disappeared about 1700 BCE. On the contrary, their descendants continued to thrive along the Pacific coast, with increased social and political complexity. However, for most areas, after 1500 BCE, the dead were buried in a flexed or seated position, and became natural mummies by the desiccating action of the desert. Post-Chinchorro cultures developed and took advantage of new technologies such as agriculture, weaving, ceramics, and metallurgy, and now the dead were furnished with paraphernalia related to these achievements. Thus, from the numerous grave goods accompanying the dead, it can be seen that post-Chinchorro people also had powerful spiritual concerns about death and the afterlife.

Munīśvara

K. V. Sarma

Munīśvara (b. 1603), son of Raṅganātha, was born into a family of reputed astronomers of several generations, who had migrated from their original home on the banks of river Godāvarī in the south to Varanasi in the north of India. Munīśvara's paternal uncle, Kṛṣṇa Daivajña, was patronized by the Mughal emperor Jehangir, who ruled from Delhi (1605–1628). Elevating references by Munīśvara to Shahjehan, who succeeded Jehangir as emperor in 1628, and casting the horoscope of the time of Shahjehan's coronation are pointers to the continued royal patronage enjoyed by Munīśvara's family. In his commentary on the *Līlāvatī,* Munīśvara states that another name of his was Viśveśvara.

Munīśvara was a prolific writer, on both mathematics and astronomy, and wrote both original works and commentaries. The *Siddhāntasārvabhauma*, written in 1646, is his major work on astronomy. In 12 chapters, of which nine chapters constituted Part I, the work dealt with the subjects of a normal textbook. In Part II, the work dealt with the armillary sphere, astronomical instruments, and astronomical queries. He also composed a commentary on the work called *Āśayaprakāśinī,* which is dated 1650. On mathematics, Munīśvara has two works: *Pāṭīsāra* and *Gaṇitaprakāśa*. He was an admirer of Bhāskara II. His commentaries on Bhāskara's *Siddhāntaśiromaṇi,* entitled *Marīcī*, and on *Līlāvatī*, entitled *Nisṛṣṭārthadūtī*, are justly famous for their exhaustiveness, lucidity, and citations from earlier authors. He also commented on the *Pratodayantra* or *Cābukayantra*, a short work on an astronomical instrument used for the ascertainment of the time of the day, by Gaṇeśa Daivajña.

Munīśvara had professional detractors whose views differed from his. One was Raṅganātha, author of the manual *Siddhāntacūḍamaṅi* (AD 1640), who, in a short work called *Bhaṅgīvibhaṅgī*, criticized Munīśvara's *Bhaṇgī* (Winding) method of computing true planets. This work was refuted by Munīśvara in his *Bhaṅgīvibhaṅ ī -khaṇḍana*. Another was Ekanātha, an astronomer of Maharashtra origin, settled in Varanasi, who seems to have passed strictures on Munīśvara's exposition of three verses on declension (*krānti*) in Bhāskara's *Siddhāntaśiromaṅi*. Munīśvara refuted Ekanātha's criticism and established his views in a short work entitled *Ekanātha-mukhabhañjana* (A Slap in the Face of Ekanātha).

Though Munīśvara accepted Islamic trigonometry as an aid to studies in astronomy, he severely contradicted the theory of precession advocated by Kamalākara, against which Raṅganātha wrote a work entitled *Loha-gola-khaṇḍana,* which Munīśvara's cousin Gadādhara refuted in his *Loha-golasamarthana* (Refutation of the Loha-gola).

Characteristics that cannot be missed in Munīśvara's writings are the lucidity, chaste language, and the elegant style in which they are couched.

Namoratunga

L. H. Robbins

Archaeoastronomy is the study of archaeological evidence documenting that ancient peoples made systematic observations of astronomical phenomena such as solstices and equinoxes (Robbins 2003, ch. 6). Most typically, archaeoastronomical evidence is reflected in the positioning and alignments of buildings, earthworks and megaliths, such as at Stonehenge in England (Robbins 2000). There, the sun rises over the heel stone on the summer solstice, or first day of summer. In most cases, archaeoastronomical sites are thought to reflect religious beliefs in which the seasons of the year were being monitored for ceremonial purposes as well as for agricultural planning. For example, at the Egyptian desert site of Nabta Playa (Malville et al. 1998: 488) have found megalithic alignments dated to before 4,800 years ago, suggesting "a symbolic geometry that integrated death, water and the sun." This Saharan site is reasoned to have been even older than Stonehenge and other European megaliths. Among other alignments, the stone circle at Nabta Playa known as E-92-9, appears to have been a place that monitored the initial rising of the summer solstice sun.

In Africa south of the Sahara, much less is known about the archaeological record relative to many other areas because of the comparative lack of intensive research. Therefore, the announcement of the discovery of the first archaeoastronomical site in 1978 was of considerable interest (Lynch and Robbins 1978). The site of Namoratunga II, overlooking the barren western shore of Lake Turkana in Kenya has been compared to a miniature Stonehenge. Namoratunga II consists of a series of 19 basalt pillars that have been placed in the ground at angles (Figs. 1 and 2).

The basalt used at Namoratunga II is locally available in the Losidok range. A stone circle surrounds the alignment of pillars, and there is at least one nearby grave marked by upright slabs. This grave is similar to graves at the Namoratunga I site (although Namoratunga I lacks stone pillars) located far to the south adjacent to the Kerio river valley (Fig. 3).

Faint rock engravings which are thought to represent brand symbols used on domesticated animals occur on some of the pillars at Namoratunga I (Fig. 4). The Namoratunga sites are believed to date to approximately 300 BCE.

Mark Lynch, who was working on his Ph.D. in Anthropology at Michigan State University, initially proposed that Namoratunga II was an archaeoastronomical site. Lynch believed that the site was most likely reflective of a calendar system similar to the traditional calendar used by eastern Cushitic speaking peoples of southern Ethiopia. Peoples such as the Borana have a 12-month, 354-day calendar that is based on the rising of Triangulum, Pleiades, Bellatrix, Aldebaran, Central Orion, Saiph, and Sirius. In the Borana calendar, the rising of the above stars and constellations is related to phases of the moon. Lynch found that there were positive correlations between the rising of the seven stars or constellations used in the Cushitic calendar and the alignments of the stone pillars at Namoratunga II.

Like many other archaeoastronomical sites including Stonehenge, the interpretation of Namoratunga II has been controversial. Soper (1982) remeasured the site and argued that the original compass measurements were in error because of magnetite in the stone pillars. For this reason, the view of the site as a calendar similar to the one used by the Borana people has been questioned. Follow up work by Laurence Doyle of the NASA Ames Research Center and Wilcox has confirmed the measurement error detected by Soper. However, when using the tops of the pillars for testing the alignments, Doyle and Wilcox (1986: 129) concluded, "the pillars were used for the specific purpose of aligning with the 300 BCE positions of the Borana calendar stars." (Doyle and Wilcox 1986: 129). They "found 25 two-pillar alignments with the 300 BCE horizon rising positions of the seven Borana calendar stars…" and an equal number of setting positions for the appropriate Borana stars (Doyle and Wilcox 1986: 127). Their statistical tests show that there is a very small chance that these correlations could be random. In a more recent paper Doyle and Frank (1997: 98) have advocated a cautious conclusion by stating that "the Namoratunga II pillars may have been the site of an ancient calendrical observatory, but much yet remains to be done for this to be convincingly concluded."

Namoratunga. Fig. 1 View of Namoratunga II stone pillars near Kalakol (Photo by Robbins).

Namoratunga. Fig. 2 Another view of Namoratunga II stone pillars (Photo by Robbins).

Namoratunga. Fig. 3 Namoratunga I cemetery site showing upright slabs marking graves. Pickup truck for scale (Photo by Robbins).

Interestingly, another stone pillar site has been reported for the eastern side of Lake Turkana at Jarigole, near Alia Bay (Nelson 1995, also see Nelson's paper on Jarigole at ►http://www.arkeologi.uu.se/afr/projects/BOOK/nelson.pdf). The Jarigole site contains

Namoratunga. Fig. 4 Namoratunga cemetery rock art on hill (Photo by Robbins).

at least 28 basalt pillars as well as a thin oval shaped platform and a mound that is about a meter in thickness. Like Namoratunga II, some of the pillars are decorated. However, the decorations appear to be freshly pecked into the surface in comparison to Namoratunga II and, therefore, may well have been added after the site was abandoned. Nelson (1995) believes that the site dates to early in the Pastoral Neolithic based on the discovery of numerous Nderit potsherds, a highly distinctive ceramic tradition centering in the Lake Turkana basin. At the east Turkana site of Dongodien such pottery dates to approximately 4,000 years ago, implying that Jarigole may be about the same age, assuming that the pillars were erected at the same time that the Nderit pottery was deposited at the site. If the age estimate for the pillars is correct than the Jarigole pillars are substantially older than those at Namoratunga II, (ca. 2050 BCE versus 300 BCE) unless the age of the latter site is much too recent.

Nelson (1995: 52) writes that many of the pillars at Jarigole "are badly tilted and are probably shifted from their original position. Therefore, it will not be possible to determine if there are significant astronomical alignments among the pillars." However, Lynch (1978) has noted that pillars are intentionally set in the ground at angles by some Eastern Cushitic peoples in nearby southern Ethiopia. Based on the discovery of human remains and other information, Nelson (1995) has concluded that Jarigole was primarily a mortuary or burial site. Could this stone pillar site be related to Namoratunga II?

Clearly, it would be important to establish accurately the age when the pillars were erected at both Namoratunga II and Jarigole. The age of Namoratunga II is currently based on similarities to Namoratunga I which has yielded a radiocarbon dated human bone sample of ca. 300 BCE (and the good fit between this date and the Borana star alignments at that time), while the age of Jarigole is based on the presence of Nderit pottery. Unfortunately, it is not possible to date when the pillars at either site were erected by the radiocarbon method. However, I have suggested elsewhere (Robbins 2006) that it may be possible to obtain optically stimulated luminescence (OSL) dates from the sediments that lie directly beneath the base of the upright pillars at both sites. OSL dating is now widely used in African archaeology to date the last time that sediments were exposed to sunlight before they were buried. We have used it successfully to date sediments at archaeological sites in the Kalahari Desert of Botswana. In the case of the erection of the Lake Turkana pillars the last time the sediments were exposed to sunlight would have been when the holes were excavated immediately before the pillars were placed in them. The OSL sediment samples could be readily obtained by using a sand auger to dig at an angle directly underneath of the pillars. The resulting ages would for the first time allow for a close comparison of when the pillars at both of these sites were erected, and the OSL method could also be applied to the dating of other stone pillar sites located to the north of Lake Turkana in Ethiopia.

Is the Namoratunga II stone pillar site an archaeoastronomical site? Megalithic sites such as Stonehenge, Namoratunga and Jarigole provide a powerful testimony to the work efforts, symbolism, and beliefs of ancient peoples. Whereas archaeologists have learned much about these sites it is quite likely that they had multiple meanings to the people that created them. It is also clear that such sites can have different meanings to other people through time, such as the use of Stonehenge by hippies, modern druids, and others (Chippindale 1986).

In the local Turkana language Namoratunga means "people of stone," referring to a legend that the pillars (as well as upright grave slabs) were once people who were turned to stone while they were dancing because they mocked a spirit that had appeared to them. It is useful to conclude with the first two lines of a Turkana song that expresses their view about Namoratunga (see Lynch 1978 for the remaining verses).

> "Who knows how the standing stones were forged?
> "Who knows how to make the fire of Namoratunga?"

N

Nanjing

Richard Bertschinger

The *Nanjing* (Canon on Medical Difficulties) appeared probably in the first or second century AD. However, the Chinese believe it was written in the first or second century BCE. Its authorship is unknown, although tradition has ascribed it to Qin Yueren, the usual sobriquet for Bian Qiao, the eminent Zhou Dynasty physician who is said to have lived in the sixth century BCE. Attribution to an ancient legendary doctor is common in Chinese medical works. The most valued commentary is the *Nanjing Benyi* (The Genuine Significance of the *Nanjing*), compiled by Hua Shou in 1366. The book further develops the ideas of the *Huangdi Neijing* in question and answer format, revealing an increasing tendency for medical books to concentrate on acupuncture.

The following are outlined in the *Nanjing*:

- The criteria for pathology and health
- The existence of *xu* (weak, deficient) or *shi* (full, excessive, toxic) conditions
- The passage of disease through the various organs

- Pathology, especially that concerned with dissipation and cold-induced fevers
- The attributes of a skilled or "divine" physician
- The structure of the organs, including their weights and measurements
- Needling technique

Methods of tonification and sedation are particularly focused upon. Acupuncture points appear for the first time in various groupings, with a concentration on the *shu* (passage) points on the lower parts of the four limbs. One of its most influential ideas is the use of the points for particular categories of disease. Pathologies of the channels, and pulse diagnosis, are also touched upon.

The *Nanjing* contains 81 chapters. The *jingluo* (channels) appear in Chapters 23–29, the *shu* points (passage points) on the limbs in Chapters 62–68, whilst Chapters 69–81 concentrate on needling. These sections show the development of extreme precision in needling, and a focused rationale during practice.

Nārāyaṇa Paṇḍita

Takanori Kusuba

Nārāyaṇa was one of the major authorities on Indian mathematics after Bhāskara II. We do not know when or where he was born. All we know about his life is that he is the son of Nṛsiṃha (or Narasiṃha). Nārāyaṇa wrote two Sanskrit mathematical texts: the *Gaṇitakaumudī* on *pāṭī* (arithmetic) in 1356 (which is confirmed by the final verses of the book) and the *Bījagaṇitāvataṃsa* on *bīja* (algebra). The two books consist of rules (*sūtras*), examples (*udāharaṇas*) and commentary (*vāsanā*) thereon. A reference to the *Bījagaṇitāvataṃsa* is found in the *vāsanā* on the *Gaṇitakaumudī* but not in the *mūla.*

The *Gaṇitakaumudī* consists of *paribhāṣā* (metrology units), *parikarman* (basic operations) and 14 *vyavahāras*: the traditional eight *vyavahāras kuṭṭaka* (a linear indeterminant equation such that $y = ax+c/b$), *vargaprakṛti* (a quadratic indeterminant equation such that $Px^2 + t = y^2$), calculations for fractions, rules for fractionizing, the net of digits (combinatorics), and magic squares. The 12 *vyavahāra* includes rules to express the number one as the sum of a number of unit fractions, which are similar to those given by Mahāvīra. The rules in chapter 13 are modeled on those of the *Līlāvatī* but are further advanced and can be compared to the rules for combinatorics in metrics and music. The *Gaṇitakaumudī* is the first Sanskrit mathematical text so far available that deals with magic squares.

The *Gaṇitakaumudī* was published by Padmākara Dvivedī in two volumes based on a single manuscript which had belonged to his late father. The numberings are not accurate. A critical edition of the last two *vyavahāras* with an English translation and his own commentary was published by Kusuba in 1993. The entire work was translated from Dvivedī's edition into English by Paramanad Singh in 1998–2002.

There are five cases of enumerations of digits discussed in the 13 *vyavahāra*. Pattern 1: digits unequal to each other are arranged in a fixed number of places. For example, there are four digits, 1, 2, 3, 6, in four places.

Pattern 1

1	1236	7	1263	13	1362	19	2361
2	2136	8	2163	14	3162	20	3261
3	1326	9	1623	15	1632	21	2631
4	3126	10	6123	16	6132	22	6231
5	2316	11	2613	17	3612	23	3621
6	3216	12	6213	18	6312	24	6321

Pattern 2: digits, some of which are the same, are arranged in a fixed number of places. For example, there are four digits, 1, 1, 2, 4, two of which are the same in four places.

Pattern 2

1	1124	4	1142	7	1241	10	4121
2	1214	5	1412	8	2141	11	2411
3	2114	6	4112	9	1421	12	4211

In the following three patterns the digits are variable. Nārāyaṇa calls the highest possible digit the final digit. In pattern 3, the number of places and the final digit are fixed, but the sum of the digits in each extension is variable. For example, the final digit is 3 and the number of places is three.

Pattern 3

1	333	10	332	19	331
2	233	11	232	20	231
3	133	12	132	21	131
4	323	13	322	22	321
5	223	14	222	23	221
6	123	15	122	24	121
7	313	16	312	25	311
8	213	17	212	26	211
9	113	18	112	27	111

Pattern 4: the final digit and the sum of digits are given but the number of places is variable. For example, the sum of digits is seven and the final digit is three.

Pattern 4

1	133	12	2122	23	2131	34	3211
2	223	13	11122	24	11131	35	12211
3	1123	14	1312	25	1321	36	21211
4	313	15	2212	26	2221	37	111211
5	1213	16	11212	27	11221	38	13111
6	2113	17	3112	28	3121	39	22111
7	11113	18	12112	29	12121	40	112111
8	232	19	21112	30	21121	41	31111
9	1132	20	111112	31	111121	42	121111
10	322	21	331	32	2311	43	211111
11	1222	22	1231	33	11311	44	1111111

Pattern 5: the number of places and the final digit are fixed but the sum of the digits is variable. This is an example where the final digit is eight and the number of places is three. The digits are arranged in ascending order.

For each pattern the order of the extension is determined in one and only one way. The numbering is put into each table. The method to restore an arrangement which is unknown though the number of extensions is given and the method to find a serial number when an arrangement is indicated are given. The calculation of the number of variations available and the rule for counting the times of each digit are also given. The arrangement of digits is treated as a number; the sum of all the numbers enumerated is to be calculated.

The *Bījagaṇitāvataṃsa*, which seems to be modeled on the *Bījagaṇita* of Bhāskara II, is divided into two parts. Part I deals with six operations (addition, subtraction, multiplication, division, squaring, and extracting the square root) for positive and negative numbers, zero, unknown quantities and surds as well as *kuṭṭaka* and *vargaprakṛti* mentioned above. The rules for indeterminant equations in the extant portion are similar to those in the *Gaṇitakaumudī* as well as those of Bhāskara II. Part II deals with four subjects: (1) linear equations in one unknown, (2) linear equations in more than one unknown, (3) quadratic equations in one unknown, (4) equations involving the product of different unknowns.

Only Part I and the opening lines of Part II were published based on a single and incomplete manuscript at Benares. The part of Sect. 1 of Part II was published by Hayashi with English translation and his commentary.

Naṣīr al-Dīn al-Ṭūsī

F. Jamil Ragep

Abū Jaʿfar Muḥammad ibn Muḥammad ibn al-Ḥasan Naṣīr al-Dīn al-Ṭūsī was born on 17 February AD 1201 in Ṭūs in the northeastern Persian province of Khurāsān and died in Baghdad on 25 June 1274. He was a preeminent figure in medieval Islamic history, being a major participant in both political and intellectual life during a century that witnessed monumental changes in the Islamic world. Politically, he was active at the courts in Iran of both the Ismāʿ'īlīs, a Shīʿite sect, and the Mongols who brought to an end both the formidable political power of the Ismāʿīlīs as well as the 500-year old ʿAbbāsid Caliphate. Intellectually, he played an even more important role, forging an intellectual synthesis that can be compared to that of

Zhu Xi (d. AD 1200) in China and Thomas Aquinas (d. AD 1274) in the Latin West. Ṭūsī, though, was not simply a synthesizer and rejuvenator of the Hellenistic tradition in Islam; he also made innovative and significant contributions in science and mathematics.

Ṭūsī was born into a scholarly family of Imāmī (Twelver) Shīʿites, one of the two major sectarian divisions of Islam. Although he received religious education at home, Naṣīr al-Dīn tells us in his autobiography, written when he was in his forties, that his father, "a worldly man," encouraged him to explore different sciences and listen to the masters of various sects and opinions. This he did and began studying the diverse branches of ancient science and philosophy, especially mathematics. Not content to remain in his hometown, he traveled while still a teenager to Nīsābūr, a major city in Khurāsān located to the west of Ṭūs, and became the student of a noted physician and a philosopher. It was at this point in his life that he began to study the works of his famous Persian predecessor Ibn Sīnā (Avicenna), whose works were influential in both the Middle East and Europe. He would later travel to Iraq and study both religious and secular subjects with several noted scholars. Though Ṭūsī's education was far from typical, one can gain some valuable lessons for trends that were occurring at the time. The fact that Ṭūsī was a Shīʿite did not prevent him from studying with persons of different sectarian affiliations. Furthermore he was motivated to travel fairly widely to receive an education. Finally, he studied both religious subjects (*al-ʿulūm al-sharʿiyya*; "the Islamic sciences") and the rational sciences that had been appropriated into Islam (*al-ʿulūm al-awāʾil*; "the ancient sciences"). The latter is important because Ṭūsī, especially in his later writings, felt that the ancient sciences – both philosophical and mathematical – could provide the means to transcend the religious disputes that had plagued Islam.

His formal education completed, Naṣīr al-Dīn would spend some 25 years (from the early 1230s until 1256) at the Persian courts of the Ismāʿīlīs, a powerful Shīʿite group that had for a time vied for ascendancy in the Islamic world. (These were the Assassins of Crusader lore.) Whether Ṭūsī himself willingly converted to Ismāʿīlism or simply pretended to do so is a matter of dispute; whatever the true state of affairs, he did find a refuge from the ravages of the Mongol invasions and did produce some of his most important work during this period of his life.

After the fall of the last Ismāʿīlī stronghold at Alamūt in 1256, Naṣīr al-Dīn, by then a famous scholar, was enlisted by the Mongol conquerors of Iran into their entourage, becoming court astrologer as well as minister of religious endowments. He was also charged with building an astronomical observatory in the town of Marāgha in Ādharbayjān in northwest Iran. This was one of the most ambitious scientific institutions that had been established up to that time; because of the resources placed at his disposal (which included the religious endowments), Ṭūsī was able to oversee construction of the observatory and its instruments as well as a large library and school. A substantial number of scientists and students were attracted to Marāgha; indeed there are reports of Chinese astronomers on the staff. In 1274, Naṣīr al-Dīn left Marāgha with a group of his students for Baghdad and died there in that same year.

Works

Ṭūsī was one of the most prolific authors of the Islamic medieval period, and his works, written in both Persian and Arabic, number something over 150. (This does not include his poetry.) He wrote on both religious topics and on nonreligious or secular subjects that had been inherited in the main from ancient Greece. Here we have an example of an important trend that was beginning to take root in the thirteenth century, namely the breaking down of the earlier division between those who wrote exclusively in the "Islamic" or "Arabic" tradition and those who devoted themselves to the Greek tradition. Among Ṭūsī's religious writings are seminal works on Shīʿīte law (*fiqh*), dialectical theology (*kalām*) and Sufism. Works in the tradition of Greek philosophy included the very influential *Nāṣirian Ethics* and his commentary on Ibn Sīnā's *al-Ishārāt wa ʿl-tanbīhāt* (Book of Directions and Remarks), which helped engender a renewed interest in his great Persian predecessor. Ṭūsī very much hoped that philosophy could provide a means toward rising above the many religious disputes that so racked Islam during his lifetime. In writing his commentary to Fakhr al-Dīn al-Rāzī's work on *kalām*, he wished to widen the opening Rāzī had made in allowing Greek philosophical concepts to enter the intellectual space of *kalām* while at the same time defending those concepts (as expounded by Ibn Sīnā) against Rāzī's attacks.

Naṣīr al-Dīn was especially attracted to the exact sciences, which, as Ptolemy had argued, provided a more sure means to truth than the murkier disciplines of physics and metaphysics. He thus devoted a considerable amount of his intellectual efforts to mathematics and astronomy. His recensions of Greek and early Islamic scientific works represent one of his most important contributions to the Islamic scientific tradition, an attempt to give vitality and renewed meaning to the translation movement of ninth century Baghdad. Because of the lack of an ongoing institutional structure for the teaching and perpetuation of science, Ṭūsī's reeditions, which often included insightful and original commentary, provided the means by which generations of students of late medieval Islam could assimilate the Greek scientific tradition, either with or without a teacher. These included Euclid's *Elements*, Ptolemy's *Almagest*, and the "Middle Books" of mathematics and astronomy with treatises by Euclid, Theodosius, Hypsicles, Autolycus, Aristarchus, Archimedes, Menelaus, Thābit ibn Qurra, and the Banū Mūsā.

In addition to this monumental role as textbook writer, Ṭūsī is also know for his original work, some of which occurs within these recensions. In mathematics, this included a highly sophisticated attempt to prove Euclid's parallels postulate, part of a long tradition that would eventually culminate in the nineteenth century with the realization that such "proofs" were not possible and that consistent non-Euclidian geometries using alternative postulates were constructible. In spherical trigonometry, Ṭūsī produced an important synthesis of earlier results of Islamic mathematicians; this marked a significant step in treating trigonometry as a discipline independent of astronomy, comparable in many respects with what was done later in Europe by Regiomontanus (1436–1476).

Ṭūsī, though, was most famous for his work in astronomy. In addition to a number of elementary treatises on practical astronomy, instruments, astrology, and cosmography (*hay'a*), many of which were meant for students, Ṭūsī also composed his *Zīj-i Īlkhānī*, a major astronomical handbook, for his Mongol patrons in Marāgha. Though not very original, and apparently compiled in haste without incorporating the Marāgha observations, it was destined to be widely used.

Ṭūsī's most original achievement was in theoretical astronomy. From a rather early date, Islamic astronomers had been disturbed by a number of inconsistencies in the Ptolemaic system, for example that some models violated the fundamental principle that all motions in the heavens should conform to the dictate of uniform circular motion. Ṭūsī responded to this by devising an astronomical model consisting of two rotating spheres the smaller of which was internally tangent to another twice as large. By having the smaller rotate twice as fast and in the opposite direction as the larger, Naṣīr al-Dīn was able to produce the linear oscillation of a given point, a property he was able to use in lunar and planetary models that could reproduce Ptolemaic accuracy while preserving uniform circular motion. Ṭūsī's new models had a decisive influence during at least another three or four centuries of late medieval Islamic astronomy, where they provided the starting point for numerous attempts to reform the Ptolemaic system. His device, which has been dubbed "the Ṭūsī couple," found its way into Sanskrit and Greek texts, and was influential in the work of several Renaissance astronomers, including Copernicus.

But Ṭūsī's most enduring influence, in fields as diverse as ethics, natural philosophy, mathematics, Sufism, astronomy, *kalām, fiqh*, music, mineralogy, and logic, was in the Eastern Islamic world, and in particular Persia, where his works continued to be studied and commented upon into the modern period.

Nāṣir-I Khusraw

Boris Rosenfeld

Abū Muʿīn Nāṣir ibn Khusraw al-Kabādhiyānī was a Persian philosopher, poet, and traveler. Born at al-Kabādhiyān in Transoxania (now in Tajikistan) in 1004, he was one of the founders of Ismāʿīlī theosophy and lived at Balkh and Ghazna (now in Afghanistan) at the court of the Ghaznewid sultans Maḥmūd and Masʿūd. After the Seljuqid conquest, he lived at Marw at the court of Seljuqid Chaghri Beg. He traveled from the Maghreb to India. In Egypt he became Ismaʿīlī and was made the Ismaʿīlī missionary in Persia and Transoxania. In this he was persecuted and was forced to take shelter in Yomghan in the Pamir mountains (now in Afghanistan). He wrote in both Persian and Arabic.

His main work is the *Safar-nāmeh* (Book on Travels), the diary of his journeys, containing an account of life in Egypt under the Fatimid Caliph al-Mustanṣir (1035–1094), and various geographic, ethnographic, and archaeological information.

In his philosophical treatise, *Kitāb zād al-musāfirīn* (Book Supply of Travelers), which is a survey of Isma ʿīlī theosophy, there is information on the history of science and fragments of the philosophical treatises of Abū Bakr al-Rāzī (854–935) on space, time, and matter.

His philosophical *Kitāb jāmiʿ al-ḥikmatayan* (Book Joining Two Wisdoms) is devoted to the harmony between Greek philosophy and Ismaʿīlī theosophy. He also wrote a philosophical *Rowshanāʾī-nāmeh* (Book of Light) in six chapters, *Saʿādat-nāmeh* (Book of Happiness), *Kitāb gushāyish wa rahāyish* (Book of Unfettering and Liberation), *Wajh-i dīn* (Face of the Faith), and *Khān al-ikhwān* (Meal of the Brethren).

He also was the author of a nonextant mathematical treatise, *Gharāʾib al-ḥisāb wa ʿajāʾib al-ḥussāb* (Marvels of Arithmetic and Wonders of Calculators), containing two hundred problems with solutions and demonstrations to solve them correctly. In this treatise Nāṣir-i Khusraw complains of the absence of good mathematicians in Khurasan in his time. He died in ca. 1088.

Navigation in Africa

MARINA TOLMACHEVA

The physical geography and environment of the African continent precluded extensive water transportation on the interior waters, although light boats have been in use at least since the Middle Ages for fishing and transit on lakes and stretches of rivers between rapids and where permitted by depth or the tides. Navigation properly speaking was determined by three distinct regional environmental systems in the north, west, and east. Available historical data are uneven over time and area. Participation of native African peoples in naval activities originating in Africa is not always attested by the sources. In the Mediterranean Sea, ancient Egyptian rulers, the kingdom of Israel, and Carthage made use of the sailing and shipbuilding skills of Phoenicians. Pharaonic Egypt, Israel, and ancient Ethiopia (Axum) used the Red Sea as part of a commercial system linking the eastern Mediterranean with the Middle East, East African coast, and India.

Under the Old Kingdom expeditions had been sent to the land of Punt (southwest coast of the Red Sea or the Somali coast facing Arabia) for gold, ivory, ebony, and myrrh. Ships built at the head of the Gulf of Suez traveled south under the Fifth and Sixth Dynasties (ca. 2470–ca. 2280 BCE). A Red Sea shipwreck under the Middle Kingdom (ca. 2000–1800 BCE) is recorded in the Egyptian *Story of the Shipwrecked Sailor.* Under the New Kingdom, expeditions were resumed by Queen Hatshepsut (ca. 1495 BCE). According to Herodotus, the pharaoh Necho II (ca. 610–595 BCE) was first to attempt linking the Nile with the Red Sea by a canal. After calling off the construction he sent a fleet manned by a Phoenician crew to circumnavigate Africa clockwise. They took over 3 years to complete the journey, discovering in the process that Africa was surrounded by water. Some time before 480 BCE, a counter-clockwise circumnavigation was attempted by Carthage. This voyage, described in the Greek document known as the *Periplus of Hanno*, may have discovered both the Canary and Cape Verde islands, subsequently forgotten and rediscovered again centuries later. In the north, Carthage reached out into the Atlantic as far as the British Isles and possibly the Baltic. Access to these routes was strictly controlled and outsiders were attacked to prevent competition. In the Mediterranean, Punic trade interests inevitably ran into conflict first with Greece and then with Rome. With the decline of Carthage, navigation on the Mediterranean effectively became part of the western scientific and technological tradition.

Oceanic navigation in the African Atlantic is poorly documented. There is no evidence of sea-worthy vessels being constructed in sub-Saharan West Africa in premodern times. However, several reports indicate that sailing in the Atlantic was occasionally attempted, usually resulting in failure. Juba II, king of ancient Mauretania and a Roman ally, sent a fleet to the Canaries in about 25 BCE and later had the Atlantic coast of Morocco explored. In the Islamic period, the route to the Canaries seems to have been forgotten, although the Arab geographers inherited knowledge of the islands from Ptolemy. The legend of a statue at Cadiz forbidding travel beyond the Pillars of Hercules was transferred to the Fortunate Isles (*al-Saʿādāt*), or Eternal Isles (*al-Khālidāt*), as the Arabs called them after Ptolemy. A report by the geographer al-Idrīsī (ca. 1154) tells of an attempted expedition to the Canaries under the Almoravid ruler Yūsuf ibn Tashfīn (1061–1106) who controlled parts of western Africa from the Senegal River to Morocco and Algiers. The admiral in charge having died before departure, the voyage never took place. Al-Idrīsī also describes an intriguing adventure originating in Lisbon. Some time before 1147, 80 explorers (*mugharrirūn*) of Lisbon built a large ship, loaded it with enough food and water for several months, and after sailing west and south for a total of 35 days came to an island where they were forced to land by light-skinned men in boats. The king, speaking through an Arabic interpreter, told of an expedition ordered into the sea by his father. After sailing "across" the sea for a month, that group had returned having found nothing. The explorers were then taken to the mainland, reached after sailing with the west wind for "three days and nights." Their final rescue was effected by the Berbers of the Atlantic coast of Morocco.

Arabic accounts of the thirteenth and fourteenth centuries, especially those by Ibn Fātima (related by Ibn Saʿīd al-Maghribī) and Ibn Fadl Allāh al-ʿUmarī) suggest continuing but accidental maritime contacts between Morocco and Spain on the one hand, and black West Africans on the other. The availability of Arabic or Berber interpreters among peoples encountered by Muslims in these voyages undermines the speculation that these expeditions constitute an African discovery of the Americas. Of special interest is one report by al-ʿUmarī which describes an attempt at exploration of the Atlantic by a ruler of Mali, Abū Bakr II, who was the predecessor of the famous Mansā Mūsā (1307 or 1312–1327). An expedition of 200 light boats was sent down the Senegal River with provisions "to last many years." Only one vessel returned, with a story of the others disappearing in a violent current at sea. The persistent ruler equipped 2,000 new boats (1,000 of them filled with stores of food and water) and departed on a second expedition, never to return. Some have suggested that Morocco was the intended destination but the text gives no such indication, citing "the extremes of the ocean" in the king's order. No such further attempts are known.

Early modern European travelers in West Africa noted the existence of large canoes in the estuaries of rivers from Sierra Leone to the Niger Delta. Some of the large dug-out canoes, made of a single tree trunk, could carry small cattle, several horses, or up to 80 men and their sleeping mats. They had cooking hearths and occasionally "a sort of quarter deck, made of strong reeds" or a platform amidships. The canoes were propelled by wooden paddles and bamboo or palm-tree poles and could have sails made of grass mats (later of woven cloth) attached to masts of light cane. Their speed varied from 1 to 3 miles per hour. Larger vessels from planks may have been made from the sixteenth century on. There is no evidence of the use of outriggers or leeboards until the twentieth century. Boat builders and crews were sometimes drawn from servile populations. In West Sudanese empires, especially Songhay, heavy river canoes were used not only for trade and fishing, but also to enhance the cohesion of the state, to move troops and captives (slaves), and to conduct "naval" attacks or blockades. States had court officials in charge of matters relating to the river or state canoes: in Songhay it was the *hari-farma* (chief of the waters), while Lagos had the *aromire* (friend of the waters). From river estuaries the largest canoes reportedly ventured into coastal waters, against prevailing currents and winds, reaching from the Niger Delta as far as Angola.

Premodern naval communications in Eastern Africa were subject to different conditions in the three subregions: the Red Sea, the East African coast with the adjacent islands, and Madagsacar with the Comoros. Numerous port cities on the coasts of Eritrea and northern Somalia are mentioned in the *Periplus of the Erythrean Sea* and in Ptolemy's *Geography* for the first and second centuries AD, respectively. Adulis (ancient Berenice, at Massawa) became the principal port of the Ethiopian empire (Axum). Both Pseudo-Callisthenes (third century) and Cosmas Indicopleustes (sixth century) attest to the presence of Ethiopian merchants in India and Ceylon (Sri Lanka). However, it is not always clear in these or later reports who the sailors and navigators were. *The Periplus of the Erythrean Sea* specifies Arab supremacy on oceanic routes leading from Yemen to Africa and India. Early Islamic history records attacks on Arabian ports and shipping by Ethiopians, repulsed by the Arabs who established their firm control on the Red Sea by the early eighth century. However, Africans from the coasts of Ethiopia, the

Horn and the Dahlak islands continued to be involved in trade and piracy on the Red Sea. They also served as sailors on boats sailing the Indian Ocean owned by Arabs, Persians, Swahili, Indians, and even Portuguese. Massawa boats were described in the eighteenth century as "very slight and unsafe," but capable of carrying a "great weight." They were, as in previous centuries, of the sewn type with mat sails, equipped with a crew of seven or eight men.

Zeila and Barbara were major African counterparts to Aden, receiving fleets from Africa heading north or Indian and Persian Gulf vessels destined for Jedda. From Zeila and Massawa trade routes led inland, providing important access for Ethiopia to major commercial networks even during the centuries of its isolation from the world by a ring of Muslim principalities bordering on the sea. The port of Suakin attracted shipping largely because of Abyssinian gold. So many Ethiopians were engaged in oceanic shipping that an important social class of *Habshis* (i.e., Abyssinians) evolved in India's mixed coastal communities. Ibn Battūta first reports their presence at Calicut and Ceylon in the fourteenth century. Sometimes associated with the East African immigrants called Sidis (who spoke Swahili and often originated as slaves from Mozambique and Mombasa), Habshis acquired special influence in the seventeenth and eighteenth centuries as sailors and soldiers protecting shipping from Gujarat in the northwest to Surat and even Bengal. One Sidi was the admiral of the Bijapur fleet and had under his jurisdiction the coast north and south of Janjira, the port attacked by the Moghuls in 1659. In the Bombay region in 1648 one area was controlled by a Habshi responsible for maintenance of a marina for the purposes of transporting pilgrims to the Red Sea and protecting commerce. The office carried the title of *wazīr* and was attained through merit. Some Habshis were non-Muslims. Habshi crews serving on Portuguese and Arab-owned ships often carried their families aboard. African sailors were apparently also involved in piracy on the West Indian coast.

In the southwestern part of the Indian Ocean, sailing between the African mainland and the island of Madagascar was made difficult by the strong southward currents in the Mozambique channel and the weak reach of monsoons. Swahili legends of origin would put Muslim settlers on the Comoros as early as the eighth century, but the first trustworthy reports speak of Malay (Wāqwāq or Qumr) people reaching African destinations at a time when Mozambique was barely known to the Arabs and no evidence exists for African voyages from the mainland.

The earliest report of a Malay attack against a northern Swahili town (Qanbalū, on Pemba Island) dates back to 945. The Arabic book *Marvels of India* tells of a 1,000 boats attacking the city from the sea and surrounding channel. The assailants had plundered parts of Mozambique and an island six days' distance away. Their home was at the distance of one year's journey. In the thirteenth century Ibn al-Mujāwir speaks of an earlier, vaguely ancient, invasion of Aden by the Malagasy people (al-Qumr) who arrived in great numbers in boats to displace local fishermen. They were later expelled by Kushites from the Somali peninsula (Barābir). These people disappeared, and their skill had been lost, but a boat from al-Qumr arrived at Aden in AH 626/AD 1228–1229. Ibn al-Mujāwir describes it as an outrigger vessel; he admires the sailing skill of these people who managed to sail from Madagascar to Aden in "one monsoon," instead of three stages involving layovers at Kilwa and Mogadishu. Around 1500 Ahmad ibn Mājid includes the Comoros in the scope of Arab navigation. After the arrival of Portuguese, and especially after hostilities developed in the north, Swahili migrations to northwest Madagascar and the Comoros expanded while the Malagasy navigation declined. Comorian sailors became occasional pirates and were involved in slaving raids against the mainland coast until the nineteenth century. Malagasy in turn attacked the Comoros from the eighteenth century, adapting for slaving raids large canoes otherwise used for whaling and capable of carrying 30 men. Some raids even reached across the Channel. Outrigger canoes were called *parabou*. There were also two-bridge galleys *coracores*, one-mast ships (*pajalas*) and *palans*, similar to small galleons.

The coast of East Africa proper, subject to the monsoon regime, is distinguished by the great number of coastal sites used as trading ports and fishing settlements. African participation in trans-oceanic navigation has not been documented for pre-Islamic or even early Islamic times but local inter-island shipping must have evolved sufficiently early to allow offshore island settlement by at least the ninth century. According to al-Idrīsī (mid-twelfth century) the Zanj people did not have seaworthy vessels and ships from Oman and elsewhere exported their goods. By that time a network of sailing routes connected harbors from southern Somalia to northern Mozambique. The Swahili-speaking coastal Africans dominated local shipbuilding and trade but other groups, including the Bajun, provided sailors as well. Navigation on the Swahili coast carried many general characteristics of Indian Ocean navigation, including the sailing calendar, dependence on the monsoon, sidereal rose, some boat types and terminology rich in loan-words from Arabic, Persian, and Indian languages. It also had some distinctive features and deeply affected the social culture of the coast. The best known is the maritime Swahili culture of the island city of Lamu (Kenya).

The sailing calendar was based on monsoons within the solar year. The marine year began in early August, when the gusty southern kusi wind subsided. The New

Year's celebration, called *siku ya mwaka*, marked the resumption of shipping activity after a pause during May–July. The Persian word Niruzi, also used for this festival, gave rise to the false impression that this calendar was Persian in origin. Different subperiods within the monsoon were best suited for plying the routes between Malindi and Madagascar, Kilwa to Sofala and back, Sawāhil (northern Tanzania) to Mogadishu, Aden and thence to Hormuz or Gujarat and the Maldives. Travel north was more difficult due to both the southwest monsoon and the strong contrary currents in channels between the mainland and the islands. The "normal" boundaries of Swahili travel were Cape Delgado in the south and Mogadishu in the north. In the fourteenth century the city of Pate briefly attempted to dominate the coast, but it always had to compete with its neighbor Lamu and the more remote Mogadishu, Malindi, Mombasa, and the powerful Kilwa. Regional and local rivalries involved sailing to foreign lands (Arabia or India) or to the mainland, and attacks and blockades from the sea. In island setting, it was generally faster, easier, and safer to sail from one destination to another than travel overland well into the nineteenth century. Traditional histories reflect everyday awareness of the tides, currents, and coastal breezes. The Portuguese arrival in East Africa did not noticeably change local shipbuilding and sailing practices, although this was not so elsewhere; the Eastern Arabian and Persian Gulf influences both pre- and postdated this European infusion. Local ships still carried traditional trade goods and even revived with the rise in slave trade before its suppression by the British in the late nineteenth century. By that time Zanzibar and Kilwa were the two leading ports of the coast, followed by Mombasa and Lamu.

Navigation proper was not highly developed. Given limited distances, boats mostly coasted. The steady daily and seasonal pattern of the winds made observation of local features such as banks, current speeds and tides more important than instruments. Actual stars rather than compass rhumbs[1] were used for determining latitude. Travel was slow, averaging one knot an hour, if rest days are included. In the fourteenth century Ibn Battūta was told that the area of Sawāhil was two weeks' sail from Mombasa. In the early nineteenth century it still took two weeks to reach Madagascar from Kenya with a fair northerly wind *kaskazi*. Traffic between Lamu and Somalia resumed immediately in August, reached its peak in November and died down in January. Foreign craft from the north began to arrive in November.

[1] A line which crosses successive meridians at a constant angle; called also rhumb line, and loxodromic curve. To sail on a rhumb means to sail continuously on one course, following a rhumb line.

The sailing calendar was paralleled by a ritual calendar. At Lamu, a local ship owner held the hereditary office of *mkuu wa pwani* (master of the strand). This dignitary led the dhow launching, invariably accompanied by both an African *ngoma* festival and a Muslim ceremony. Other elders (*wazee*) gave the blessing and burned incense. The shipwright (*fundi*) was given a ceremonial present and the captain (*nakhoda*) declared by the *mkuu*. Magic was resorted to in order to bring favorable sailing conditions or take wind out of an opponent's sail, break his mast, etc.

Today's dhows (*daus*) are sea-going sailing ships with very large lateen sails, which still may be rowed or poled when necessary. They serve as fishing vessels and may be flat-bottomed or keeled. Newer dhows are made of fiberglass and have motors. The formerly prevalent *mtepe* (*dau la mtepe*), no longer in existence, was a type of sewn boat of up to 30 tons carrying a square sail of matting, double-ended with an upright mast. The local "big ship" is *jahazi*, a fairly recent type of sea-going coaster, single-masted, transom and with upright stem, with a cargo capacity of 25–60 tons. A smaller version of the same type used for intercoastal shipping is called *mashua*. *Buti* was a large (20–60 tons) coastal vessel type, now obsolete, with one mast, and a slightly curved upright stem and square stern. *Baghala* is the most beautiful and largest (100–300 tons) of the dhows, a two-masted vessel with square stern, originally from the Persian Gulf. Bum is a layman's name for lateen-rigged sea-going dhows. The small-keeled *msumari* (*dau la msumari*) also carries a lateen sail. The double-outrigger canoe *ngalawa* rarely occurs north of Mombassa. Lack of timber limits shipbuilding; local wood may suffice for plank-built boats of small dimensions but dugout canoes have to be imported (for example, from Madagascar).

Navigation in China

Ho Peng Yoke

Did the Chinese visit North America before Columbus? Did Chinese navigators land in Australia before Dampier and Cook? These two puzzles often pass our minds when we turn to the topic of Chinese navigation. In 1761 C.L.J. de Guignes wrote that in the early part of the sixth century a Chinese monk named Huishen had sailed to the west coast of North America. The story did not gain much support, but some interest in the issue was revived in the last two decades by the discovery of two pre-Columbian stone anchors off the Californian coast. One of the anchors is in the shape of an equilateral prism, and the other looks like a large cylinder with a hole bored through the center. Both were suggested to be of Chinese origin. As for Australia, aborigines along the northern coast still remember contacts with their northern neighbors who visited them annually in the past for the purpose of trade. Among them were the Macasarese and the Buginese; the former were preceded by the Baijini. The Baijini were said to be technologically advanced, with much lighter skin color; among the things they bartered for was *trepang*, from which the typical Chinese delicacy sea-slug was prepared. Hence they could be identified with the Chinese, the only people who knew how to prepare sea-slug. While we cannot yet arrive at a definite answer to the two questions it is possible to show that at least the technology and skill were already there in the past for Chinese ships to reach their destinations.

The Chinese must have navigated their rivers and coastal waters since the dawn of history. The character *zhou* for boat written on tortoise shells and buffalo shoulder-blades used for the purpose of divination during the Shang period (traditional dates 1766–1122 BCE) took the form of a boat. Documentary records on navigation in ancient China are, however, rather scanty. Confucius himself once made a remark on venturing upon the open sea in a raft. Then comes the story about the emperor Qin Shihuangdi sponsoring expeditions to the East China Sea to seek the elixir of immortality during the third century BCE. Modern archaeology has provided evidence that Chinese sailors had taken to the high sea at least by the third century BCE. In 1976 the ruins of a large shipbuilding site of that period was discovered at Guangzhou in South China. The site could hold ships weighing between 50 and 60 tonnes and measuring up to 30 m in length and about 8 m in width.

In the year 118, the Han astronomer Zhang Heng (78–139) noted that there were stars not visible to people in China itself, but that were seen by seafaring people. There were already a number of books on this subject then, but unfortunately none of them has survived. Those seafaring people could have steered their boats by the sun and the stars. Star catalogs were already available in China, even before Zhang Heng made observations with the new astronomical instrument he constructed. By about the seventh century maritime trade between China and the Arab countries saw Chinese and Arab sailors traveling between the ports of east and southwest Asia. Arab merchants traveled in Chinese boats. The large number of Tang potsherds of about the mid-eighth century discovered by the Japanese Idemitsu Archaeological Mission in 1966 at Fustat near Cairo and in Aidhab on the Red Sea coast of Egypt bear testimony to this trade. It could be during the mid-ninth century that Chinese navigators first made use of the magnetic compass. This could have taken place later, but not after the mid-eleventh century when Shen Gua (1031–1095) described the mariner's compass. This early form of compass consisted of a magnetic needle suspended by a thread.

With the invention of the mariner compass and increase in maritime trade the shipbuilding industry became highly developed during Song China (960–1279). In 1960 the remains of a Song wooden craft measuring 24 m long and about 4 m wide for navigating in rivers and canals was discovered in Yangzhou, Jiangsu province. Then in 1974 the remains of a *Fuchuan* – Fujian-built ship – was recovered in Quanzhou, Fujian province. Measuring over 34 m and weighing about 374 tonnes, it was composed of 13 water-tight compartments, the bulkheads. The shipbuilding industry continued to flourish during the time of the Mongols (1271–1368). Marco Polo gave an estimate of over 200,000 sailing vessels in China.

The most famous maritime exploration ever made by the Chinese was that of Zheng He (1371–1434). His fleets included some very large vessels. According to the *Mingshi* (Official History of the Ming Dynasty), the largest ones measured 134 m in length and up to 55 m in width. Modern scholars gave different estimates for their displacement, varying from over three thousand to just over eight hundred tonnes. In 1405 Zheng He made his first expedition to Southeast Asia and the Indian Ocean, employing a fleet of 63 ocean going junks. During the next thirty years he made six other expeditions to the Indian Ocean. His explorations preceded the Portuguese by several decades. For example, he visited Calicut in India in 1405, some ninety years before the latter arrived. He brought home strange animals like zebras and giraffes, and rare drugs, minerals, and other curiosities during his visits to Africa. He sailed along the eastern coast of that continent. One unanswered question is whether he had navigated round the Cape of Good Hope and ventured into Atlantic waters.

The late Ming military compendium *Wubeizhi* (Treatise on Armament Technology) compiled by Mao Yuanyi in 1628, contains the original schematic sailing charts tracing the routes followed by Zheng He and navigational diagrams indicating the star positions to be maintained during the voyages. The charts show the courses of the ships across the seas, with legends giving detailed compass-bearings, with distances expressed in number of watches. They also describe more interesting coastal features, showing half-tide rocks and shoals as well as ports and havens. For example in the description of the voyage from Bengal to Malé in the Maldive Islands through Sri Lanka, it gives the polar elevation for every stage of the journey, such as mentioning that a certain mountain in Sri Lanka would be sighted when the polar altitude had sunk by a certain number of degrees. Hence Chinese sailors in the early fifteenth century already knew the method of finding and running down the latitude. For measuring the altitude of a star, Zheng He's crew probably made use of the cross-staff, which was an instrument used by Chinese surveyors as early as 1086. The traditional Chinese clepsydra would not function properly at sea. Needham suggests that they had an alternative, by simply using the incense or joss-stick, which was a popular method used for timekeeping.

The Chinese constructed many types of sailing vessels to suit different needs and environments. Navigating rapid shallow streams, sailing on big rivers and along the coast, transporting food and merchandise along the Grand Canal, and venturing further afield to the Indian Ocean would require different types of ships. Chinese sailing vessels differed from Western sailing ships in their hull structure and in their sails, as well as in their methods of propulsion. The word "junk" was first given to Chinese ships in records of the travels of Odoric of Pordenone and that of Ibn Baṭṭūṭa during the fourteenth century, but the origin of this word is uncertain. Needham suggests that it could have come either from the Chinese word *chuan* or from the cognate Javanese and Malay words *jong* and *ajong*. The term *sampan* is used for smaller Chinese sailing vessels. Undoubtedly it originated from the Chinese term *sanban*, which is written in two forms. One form literally means "three boards", indicating its size. In the nineteenth century the term referred to river gunboats rowed by eight oars on each side.

The oldest form of Chinese ship had a carvel-built hull without the keel, the stempost and the sternpost of European and Arabian ships. Generally, the Chinese junk could be either flat or slightly rounded at the bottom. However, there were also junks with a V-shaped bottom as in the case of the Fujian-built ships. The planking of the Chinese junk did not meet at a point at the stern and the stem, but stopped abruptly and was joined transversely by straight planks.

Also unlike its European counterpart, the Chinese junk had neither frames nor ribs; instead it was composed of solid transverse bulkheads, which gave rise to several water-tight compartments. This valuable shipbuilding technique could have been inspired by the bamboo that the Chinese used for some smaller rafts and for so many other purposes. Many types of bamboo raft still ply the rivers in China today, Some of them are made with the giant bamboo *dendrocalamus giganteus* that grows to a height of some 25 m and has a diameter of about 30 cm. To enable the raft to slide over river rocks, the bow is usually bent upward by heating. If a piece of bamboo is bisected longitudinally the nodal septa would represent the transverse bulkheads and the stem and stern transoms.

The sails used in Chinese ships were also different from those of their European counterparts. Different cultures developed different types of sails to take advantage of winds coming from different directions. For example the ancient Egyptians had the symmetrically hoisted square sail. The Chinese on the other hand had the lug-sail, which consisted of an upper sail support slanting upward away from the mast, called the canted yard, and a horizontal sail support at the bottom called the horizontal boom. The sail was often strengthened by battens of bamboo, the ends of which were fastened to bolt-ropes suspended from the yard to take the weight of the sail. The sail was often made of bamboo matting and was kept flat and taut by using multiple sheets of matting. Several masts were used for larger vessels, the number varying from two to five. These masts would be staggered thwartwise such that one would not becalm another. The rake of a system of masts often radiated like the spine of a fan. The Chinese mat-and-batten sail had several advantages over the canvas sails used in European ships. It could manage with a material which, although not as strong as canvas, was aerodynamically more efficient. It offered more protection against tearing, and could easily be furled, as it would readily fall into pleats thus dispensing with having to send some crew member aloft to take in reefs.

The Chinese propelled their boats by punting with long poles and by rowing using steering oars and stern sweep. However, they also employed an ingenious method of mounting the oar approximately in the line of the main axis of the boat, and moving the oar from side to side about a fixed fulcrum. This was the Chinese *yaolu* that had fascinated many Western observers in the past. Louis Lecomte remarked that they made use of the *yaolu* as the fish did its tail.

The rudder is standard equipment in a sailing craft to control the direction of movement, although the same function may be performed by other means, such as by the oar and the paddle, albeit less efficiently. In the Western tradition the sternpost rudder is hung on pintle and dudgeon. What the Chinese did was to develop an axial rudder that could move up and down in guides. In shallow water it could be raised to its highest position to avoid damages, while in a heavy monsoon in the open sea it could be set in the lowest position for protection from the breaking water and to improve the ship's windward sailing quality. Sometimes the rudders were riddled with holes. These were fenestrated rudders. The holes were supposed to minimize the drag on the ship caused by the turbulence of the water flowing past the rudder, thus improving the hydrodynamics of the rudder. A ship would sometimes carry rudders of different sizes for use in different conditions. Sometimes instead of the rudder, the steering oar was developed into a long stern-sweep in boats that navigated rapid rivers and land-locked waters. The rudder is only effective where there is relative motion between the boat and its surrounding water. When a boat comes down with the same speed as a descending rapid, the rudder does not operate. A long sterns-weep, however, depends on the reaction to water resistance and controls the movement of the boat.

Thus Chinese ships ruled the waves in East Asian waters for a long period of time until the sixteenth century when the Portuguese arrived in East Asia and found no equal to their *calivers* outside the Atlantic. In the meantime from the days of the arrival of the latter until the second half of the twentieth century, the progress of modern science and technology had also left Chinese shipbuilding far behind. Although modern technology has already taken over from the traditional shipbuilding industry in China, we can still see Chinese junks and sampans navigating between ports in coastal waters in the China Sea and traditional rafts of all kinds sailing the rivers and the lakes in China today.

Navigation in India: Sea and Inland Navigation

R. S. Varshney

Ancient Tradition

The great landmass of India is surrounded by sea on the east, south and west and has a large number of sheltered harbours situated all along its 5,700 km long indented coastline. There are also many large navigable rivers. Careful examination of ancient scriptures and archaeological discoveries has brought to light actual remains of docks, wharfs, jetties and warehouses in ancient times. References to sea journeys, navigation, boats, ships and docks are scattered in various verses of the *Vedas*, *Purāṇas*, *Meghamala*, *Mayurcitraka*, *Vṛhatsaṃhitā*, *Harivamsa* and other texts.

The *Ṛgveda* Aryans knew the slopes of a region by the help of rivers. That Aryans navigated on seas is clear from their worship of Jalnath (The Lord of the Sea). The *Ṛgveda* says, "Do thou convey us in a ship across the sea for our welfare."

Aryans possessed knowledge of boats which were something like submarines. Here is a *shloka* (verse) from the *Ṛgveda*. "O Pushan, you work as a messenger by use of your boats which move under the ocean and also in the air. These boats have instruments with which things inside and outside sea can be seen." The Vedic Aryans understood the construction and operation of sea boats.

In the *Ṛgveda*, the God Varun has knowledge of the routes of the oceans and also of the vessels sailing on them (*Rig*. 1.25.7). The same text further adds that merchants used to send out ships to foreign countries. A hymn in the *Atharva Veda* says that the boats which rode the waves were broad in beam, spacious, comfortable, resplendent with strong rudders and faultless in construction. The *Ramayana* refers to distant lands where the worm grew that yielded the silken thread and to the Lohit sagar, the references being to China and the Red Sea, respectively. *Rāmāyaṇa* also describes the boat journey undertaken by Bhagwan (Lord) Rama. The epic *Mahābhārata* mentions the naval activities of Pandavas. *Vriksha Āyurveda* a botanical treatise written in the sixth century BCE, mentions the types of wood best suited to boat building. *Yuktikalpatru* by Bhoj served as a textbook to later Indian shipbuilders.

The *Ṛgveda* mentions a naval expedition sent out by Rsi-king Turga under the command of his son Bhujyu. The ship was wrecked in a storm, but some of the occupants, including King Turga and his followers, were rescued by Ashvins, the twin brothers, who came in their hundred-oared galley.

Three things emerge from these references: first, ships were sent to foreign countries for trade; second, multi-oared boats were used in expeditions, and third, Vedic Aryans knew sea routes.

Archaeological excavations have revealed that, during the Harappa period (2500 BCE), there was a flourishing maritime trade between Kathiawar and the Persian Gulf countries. Of special significance is the evidence of the existence of a port city, called Lothal, 80 km southwest of Ahmedabad, which had docking facilities comparable to the modern ports of Mumbai and Vishakhapatanam. There were other ports also along the Gujarat Makrau and Konkan Malabar coasts.

The Bible also refers to early maritime commerce from India. In the days of Solomon items such as ivory, spices and peacocks could only have come from India.

In Mauryan times, for an account of navigation, we rely mostly on the *Jataka* stories. Greek writers often corroborate the facts mentioned therein. According to Greek writers like Arrian and Curtius, shipping was a highly developed industry in India in the fourth century BCE, and the same facilitated the passage of Alexander's army of over 100,000 soldiers through the Indus. Mauryan kings not only encouraged sea trade but also streamlined the administration of the navy. The *Arthaśāstra* of Kauṭilya (321–297 BCE) vividly describes the duties of the head of the naval department and the port officers. Important port installations of this period have been found recently at Kaveripattinam and Dharnikota on the east coast. Overseas navigation encouraged by the Mauryan emperors received further impetus under the Andhra-Satavahan kings and the rulers of the Chola–Pandyan kingdoms. The most important source of information concerning seaports of India in those days is the author of *Periplus* who hailed from Alexandria. He mentions a number of ports on both the western and the eastern coasts.

The Shravathi River in Karnataka is navigable from Honavar up to Gersoppa, which is mentioned in ancient texts. The most important port discovered is at Udyavara (called Odara in the Oxyhydrinchus papyrus), a small village 6 km south of Udipi, from which the saint Madhavacharya hailed. The mound known as Baleragudda marks the citadel of this ancient port city.

The early Tamil works of the first century AD describe at length the port establishments of the east coast such as Poomphar, i.e. Kaveripoopattinam, the chief port of the Chola kingdom. Other ports which are significant from the point of view of commerce during the first few centuries of the Christian era are Arikamedu near Pondicherry now identified as Pokduke or Poduca and Kainapara or Konark in Orissa. The Gupta emperors also encouraged inland and overseas navigation for trade. In the fifth century AD, Hamza of Isahan writers mention that Indian ships used to be moored at Hira near Hufa on the Euphrates River, the major role in the sea trade being played by the merchants from Sindh and Gujarat. The merchants of Gujarat colonized Java.

After the decline of trade with Rome, the Chalukyan and Chola kings encouraged sea navigation with the eastern countries especially Burma, Sumatra, Java, Borneo and the Island of Bali. I-tsing, the Chinese traveller who visited India (630–644 AD) says that Indian navigators and traders could be seen at all the busy ports of the east coast from Burma to China and in the Malayan Archipelago.

The four centuries between 200 BCE and 200 AD marked the heyday of Indian shipping. It was during this period that the Indians carried on their colonization of distant lands as far as Sumatra and Java, the latter of which still manifests its ancient Indian connection.

Marco Polo, who visited India in the thirteen century, left a vivid description of Indian ships. He saw ships that carried ten small boats slung on the sides, like present day lifeboats, with falls and tackles to lower them into water and heave them over the sides, along with 60 cabins below the rain deck for passengers. They were mostly foremasts and with as many as 14 watertight compartments.

A notable event of the early eighth century was that under the Arab onslaught on Persia, a good number of Persians, refusing to be converted to Islam, left their motherland by sea and sought asylum in the western ports of India. Their descendants are the Parsis of India.

They contributed greatly to the commercial, shipping, shipbuilding and industrial development of the land of their adoption.

Ibn Baṭṭūṭa, in the account of his travels in India, mentions the large boats that plied in the Indian rivers. He also describes in detail the manufacturing techniques of Indian ships. In the first quarter of the sixteenth century, on the western coast, the Zamorins of Calicut maintained a great naval force. Vasco da Gama also left a graphic description of the fleet of Calicut.

European travellers in India spoke highly of the strength and durability of Indian boats and ships. Nicolo Conti observed, "They build some ships larger than ours with five sails and as many masts."

India's maritime supremacy was maintained with the Mughals. Emperor Akbar gave impetus to shipping and shipbuilding. According to the *Ain-i-Akbari*, 40,000 vessels were engaged in commerce in the river Indus alone. Abul Fazal, the author of *Ain-i-Akbari*, mentioned the elaborate rules for the organization of the navy.

Advent of Europeans

In the last few years of the fifteenth century, events took place which had far reaching effects on navigation and the maritime world. The hostility between the Christians of Europe and the Muslims of Asia acted as a powerful factor in intensifying the efforts towards navigational exploration. In 1487 Bartholomeu Diaz passed the Cape of Good Hope and reached the Indian Ocean. The 'Hope in Good Hope' was the hope of the imminent discovery of the sea route to India. Vasco da Gama sailed from Portugal on 8 July 1497 and landed at Calicut on 27 May 1498. For the first time, a ship from Europe had arrived in India by an all-sea route.

By the middle of the seventeenth century the Dutch had become the masters of the trade of the Eastern Archipelago, ousting the Portuguese from the area. They then turned towards India, drove the Portuguese out of Sri Lanka, and operating with Colombo as their base, unleashed a sustained attack on Portuguese settlements in India. The Cochin establishment soon came under Dutch control; only Goa, Diu and Daman were left to the Portuguese.

It was now the turn of the English to establish direct contact with India. The East India Company was formed to break the Dutch monopoly and got a charter from Queen Elizabeth on the last day of the year 1600 granting it the monopoly of the Eastern trade. By and by Indians lost control of navigation of sea routes and Indian shipping gradually declined.

For nearly a 150 years the East India Company's main activities were confined to commercial aggrandizement. Within 50 years of Auragazeb's death (1707), the country was so confused in its political affairs that it provided an inviting ground for adventurers. The English emerged superior in naval power and they were able to displace the French and others.

In the final burst of glory, preceding extinction as it were, Indian naval power under the Marathas put up a brave fight against the supremacy of the European powers. Shivaji, the builder of Maratha power, had patronized the shipbuilding industry too. With the help of Tukoji Angray, the head of the Koli community of Ali Bagh, he built up a formidable fleet which, from 1694 to 1758, under the command of the Angrays, established complete control of the sea from Malabar to Travancore. The Indian shipbuilders of those times had such a high reputation that the Dutch and the English had some of their ships built by them.

During all this time, the seaborne trade of India had been rapidly increasing. But with the passing of trade in the more important commodities and the control of navigation on the high seas into English hands, Indian merchants and their shipping gradually disappeared from the scene. In a limited way, Indian shipping operated in the coastal waters and there were perhaps a few ships in trade with the Persian Gulf, the Arabian and the East African ports. The pilgrim traffic to Jeddah which had state patronage under the Mughals continued in Indian hands. Despite heavy setbacks, there were still many Indians who ventured into shipping and kept alive the tradition of shipping enterprise. It is on record that even after the rule of the sea had passed to the Europeans, Gurjarat businessman continued to show courage and skill as merchants, seaman and pilots. According to historian Tod (1025 AD), for Biji Singh of Bhavnagar, his port was his grand hobby and shipbuilding his chief interest and pleasure.

Any account of shipbuilding in the eighteenth and nineteenth centuries must include the work of the great Parsi family of Wadias. For nearly a century and a half, from 1736 to 1884, the members of this family were master builders at Bombay dockyard and built over 350 vessels.

However, the encouragement to Indian shipbuilding in the early days of the Company's rule had been vigorously opposed in Britain by many of the Company's Directors themselves. In India itself measures were taken to discourage shipbuilding.

Steamships

In the meantime, a great revolution had taken place in shipping. Steam had begun to be used for propelling ships. Only those countries that were mechanically advanced could rule the high seas. All these advantages were held mostly by England and she made the fullest use of them. In the third and fourth decades of the nineteenth century the steamship began to prevail over the sailing vessel which gradually disappeared from the high seas. In 1825, the steamship “Enterprise”, a small ship comparable with the coasters of today, left England on August 16 and reached Kolkata on December 7. This was the first steamer to perform a transoceanic voyage to India.

The two years, 1819 and 1919, stand out significantly in the history of modern Indian shipping. While 1819 saw the steamboat appear in Indian waters for the first time, 1919 saw the establishment of the first large Indian steamship company.

Decline of Indian Shipping

A number of small shipping companies owned by Indians were registered in the nineteenth century mainly to carry on coastal trade. All of them faced stiff competition and hostility from the British companies, mainly the Peninsular and Oriental (P&O) and the British India Steam Navigation Company (BI); they could not survive long.

But in the wake of the *swadeshi* movement at the turn of the nineteenth century, Chidambaram Pillai, a disciple of Lokmanya Tilak, entered the fray by launching the Swadeshi Shipping Company of Tuticorin in 1906. The flag of Swedeshi Shipping vessels bravely bore the words “Vande Mataram” (Mother, I bow to thee, which is the National song of India) a slogan which then served as a red rag to the bureaucratic bull. The fate of such a defiant patriotic venture can easily be imagined. An offensive was promptly launched against it. Pillai was arrested and sentenced to a long term of imprisonment for taking part in political meetings. The company crashed on the rocks of politics, not on the rocks of business. Similar was the fate of the Bengal Steamship Company, established in 1907 by Jyotindranath Tagore, brother of the famous poet and Nobel laureate Rabindranath Tagore. How disappointing the situation was is clear from the fact that about eighty shipping companies were registered in India between 1836 and 1918. By 1946 only seven still existed, and all of them were very small.

Revival

By now the patriotic fervour of the country had developed a strong economic flavour. Impressed by the generous contribution of the people to the war effort and especially by the bravery of Indian soldiers, the Government of India also was inclined to modify its imperialist policy a little.

The year 1919 provided a suitable setting for the entry of the Scindias on the Indian maritime scene. Scindia’s owe their birth to a stroke of inspection, a moment of illumination, almost to an accident of history. It was a chance meeting between Walchand Hirachand and Watson, a British engineer, during the former’s railway journey from Delhi to Bombay on sixteenth Feb. 1919, that disclosed to him that a passenger ship was for sale in Bombay. It was the S. S. Loyalty owned by the Maharaja Madhavrao Scindia of Gwalior.

Walchand decided to bid for it. After getting down in Bombay he proceeded straight from the Victoria Terminus station to the dock to have a look at the Loyalty. After inspecting the ship, Walchand decided to form a syndicate to buy the Loyalty and establish a limited company to run it. On March 27, 1919, the Scindia Steam Navigation Company was registered with an authorized capital of Rs. 4.5 crores. On April 5, 1919, the S. S. Loyalty sailed from Bombay as an Indian passenger ship bound for Europe and the United Kingdom. It was a historic day in India’s maritime annals, the day on which Indian shipping was reborn. Appropriately, since 1964, April 5 is celebrated annually as India’s National Maritime Day. Although the Gwalior Maharaja retained no interest, financial or otherwise, his name came to be permanently associated with the company.

River and Canal Navigation

Rivers have been used for navigation since the earliest times, and in some cases water transport was the only means of communication between places. Big rivers in the north, like Ganga and Yamuna, have always been used extensively for navigation especially in eastern UP, Bihar and Bengal. Similar is the story of southern rivers like Krishna, Kaveri, Godavari, etc. The central India rivers have also been used as waterways.

Steamers on the Ganga

Various types of Indian boats were used on the Ganga and houseboats were popular among European officers. Boats carrying merchandise from Allahabad to Calcutta, a distance of 1,300 km normally took about 20 days in the dry season. The Journey upstream was difficult and took almost three to four months.

Lord William Bentinck, Governor General of India (1828–1835), showed keen interest in the development of steam traffic on the Ganga. In 1834 a regular passenger service started on the Ganga. The passenger boat, William Bentick, was launched in Calcutta in April 1934. In October, its sister ship, “Thames” was also commissioned for service.

River and Canal Navigation in the South

The Madras Presidency also experienced water transport improvements early in the nineteenth century. A canal linking Madras with the Egmore backwater was completed in 1806, and it was named after Cochrane, who became its proprietor. Lord Dalhousie, Governor General (1846–1856), acknowledging the benefit derived from the Ganga Steamers, was eager to extend such facilities to the Godavari, Indus and other rivers. On the west coast, canals were also built. In Malabar the important canals were from Cochin to Tirur, 125 km from Baypore to Badagara, 69 km and from Balaptom to Canara frontier, 35 km.

Indian Ports, Maritime Transportation and Inland Waterways After Independence

After Independence there was tremendous progress in sea and inland navigation. India has 11 major sea ports: Kandla, Mumbai, Nhava Sheva, Marmagao, New Mangalore and Kochi on the west coast and Kolkata Haldia, Vishakhpatnam, Chennai, and Tuticorin on the east coast. The 11 ports in India are the responsibility of the Ministry of Shipping but are managed by semi-independent port trusts overseen by boards appointed by the Ministry from Government departments, including the navy, port labour and industry, ship owners and shipping companies.

In order of gross weight tonnage conveyed annually, Mumbai, Vishakhapatnam, Chennai and Marmagao are the most important ports in India. In addition there are some 139 minor working ports along with the two coasts and on offshore islands. Total traffic at the 11 major ports increased from 107 million tonnes in 1984 to 179 million tonnes in 1993. In 1993 there were three Indian government owned Shipping Corporations, the most important of which was the Shipping Corporation of India. There were also between 50 and 60 private companies operating a total of 443 vessels amounting to 6.5 million gross registered tonnes, more than 300 of which were 1,000 gross registered tonnes or more. Indian tonnage represented 1.7% of the world's total. Over all, the share of Indian vessels in total Indian trade is around 35%.

Some of the important shipping companies are: Indian National Ship Owners Association, Mumbai; Varun Shipping Co., Mumbai; Great Eastern Shipping Co. Ltd, Mumbai and Essar Shipping, Bangalore. India has four major and three medium sized shipyards, all government run. The Kochi Shipyard in Kochi, Hindustan Shipyard in Vishakhapatnam and Hooghly Dock and Port Engineers in Kolkata are the most important ones in India. Thirty-five smaller shipyards in India are in the private sector. Dry docks at Kochi and Vishakhapatnam accommodate the nation's major ship repair needs.

In addition to its coastal and ocean trade routes, India has more than 16,000 km of Inland waterways. Of that number, more than 3,600 km are navigable by large vessels, although in practice only about 2,000 km are used. Inland waters are regulated by the Inland Waterways Authority of India, which was established in 1986, to develop, maintain and regulate the nation's waterways.

Navigation in the Indian Ocean and Red Sea

Marina Tolmacheva

Navigation in the Indian Ocean has historically used the monsoons. The Chinese knowledge of monsoons was documented first but the Indians and Middle Easterners benefited from them as well. The Greeks learned about sailing with monsoons between the Red Sea and northwest India no later than the expedition of Nearchus (326–325 BCE). A Roman port was established at Adulis on the Red Sea to trade with India under Ptolemy III Euergetes (247–221 BCE). The Greek *Periplus of the Erythrean Sea* (first century AD) attests to the Arab domination of routes between Arabia, East Africa, and India. With the rise of the Persian Sassanid Empire, Yemen, a crossroads of sea trade, became subject to rival interests of Persians, Byzantines, and Ethiopians. Persians seemed to control the navigation in the western part of the ocean until shortly before the rise of Islam. In the mid-sixth century, the Nestorian Christian merchant Cosmas Indicopleustes of Alexandria described travel by sea to Yemen, Axum (Ethiopia), and Taprobane (Sri Lanka), where he observed various ethnic groups participating in the Indian Ocean trade. It is often believed that Indian participation in ocean navigation was discouraged by Hindu restrictions on travel, but South Indian archaeology shows the existence of deep-water harbors accessible to large vessels at least from the second century BCE, and South Indian languages contain extensive vocabularies related to ships, shipbuilding, and navigation, albeit recorded sometimes in sources dating from the tenth century AD or later. Established practices of shipping, travel and contact were behind the faster progress of Islamization in the coastal areas of India, and there was a smooth transition of groups engaged in navigation and trade to participation in the networks following the Islamic religion and using Arabic as one of their languages.

Islamic navigation in the Indian Ocean and the Red Sea and the Persian Gulf is often referred to as Arab navigation largely because the known sailing instructions and literary works describing methods of navigation are in Arabic. Early statements by some European scholars to the effect that the Arabs did not like or know the sea ignore the fact that Islam arose among northern Arabs at the time when south Arabians had accumulated many centuries' worth of sailing experience. The revival and expansion of oceanic trade under the Abbasid caliphate (750–1258) must have involved not only Arabs and Persians but also coastal populations who converted to Islam later, but the sources are not specific on this point. Participation of Gujarati sailors is well documented in medieval and early modern periods. The Sind port of Daibul (Dewal, east of Karachi) gave the name to the East African group WaDabuli, descendants of the Daibul settlers who are mentioned in Swahili chronicles and dynastic oral histories recorded in the sixteenth–twentieth centuries. The first Dabuli migrations probably took place before 893, when an earthquake severely damaged the city, which was later abandoned. In the fourteenth century, participation of Indian Muslims as well as non-Muslims in merchant navigation and piracy is recorded by Ibn Baṭṭūṭa. According to Marco Polo and Conti, the Malabar coast of southwest India was where ships from China met with those arriving from the west.

The Red Sea was the scene of early contacts between Muslims and Africa, especially Egypt and Ethiopia. It continued to play a role of conduit between the Mediterranean and the Indian Ocean and eventually carried heavy annual pilgrim traffic to Jedda and al-Jār (the port of Medina during much of the Middle Ages). Mocha was the main port in the south, Aqaba in the northeast, Qulzum (a major naval base) and Quṣayr were prominent on the Egyptian coast, and 'Aidhāb on the African coast opposite Jedda. Outside the Bab el-Mandeb the ships stopped at Aden on the Arabian side or Zeila on the African side. Pirates found refuge on Dahlak and the smaller islands; once out in the Gulf of Aden, Socotran piracy was a threat.

During the Crusades the Red Sea became a scene of European attacks on Muslim shipping. Rulers of Egypt always tried to gain control of both coasts of the sea as well as Yemen. The Turkish conquest of Egypt and Yemen in the early sixteenth century made the Ottomans masters of the Red Sea and allowed them access to the Indian Ocean, where they tried to take over shipping routes leading to India, the Persian Gulf, and Africa. However, they were forced to yield to superior Portuguese force and later suffered naval intrusions into the Red Sea by both European and Indian (Gujarati) vessels. A major concern for Turkish authorities at Mocha and on the Ethiopian side (*eyelet of Ḥabasha*) was the security and provisioning of the pilgrims to Mecca. Bombay, Goa, and Surat served as major ports for the Red Sea India trade, and Massawa had a colony of Indian merchants (*Banyans*) from the late sixteenth century.

Sailing from the north was relatively easy, although passing the tip of the Sinai Peninsula was feared because the winds from the Gulf of Aqaba and Gulf of Suez met there. Ships carried from the ocean to the Red Sea by the monsoon had to sail against northerly winds once past the strait of Bab el-Mandeb. Jedda was the terminus of oceanic routes; transit further north had to use smaller boats. The only extant sailing instructions for the Red Sea cover the distance from Jedda to Aden (by Ahmad ibn Mājid, ca. 1500). Latitude measurements taken by the stars could use the Polaris *Jāh* because of the northerly location. "Triangular instruments," not described otherwise, and quadrants are mentioned. Finding one's location was not difficult in confined waters but navigation was dangerous because of numerous coral reefs, contrary winds, and currents. The journey from the north to the south end took 30 days (sailing by day only and coasting), but the ships of Saladin's navy could reach the speed of four to five knots. The north wind of the Red Sea *shamāl* reached the southern part only from May to September, coinciding with the short period when the prevailing wind in the Gulf of Aden was westerly, thus propelling ships into the Indian Ocean. The southeasterly wind of the Red Sea *azyab* reached half way up.

Navigation in the Indian Ocean was dominated by the monsoon (from Arabic *mausim* 'season'), a wind system that reverses direction seasonally. Both halves of the Indian ocean are subject to monsoon regime. The southwest monsoon *kaws* begins in March on the East African coast, slowly spreading eastwards. It reaches its maximum strength in June and blows across the ocean until October, bringing the heaviest rains to India in June and July and causing heavy swells which made landing difficult and even closed the ports. The northeast monsoon *azyab* originates from the Indian mainland in early October, reaching Zanzibar by late November. It makes it easy to sail almost directly from Malacca to Jedda as the wind continues into the Gulf of Aden. Between the monsoon periods, voyages were made in other directions, using variable winds and breezes. March to May are such changeover months in the northwest corner of the ocean. In the Gulf of Aden the predominant non-monsoon wind is easterly. Travel from India to Africa had to be begun by early February. From Aden and Yemen one needed to leave in mid-October, and from northeast Arabia by late January, but one could not sail to Socotra during the same season. From Socotra to southeast Arabia one sailed in March–April, while India could be reached also by departing in May and during the August–September season *dūmānī*. Travel down the African coast was recommended from mid-November to April. From Bengal one had to leave westward by January; leaving from Malacca, Java, and Sumatra in February or March one could still reach Ceylon. Travel from Gujarat to Bengal and Indonesia began in April or late summer. October brought cyclones to the Bay of Bengal. The eastbound roundtrip journey from the Persian Gulf across the ocean took 18 months. China-bound ships started from the Gulf in September or October, reached Kalah Bar in January and passed through the Strait of Malacca in time to use the southern monsoon in the Sea of China. Return to Malacca took place with the NE monsoon between October and December, then ships could cross the Bay of Bengal in January and reach Arabia in February or March.

Navigation between the Middle East and China is confirmed by reports of an Arab embassy to China in the seventh century, a Persian settlement in the island of Hainan in 748, and a mixed Arab-Persian colony at Canton in the eighth–ninth centuries. In the seventh century Persian ships took 20–30 days to reach Sumatra from China, and one month from Ceylon to Palenbang. In the ninth century "Chinese ships" or "China ships" (that is, ships sailing to China) are reported in the Persian Gulf. Smaller boats brought goods from Basra and other ports of Siraf where they were reloaded on the large China boats. Ceylon (Sarandīb) was also visited and described by Arabic authors. Sea travel from the Persian Gulf to East African islands is mentioned by Arabic sources in the ninth century and described as routine in the tenth by the historian and traveler al-Mas'ūdī, although the country of Sofala (southern Tanzania and northern Mozambique) was then still poorly known. The Persian Gulf ports of Siraf and Hormuz as well as Oman were dominant on that route at the time; Aden emerged to prominence somewhat later. Some of the tales of Sindbad the Sailor (of Basra) originated in stories of Indian Ocean sailor and merchant adventures collected in the book *The Marvels of India* by Buzurg ibn Shāhriyār (ca. 950). Much of Marco Polo's return journey in the late thirteenth century must have taken place in Muslim boats and followed routes mentioned in this book. In the fourteenth century Ibn Baṭṭūta. traveled by ship across the Red Sea and later to Africa, visiting Mogadishu, Mombasa, and Kilwa. On other occasions he sailed along the west coast of India and possibly to China. In India he encountered merchants from Cairo and Northwest Africa and fell victim to Indian pirates. He reported the presence of Chinese junks at Ceylon and planned to travel on one himself. The famous Chinese voyages led by the Ming court official Zheng He (Jeng Ho) constitute the last known attempt by China to break into the Indian Ocean network. Two of these, in 1417–1419 and 1421–1422, reached Africa, visiting Malindi and the Horn of Africa. Even the arrival of the Portuguese caused only a disruption and reorganization of shipping. Lodovico Varthema (ca. 1510) and the early Portuguese sources note the continuing international presence at western Indian ports: Egyptians and "Moorish" mechants and ships from Hormuz, Arabia, Abyssinia, Kilwa, Malindi, Mombasa, and Mogadishu at Cambay, on the Malabar coast and the islands (Maldives and Laccadives). Early naval battles between the Portuguese and combined Muslim navies (e.g., at Diu in 1512) resulted in capture and destruction of numerous Muslim vessels (In the sixteenth century only the Chinese had ships able to withstand attacks of the Portuguese galleons). However, the Portuguese soon realized that they would be unable to stop native shipping, and turned their efforts to diverting trade to ports which they controlled, carriage in their own ships, and taxation of all others. By the time the Dutch and the English arrived, an accommodation had been reached. However, intra-European competition, added to Christian–Muslim rivalry, contributed to preexisting pirate activity, especially in the Persian Gulf and on the Gujarat and Malabar coasts. The maritime Muslim trade revived somewhat in the seventeenth–eighteenth centuries and declined again in the nineteenth century, at least in part due to increased British control over the routes and ports of the western Indian Ocean. Another factor was the growing dominance of European companies in the long-distance East–West trade and their penetration of local trade.

The sources for traditional Arab navigation date mostly from the late fifteenth through the sixteenth century, while our knowledge of ships and shipbuilding in the region is modern or contemporary. There are vague, scattered references to earlier sailing guides *rāhnāmaj*, devices and ships. Naval law is best known from the Malacca code of Shāh Maḥmūd (1488–1530). A sixteenth century Persian source lists 12 categories of crew members with job descriptions. The best information on navigation proper and sailing routes comes from the works of Aḥmad ibn Mājid of Julfar in Oman (d. ca. 1504) whose recognized expertise made him into a patron saint of Muslim sailors. A learned practitioner, he composed navigation manuals and sailing instructions, largely in verse, to ease memorization. From him we learn the names of several earlier pilots, dating back to the tenth-twelfth centuries. To these Aḥmad ibn Mājid added the names of his own father and grandfather; apparently, the profession of pilot was hereditary but not highly regarded. It has been asserted by some scholars that Aḥmad ibn Mājid was the pilot who guided Vasco da Gama from Malindi to Calicut but this has been contested by others. Although he spent his life on the Indian Ocean, it appears that Aḥmad ibn Mājid was aware of the different methods of navigation in the Mediterranean. Other extant works on Islamic navigation belong to Sulaymān al-Mahrī (ca. 1511), a native of Shihr who wrote several practical and theoretical treatises, and the Ottoman writer Sidi Ali Çelebi who compiled a Turkish summary of the former two authors' work while moored in Gujarat in 1554 after a Portuguese attack on the Turkish Indian Ocean fleet originally commanded by the portolan-maker Piri Reis.

Contemporary Arabic names of ships, *baghala*, *ganja*, *sanbūq*, *jihāzī*, apply to vessels with square, transom, sterns showing European influence. The older type is represented by vessels now called *būm* and *zārūq* – double-edged, coming to a point both at bow and stern. The name *sanbūq* was formerly applied to the small craft of the Red Sea; *jalba* was the sewn boat typical of the Indian Ocean region. First mentioned in the *Periplus of the Erythrean Sea*, sewn boats were carvel built, with planks edge-to-edge, and stitched with ropes of palm fiber. The timber was teak or coconut wood. They were leaky and frail but had advantage over clinker-built boats with overlapping planks when striking a coral reef. A common legend explained that nails were not used because of the dangerous power of a magnetic rock somewhere in the middle of the ocean which could attract the nails. However, iron as well as stone anchors were used. The generic names for "ship" were *markab* and *safīna*. Indian pirates had *bārijas*; smaller boats called *zawraq*, *qārib*, and *dūnij* are also mentioned in medieval texts but no particular shape is indicated. *Dau* is a generic name for lateen-rigged vessels; the Arabs do not use it. The basis of classification was the form of the hull. The ships were usually one-masted, often without decks, with a cargo capacity of up to 200 tons. Erecting the mast and the rigging, and even making the sail was the responsibility of the owner *nakhūda* and the crew rather than the shipwright. The lateen sail associated with Arab ships probably evolved from a square sail on the Indian ocean; its use in the Mediterranean is first noted in the ninth century. African and Indian vessels continued using square sails of coconut matting into the twentieth century. The lateen is a tall, triangular fore-and-aft sail with the fore angle cut off to form a luff [the front edge of a sail]. It allows sailing into the wind by going on the tack, although Arab mariners preferred not to sail closer to the wind than 90°. It is possible that a second sail (topsail) was sometimes used. No reefing was done in strong wind, but the yard could be lowered. Two side rudders were originally used for steering, although by the thirteenth century the stern rudder was known. Sailing speeds averaging 1–3 knots were normal but could reach 6 knots under favorable winds.

The most important person on board ship was the *mu'allim* who served both as captain (*rubbān*) and pilot. He was hired for the voyage and allowed to carry merchandize as part of his pay. The shipmaster (*nakhūda*) was a merchant; ships were often owned by shareholders. We know Persian terms for eleven ranks of crew members; of these, the most important were the bo'sun (*tandīl*), the ship's mate (*sarhang*), the steersman (*sukkān-gīr*), and the look-out (*panjarī*). Sailors were called *khallāsī* or *khārwah*. The captain was responsible not only for navigation but for the safety of passengers and goods as well. Among the necessities he carried were a nautical directory (*rahnāmaj*), measuring instrument (*qiyās*), bussole (a very exact compass) (*huqqa* or *dīra*), lodestone (*ḥajar*), lot (*buld*) and lantern (*fānūs*). The pilot's principal science consisted of knowing the coasts, winds and seasons, and his ship. Before departure, the Muslim prayer, *Fātiḥa,* was recited and an invocation was made to Khidr, the mythical patron saint of mariners.

By the sixteenth century, Arabic sailing manuals list over 30 different routes. Navigational books (*dafātīr*) and charts (*ṣuwar*) carried on board are mentioned in the tenth century; Aḥmad ibn Mājid calls his "chart" *qunbāṣ*, but no charts have come to light. G.R. Tibbets argues that the Arab pilot plotted his course in his head and did not need a chart; besides, proper charts could not be made because the Arabs had no way of correctly determining longitude at sea. The winds and geography of the Indian Ocean allowed the pilot to be guided roughly by the latitude of his destination (determined by the Pole star altitude). Once that was reached, he sailed down the latitude toward his goal. Another way was to keep to a recommended bearing until land was in sight and then make corrections. Extant Arab maps do not allow practical application to navigation. A Chinese chart based on the Zheng. The expedition shows the routes from China to Hormuz, the Red Sea and Africa, but no measurements can be taken from it. Charts from Muslim Indian (Gujarati) nautical manuals (*roz nāmah*) of the seventeenth–eighteenth centuries show some European influence and use stellar compass bearings and Arab units of time-distance. A possibility of Chinese influence has been suggested as well. Considering that Arab information is already found on early sixteenth century Portuguese maps, it is clear that the sharing of information among mariners created a truly international maritime culture drawing on indigenous and regional traditions and innovations.

The Arab system of nautical orientation evolved on the Indian Ocean in the intertropical region, but probably north of the Equator; it may have been representative of all Indian Ocean sailing. It is based on a 32-rhumb (*khan*) sidereal rose (*dīra*) divided into eastern and western halves separated by the Polaris (*Jāh*) in the north and the South Pole (*al-Quṭb*) in the south. The east and west divisions approximate the rising and setting of certain bright stars and constellations (Ursa Minor, Ursa Major, Cassiopeia, Capella, Vega, Arcturus, Pleiades, Altair, Orion, Sirius, Scorpio, Antares, Centaur, Canopus, Achernar). This system may have been in place by the ninth century. The bearings (*majrā*) were set by the actual stars, visible in the clear skies, not by the mathematically correct rhumbs. The compass was not unknown but rarely used or even carried. Star altitude (*qiyās*) was measured in units called *iṣba‘* (finger), supposed to correspond to the arc covered by the little finger of an outstretched hand. Its degree value measured 1/2 of the distance from the Polaris to the true pole, and thus varied with precession. In 1394 one *iṣba‘* equalled 1°56′ but in 1550, 1°33′. The full circle of 360° corresponded alternatively to 210 or 224 *iṣba‘*. *Iṣba‘* also measured 1/24 of a cubit. For longitude estimates, one *iṣba‘* equalled 8 *zām*, each *zām* corresponding to the distance covered in 3 h of sailing. A variety of other measurements, including something approximating triangulation, were calculated in these units. The altitude of the Polaris was supposed to be taken at its inferior elevation.

The instruments used for measurements included the *kamāl*, *lawḥ*, and *bilistī*. The *kamāl* was a rectangle of horn or wood with a string through the middle. It was held against the horizon in an outstretched hand, with the cord held in the teeth by the knot. Knots tied at certain intervals on the cord corresponded to the varying arcs covered by the rectangle. Variations of this instrument included knots tied at intervals corresponding to locations on a set route, a set of boards (*lawḥ*) corresponding to different arc values fixed on the cord, and the cord being held to the nose. The *bilistī* was a later version of the *kamāl*, with a rod replacing the cord, and four sliders of different sizes; most likely it postdates the Portuguese arrival because its function is essentially that of the *balestilha* (a nautical instrument of orientation, similar to the astrolabe). By the nineteenth century, the traditional system and the instruments had been largely driven out of use or forgotten, although the name and expertise of Aḥmad ibn Mājid were still respectfully remembered. Today's fiberglass dhows are equipped with motors and navigated with modern charts and instruments.

Navigation in the Pacific

Nicholas J. Goetzfridt

Three thousand years ago, Polynesian voyagers had already reached the small Pacific island chains of Tonga and Samoa. A thousand years later, following, as some scholars believe, the refinement of navigational capabilities and canoe design, they reached the far distant Marquesas, Tuamotus, and Society Islands. Geoffrey Irwin maintains on the basis of archaeological evidence and empirical analysis that there probably was no pause in the prehistoric settlement of eastern Polynesia. The rate of voyaging may very well have increased in accordance with the larger ocean gaps between archipelagoes. Voyagers eventually reached the small and very isolated Easter Island, may very well have established voyaging routes between the Society Islands and Hawaii, and may have even reached the coast of South America as is suggested, among other things, by the transmission of the sweet potato.

The questions of when the Pacific was settled are not as variable and questionable as those about how it was settled. The challenge of this issue, at least in terms of distance and the diminishing target areas of land as one moves east, becomes increasingly great as one can see by looking at a map of the Pacific Ocean. Several scholars consider all of these movements to have been the consequence of population demands, warfare, and the basic desire to explore and keep seeking. But the notion of great navigators who controlled their destiny and the destinies of those who put their trust in them, and who could ride the sea at will, prompted many articles and treatises. It also provided the easy and attractive answer to the haunting questions concerning the ancient settlement of Oceania.

Percy Smith, who wrote mostly between 1890 and 1920, promoted a migration of deliberate and controlled dimensions which he believed was most evident on the basis of Polynesian traditions and the inferences that one could make from them. He acknowledged the importance of applying the fields of ethnology, historical linguistics, and especially oral traditions to his theories on the ancient Aryan origins of the Polynesians. These alleged achievements included a voyage from Borneo to Hawaii in about AD 450 (the fact that voyagers continued on to Hawaii even after reaching hospitable islands along the way indicated to Smith that they were following the directions of a previous navigator), the reaching of Antarctic waters by two deliberate voyagers described in traditional histories, and the frequent voyaging between Tahiti and Hawaii (using the Line Islands as resting points) which eventually ceased in the fourteenth century, because the "boldest navigators of the race" had departed

N

to New Zealand in the fourteenth century Great Fleet of the Maori people.

Elsdon Best, writing during the same time, also endowed navigators and voyagers in the Pacific with a perceptiveness of the environment and an adherence to the messages of traditions which made well planned, deliberate voyagers of settlement and communication a reality among the far flung islands of Oceania. While numerous early European explorers in the Pacific expressed wonderment in their journals at the existence of complex and populous societies on both low and high islands, which were at one stage thought to be remnants of a sunken continents occupied by survivors, very little was ever recorded on the actual means by which indigenous navigators dealt with practical problems related to the art of oceanic path-finding.

Buck, during the next 30 years, considered more practical questions on canoe capabilities and types, and the evidence that ethnology in Polynesia suggested in relation to early Polynesian migration. He also asserted the probable movements and routes used by Polynesians to reach islands throughout Polynesia and the eastern regions of Micronesia and Melanesia. He recognized the relevance of Polynesian traditions and related genealogies for tracing Polynesian origins and for understanding early voyaging and settlement in the Pacific, with an emphasis on voyages between the Society Islands and New Zealand.

But these speculations and the assignment of great skills to navigators who then sailed the Pacific with complete control, denied, or superficially addressed issues. They thus failed to consider the diverse problems of both natural and human origin which confront a navigator without modern instruments on an open ocean. Were there explicit strategies followed for the initial exploration of islands to the east of the easier "voyaging corridor" from Southeast Asia to Melanesia? If they were deliberate voyages with the intention of settlement, were such initial voyagers and those that were to follow one-way or two-way voyages? If two-way voyages were accomplished, were they done so regularly or perhaps even for the purposes of inter island communication? What might have been the distance limit for such intentional voyages of return? How did changes in climate and stellar positions over a long period of time affect the success rate of such voyages? Why did voyaging in some areas apparently cease before it did in other areas? Then, there is the question which has generated a significant amount of literature on the overall issue of oceanic voyaging and settlement. This involves numerous practical problems of reaching land, including the use of land indicating signs such as the flight of birds, the swell of waves generated from an unseen island or islands, the "loom" of land produced from an island's white sand and a still lagoon reflecting the sun's glare, the ability to determine set and drift en route, the ability to steer and maintain a course from a known sequence of stars, and the ability to maintain or to eventually recover such a course when stars are obscured or the winds change.

Was it possible that early voyagers in the Pacific were capable of using island "blocks" and "screens" that are created by the ability to perceive and interpret these wave patterns emanating from unseen islands, the flight of certain sea birds (or "bird zones"), types of fish, seaweed, water color, and clouds gathering over a distant island? These elements may have offered a 30–40 mile radius around each island which essentially expanded the size of an island target. Such perceived circles ultimately overlap throughout significant areas of the Pacific and could have enabled navigators to sail for an archipelago from even great distances before seeking a specific island within the archipelago.

Voyaging researcher David Lewis in his numerous voyages with present-day indigenous navigators of the Pacific has also recorded the glowing plaques of bioluminescence that can indicate the existence of land 80–100 miles away. But the elements of darkness and overcast skies have often been used by critics to maintain that many components of these blocks were not consistent enough to be dependable.

The academic granting of voyaging prowess to indigenous voyagers of the Pacific by these early writers and the lack of precise information on the practicality and effective means of using these natural elements to find land (not to mention the formidable question of how a course could be maintained over long distances before arriving at these island blocks), was underscored by Andrew Sharp's books and articles between 1956 and 1969 which dismissed the ability of Polynesians to exercise any significant control over their voyages. Sharp maintained that these voyagers were incapable of compensating for set and drift during the course of a voyage, of maintaining a course in accordance with star paths or movements when the night sky was obscured, and of being unable to comprehend their position and the position of their destination once they were driven off course by a gale or storm. According to Sharp, Polynesian traditions with names of distant islands and directions for reaching them were actually derived from European contact. Polynesians knew of distant archipelagoes. The Raiatean navigator Tupa'ia expressed this knowledge to Captain James Cook in 1769 whose assistants in turn created a map (apparently misunderstanding Tupa'ia's directions for north and south) that stretched from Fiji to the Marquesas. This merely demonstrated that Polynesians had traveled these distances but not necessarily as a result of deliberate and return voyages. Sharp also stressed that the apparent random distribution of several important plants and animals is simply reflective of the haphazard nature of Pacific settlement.

While the accidental settlement of Polynesia, according to Sharp, did occur primarily from west to east (a direction which is generally agreed upon by Pacific scholars), winds and currents drove later voyagers in all directions. Although Sharp did allow for the ability of Polynesians (particularly in Tonga and the Tuamotu Archipelago) to undertake voyages of no more than 300 miles without intervening islands with the intention of marking a return voyage home, the severe limitations of a noninstrumental navigational system nevertheless made even these voyages open to chance. The use of this "primitive navigation" by Pacific voyagers made them unable to protect themselves against any lateral displacement and did not enable them to derive much consistent and valuable information from horizon stars or to use stars to establish either latitude or longitude.

Thor Heyerdahl meanwhile challenged the general acceptance of an oceanic settlement pattern from west to east, maintaining that archaeological, botanical, ethnological, biological, geographical, and navigational evidence supported a Peruvian movement from South America into Polynesia using balsa rafts with strategically arranged guara hardwood centerboards. He maintained that Spanish expeditions into Polynesia actually followed sea routes established by the Incas and often referred to traditional accounts of the voyager Yupaanqui Inca Tupacor Tupac Inca. He was said to have departed from Peru in search of legendary Pacific islands, using the traditionally known island of Sala-y-Gómez as the primary landmark for beginning a voyage to the west, and to return 9–12 months later with "dark" people, which suggests that he may have voyaged as far west as Melanesia. In an attempt to prove that such voyages were possible, Heyerdahl and a crew sailed the Kon Tiki balsa raft from Peru to an eventual landfall on the atoll of Raroia in the Tuamotus in 1947. Heyerdahl, however, has been criticized by various scholars for, among other things, selectively neglecting evidence which strongly suggests a Southeast Asian origin of the Polynesians, his contention that "primitive asiatic craft" could not have successfully sailed from Southeast Asia to Polynesia, and for undermining or ignoring the fact that seasonal shifts in the prevailing winds of the Pacific do occur, making well planned voyages from west to east possible.

Sharp's works instilled what researcher Ben Finney characterizes as a "healthy corrective to some extravagant claims." The inferring of the abilities or inabilities of indigenous voyagers to control their destinies at sea on the basis of poor references in the journals of European explorers, simply produced theories which had little practical, at-sea evidence to support them. Ben Finney's and David Lewis' investigations into the navigational abilities of indigenous voyagers in the Pacific have made significant contributions to scholarship in this area.

Finney was and has been involved for a number of years in the building and sailing of the Hawaiian double canoe Hōkūle'a. Beginning with its first, noninstrumental voyage from Hawaii to Tahiti in 1976, it has provided an important component to Hawaiian cultural revival in the immediacy of its connections with the voyaging heritage of the Hawaiian people. It has also offered numerous opportunities for navigators (first the Satawalese navigator Mau Piailug and more recently the Hawaiian navigator Nainoa Thompson) to test and develop their use of various noninstrumental, navigational strategies to deal effectively with the voyaging problems of maintaining an accurate course under various natural conditions. This has also given other scholars the opportunity to apply these voyaging experiences to important questions related to the early settlement of Oceania, particularly the question of the movement from west to east which is normally a movement against prevailing winds. The Hōkūle'a 1985–1987 "Voyage of Rediscovery" in the Pacific engaged in experiments in west to east movements (in this case, from Samoa to Rarotonga via Aitutaki and from Rarotonga to Tahiti) to attempt to understand how voyagers effectively exploited periodic westerlies to cross the crucial gap between the Western Polynesia and Eastern Polynesia cultural provinces via the Samoa–Tahiti expanse. These methods for exploiting changes in the trade winds, often interrupted by low pressure systems, if they were undertaken by skilled navigators, would necessarily have required strategies for perhaps specific legs between western and eastern Polynesian islands.

Some items out of the rather voluminous literature on indigenous noninstrumental navigation and voyaging in the Pacific address the impact that climatic changes between the warming period of the Little Climatic Optimum (up to the twelfth and thirteenth centuries) and the advent of the Little Ice Age (approximately the fifteenth century) could have had on the occurrence of storms and thus the ability of voyagers to engage in long distant trips of exploration and settlement. Some scholars theorize that although voyagers from Eastern Polynesia were able to reach and settle in New Zealand by the early fourteenth century, this climatic change may have ultimately prevented them from going further to reach Australia and Tasmania. Some scholars have also conjectured on the impact that changing star patterns over several millennia may have on present-day investigations into this great achievement of human migration. At least one scholar has investigated how this change may provide a historical link between Arab and current Carolinian navigational star systems (Halpern 1986).

It should be emphasized, however, that all this scholarship on indigenous navigational abilities in relation to the chronology and patterns of human settlement on Pacific islands is incomplete without incorporating the findings and theories of other areas of scholarship, particularly archaeology. While not necessarily being directly concerned with navigational capabilities, they often provide solid physical evidence of the past, from which theories on such migration and voyaging achievements can be made and developed and/or challenged. The part that archaeology plays in attempting to answer many of these questions cannot be understated, although the extensive work that has been done in the field and remains to be done cannot be given adequate summary in this article.

The literature on indigenous voyaging in the Pacific has also covered the use and possible use of several indigenously devised navigational aids – the best known of which are the Marshall Islands stick charts which a German writer, Schück, attempted to describe in 1887, noting European references to the existence of Marshallese maps as early as 1817. Europeans in the late nineteenth century noted the use of these charts which are basically intended, through unique connections of various sticks of wood and shells, to document wave patterns and swells in relation to specific islands in the two archipelagoes of Ratak and Ralik in The Marshall Islands. Several articles refer to the secrecy that was once associated with them, while Hops noted that only the Marshall Islands may have the natural prerequisites which make the existence of stick charts unique to them. Another device that has been explored in the literature has been the sacred calabash filled with water whose holes near its top allegedly enabled a navigator to establish the latitude of Hawaii. This was accomplished by lining up Polaris at a 19° angle during a voyage from the south, and thus allowed a navigator to turn confidently to the west where he would eventually find Hawaii. Although confusion over a large calabash in the Bishop Museum in Hawaii added to the controversy, the use of the sacred calabash has generally been dismissed as being impractical. Others include the existence of nine coral stones on the northwestern end of Arorae atoll in Kiribati, perhaps used at one time by voyagers to set their courses to neighboring islands in Kiribati, a stone canoe in Beru (*kiribati*) for instructional purposes, a coconut wind compass with four directional holes used by Tahitian voyagers, the use of dials with wood hanging from strings with knots to indicate the position of stars, a bow hole and cord used for star course steering, the seeking of divination before a voyage through the tying of knots in palm leaves, and a cane filled with water to determine latitude and perhaps used in the Caroline Islands.

Research on the cognitive systems of indigenous navigators who still undertake voyages in the Pacific, particularly from the atolls of Satawal and Polowat in the central Caroline Islands of Micronesia, is far more extensive than these occasional references (with the exception of Marshallese stick charts) to these unique devises. Gladwin's groundbreaking study on thought processes involved in ixPolowatese navigational knowledge which he related to the academic test performance of economically underprivileged individuals in the United States, has been followed by numerous works concerned with the canoes, navigators, and navigational systems of Polowat and Satawal. There are also ethnographic concerns about cultural and social elements which enable noninstrumental indigenous navigation on these islands to survive in a modern technological world. While Western material influence has contributed to the decline of indigenous voyaging in areas where it was pursued until relatively recently, as has the actual government banning of voyaging, traditional navigation on these two atolls forms an integral part of their identity and society.

One well documented navigation technique found in the literature which discusses these esoteric systems is the technique of *etak*. The system of etak defies Western conceptualizations of movement in that a reference (sometimes imaginary island) to the side is seen as moving toward and past the voyager's canoe while the canoe remains stationary. The navigator is subsequently able to determine his position and progress in relation to stars and the etak segments that they provide. The survival of these systems of course depends upon how successfully they are transmitted to the young. The maintenance of star courses through songs and chants allowed for these courses to be used in recent 600 mile voyages between Satawal/Polowat and Saipan in the Northern Mariana Islands, despite the fact that such voyages had apparently not been undertaken since the early part of the twentieth century.

We now know of this rich voyaging heritage which many Pacific islanders value in the context of their cultures today. And we are aware of the questions that relate to what must be seen as an astonishing achievement in human movement throughout a vast Pacific Ocean at a time when Europeans were still depending (and would continue to depend for a long time) upon the sight of a coast. It is little wonder why the literature on indigenous navigation voyaging in the Pacific has developed as it has since the latter portion of the nineteenth century.

Navigation in Polynesia

Richard Feinberg

Polynesian dispersal through the Pacific islands is one of the great maritime accomplishments of human history. In wooden boats held together with cord fashioned from coconut husks, and following the stars, sun, waves, and wind, they populated the vast triangle bounded by Hawai'i, Rapanui (Easter Island), and Aotearoa (New Zealand).

The Polynesians' ancestors migrated from Island Southeast Asia to the Bismarck Archipelago in northeastern Papua New Guinea by 2000 BCE, where they left their distinctive Lapita pottery. Around 1500 BCE, they moved out into Fiji, and then to Tonga and Samoa. During the next two millennia they spread throughout the area now known as Polynesia. Later, a series of back-migrations populated the western Polynesian "outliers" scattered through the regions commonly identified as Melanesia and Micronesia.

Some of these voyages were likely purposeful exploratory forays. Others were forced migrations resulting from population pressure or political and military conflict. Some were accidental drift voyages by sailors who had lost their way, or by fishermen swept out to sea. At each stage, return voyages probably were made for purposes of trade, marriage, and exchange of information.

Thinking about Polynesian seafaring abilities has shifted several times since early European contact. The French explorer Bougainville was so impressed by the canoes he witnessed in Samoa in 1768 that he called the archipelago "The Navigators' Islands." Britain's Captain James Cook noted that Polynesian canoes were often as fast and maneuverable as his ships, and he carefully recorded Raiatean Tupaia's impressive geographical knowledge. Even as late as the middle twentieth century, Sir Peter Buck (Te Rangi Hiroa), director of Hawai'i's Bishop Museum, took Polynesian traditions of voyaging, exploration, migration, and settlement quite literally.

The tone of the discussion altered radically with the publication in 1957 of Andrew Sharp's *Ancient Voyagers in the Pacific*. Sharp argued that, in the absence of instruments, human beings lacked the ability to navigate successfully for more than a few hundred miles. In particular, he argued, one could not detect, accurately estimate, and correct for current or leeway drift. Over distances of the many hundreds (sometimes thousands) of miles claimed by Polynesian oral traditions, he argued, errors would have been compounded, making the prospect of intentional landfall almost nil. Therefore, exploration and settlement were almost certainly the result of accidental drift voyages by sailors blown off course or forced, against their will, to put to sea.

This view again shifted with the pioneering ethnographic work of Thomas Gladwin (1970) on the Micronesian atoll of Puluwat and David Lewis' more wide-ranging survey in 1972. They and others have documented voyages of hundreds of miles with accuracy comparable to that achieved with modern instruments, as well as the techniques through which this is

N

accomplished. Most of the active voyaging in recent times has been conducted by Micronesians, but the techniques are similar to those employed by Polynesians in the past. This is confirmed by comments from Polynesians recorded by early European explorers, and those few Polynesian communities where traditional wayfinding techniques have been retained in recent times.

A second line of evidence casting doubt on Sharp's drift voyage argument is provided by the direction of settlement. Linguistic and archaeological data make it clear that migration was predominantly west to east, against the prevailing winds. Recorded drift voyages, by contrast, are almost always in the opposite direction. Such voyages have certainly occurred, and more than a few sailors have been lost at sea. This however, cannot account for exploration and settlement of the Pacific.

A third strand of evidence comes from computer simulations. Importantly, in 1973, Levison, Ward, and Webb demonstrated that Oceanic exploration and settlement could not have been a result of accidental drift, but must have resulted primarily from purposeful voyaging by skilled seafarers and navigators. They did this by taking into account prevailing winds and currents, and comparing them with the geographical relationships among the various islands and archipelagoes.

The final line of evidence supporting the proficiency of Oceanic navigators comes from experimental voyages with replicas of traditional voyaging canoes, using traditional navigational techniques. In 1980, a group of Taumako (Duff) Islanders from the eastern Solomon Islands built a traditional voyaging canoe (*te puke*), which they successfully sailed to Guadalcanal, over 400 miles away.

At least equally impressive are the exploits of *Hōkūle'a*, a replica Hawaiian double-hulled voyaging canoe, built with modern materials but to traditional design, which has been sailed successfully through most of Polynesia. Its first major voyage was to Tahiti, following traditionally prescribed star paths, and performed under the guidance of Mau Piailug, a master navigator from Satawal Island in Micronesia. Later, Nainoa Thompson, a Hawaiian trained largely by Piailug, navigated *Hōkūle'a* without instruments through all the major Polynesian archipelagoes. From 1991 to 1994, the Hawaiian Voyaging Society constructed *Hawai'iloa*, a double-hulled canoe built of traditional materials. Since that time, *Hawai'iloa* has been sailed through much of Polynesia. Most prominently, in 1995, she joined a fleet of voyaging canoes from Aotearoa (New Zealand), Cook Islands, and Hawai'i to sail, without instruments, from French Polynesia to Hawai'i (Finney 2003).

Canoe Design

To travel safely on the vast Pacific Ocean requires seaworthy vessels. These had to be sturdy, maneuverable, able to resist leeway drift, and (to some degree) sail into the wind. For lengthy journeys, they had to be large enough to carry a good quantity of food, drink, and sometimes crops and livestock. This was accomplished differently in different parts of Oceania.

Most common were single-outrigger canoes ranging from small vessels paddled by one or two men (or occasionally women) for coastal travel and inshore fishing to the great Fijian *camakau* which might approach 100 ft in length and rival European sailing ships for speed. Resembling the *camakau* were voyaging canoes of several Polynesian outliers: e.g., Takuu (*vaka fai laa*), Nukumanu (*vaka hai laa*), and the Polynesian islands of the Santa Cruz group in the eastern Solomons (*puke*). Outlier Polynesians on Anuta still make single-outrigger sailing canoes which they have been known to sail hundreds of miles – to Vanikoro, northern Vanuatu, and recently to Santa Ana Island off Makira. In the outlier atolls, such as Nukumanu and Takuu, islanders have adapted the Fijian and Micronesian design of interchangeable bow and stern, where the canoe is tacked by moving the sail to the opposite end of the vessel, thereby always keeping the outrigger upwind. On other islands, such as Tikopia and Anuta, the more common Polynesian pattern was adopted. Bow and stern are distinct; the outrigger is always kept to the same side (most often, to port); and the canoe is sometimes sailed with the outrigger to the lee side of the craft.

Most imposing of the Polynesian voyaging canoes undoubtedly were the great double-hulled vessels of the Polynesian heartland. Such canoes have been reported from Rotuma and Tuvalu, south to Tonga and Aotearoa, and north to Hawai'i. More specialized developments included the New Zealand Maori's impressive single-hulled, outriggerless canoes, designed to carry scores of warriors primarily in coastal waters. For an inventory of Pacific Islanders' canoe construction and design, Haddon, and Hornell's encyclopedic treatment remains unparalleled.

Polynesian voyaging canoes could cover well over 100 miles a day with a favorable wind. The outrigger or double-hull design provides resistance to leeway drift without the need for a deep keel, which is a hazard sailing through a sea studded with shallow reefs. It is difficult, however, to beat into a head wind; and even the best outrigger canoes cannot sail at better than a close reach or approximately 75° off the wind.

Navigational Techniques

The most important tool for Oceanic navigation is the stars. Near the equator, stars rise from the east, travel more or less straight overhead, and set toward the west. The expert navigator knows the relationship between the bearings of various islands and the rising and setting points of various stars. Ideally, he identifies a star that he knows rises directly over the target island and points the bow of the canoe toward that star. When the star rises too high to be a reliable guide, the navigator turns his attention to another star following approximately the same trajectory. A sequence of such stars may well continue through the night, and it forms a star path.

In reality, it is unlikely for a sequence of stars to rise or set directly over the target island, so the navigator must set off the bow at an appropriate angle from the stars' actual position. In addition, the navigator must be able to estimate the direction and speed of wind, current, and leeway drift in determining a proper heading.

Wind strength and direction are not overly difficult to estimate as long as one can see the stars, moon, or sun, while leeway drift depends on the contours of the canoe's hull and heading in relation to the wind. It often can be gauged by the angle between the canoe and its wake.

Current is most difficult to estimate, but not impossible. First, a navigator knows the prevailing currents in the region that he plans to sail. These tend to be fairly constant at a particular time of year. The current's velocity is confirmed when the canoe is still near the point of embarkation, or when sailing over shallow reefs. The greatest danger is if currents change direction while one is in deep water, far from land. Such shifts are difficult to detect, but there are sometimes useful clues. Anutans, for example, say that when the current and wind are running in opposite directions, seas tend to be unusually steep and white-capped. Conversely, when wind and current coincide, the seas are exceptionally flat in relation to the strength of the wind. Thus, by feeling wind strength and seeing or feeling the condition of the sea, one often discerns the current's direction even in deep water.

Fixing one's position on the ocean is another major problem. Latitude can be gauged with some accuracy by identifying zenith stars: stars located at a point that is directly above the observer. In addition, the configuration of stars at a given latitude at the same time on any given night is identical regardless of longitude. Therefore, one can estimate latitude by observing the altitude at which specific stars rise and set. Longitude, however, cannot be gauged from observation of the sky and must be estimated by dead reckoning. This means that the navigator fixes the position of his canoe in relation to the islands in his universe by estimating the vessel's speed, direction, and how long it has been at sea.

This is difficult, requiring the navigator to keep a running total of his vessel's progress at all times. One consequence is that he cannot sleep, other than occasional brief naps, even on a lengthy journey. Sharp argued that the element of human error inherent in dead reckoning is cumulative and, over a distance of many hundreds of miles, would be too great to permit accurate landfall. Empirically, it has been demonstrated, however, that the error is random and tends to cancel itself out. Therefore, the longer the voyage, the smaller the probable error.

During the day, when stars are unavailable, Polynesian navigators use the sun. This is practical in early morning and late afternoon, when the sun is low on the horizon. Toward mid-day, however, it loses value as a navigational aid. The sky also loses its navigational value when it is obscured by clouds, whether in the day or night. Under such conditions, auxiliary techniques are needed.

Navigators are aware of the prevailing wind patterns. If the sky is overcast, they assume that winds will remain constant until the stars and sun can once again be seen.

Still more stable and reliable are swells. A regular ground swell is produced by winds from far away, blowing over a vast expanse of ocean. Such swells remain constant despite shifts in local wind direction. An expert navigator can distinguish the regular ground swell from choppier seas produced by local winds. Indeed, some Micronesians have demonstrated the ability to distinguish several swells caused simultaneously by different far-off wind patterns. Polynesian master navigators almost certainly could do the same. By holding a steady course in relation to the swell pattern, then, the navigator maintains his bearings until celestial bodies become visible again.

In addition, sea marks such as deep reefs that can be detected from the color of the water may help indicate one's route. Use of such marks has been reported ethnographically for Micronesia, and at least some Polynesian navigators undoubtedly employed similar techniques.

Sailing strategy, particularly for exploratory voyagers, was clearly to sail counter to prevailing winds. This could be accomplished by waiting for a westerly shift at a time when the prevailing winds were from the east. If landfall was not made in a reasonable amount of time, it was expected that the wind would shift again, making for an easy return home. This accounts for the generally west-to-east direction of Polynesian migration.

Likewise, in historic times, Anutans like to sail at the beginning and end of the trade wind season, when breezes are relatively light and unstable, but the prevailing wind is from the southeast. During this period, they can usually find a period of a few days when wind of moderate strength is blowing in the preferred direction. Should it shift before they reach their destination, they can almost always return to their point of departure.

Geoffrey Irwin further suggests, plausibly although without definitive evidence, that long-distance voyagers employed "latitude sailing." This involves sailing to the latitude of the target island but at a point well to windward, then making landfall by running downwind. Sailors from all parts of the Pacific also minimized their risk by island hopping, thereby breaking lengthy journeys into shorter segments. And they aimed, wherever possible, for groups of islands rather than isolated targets.

Land-Finding

As the navigator approaches land, he uses a variety of techniques for homing in on his objective. These include attempting to make landfall during daylight to minimize the chance of either being swept onto an exposed reef or overrunning the target. Then, before land is visible, it may be located via one of several indicators.

Among the most important of these are the flight patterns of birds that roost on land at night and fly to sea to feed during the day. Reflected waves are shaped differently from waves produced directly by the wind, and they can, at times, be felt at distances of more than 20 miles from land. Refraction patterns are more difficult to decipher but are used by a few peoples. Clouds tend to accumulate around the peaks of high islands, indicating their presence; and a greenish tint to clouds may sometimes indicate the presence of an atoll when it still cannot be seen from a canoe.

Polynesia in Comparison with Other Culture Areas

A few writers have made much of the distinction between Polynesia and other Oceanic culture areas in terms of seafaring acumen. Edward Dodd, for example, has suggested that the comparatively short distances traversed by Melanesians and even Micronesians means their vessels and wayfinding techniques could be less sophisticated than those of Polynesians, who sometimes had to sail thousands of miles, e.g., on journeys from Tahiti to Hawai'i or Aotearoa.

Clearly, the logistics of such lengthy voyages posed problems not faced by Micronesians sailing from the Carolines to Saipan – a distance of about 500 miles. On such journeys, for example, the importance of dead reckoning increases and a smaller proportion of the voyage is guided by land-finding techniques such as reflected waves or flight patterns of birds. However, modern ethnographic evidence from around the Pacific and beyond supports the view that navigational techniques were fundamentally similar throughout Oceania. The transferability of old skills to new locations, and their ability to meet new challenges, is demonstrated by the success of Mau Piailug and Nainoa Thompson, piloting the *Hōkūle'a* through major portions of the Polynesian Triangle.

Nazca Lines

David M. Browne

On the desert plains and the fringes of the valleys that form the heartland of the ancient Nasca culture of the south-central coast of Peru is a vast array of ground markings that are known collectively as the "Nazca Lines." The most extensive concentration of these constructions, termed *geoglyphs* by archeologists, is found on the Pampa de Nazca between the Ingenio and Nazca valleys. The pampa is an elevated desert plain 200 km^2, between 400 and 600 m above sea level. It is severely dissected by dry watercourses formed by periodic flash floods. About 3.6 million m^2 of this area are covered by geoglyphs. Concentrations of markings also occur on the slopes of and on the plateaux and pampas between the other valleys of the Nazca drainage, and are particularly dense in the Palpa area. Geoglyphs are also known further north, in the Ica valley, where the other major centers of the Nasca culture are found.

Geoglyphs take many forms, but can be grouped into four main classes: biomorphs, enclosures, lines, and geometric figures.

Biomorphs are stylized representations of various creatures, the commonest being birds, among which are hummingbirds, the condor, pelican, and frigate bird (Figs. 1 and 2). There are also depictions of a monkey, fox, lizard, spider (Fig. 3), killer whale (Fig. 4), and fish, as well as a few drawings of plants or flowers and bizarre combinations of body parts (Fig. 5). Humanlike figures are also found, particularly in the Palpa area. Most forms are outlined by a continuous line usually about 0.6-m wide, which never crosses and ends near where it starts. The greatest concentration of biomorphs occurs in the northwest corner of the Pampa de Nazca, above the south edge of the Ingenio valley and close to a major regional center of the Nasca culture. Some biomorphs appear to be isolated drawings, but others, for example the monkey, seem to have a direct association with other geometric figures. Despite the impressive size of some drawings they are generally insignificant in scale when compared to many of the enclosures.

Enclosures are trapezoidal, triangular, quadrangular, and rectangular clearings defined by stone banks up to 1-m high (Fig. 6). They vary greatly in area and proportion, the largest occupying the space of several football fields. This class of geoglyphs is the most frequently occurring form outside the Pampa de Nazca.

N

Nazca Lines. Fig. 5 Nazca biomorph: "pair of hands"; possibly stylized root crop (from the author's photo collection).

Nazca Lines. Fig. 6 Nazca Lines: trapezoids (from the author's photo collection).

Where they are built on the flat spurs between valleys they follow the long axis of the topography; on hillsides their narrow ends point toward the top of the hill; and where they are constructed in the bottom of a small, dry tributary valley their narrow ends point toward its head. About 300 are found across the Pampa itself, roughly two-thirds of which are orientated to the line of watercourses, with their ends pointing upstream. Enclosures are commonly found in association with other forms of geoglyphs such as line centers, spirals, and zigzags.

Line centers consist of a series of straight lines converging on or radiating from usually a hillock or low mound on the periphery of the Pampa de Nazca. The lines vary in width and length, some running for several kilometers. Over 90% of the geoglyphs found on the Pampa are associated with the 62 line centers identified so far. However, only about a quarter of the centers are interconnected, suggesting that these features cannot be interpreted as a simple coherent system. Line centers are frequently connected to enclosures. Long lines, unconnected to line centers, running dead straight for several kilometers with no regard for topography are another feature of the Pampa and elsewhere, as are pairs of parallel straight lines.

The most prominent of the geometric forms found are spirals created by a single line along which it is possible to enter and exit in an unbroken progress. Other figures include zigzags and "fingers" consisting of a series of concentric semicircles formed by a single line continuously running parallel to itself in a set of arcs.

Contrary to some assertions, constructing the geoglyphs required no great engineering skill and no more complicated surveying equipment than simple stakes and rope. The surface of the pampa is covered by rocks which are subjected constantly to daily extremes of temperature and humidity which lead through bacterial action to the formation of characteristic dark-collared varnish on their upper parts. The underlying soil is lighter in color, and if the surface stones are removed a bright patch of ground is created, contrasting strongly with the darker, undisturbed desert floor. This contrast will persist for centuries, only gradually diminishing as the same weathering agencies act upon the newly created surfaces. In most cases the construction of a Nazca geoglyph involved nothing more than stripping the required width or area of its upper stones and regularly piling the rocks along the edge to form a boundary. Judging from some apparently incomplete examples, an intermediate stage in the construction of an enclosure was to collect the surface stones in a series of small piles on the surface of the intended clearing, probably in baskets rather than by sweeping, before removing them to the edges. It has been estimated that it would take ten people to clear 16,000 m^2 in a week, and in a trial a spiral of 10-m diameter was built in less than 2 h. The construction of the biomorphs probably required a preliminary model such as a figure etched on wood, sand drawing, or textile embroidery. The precise method whereby the final geoglyph depiction was scaled up from this model is unknown, although several geometric systems have been suggested. Attempts to demonstrate the use of a particular standard unit of measurement in their formation have been unconvincing.

The practice of etching or building figures in the unoccupied desert adjacent to settlements seems to have been started by the communities sharing the Paracas material culture in the two centuries before ca. 200 BCE. Evidence is emerging to show that the activity may have started in the Palpa region with the construction of humanlike figures, perhaps inspired by a tradition of inscribing petroglyphs. Roughly contemporaneously, mythical beings related to the so-called "Oculate Being" of Paracas iconography were built on the Pampa de Nazca. There is little doubt, however, that most geoglyphs were built by the peoples of the Nasca culture (ca. 200 BCE–AD 600), although the practice was continued locally on a small scale by some communities until the late fifteenth century. Two radiocarbon dates from wooden posts supposedly associated with lines fall within the later Nasca period. Nasca pottery is found so repetitively on the surface of many enclosures as to indicate their construction and use during its currency. Radiocarbon dating of the organic material sealed under the varnish on rocks lifted by line builders indicates a similar date range. Additional support is given by the clear association of some geoglyphs with Nasca ceremonial architecture at the great pilgrimage center of Cahuachi and the lesser complex at Llipata.

Various explanations have been advanced for the Nazca Lines that they were fields, the sites of textile workshops, a giant sports arena, and even markers and landing places for extraterrestrial spacecraft! The idea that they fulfilled primarily an astronomical function has been championed by the principal fieldworker on the Lines, Maria Reiche. In her view the linear geoglyphs functioned to mark the solstices, the rising and the setting of the moon, and the rise of the Pleiades. The multiplicity of some lines she explained as the attempts of ancient astronomers to compensate for the precession effect, the subtle shifts over time in star rising and setting positions. The biomorphs were regarded as representing constellations, for example the spider for Orion and the monkey for Ursa Major. The whole system was supposedly elaborated for calendric purposes, principally to predict the onset of the rains so essential to agriculture in the extremely arid Nazca environment.

Reiche's claims for significant, repetitive astronomical alignments have not been supported by other studies. A more basic objection to her approach is that it projects on to the evidence a European, Northern Hemisphere perspective which ignores Andean peoples' astronomical perceptions. By using historical and ethnographic analogies it is possible to offer plausible explanations of the geoglyphs' forms and functions which make sense in the context of a general Andean religious tradition.

The location and form of the Lines leaves little doubt that they were built for ritual purposes. Many of the lines connected to line centers bear a general resemblance to Inca roads, and footpaths are still discernible within them, supporting the view that they were processional ways. The use of straight-line paths has been shown to have been in widespread use up to the present day in Andean religious observances. The lines defining biomorphs and geometric figures are also laid out in a fashion which would allow uninterrupted procession through the figure. The core of the line centers, and the enclosures, were probably the foci of the processions where the principal rites and offerings were enacted. Depictions on Nasca pottery suggest that the participants in these rituals would have been specially attired, often wearing masks, and proceeded by rhythmic dancing to the accompaniment of drums and pan pipes (Fig. 7). The evidence of broken pottery and offerings of foodstuffs attests to ritual feasting and sacrifice.

It is highly probable, given general Andean practice, that kinship groups (*ayllus*) in acts of obligatory communal labor would have been responsible for the construction and maintenance of particular lines and figures and for the organization of the relevant rites at a certain time of year, imparting a type of calendric significance to the geoglyphs. Some of the biomorphs, such as those along the edge of the middle Ingenio valley, may have been ancestral emblems of such social groups. The palimpsest of geoglyphs found can be explained in part by a practice of periodical renewal of the sacred site at a slightly different location.

The basic concern of the Nasca people was the fertility of their valleys, which was entirely dependent on the arrival of waters from the Andes to the east. It is not unlikely that peaks in these mountains were deified

Nazca Lines. Fig. 7 Early Nazca figurine: masked shaman (from the author's photo collection).

N

and perceived of as the sources of this lifeforce. The shape and orientation of many of the enclosures can be argued to be symbolic of the flow of water from the highlands. Similarly, certain geometric geoglyphs such as spirals and zigzags may have been symbols of a water cult. Offerings of *Spondylus* shells, associated with rain in Andean lore, have been found in connection with mounds, possibly altars, at the ends of some trapezoids. One recent theory (Silverman and Proulx 2002) proposes that the geometrics actually indicate the position of water-bearing faults and that the trapezoids show the line of subterranean watercourses determined by dowsing. In some cases, such as at Cantalloc, south of Nazca, the layout of a trapezoid in relation to a lesser hill seems to be a model of the topographic relationship of a valley with an adjacent mountain.

The Nazca Lines were a product of intense, repetitive ritual activity over several centuries, concerned with guaranteeing the continuing fertility of the valley oases upon which human society is utterly dependent in southern Peru.

Nīlakaṇṭha Somayāji

K. V. Sarma

Nīlakaṇṭha Somayāji (AD 1444–1545) was one of the eminent astronomers of Kerala in South India. He was a pupil of Parameśvara, the promulgator of the Kerala Dṛggaṇita School of astronomy, and left after him a long line of astronomers. He was also a prolific writer on astronomy.

Nīlakaṇṭha's writings include *Golasāra* (Essence of Spherics), *Siddhāntadarpaṇa* (Mirror of the Laws of Astronomy) with his own commentary, *Candracchāyāgaṇita* (Computation of the Moon's Shadow), *Tantrasaṅgraha* (Resumé of Astronomy) in eight chapters, composed in AD 1501, Commentary on the *Āryabhaṭīya* of Āryabhaṭa, and *Jyotirmīmāṃsā* (Investigations on Astronomical Theories). Two of his works, *Grahaṇanirṇaya* and *Sundararājapraśnottara* are known from references but are yet to be retrieved.

While Nīlakaṇṭha's commentary on the *Āryabhaṭīya* is elaborate and exhaustive, and is infused with novel interpretations and new ideas, his *Jyotirmīmāṃsā* is of particular interest, in that it is wholly devoted to certain fundamental matters relating to Hindu astronomical theories and practices. It throws ample light on Nīlakaṇṭha's practical approach to astronomical studies. He says that there is no place, in a physical science like astronomy, for mythological explanations to astronomical phenomena. Enhanced by examples, the *Jyotirmīmāṃsā* emphasizes that astronomical computations should tally with actual observation. According to Nīlakaṇṭha, continued observation of planetary movements, experimentation, logical deduction, and enunciation of periodical corrections towards correlating computation with observation are the *sine qua non* of practical astronomy. Results obtained by the application of such corrections have to be verified at times of successive eclipses, which are visible celestial phenomena. Small errors that arise on account of observations being made from the surface of the earth, instead of from its center, are to be corrected by reducing the basic angular distances to the *dṛggola* (visible celestial sphere). Conversely, it is stated that in the case of the gnomonic shadow, it is the measure in the *dṛggola* that needs to be reduced to that of the *bhagola* (sphere of the zodiac). The *Jyotirmīmāṃsā* of Nīlakaṇṭha reveals him as an astronomer of extraordinary ingenuity and acumen.

Nilometer

Zaraza Friedman

The Nile played an important role in the historical and the economic life of Egypt. Throughout history, Egypt was an agricultural nation that became the granary of the Mediterranean Basin. The river Nile is one of the most predictable rivers in the world. The rise and fall of the Nile is regular and quite precise with floods that are rarely destructive. After the beginning of the rainy season in Ethiopia, the Nile starts to rise in early June and gradually swells to its maximum by the end of September, when the lands in Egypt are flooded with the appearance of islands. Diodorus Siculus gives a detailed description of this phenomenon:

> The rise of the Nile is a phenomenon which appears wonderful enough to those who have witnessed it, but to those who have only heard of it, is quite incredible. While all other rivers begin to fall at the summer solstice (beginning of June 21) and grow steadily lower, this one (Nile) begins to rise at that time and increases so greatly in volume day by day that it finally overflows practically all Egypt… And since the land is level plain, while the cities and villages, as well as the farm-houses, lie on artificial mounds, the scene comes to resemble the Cycladic Islands (Diodorus, I.36.7–9).

This period of the inundation is also dedicated to festivals and ceremonies such as the account given by Diodorus:

> The masses of people being relived from their labours during the entire time of the inundation turn to recreation, feasting all the while and enjoying without hindrance every device of pleasure (Diodorus, I.36.10).

The flood remained quite static for about one month, then subsided more and more until December or January, when the Nile returned to its original bed. In early June the river was reduced to its half of the flood breadth (Said 1993: 96).

Metrology and the Inundation

The Nilometer was invented for recording the annual inundations in Egypt and to control the floodwater. As the name suggests, the device originates from the area of the Nile in Egypt. The significance of the Nile's floods is associated with Memphis, which is located at the root of the Delta. Diodorus (first century BCE), wrote that the kings of Egypt constructed a *Niloscope* [Nilometer] at Memphis where administrators were appointed to make accurate measures of how many cubits or fingers the river (Nile) had risen or when it commenced to fall (Diodorus, I.36.11). These inundation levels could predict the grain and corn harvest, since the Egyptians kept accurate records of their observations over a long period of terms (Diodorus, I.36.12).

The surveying records of the Nile's levels are difficult to interpret since various measuring devices throughout historical periods did not use the same zero point and most probable not the same scale. The oldest records come from a stone stele, dated to Dynasty V (2480 BCE), known as the "Palermo Stone", named after the Museum of Palermo, where it is found (Fig. 1). Additional parts of this stone are found in the Cairo Museum. The Palermo Stone is assumed to come from the Memphis area. W. Helck completed a study of the stone in 1966 and also converted these records into the metric system:

1 cubit = 7 hands/palms = 28 fingers = 2 spans = 0.524 m (Said 1993).

Nilometer. Fig. 1 Palermo Stone (From Said 1993: 135, Fig. 2.13).

The gauges to record the Nile flood levels were marked in cubits, a metrological unit comprising 6 or 7 palms, thus indicating two kinds of measures: the small cubit = 6 palms and the royal cubit = 7 palms. The hieroglyph used on cubit rods to indicate metrological fingers appears as 4 (a palm with four stretched finger), 5 (a palm with five stretched finger) and 6 (a clenched fist). The small cubit was considered the length of the forearm from the elbow to the thumb, equaling 45 cm, while the royal cubit was the length of the forearm from the elbow to the tip of the middle finger, equal to 52.5 cm (Robins 1982). Since the cubit was the length of a forearm and Egyptian men were of varied height and arm length, there were different cubit units. The royal cubit was divided into 7 palms or 28 fingers (524 ± 5 mm), while the small cubit into 6 palms or 24 fingers (449 mm). The double remen (740.7 mm) was the length of the diagonal of a square with each side of one royal cubit (Singer et al. 1965: 777). This metrological unit was the base of the Egyptian land measure. The double remen was divided into 40 digits (each digit = 18.5 mm).

One of the most significant Nilometers in history was found at Memphis; in ancient literature it was referred to as the "House of Inundation". The zero point in this Nilometer must have been at the ground level of the Memphis agricultural plains. In the Aswan Nilometer at the Temple of Khnum there were two zero points: the lower level corresponded to the low water level of the Nile; the high level equaled the level at which the fields were watered. Said (1993) suggested that the Memphis Nilometer may have had two zero points; thus the records of the flood levels on the Palermo Stone were probably taken in the same way as at Aswan.

The Elephantine Nilometer was considered the most significant station for measuring the Niles's levels (Herodotus II.32, Diodorus I.36.11, Pliny, *NH* V.x.58, Popper, 1951, Pearl, 1956: 52), due to its location off the First Cataract, where the floodwaters reached their maximum height. Plutarch said that the greatest rise at Elephantine amounted to 28 cubits, at Mendes the smallest was 6 cubits, while at Memphis the intermediate (between the high scale at Elephantine and the smallest at Mendes), when normal, was 14 cubits (Pearl 1956: 52). The inundation heights of 15 or 16 cubits given by Herodotus (II.23.), appeared to be the adequate level for the fifth century BCE. The big difference between 28 cubits at Elephantine and 14 cubits at Mendes shows that the readings from the Elephantine Nilometer were done from a scale and not from high and low waters (Pearl 1956: 57). The high numbers in these scales were probably done when they attempted to establish the same zero point at the Nilometers upstream from the Nile's mouth starting at the Delta, on a theoretical fall line which did not correspond to the gradient of the river (Pearl 1956).

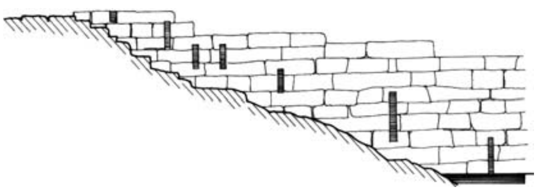
The level of 16 cubits was considered the optimal level for the inundation of fields from the Greco-Roman and early Arabic periods (the measures were taken at the newly built Cairo Nilometer at Roda Island, 715 CE). Pliny (V.x.58) said that when the flood level was 12 cubits (in the province of Memphis), it was a sign of starvation, and even with 13 cubits it still meant hunger. Fourteen cubits brought joyfulness, 15 was freedom, and 16 sheer delight. At Elephantine a good flood meant a rise of 28 cubits, while at Edfu 24 cubits and 3¼ palms were required (Elephantine and Edfu were the main stations off the First Cataract) (Moret 1927: 32). Descending northwards to the Delta, the needed flood level was less than in Upper Egypt; at Mendes and Xoīs, 6 cubits were sufficient (Moret 1927: 32). A record for a "good flood" in the Middle Kingdom during the reign of Senwosret I (1971–1928 BCE) was registered at the level of 21.5 cubits (11.3 m) at the Elephantine Nilometer, 12.5 cubits (6.6 m) in the "House of Inundation" at Old Cairo, and 6.5 cubits (3.4 m) at Diospolis (Tell Balamoun), in the northern Delta.

The Roda Nilometer built at the southern tip of the Island, during the reign of Caliph Abdel ibn-Marawan (715 CE), and later rebuilt by Caliph el-Mutawalik (861 CE), is a covered structure with a well inside. An octagonal marble pillar stands in the middle of the well. On the pillar are inscribed the calibration units in cubits and subdivisions in fingers. Due to both changes of the Roda Nilometer, the scale had different values. The cubits in the oldest scale were divided into 28 fingers from cubit I to XII, and the new scale was divided into 24 digits from cubit XIII to XXI. Since the finger in both scales is the same (1 finger = 1.925 cm), the cubits in the lower part measure 53.9 cm (royal cubit), while those on the upper part equal 46.2 cm (small cubit). The zero point of the scale was fixed at the level of the well's floor; thus the cubit XVI was 8.3 m above the floor of the well (or 16.4 m above sea level). At the time of building the Nilometer, level XVI was considered the effective level of the flood at which the dikes were opened to release the water in the fields at the inundation season.

In the Greco-Roman periods the figure XVI and the floodwaters of the Nile became the symbol of life and prosperity not only in the Egypt but also through the Mediterranean World, where the cult of the Nile developed. The Nile Statue at the Vatican Museum in Rome is a relevant example of the personification of the Nile's fertility at the inundation season; sixteen *putti*, each of one royal cubit height, surround the god Nile reclining on his left side, while he holds ears of corn and a cornocopia (Fig. 2). The *putti* symbolize the optimal 16 cubits required for a successful flood.

In ancient Egypt, the god Hapi was the incarnation of inundation and deification of the flood, as attested by

Nilometer. Fig. 2 God Nile with 16 *putti*, each one royal cubit height (From Freeman and Ray 2000: 147).



Nilometer. Fig. 3 Wall or corridor Nilometer (From Said 1993: 153, Fig. 2.25).

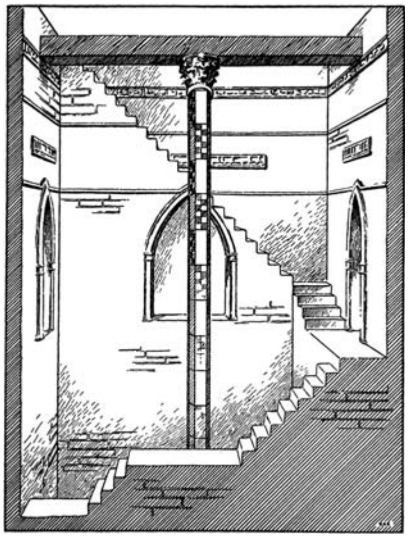
many Egyptian paintings, statues and reliefs. He was the god bringing fertility to the land.

Types of Nilometers

Surveying the remains of ancient Nilometers and their representation in art we may classify them in three main types and some combined types: a wall or corridor with steps (Fig. 3), a well (Fig. 4), and a column (Fig. 5).

The combined types are a well with a projecting column (Fig. 6), or a covered structure with a well in which a column is set in its center, as represented by the Islamic Roda Nilometer (Fig. 7). In all Nilometers the gauge is marked in cubits and subdivided into fingers. Nilometers depicted in art are shown with whole metrological units missing the subdivisions in fingers. The cubits value is indicated by Greek letters. These representations were done for convenience, with the purpose to transfer to the viewer the symbolism of the device and its importance associated with the floodwaters of the Nile. Each type of Nilometer will be described and illustrated with relevant examples.

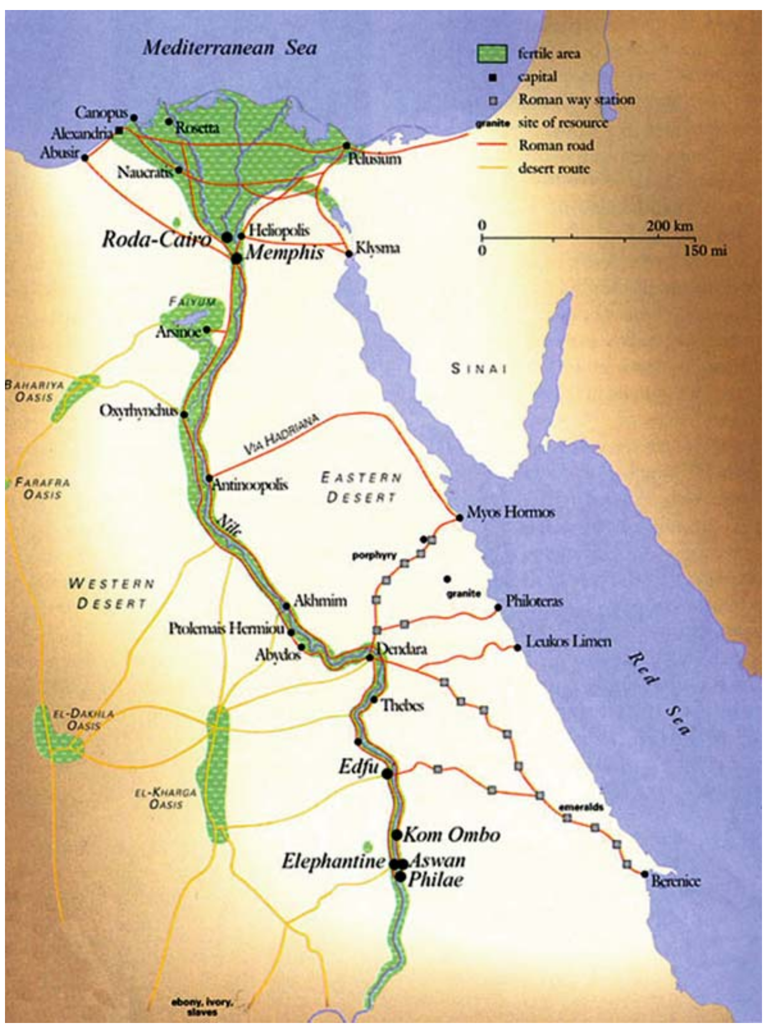
1. Wall or corridor types of Nilometers had their zero point set where the water level was against the steps, thus showing the height of the floodwaters. Such Nilometers were built in temples at Elephantine, Philae, Edfu, Kom Ombo and Dendera (Fig. 8). These devices have the calibration marked on the wall and were built from the Pharaonic periods to the Roman era. The



Nilometer. Fig. 7 Roda Nilometer (From Popper 1951: inner cover).

Nilometer on Elephantine Island (Fig. 9a,b), north of the First Cataract, was one of the most important devices, due to its location where the floods began. This device was located in the Temple of Khnum dedicated to the ram-headed god of Inundation. The Nilometer dated to Dynasty XI, was replaced by a new one built during Dynasty XXX, at the Temple of Satet, one of the Khnum's celestial consorts (Seawright). When Egypt fell to the Roman Empire, the Nilometer at Khnum temple underwent some changes. The new calibrated staircase was roofed with granite slabs.

On the quay of the Karnak Temple gauges were engraved to measure the height of the floodwaters. Many authors have researched them since the late nineteenth century. Legrain (1896), Borchardt (1906), and Beckerath (1966) recorded 45 levels of inscriptions running from the reign of Shosheq I to Psammetik I (Dynasties XXII–XXVII) (Fig. 3). The elevation of the zero point of the Nilometer was fixed at 64 m above sea level. The floods rises recorded at Karnak quay ranged



Nilometer. Fig. 8 Map of the Nile with locations of Nilometers (From Freeman and Ray 2000: 133).

Nilometer. Fig. 9 (a) Staircase Nilometer at Elephantine: ►http://www.lexicorient.com/egypt/aswan04.htm. (b) Close-up of the Elephantine gauge: ►http://www.touregypt.net/featurestories/nile.htm.

from 9.22 to 11.1 m. The years marked "joyful" were those which had an average flood rise of 10.6 m (Said 1993: 152).

2. Well Nilometers seem to be a later type that appeared during the Ptolemaic period. Strabo (first century BCE) gives a detailed account about where such Nilometers were placed at Syene and Elephantine Island:

> The Nilometer is a well on the bank of the Nile constructed with close-fitted stones, in which are marks showing the greatest, least, and mean rises of the Nile; for the water in the well rises and lowers with the river. …Accordingly there are marks on the wall of the well, measures of the complete rises and of the others. So when the watchers inspect these, they give out the word to the rest of the people, so that they may know (Strabo *Geo*. 17.I.48).

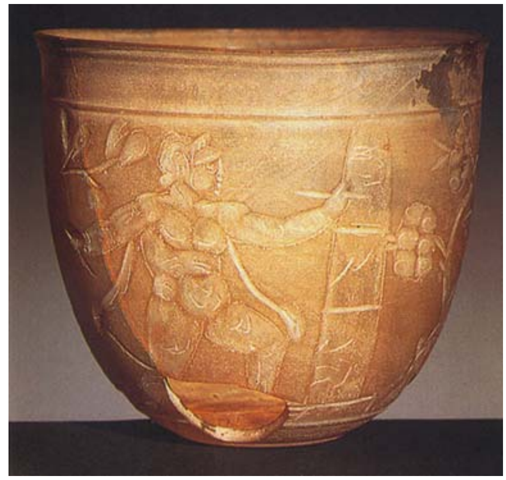
Nilometer. Fig. 10 Well Nilometer in the Nile mosaic from Palestrina (Photo by Z. Friedman).

Pliny informs us that when the inundation season started, it was observed through the well Nilometers, and that it was also advisable not to sail during the high floods:

> The view has been held that it is unlawful for kings or rulers to sail on the Nile when it is rising. Its degrees of increase are detected by means of wells marked with scales. An average rise is one of XVI cubits. The smaller volume of water does not irrigate all locations, and a larger one by retiring too slowly retards the agriculture (*NH*. V.x.57–58).

Both Strabo (*Geo*. 17.I.48) and Pliny (*NH*. II.183), said that the midday sun in the summer solstice did not cast any shadow in the wells and that the light reaching their bottom showed the water level, probably at the crest of the flood (Friedman 2001: 59). The well in the Palestrina Nile mosaics may be considered an illustrative example for a well-type Nilometer (Fig. 10). The rounded well is built with stone blocks. On its right lower edge (at the water level) there are two arched openings that water goes through. The well is placed on the bank in the vicinity of a Hellenistic temple. The splashing water inside the well, viewed from above, may suggest rising floodwaters. A gauge may have been engraved on the walls of the well. Well type Nilometers were modified during the Ptolemaic periods, with stairs in or around them. Such wells were found in temples at Kom Ombo and Edfu. A spiral staircase set in the inner side of the well reached the water level in Kom Ombo Temple (Fig. 11). A gauge

Nilometer. Fig. 11 Well Nilometer at Kom Omb: ►http://hometown.aol.com/_121b_xzkSKIDq8Ea2ZwvSQf8wsKD5Urprh6; p. 2 bottom.



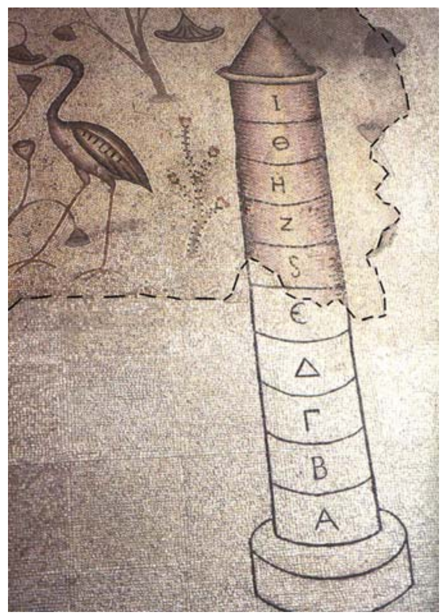
Nilometer. Fig. 12 Column Nilometer on a Roman glass cup (From Harden 1987: 200, Fig. 109 bottom).

may have been engraved on the walls of the well or on the steps as well. A similar type of Nilometer with a rectangular basin with stairs leading to it, dating from early Imperial period, is found in the Temple of Khnum at Elephantine (Meyboom 1995: 244, n. 77).

3. Column Nilometers appeared during the later Imperial period, when the scale was removed from the well to a column. It was much easier to carry such a device and place it at different points to record the flood levels. Tousson (1925:302), mentions that at least during the Greco-Roman periods there was a portable device, which when not in use, was kept in the Temple of Serapis (Moret: 302). In the flood season it was taken out and set up in a well shaft (Bell 1970: 571).

A column Nilometer is quite a common object in art. It is depicted as an individual item or shown with human figures engraving the newly risen flood level. Such an example appears on a Roman glass cup (Fig. 12), probably of Campanian origin, dated 200–300 CE, now at the British Museum (Reg. 1868.5.919; Versluys 2003: 169–170). A single column Nilometer with a conical top appears in the mosaic floor, to the right of the transept, in the Church of Multiplying of the Loaves and Fishes, at Tabgha, on the northwestern shore of the Lake of Galilee (Kinneret), Israel. A considerable part of the mosaic was destroyed and in the past several years it had been reconstructed. The upper part of the Nilometer belongs to the original mosaic, while the lower section is reconstructed (Fig. 13). The mosaic was dated to the fourth to fifth century CE (Schneider 1937). On the shaft are inscribed Greek letters referring to the calibrations from 6 to 10 cubits: S = 6, Z = 7, H = 8, Θ = 9, I = 10 (Friedman 2001: 60).

A column Nilometer associated with Alexandria appears in two mosaics from Israel. The first device is



Nilometer. Fig. 13 Tabgha mosaic (Friedman 2001: 86, Fig. 105).

found in the lower frame with a Nilotic scene, in the mosaic floor from the House of Leontis, at Beit Shean. The mosaic was dated to the fifth to sixth century CE; now it is found at the Israel Museum, Jerusalem. The vertical shaft set on a rectangular pedestal and topped by a rounded tip is placed to the left side of a small temple with a tiled pitched roof (Fig. 14). On the shaft are inscribed the cubits from 10 to 16: I = 10, IA = 11, IB = 12, IΓ = 13, IΔ = 14, IE = 15, IS = 16. The adjacent building may have been the checkpoint where the keepers recorded the flood levels. Above this structure Alexandria is written in Greek letters. The

Nilometer. Fig. 14 House of Leontis, Beit Shean (Photo by Z. Friedman).

Nilometer. Fig. 15 Nile festival mosaic from Sepphoris (Friedman 2001: 86, Fig. 104).

House of Leontis was a synagogue and the room where this mosaic was found probably served as a guestroom. The second Nilometer associated with Alexandria appears in the Nile festival mosaic from Sepphoris (Diocaesarea), in the Lower Galilee (Fig. 15). This mosaic in situ was dated to the fifth to sixth century CE (Netzer and Weiss 1992). The rounded column is set on a structure with an arched opening placed in the water. The cubits on the shaft are inscribed with Greek letters, from 13 to 17: IΓ = 13, IΔ = 14, IE = 15, IS = 16, IZ = 17 (Friedman 2001: 60). Mark 13 is not visible, due to the damage of the mosaic in this section, while the head of the man bent to support on his back the person who engraving the new flood level at 17 hides cubit 14. Alexandria is inscribed above a tall fortified structure; a rounded tower on each side flanks its entrance. The structure is found beneath the lower bank of the river. The number 17 appears twice on the lower bank; the first is found just to the right side of the right-hand tower, and the second is beneath the right arm of the figure placed on a Corinthian column. The newly engraved cubit 17 on the Nilometer and the marking on the lower bank indicate that this level was reached at that particular period of the flood. To the right side of the Nilometer is a large naked figure, with his back turned to the device. He holds a staff in his right hand, probably a ruler of double remen used for measuring the land after the inundation, for tax evaluation. In a mosaic from Sarrīn (Osrhoène), Syria, dating fifth to sixth century CE (Balty 1990: 83), is a Nilotic scene within a wide border. On the left side of a stone-built structure with a pitched tile roof is a two-stored square pillar. The calibration numbers are inscribed with Greek letters on the upper part of the shaft. A large naked figure with a hammer in his right hand and a chisel in the left engraves the number IH = 18 above the existing IZ = 17 (Fig. 16), which seems to show the new flood level at that particular time.

Nilometer. Fig. 16 Nilometer in the Sarrīn mosaic, Syria (From Balty 1990: Pl. XXXIII/1).

Combined types of Nilometers comprise a well with a rounded or square column projecting from it. There are several art depictions dating from the fifth to the seventh centuries CE. A silver plate, which probably was produced at Constantinople at the turn of the fifth or beginning of the sixth century CE, depicts a slim

Nilometer. Fig. 17 Silver Plate from the Hermitage Museum (From Balty 1990: Pl. XXXIV/2).

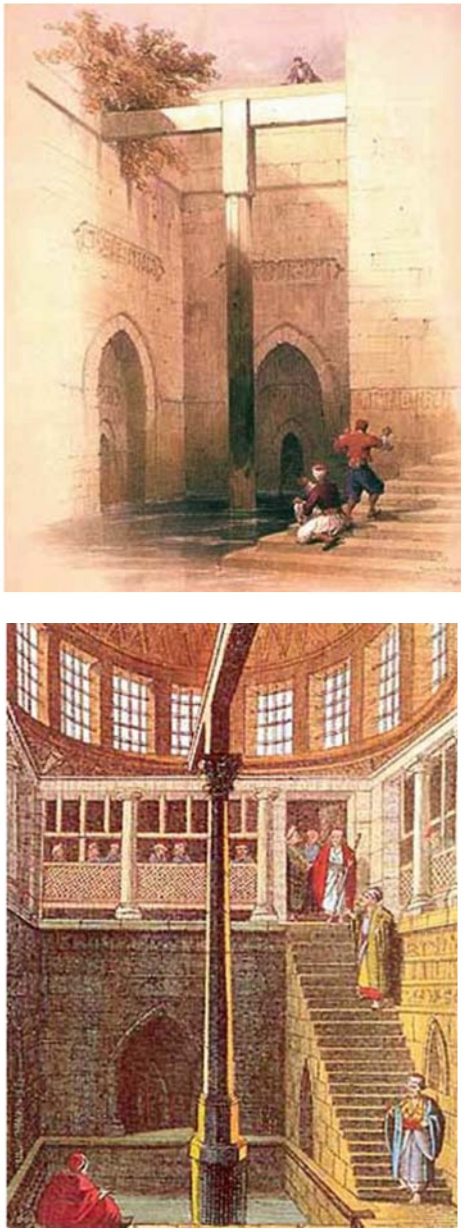
rounded column projecting from a well built with stone blocks (Fig. 17). One man standing on the back of another engraves cubit 5 (Θ = 5), on the upper part of the shaft. This plate is found at the Hermitage Museum at Petersburg, Russia.

Two Coptic rounded textiles dating to the sixth or seventh century CE, at the Louvre Museum, Paris, depict the personification of the Nile together with the Abundance (Euthenia), (Maguire 1990: 218). On the lower part of both textiles is a rounded well, built with stone blocks, with steps ascending to an arched opening at the base of the well (Fig. 18a, b). A large naked figure with a hammer in the right hand and a chisel in the left engraves the number IH = 18 above the existing IZ = 17, on the upper part of the square column. The new number may refer to the new flood level reached at that particular moment.

Nilometer. Fig. 18 (a) Coptic textile (From Maguire 1990: Fig. 14 top). (b) Coptic textile (From Maguire 1990: Fig. 14 bottom).

The Roda Nilometer is a combined type of well with a column set in its center and placed into a covered structure (Fig. 19a,b), roofed by a dome. This first Islamic device was built in 715 CE, at the southern tip of Roda Island, opposite Old Cairo. In Arabic, the Nilometer is known as *miqyas* (Mikyas el-Nil) (Hansen 2003). The Roda Nilometer was built by the Umayyad Caliph Abed Malek el-Marawan, which later was rebuilt by Caliph el-Mutawalik in 816 CE. A flood in 850 CE destroyed this Nilometer. When the new device was built, Abu el-Raddad of Basra was appointed as the guardian of the Nilometer. This tradition was then transferred to his descendents. The priests kept the records of the Nile's levels in ancient times. After Christianity was introduced into Egypt, the office was kept until the Arab conquest, but the Coptic priests still kept the records at Mekyas (Nilometers). The guardian of the Nilometer was Said Mahommed el-Sowafi, a man with no formal education. His records were done by the rule of the thumb, handed down to him by his forefathers who did not pay attention to the original column (gauge) or its gradations (Said 1993: 155).

The Roda Nilometer comprises a covered structure with a well. A marble column was inserted at its center (Fig. 19a,b). This device is connected to the Nile by three tunnels. The southern one is at the level of the well's floor (8.15 m above the sea level), while the other two are at the east, are placed one above the other (Said 1993: 155). The octagonal column inside the well is set on a pedestal (Fig. 19b). Inside the Nilometer structure, leading down to the well, are 45 steps; the height of each is 24 cm (Hansen 2003). The steps also allowed for a quick reading of the water level of the Nile. The scale on the pillar is marked in cubits with a subdivision of fingers. It was mentioned above that the metrology of this column comprises two scales: one subdivided into 28 fingers (royal cubit),



a

b

Nilometer. Fig. 19 (a) Roda Nilometer (David Roberts: ►http://www.touregypt.net/featurestories/nilometerroda.htmp. (b) Inside the Roda Nilometer ►http://www.touregypt.net/featurestories/nilometerroda.htm.

from cubit I to XII, while the other is divided into 24 fingers (small cubit), from cubit XIII to XXI. The zero point was fixed at the level of the well's floor. In different periods, this Nilometer underwent changes. In 1517 (five years after the Turkish conquest of Egypt), a new scale was set up in which the zero point was elevated by 1.62 m above the level of the well and the cubits from IX to XXVII were reduced to 36.1 cm each. In 1861, during the reign of Khadive Ismail, his engineer Mahmoud Saleh el-Falaki repaired the gauge and replaced the older one by a new scale in which the zero point was fixed at 66 cm above the well's floor, and the elevations in meters was changed. Each cubit in the new scale measured 54.1 cm, except for cubits XVI to XXII, which measured 27.1 cm. This change was done to adjust the Cairo readings to those at Aswan. When the level reached 16 cubits at Aswan, the basins in Upper Egypt were inundated, while in Cairo the level was reduced to one half (Said 1993).

In the medieval era, the importance of the Roda Nilometer was celebrated in Fath al-Khalij, the festival of the opening of the canal. The canal was blocked with earth dams and cleaned before the flood. When the Nile reached the level of 16 cubits, the dam was opened to water the agricultural lands. The celebration started at this time and lasted for seven days. During this period, decorated boats crowded the waters. In the hot summer months, the Khalij canal and the ponds were still crowded with boats, and along the shores there were many kinds of entertainment. The grand celebration was not an annual event. When the floodwaters failed to reach the 16 cubits level, the celebrations were canceled and prayers were held instead, to ward off the draught and famine (Abaza 2003). These celebrations ceased in 1899, when the Khalij canal was filled in. The Roda Nilometer was no longer necessary after the building of the High Dam at Aswan in the 1970s, which continues to regulate the Nile's waters.

The purpose of this article was to survey the Nilometer historically and to show how it was depicted in varied art forms. The Nile and its floodwaters were subjects for many historians (ancient and modern), while it symbolized fertility, plenty and prosperity. Through different periods and even in the modern era, measuring the Nile's flood levels was an important factor in the economics of Egypt, which made her the main granary of the ancient world in the Mediterranean Basin. A survey of Nilometers from the early Pharaonic Dynasties revealed that Egyptian society was unified and had an organized system of recording the distribution of the floodwaters, dividing the agricultural lands and assigning tax levels according to the quality of the year's flood.

Pliny (*NH*. V.x.57–58) and Strabo (*Geo*. 17.I.48) attested that the optimal flood level of the Nile was 16 cubits at Memphis. The numbers inscribed in the Sarrīn mosaic and the Coptic textiles (IZ = 17, IH = 18), as well as the lower numbers in the Tabgha mosaic and in the Hermitage plate, do not refer to the desired flood level. They symbolize the importance of the Nilometer and the Nile waters. From historical references we know that a flood level less than 16 cubits brought famine, and if it exceeded that disaster came and the crops were destroyed. This survey of the Nilometers attests that the flood levels were not the same along the

Nilometer. Table 1 Egyptian Chronology

Date	Period	Culture/Dynasties

course of the Nile and also their readings were not based on the same zero point. It appears that there were at least two local zero points, which corresponded to the agricultural plain levels and also to the level where the floodwaters were released into canals to irrigate the fields.

Number Theory in Africa

PAULUS GERDES

Through the ages the peoples in Africa south of the Sahara invented hundreds of numeration systems, both spoken systems and symbolic ones that use body parts or objects to count or to represent numbers.

Verbal Numeration

The most common way to avoid the invention of completely new number words as one counts bigger quantities has been to compose new number words out of existing ones by relying on the arithmetical relationships between the involved numbers.

For example, in the Makhwa language spoken in northern Mozambique, one says *thanu na moza* (five plus one) to express six. Seven becomes *thanu na pili* (five plus two). To express twenty, one says *miloko mili*, tens two or 10 × 2. Thirty is *miloko miraru* (tens three). *Thanu* (5) and *nloko* (10) are the bases of the Makhwa system of numeration.

The most common bases in Africa are 10, 5, and 20. Some languages like Nyungwe (Mozambique) use only base ten. Others like Balante (Guinea Bissau) use 5 and 20 as bases. Verbal numeration in the Bété language of Côte d'Ivoire uses three bases: 5, 10, and 20. For instance, 56 is expressed as *golosso-ya-kogbo-gbeplo*, that is 20 times two plus ten (and) five (and) one:

	Number word	Structure
1	Blo	
2	Sô	
6	Gbeplo	5 + 1
20	Goloblo	20 × 1
40	Golosso	20 × 2

The Bambara of Mali and Guinea have a ten–twenty system. The word for twenty, *mugan*, means one person; the word for forty, *debé*, means mat, referring to a mat on which husband and wife sleep together, and jointly they have 40 digits.

The Bulanda of West Africa use six as a base: 7 is expressed as 6 + 1, 8 as 6 + 2, etc. The Adele (Togo) count *koro* (6), *koroke* (6 + 1 = 7), *nye* (8) and *nyeki* (8 + 1 = 9).

Among the Huku of Uganda the number words for 13, 14, and 15 may be formed by the addition of 1, 2, or 3 to 12. For instance, 13 is expressed as *bakumba igimo*, meaning 12 + 1. The decimal alternatives 10 + 3, 10 + 4 and 10 + 5 were also known.

A particular case of the use of addition to compose number words occurs in the situation where both numbers are equal, or one of the two is equal to the other plus one. For instance, among the Mbai one counts from 6 to 9 in the following way: *mutu muta* (3 + 3), *sa do muta* (4 + 3), *soso* (4 + 4), and *sa dio mi* (4 + 5). Among the Sango (northern Zaire), 7 is expressed as -*na na-thatu* (4 + 3), 8 as *mnana* (4 + 4) and 9 as -*sano na-na* (5 + 4).

In several African languages, besides the additive and multiplicative principles, subtraction has also been used in forming number words. For example, in the Yoruba language of Nigeria, 16 is expressed as *eerin din logun* meaning four until one arrives at twenty:

	Number word	Structure
16	Eerin din logun	4 until 20
17	Eeta din logun	3 until 20
18	Eegi din logun	2 until 20
19	Ookan din logun	1 until 20
20	Ogun	
21	Ookan le logun	1 + 20
34	Eerin le logban	4 + 30

Another example of the use of the subtractive principle may be found among the Luba-Hemba of Zaire. Seven is expressed as *habulwa mwanda* (lacking one until eight), and nine is *habulwa likumi*, lacking one until ten.

That spoken numeration systems may vary greatly in relatively small geographic regions is shown by the example of Guinea Bissau. The Bijagó have a pure decimal system; the Balante use a five-twenty system; the Manjaco have a decimal system with exceptional composite number words as 6 + 1 for 7 and 8 + 1 for 9; and the Felup use a ten–twenty system in which the duplicative principle is also employed in forms like 7 as 4 + 3 and 8 as 4 + 4.

Sometimes some number words are adjectives, while others are substantives. Where this happens, number word structures may appear that do not correspond directly to an addition, multiplication or subtraction. For instance, in the Tshwa language (central Mozambique) sixty is expressed as *thlanu wa makumi ni ginwe*, five times ten plus one more (ten).

In those contexts where it was necessary to have number words for relatively large numbers, there often appear completely new number words or ones that express a relationship with the base of the numeration system. For instance, among the Bangongo of Zaïre

N

one says *kama* (100), *lobombo* (1,000), *njuku* (10,000), *lukuli* (100,000), and *losenene* (1,000,000). Among the Ziba (Tanzania) one says *tsikumi* for 100, *lukumi* for 1,000, and *kukumi* for 10,000. All three terms are clearly related to *kumi* (10). Only the prefixes change.

Gesture Numeration

Gesture counting was common among many African peoples. The Yao (Malawi, Mozambique) represent 1, 2, 3, and 4 by pointing with the thumb of their right hand at 1, 2, 3, or 4 extended fingers of their left hand. Five is indicated by making a fist with the left hand. Six, seven, eight, and nine are indicated by joining one, two, three, or four extended fingers of the right hand to the left fist. Ten is represented by raising the fingers of both hands and joining the hands. On the contrary, the Makonde, who are also in the North of Mozambique, start counting on their right hand with the help of the index finger of the left hand. Five is indicated by making a fist with the right hand. For six to nine, the representation is symmetrical to that of one to four, that is, right and left hands change roles. Now the index finger of the right hand points at the fingers of the other hand. Ten is represented by joining two fists.

The method of gesture counting adopted by the Shambaa (Tanzania, Kenya) uses the duplicative principle. They indicate six by extending the three outer fingers of each hand, spread out; seven by showing four on the right hand and three on the left, and eight by showing four on each hand.

To express numbers greater than ten the Sotho (Lesotho) employ different men to indicate the hundreds, tens and units. For example, to represent 368, the first person raises three fingers of the left hand to represent three hundreds, the second one raises the thumb of the right hand to express six tens, and the third one raises three fingers of the right hand to express eight units. This is in fact a positional system, as it depends of the position of each man if he indicates units, tens, hundreds, thousands, etc.

Tally Devices

Many types of tally devices were used in Africa south of the Sahara. Two examples of widespread tallies are the following from Mozambique.

Among the Tswa, trees are used to record the age of children. After the birth of a child a cut is made on a trunk of a tree. Each year one adds a new cut until the person is old enough to count for him or herself. Tally sticks are used to control the number of animals in a herd. Each cut corresponds to one animal.

Among the Makonde, knotted strings were used. Suppose a man was going on an 11 day journey. He would tie 11 knots in a string and say to his wife, "This knot" (touching the first) "is today, when I am starting; tomorrow" (touching the second knot) "I shall be on the road, and I shall be walking the whole of second and third day, but here" (seizing the fifth knot) "I shall reach the end of the journey. I shall stay there the sixth day, and start for home on the seventh. Do not forget, wife, to undo a knot every day, and on the tenth you will have to cook food for me; for see, this is the 11th day when I shall come back." Pregnant women used to tie a knot in a string at each full moon, to know when they were about to give birth. In order to register the age of a person, one uses two strings. A knot is tied in the first string at each full moon; once one has completed 12 knots, one ties a knot in a second string to mark the first year, etc.

Other Visual Numeration Systems

There are a variety of numeration systems in Africa that are written in one way or another.

The *koti zigi* game is played by the Gbundi and Mende in Liberia and in the western parts of Côte d'Ivoire. The players form standardized patterns of stones on the ground to represent numbers. One observes that 6 is expressed 3 + 3, 7 as 3 + 1 + 3, 8 as 4 + 4, 9 as 4 + 1 + 4, and 10 as 5 + 5 or 4 + 2 + 4 (see Table 1).

The Fulani or Fulbe, a seminomadic pastoral people of Niger and northern Nigeria, place sticks in front of their houses to indicate the number of cows or goats they possess. One hundred animals are represented by two short sticks placed on the ground in the form of a ∨. Two crossing sticks, ×, symbolize 50 animals. Four sticks in a vertical position, ||||, represent four; two sticks in a horizontal and three in a vertical position, — — |||, indicate 23 animals. For example, the following was found in front of the house of a rich cattle owner:

∨ ∨ ∨ ∨ ∨ ∨ × ||

showing that he had 652 cows.

The Akan peoples (Côte d'Ivoire, Ghana, Togo) used money weights. That is to say, they used figurines in stone, metal or simply vegetable seeds as coins. The weight of a figurine was agreed to represent the

monetary value that corresponded to a certain quantity of gold dust of the same weight. The figurines show animals, knots, stools, sandals, drums, etc. Figurines may also have diverse geometric forms such as step pyramids, stars, or cubes. Many display graphic signs representing numbers. Although in the languages spoken by the Akan peoples, like Anyi, Baoulé, Aboure, Attie, and Ebrie, only base ten is used, base five is also found on the money weights (Fig. 1):

Number Theory in India

Takao Hayashi

It is difficult to find "number theory" in its proper sense in Indian mathematics. What I am going to describe below is how the Indians have treated kinds of numbers.

In the Vedas (ca. 1200–800 BCE), the oldest Hindu literature, a number of numerical expressions occur. Their favorite numbers were three and seven as well as a hundred and a thousand. The largest number contained in their common list of names for powers of ten is 10^{12} (called *parārdha*). Later (by the fourth century AD), those names came to be employed for denoting decimal places, and became the nucleus of the Hindu list of decimal names (18 in number), while the Buddhists and the Jainas developed longer lists, which contained numbers as large as 10^{53} (*tallakṣaṇa*) or more.

The Jainas even speculated about different kinds of uncountable and infinite numbers (*Aṇuogaddārāiṃ*, between the third and the fifth centuries AD). They divided the whole set of "numbers (*saṃkhyā*) concerning counting (*gaṇanā*)" into three subsets (1) countable (*saṃkhyeya*), (2) uncountable (*asaṃkhyeya*), and (3) infinite (*ananta*) numbers; and further divided the last two sets into three each (Table 1). The entire system of countable–uncountable–infinite depends upon the smallest number (a) of the "restrictively uncountable" set, which in turn is defined by means of white mustard seeds. The text is not very clear on this last point, but its intention was probably the same as what is meant by "the aleph zero" in modern mathematics, the smallest transfinite cardinal number.

Vedic stanzas also contain various series of numbers such as an integer series up to 200, an odd series (1, 3, 5,…) up to 99 (accompanied by 100), an even series (2, 4, 6,…) up to 100, and series made from multiples of 4, 5, 10, and 20, up to 100, etc.

The Vedas tell us that only the gods Indra and Viṣṇu could divide a thousand equally into three, but it is a matter of argument how they did it. Natural fractions (1/2, 1/4, 1/8, and 1/6) also occur in the Vedas.

The *Śulbasūtras* (ca. 600 BCE and later), compendia of geometric knowledge related to the construction of various altars for the Vedic ritual, clearly state the so-called Pythagorean theorem: "The diagonal rope of an oblong produces both [areas] which its side and length produce separately." They explicitly mention several Pythagorean triples also: (3, 4, 5), (5, 12, 13), (8, 15, 17), (7, 24, 25), and (12, 35, 37). Moreover, they give an algorithm for calculating the diagonal d of a square whose side is a:

$$d = a + \frac{a}{3} + \frac{a}{3}\cdot\frac{1}{4} - \frac{a}{3}\cdot\frac{1}{4}\cdot\frac{1}{34}$$

and call this value "one that has a difference" (*saviśeṣa*), which probably means the difference between this approximate value and the true one $(\sqrt{2}a)$. The latter was called "one that makes [a square equivalent to] two [unit squares]" (*dvi-karaṇī*). There is, however, no indication that they recognized the incommensurability of the diagonal and the side. A root approximation formula of the same type is employed in the Bakhshālī Manuscript.

Number Theory in India. Table 1 Classification of numbers according to the Jainas

numbers for counting	countable	....	lowest: 2 middle: 3,4, ..., a–2 highest: a–1
	uncountable	restrictively uncountable	lowest: $a(=\aleph_0\ ?)$ middle: a+1, a+2, ..., b–2 highest: b–1
		properly uncountable	lowest: $b=a^a$ middle: b+1, b+2, ..., c–2 highest: c–1
		uncountably uncountable	lowest: $c=(b^2)^{b^2}$ middle: c+1, c+2, ..., d–2 highest: d–1
	infinite	restrictively infinite	lowest: $d=c^c$ middle: d+1, d+2, ..., e–2 highest: e–1
		properly infinite	lowest: $e=d^d$ middle: e+1, e+2, ..., f–2 highest: f–1
		infinitely infinite	lowest: $f=(e^2)^{e^2}$ middle: f+1, f+2, ... highest: does not exist

Later Indian mathematicians and astronomers, such as Varāhamihira (ca. AD 550) and Brahmagupta (AD 628), used the word *karaṇī* in the two contradictory (but mutually related) senses, the square root of a nonsquare number and the number whose square root should be obtained (or the square of any number), and easily performed the six arithmetical operations involving irrational numbers. Even the irrationality of *karaṇīs* may have been understood by Bhāskara of the seventh century, because he says, in his commentary on the *Āryabhaṭīya* (AD 629), "*Karaṇīs* have a size that cannot be stated exactly," although whether he proved it or not is not known.

Varāhamihira recognized zero (*kha, śūnya*, etc.) as an object of the arithmetical operations. In the *Bṛhatsaṃhitā* he added and subtracted zero in exactly the same way as he did other integers. Brahmagupta in the *Brāhmasphuṭasiddhānta* gave a complete set of rules for the six arithmetical operations involving zero as well as negative and irrational numbers and referred to the quantity called "zero-divisor," $\frac{a}{0}$. Thus by the seventh century AD the Indians acquired a very large domain of numbers including positive and negative integers (they accepted both the positive and the negative roots of a square number), fractions, irrational numbers, and zero, which enabled them to develop *bījagaṇita* ("seed mathematics") or algebra, the theory of equations.

In his *Āryabhaṭīya* (AD 499), Āryabhaṭa provided a solution (called *kuṭṭaka* or the pulverizer) to the linear indeterminate equation: $n = ax + r = by + s$, or $y = (ax + c)/b$. He "pulverized" (i.e., reduced) the coefficients a and b by means of their mutual divisions (the so-called Euclidean algorithm), and found a set of solutions to the reduced form by trial and error. Mahāvīra (ca. AD 850) removed the trial and error by carrying out the mutual divisions until the remainder became 1.

Brahmagupta treated indeterminate equations of the type $Px^2 + t = y^2$.

He showed, among other things, that this equation (called *vargaprakṛti* or the "square nature") can be solved for $t = 1$ if it is solved for $t = \pm 4, \pm 2$, or -1. Jayadeva (the eleventh century or before) gave a rule for arriving at a solution for $t = \pm 4, \pm 2$, or -1 from any solution for any t. Bhāskara of the twelfth century called it the "cyclic" (*cakravāla*) method.

Several rules given by Mahāvīra in his *Gaṇitasārasaṃgraha* indicate that he recognized two roots of a quadratic equation with one unknown, but all of his examples for those rules have two positive roots. (He, however, admits the negative root of a square number when he gives his rules for the six arithmetical operations.) He was interested in the partition of numbers, and gave many rules for partitioning unity into the sum of unit fractions, a fraction into the sum of several fractions, etc. He also treated various mathematical progressions.

Śrīpati, perhaps for the first time in India, gave several rules for factorization in a chapter devoted to algebra in his astronomical work, *Siddhāntaśekhara* (ca. AD 1040). This topic, as well as the partition of numbers, mathematical progressions, combinatorics, and magic squares were highly developed by Nārāyaṇa in his *Gaṇitakaumudī* (AD 1356).

Bhāskara challenged various types of polynomial equations of the second and higher degrees (of special types) with the help of the "pulverizer" and the "square nature" in his work, *Bījagaṇita*, AD 1150. He compared the infinity and the invariability of the "zero-divisor," $\frac{a}{0}$, to those of god and interpreted the negative-ness of a quantity as the contrariness of direction.

Mādhava (fl. AD 1400) and his successors obtained, for the first time in the world, a number of power series for the circumference of a circle, sine, cosine, arctangent, etc. One of the most eminent scholars in his school was Nīlakaṇṭha. A great mathematician and reformer of Indian astronomy, he explicitly stated the incommensurability of the diameter and the circumference of a circle in his commentary on the *Āryabhaṭīya* (ca. AD 1540), although its proof is not found in his extant works.

Number Theory in Islamic Mathematics

JACQUES SESIANO

Islamic number theory is characterized by two main developments, both of which stemmed from Greek knowledge. One of them is the relation between natural numbers and the sum of their proper divisors, the other the field of quadratic indeterminate equations.

Numbers and Their Sums of Divisors

If N is a natural number, $\sigma(N)$ the sum of its divisors, and $s(N)$ the sum of the divisors without N itself, then $\sigma(N) = s(N) - N \geq 1$. The Greeks called N "abundant" if $s(N) > N$, "defective" if $s(N) < N$, and "perfect" if $s(N) = N$. Euclid had demonstrated that $N = 2^{m-1}(2^m - 1)$ is perfect if $2^m - 1$ is prime; we know today that it gives all even perfect numbers and possibly all perfect numbers. Thābit ibn Qurra (836–901) noticed that 2^{m-1}, p, m given and p prime, is defective or abundant depending on whether $p > 2^m - 1$ or $p < 2^m - 1$. In the same treatise, he provided for the first time a rule for finding a pair of "amicable" numbers, in which each number is equal to the sum of the proper divisors of the other: numbers N_1, N_2 such that $s(N_1) = N_2$ and $s(N_2) = N_1$. The Greeks knew of only one pair (220, 284). His rule, proved in true Euclidean manner, is: if $s = 3 \times 2^m - 1$, $t = 3 \times 2^{m-1} - 1$, $r = 9 \times 2^{2m-1} - 1$ ($m \neq 0, 1$) are prime, then $2^m \times s \times t$ and $2^m \times r$ are amicable numbers. The severe restrictions on N_1 and N_2, however, limit the numerical application considerably.

Evidence of an apparently novel consideration appears in two incidental remarks made by al-Baghdādī (ca. 1000) concerning the solubility of $s(N) = k$, k given natural. It is asserted that $s(N) = k$ has no solution N for $k = 2$ and for $k = 5$. It is indeed true that, among all odd k, only 5 cannot be a sum of (proper) divisors, and a simple rule used by al-Baghdādī for finding numbers N_1, N_2 such that $s(N_1) = s(N_2)$ may be used to verify it (under assumption, though, of the still unproved Goldbach conjecture). If k is even, we know today that, besides 2, there is an infinite number of exceptions.

Quadratic Indeterminate Equations

Two Greek sources inspired Islamic mathematicians. The principal one is Diophantus's *Arithmetica*, of which seven of the original thirteen "books" (i.e., large chapters) were translated into Arabic. The other one is unknown to us today but was the origin of a set of indeterminate equations solved in Abū Kāmil's *Algebra* by Diophantine methods. Abū Kāmil says that such problems were the subject of discussion in his time. A good introduction to Diophantine methods occurs in al-Karajī's *Badīᶜ fī'l-ḥisāb* (Wonderful on Calculation). The theoretical approach to the solution of finding a square which, increased or diminished by a given integer, produces a square in both cases, was treated in the tenth century by al-Khazīn; it later became the central subject of Leonardo Fibonacci's *Liber quadratorum*.

Other Indeterminate Equations

The above-mentioned indeterminate equations always require positive rational solutions. Linear indeterminate equations with positive integral solutions were the subject of a separate treatise by Abū Kāmil, who searched for all such solutions for six typical pairs of linear equations with three to five unknowns. Of note also are attempts to prove the impossibility of $x^3 + y^3 = z^3$ in the tenth century.

Nyāya

Purushottama Bilimoria

Nyāya is one of the six schools of Indian philosophy (ca. 500 BCE to 1500 CE). It represents reasoning or logic, *nyāya,* into the ideals of *adhyātma* (treating of things elusive, such as Being and Self), and *hetu* (reason, treating of things conventional and empirical) (Halbfass 1992: 32). While the former inquiry is reminiscent of the medieval reconfiguration of Aristotelian metaphysics from Aquinas to Dun Scotus, Nyāya metaphysic does not easily fit this frame. Rather, the goal of enquiry is *niḥśreyasa* or the greatest good of wisdom and liberation from ignorance and suffering or *duḥkha*. Thus, this *prāçiṇa* or "ancient" school of Brāhmaṇic thought is enlisted in the service of the erstwhile Vedic orthodoxy (*śruti*) to bolster defense against the "negative ontology" of a threatening Buddhist antirealism. However, the Nyāya is better known for continuing a certain development of the realist thrust of a prior system known as Vaiśeṣika, that is described as "physics," or "rigorous descriptive metaphysic" (Mukhopadhaya 1984 via Mohanty 2001: 209). In time it provided the nascent Brāhmaṇic philosophy with the needed natural-kind category of substance, a theory of universals, and the assumption of a well-structured universe of enduring and individually identifiable entities or particulars described as objectively as possible, albeit, with a parsimonious stringency, foreshadowing the positivist movement in science and ("natural") philosophy closer to our era. This came to imply that we *can* have true knowledge of what there is *as is* (*astitva*). As such Nyāya embodies a metaphysic of thinking and doctrines on what is knowable and the proper means to their knowing – under a theory known widely in the Indian scientific tradition as *pramāṇa*. Both the Vaiśeṣika and the Nyāya begin their disquisition by enumerating the large number of *padārthas* (literally, a "thing denoted by a word") or epistemic categories of that which the correct application of *pramāṇas* will disclose, as expanded *prameyas* or things so known. Unlike Kant's categories of understanding as the analytic conditions for knowledge of things, the Vaiśeṣika–Nyāya categorical schema go much beyond the reductive rational schema and capture substances, properties, universals, and episodic events in the real world.

Enumerating Vaiśeṣika

Let us begin with a discussion of the *padārthas*. The Vaiśeṣika had settled for six (at most seven) positive categories as evidence of the independently existing reals taken to cover the entire knowable sphere, the subjective process of thought included. Although stated as ontological descriptors they really underpin the epistemic fact of what these are expressively known as. These are: substance (*dravya*, e.g., a banana), quality (*guṇa,* yellowness of its skin), motion (*karman,* its ripening, falling), universal (*sāmānya,* its fruity bananeness), particularity (*viśeṣa*, this banana fruit in my hand), and the relation of inherence (*samavāya*, whole to its parts). Each category is further classified into subsets of different natural kinds (a class-defining property within a unique class), again epistemically laden; e.g., there are nine substances (that are marked by their unique respective *jāti* or universals), notably, earth (*pṛthivi*), water (*apa*), heat (*teja*), air (*vāyu*) space (*ākāśa*), time (*kāla*), place (*dik*), self (*ātma*), and mind (*manas*). Qualities (*guṇa*) comprise pain (*duḥkha*), desire (*icchā*), aversion (*dveśa*), and pleasure (*sukha*). Why are there just nine substances? That is because of the commitment to *jātibādhaka*, "a reductive mechanism necessary to avoid excessive realism which posits universals for every general term" (Mukhopadhaya 1984). Besides, all other entities can be subsumed and explained under this category, or rather admitted under newly formed *concepts*, such as of a composite of natural kinds in an artifact that invites apprehension of a general property, e.g., potness (*ghatatva*) in respect of a wheel-turned pot. Motion or *karman* involves a cause–effect process, within strictures. For instance, even though something cannot come out of nothing, the effect is thought not to be preexistent in the originary or prior causal base (e.g., milk), which is radically different from, say, the curd or butter that is produced from it, as the causal process enlists various instrumentations and additional conditions or qualifiers (e.g., enzyme culture, churning, solidifying, and *kāma* or desire of the consumer): a transformation is more than a mere manifestation (Chakrabarti 1995: 318–323). In this descriptive ontology, substance, quality, and motion or effect–cause are coextensive; one and the same being (*sat*) may possess all three; and nothing is possible without these inhering in a substance of one sort or another. So "isness" which accounts for self-identity and individuation, along with the ability to designate (*abhidheyatva*)

N

and to know (*jñeyatva*), are the common characteristics of the six categories or classes of reals (Praśastapāda via Sharma 1995: 138–155).

The *Nyāya* Canon

The first systematic exposition of the Nyāya metaphysics occurs in the celebrated work of one Gautama, in his canonical *Nyāya-sūtras*.[1] The true force of "*nyāya*," derived from the exegetical hermeneutic of *reasoning with texts* (via the hermeneut Mīmāṃsā) now bares out in the single-minded pursuit of rooting for an epistemic foundation for knowing with equal concern for good debate and clinching arguments. This exercise of quasi-formal reasoning is aided by other technical discursive moves which came into currency, viz., *saṃśaya, vāda-vivāda, bādha, pakṣa, pūrva-pakṣa*, *vitaṇḍa, jalpa, nigrahasthāna, samayabandha* (or doubt, rules of discussion, criteria of coherence and noncontradiction, proofs, disproofs, basis of agreement and disagreement, cavil, sophistry, time and point of defeat, treatment of the vanquished). Thus "*nyāya*" becomes the formal structure and format of such argumentation, and by refuting the adversaries, or demonstrating the superiority of its own paradigm for understanding and overcoming suffering (*duḥkha*), establishes its own or "*ortho-doxa*" (Daya Krishna 1996: 81).

Now three moves occur in respect of this schemata when Gautama enters the scene. First, the *adhyātma* or theological quest is all but shunned. Second, Gautama shifts the metaphysical emphasis from the Vaiśeṣika framework of substance ontology to a more narrowly conceived epistemic taxonomy. Third, he reconfigures the catalog by expanding it to cover 16 *padārthas*, headed by *pramāṇa*s or methods of knowledge. Only one of these is ontological, *prameya,* restricted object of knowledge, as the second *padārtha* in the constellation. Things that fall under the *prameya* set and its subsets are alone truthfully cognizable (*prameyatva*). Gautama reduces these to 12, namely, self (*ātma*), body (*sarīra*), sense organs (*indriya*), mind (*manas*), cognition (*buddhi*), sensoria (*artha,* like smelling), activity (*pravrtti*), its outcome (*phala*), impurity (*doṣa*), pain (*duḥkha*), transmigration (*pretyabhāva*), and finally, release through *theoria* (*apavarga*) of the self from all these insufferable tropes. Again, for reasons of economy, the ontic-*prameya* class of reals are kept to the minimum. For instance, "darkness" need not be taken to be a separate entity because its presence can be explained in terms simply of the absence of light. Note however that nameability and knowability do not necessarily make the "isness" (*esse*, or "essence") of the object supervenient on the conscious minds, for things exist in their own right independently of being perceived: it is enough that they are perceivable (and nameable). Even after God enters the Nyāya's possible worlds, the Berkeleian imperative of subsuming *esse* to *percipii* is here resisted to the end.

Modern Development

In more recent times, in the hands of a leading Indian philosopher, Bimal Matilal,[2] a somewhat muted form of common sense realism – "direct realism" – both defends and qualifies the thesis of the inexorable independence of things from the perceiving mind. It begins by suggesting that we do indeed see the objects we take ourselves to see, that those objects exist by having parts without being merely the sum of their parts, and that they fall into objective, natural categories. Thus, we see "redness" as a patch (substantial ground) and thence attach qualities of "hot," "ound," "pepperness" to it. Two ingredients in Matilal's defense of this theory have a particular significance: the doctrine that perception is nonpartitive, and an interpretation of the concept of objectivity. Nonpartitive indicates that we can see objects without seeing their parts (e.g., their front-surfaces) or their class-properties (e.g., color and shape). Further, the parts and properties of an object may well feature in the explanation of our coming to see it; but the thesis denies that the parts or properties of the object can enter into the explanation only if they themselves become entities of perceptual awareness. If this is correct, Matilal points out, then the move typically made by the Buddhist phenomenalists that the "support" (*alambana*) for perceptual awareness must be unstructured and immediately given, is blocked. This leads to what Matilal recognizes to be the indefeasible challenge for the Nyāya realist: if phenomenal entities like sense-data have no explanatory role in perception, how do we account for such apparently purely phenomenal illusions as seeing the blue dome of the sky, a rainbow, or a circular disk as elliptical? Matilal's solution introduced a new concept of objectivity. To be objective is to be independent of minds. Being "mind-dependent," however, need not mean being a private, intentional object in the way that sense data and other purely phenomenal entities are. It can mean simply

[1] Gautama's date is given by Vidyābhusan as circa 553 BCE, but this may be way off the mark; Jacobi places the date of *Nyāyāsūtra* between 200 CE and 450 CE, but then there is controversy as to whether this is not the date for the later redaction of the *śāstras* by one Akṣapāda. 7) and See Bijalwan (1977): Daya Krishna (1991: 133).

[2] Matilal (1935-1991) was a rare kind of thinker, a philosopher of sensibility who embodied east and west in balanced proportions and who demonstrated that Indian thought, even in its most metaphysical and soteriological concerns, was rigorously analytical and logical as well as discursive. His work has found broad endorsement and inspired lively debate not only among many contemporary Indian philosophers and Indologists, but also in international philosophical circles.

having a mental event as a causal condition, an event on whose continuing existence the object depends. Although illusory, the blueness of the sky and the ellipticality of the disk are objective at least in the sense that they are not purely private objects of sensation, but are produced and shared by the perception of any observer located in the appropriate position. This is a softer realism than that to which skeptics (and at least some mystics) are committed, according to which objects can exist independently of anyone's capacity to know they exist.

From Absence to the Ultimate

A category Gautama is conspicuously silenton but which becomes increasingly important in Nyāya epistemology is *abhāva*, "absence." It comes in three forms: prior and post-nonexistence (before the food is made and after it has been eaten), unnihilatable nonexistence (once born cannot be rendered *dhvaṃsita* or extinguished, e.g., the absentee gods), and atemporal nonexistence (the blue of the sky).

Notice here another line of controversy that arises between earlier and later-day Nyāya stalwarts. Vaiśeṣika began with a fixed number of *padārthas* (six, or seven), whereas the *navya* (new-) Nyāya school (circa thirteenth century) came to advocate a theory of almost undetermined number of *padārthas*. The economy of distinguishing "limit categories" from limitless concepts is blurred. As Mohanty rightly notes, "[T]here is no doubt something dissatisfying about making a list of categories open. It goes against our love for order, simplicity and system" (Mohanty 2001: 212).[3]

Coming now to the end or goals of this ardent pursuit for knowledge of the reals, actual, possible, and their relative absences, paradoxically, at the end of the journey, even the strictly knowables have their down side – in that they vanish. Nevertheless, these constitute the "ultimates" or necessaries of human knowledge, all else is of contingent value. Everything is determinable in their specific particularity, including the self (*ātma*), which is an object of positive inference (via recognition) based on desire, aversion, motivation (*prayatna*), pleasure, pain, and knowledge: not unlike the instance of the single glance at the dancing girl that evokes several aesthetic and other sorts of responses in the cultured mind (*Vārttika on Nyāya-sutras*. 1.I.10).

Theoria and Nirvāṇa-Soft

Some remarks are apposite at this point. First, that the *whole* is always greater in complexity and composite relations than the *sum* of its parts, such that the Buddhist alternative of partible-aggregation, from simple to general, from *dharmas* to *nirvāṇa,* will just not do. Second, the objects of knowledge are subordinate to and supervene on correct cognition, deliverable by the *pramāṇas* and aided by logical illumination at every stage. However, there is an incremental recourse to *yogaja-pratyakṣa*, or "empirical mysticism," which provides the wherewithal through appropriate yoga-culture, for quantum shifts toward grasping more elusive universals, and universals undergirding generals, composite universals, and such higher-order universals in the hierarchy of omniscience that God might be entertaining on a good day or night. Third, there is the possibility of release from the pleasure and pain in a state of perfection or greatest good – *niḥśreyasa* – which results from reaching a state of *theoria,* which in Nyāya amounts to attaining comprehensive knowledge (*tattvajñana*) of the *padārthas in toto* (or "what all there is to know"). This is not the same transcendental state that is underscored in the more "spiritually" – aligned philosophical systems – such as, in particular, *mokṣa*, or salvific liberation from embodied existence, although *niḥśreya* of the Nyāya will presumably inform the inquirer's ethico-religious practices as well. It is this that is the veritable philosophic end or *theoria* and as such has no necessary connections with life-hereafter, in some remote *loka* (planet-world), or merger with the ultimate Being and so on (Mohanty 1996: 46–50; cf. Potter 1995: 29–59.). It amounts to nothing more nor less than the destruction of all *mithyajñana*, false understandings, as Gautama tells us (*Nyāya-sūtras.* I. i. 22): "Absolute freedom from the aforesaid (pain, wrong knowledge, attachment, etc.)." The commentators dispute the view that in the Final Release the self manifests happiness, being the untenable view of the Vedāntins. For a self that is still enmeshed in *saṃsāra* exudes happiness and so it would make no difference. No pleasures are transported across to the *niḥśreyas* state, not even the positive pleasures of life, desire-driven satisfaction, from luxuries of appetite to Donigerian *kāma-sezama* or other such sensual-sexual pleasures (Halbfass 2003: 156). Thus, like the Buddha's Third Noble Truth and more like the negative utilitarians' liberative ethics, this embeds simply the minimization of pain and suffering, and the eventual elimination of all pains and pleasures, beginning with the exemplary individual (*stoic*) and universalizing this preference–satisfaction for the entire human race. If not that of a semi-somnambulant zombie-like stupor, it is at least a godog's life – a joyless unending free-time verizone – and steeped in *svapnavastha suṣupti*, deep-sleep dreamy state minus the dreams – which in Freudian

N

[3] Mukhopadhaya, whose reconstruction of the division between restricted categories (of which he admits only three) and the open-ended concepts that Mohanty is questioning, nevertheless is confident that the controversy is settled by his own conceptual intervention in just this manner, and further that his liberalization of concepts assures progress of knowledge and new epistemes and dimensions of experience. *Explorations* 212.

terms would amount to the sublimative phantasy or working out of unconscious desires, compulsive-obsessive traces, etc. (*Vārtikka* on *N.S.* 4.1.62). There is also a suggestion of the possibility of omniscience without self-consciousness – on a parity apparently with the natural light of divinity. Herein the self reposes in its disinterested or detachedly indifferent beingness, released from both the polarities of pain and pleasure (*Vārtikka* on *N.S.* I.i.22). More than knowledge of the self, it is an all-encompassing knowledge-state. And there is no merging with the Other, no greater or smaller of which could be thought: all such assumptions are tantamount to the transcendental illusion (*viparitabhāvana*) or, worse, transcendental reductionism. The end amounts to "release without transcendence": perhaps "*Nirvāṇa*-lite" is after all merely the desire-cleansed imaginary of *saṃsāra*. And this is the Nyāya's alternative modal possibility of liberation to the Advaita Vedānta and Buddhist contingents.

And so this end-game of all quests is nothing like the unity of all categorical knowledge (as, say, in Kant's "kingdom of ends"), much less the "Thing-in-Itself" or the World-as-Will, nor merely *contemplative theoria* as in Aristotle, nor the nondual self-knowledge as in Śaṅkara's Advaita philosophy.[4] It is as though the diaphanous self reaches a near-death moment, detached from the body and the mind, but not (yet) dying or euthanaized, because that which is external and *nitya* (atemporal) cannot be extinguished. In the end it may be said, the feared antirealist apparition of the Buddha did manage to make a dent in the parsimonious realist ontology of the Vaiśeṣika and its rescue operation in the epistemologically driven antitheological poundings of the Nyāya "analytical" philosophy, despite itself.

[4] Although, Śaṅkara approbatingly cites Gautama from *N.S.* IV.ii.35 where this issue is discussed, under *Brahmasūtra* I.i.iv, because the Advaitin Adiguru also believes that in this state the self has no further contact with the mind, sense-organs, *antaḥkaraṇa*, or inner unifying sense, much less with the world of objects outside. The difference between *apavarga* and *ātmatattva* in Śaṅkara's ideology is that for the latter there is knowledge of the self by the self, in Nyāya there is no knowledge of it as it is not necessary. For other Vedāntins of course, this state of *mokṣa* is full of all kinds of knowledge, including *sarvajñāna* or omniscience (except at its very peak, since Brahman has no name and distinction from the self, Brahman is not an object of knowledge whatever kind of "knowingness" this might involve). Later Nyāya writers introduce *sarvajñāna* via *yogic pratyakṣa* (mystic perception) in one of its two types. On some problems with Śaṅkara's treatment of self, its knowledge and *ānandas*, see two articles on Saṅkara in the Matilal Memorial Volume I (*Bibliography*), Bilimoria 2003 (252-277) and Julius Lipner, "Śaṅkara on *Satyam*, *Jñānam Anantam Brahma*" (301-335).

Obelisks in Ancient Egypt

Brian A. Curran

Among the characteristic monumental forms employed by the Egyptians – pyramids, sphinxes, etc. – the obelisk seems to have enjoyed the richest and most distinctive "afterlife." Over the two millennia of their original production, Egyptian obelisks varied in size from relatively small funerary stones to the slender, towering monoliths of red Aswan granite that were erected before and within the precincts of the greatest Egyptian temples. Obelisks were dedicated in most cases to the solar gods of Egypt, and their soaring height and tapering shape – capped by a pyramidal (and originally gilded) pinnacle called a *pyramidion*, seemed to reach from the earth into the heavens and touch the rays of the life-giving sun. For centuries to come, these great stones have challenged the imaginations of spectators: Greek and Roman, Christian and Muslim, Renaissance and Modern – who were awed by their soaring height, titanic weight, and paradoxically slender and tapering shape. They were endowed with an aura of sanctity and power through their association with the gods and rulers of a civilization that was already viewed as almost unimaginably ancient by the Greeks and Romans. This aura was embodied for many by the hieroglyphic carvings that covered their four faces, which were believed from Classical times to the age of Napoleon To encode, in veils of allegory and enigma, the most secret doctrines of Egyptian religion and science (Iversen 1961; Curran 1998/1999, 2003).

In the classic formula of the New Kingdom, best represented until the 1830s at the Temple of Amun-Ra in Luxor, a pair of obelisks was erected before the sanctuary's main entrance pylon. These pylons were conceived as sacred "horizons" that marked the passage from the realm of mortals to the kingdom of the gods. In this context, the obelisks literally rose to "pierce" the sky and commune with the deities of the rising and setting sun, just as the ceiling of the temples' colonnaded halls supported ceilings carved with the stars and constellations of the heavens (see Bell 1997: 133–134). But the biggest obelisk ever erected – the 32.15 m (105.5 foot), 455–510 ton obelisk of Thutmose III (1479–1424 BCE) was set up as a single monument at the Great Temple of Amun-Ra in Karnak. This towering monolith of red granite was quarried – like all the major Egyptian obelisks – at Aswan in Upper Egypt. Still incomplete at Thutmose III's death, the obelisk was completed (with additional inscriptions) and erected some 35 years later by the King's grandson, Thutmose IV (1400–1390 BCE). For nearly two millennia the great obelisk stood alone as an object of special veneration at Karnak, until it was torn from its base by order of the emperor Constantine (306–337 BCE) and, after a series of delays, transported to Rome by his successor, Constantius II (337–361 BCE), in 357 BCE. Upon arrival, it was raised on the *spina* or median strip of the Circus Maximus; next to a very large (but smaller) obelisk erected more than three centuries earlier by Augustus (see below). In 1587–1588, the obelisk was located and excavated from the ruins of the Circus by order of Pope Sixtus V, who initiated the second great phase of obelisk installations in Rome. The obelisk was moved to the Piazza of San Giovanni in Laterano and its broken pieces were set in place by a great "obelisk machine" devised by Domenico Fontana (for its present location, see Fig. 1). In 2006, the obelisk was again surrounded by scaffolding, erected to preserve and restore the monument from the ravages of traffic, pollution, and a terrorist bomb (for the full history of the Lateran obelisk; see Iversen 1968–1972, 1:55–64; Habachi 1984: 112–117; D'Onofrio 1992: 243–259).

History

As the story of this largest of all Egyptian obelisks amply illustrates, these monuments attracted the envious and acquisitive eyes of self-styled successors of the Pharaohs from the time of the Ptolemies and Roman emperors to relatively modern times. As a consequence, a large number of them have been yanked from their original locations in Egypt and transported at great expense (and with great fanfare) to provide ornaments for the capital cities of the Roman and later empires. Rome received the bulk of them, to the extent that some 48 of them were visible in the city by the middle of the fourth century BCE. Thirteen of these can be seen in

Obelisks in Ancient Egypt. Fig. 1 Lateran obelisk of Thutmose III and IV, Rome.

Obelisks in Ancient Egypt. Fig. 2 Alexandria/Central Park obelisk of Thutmuse III, New York City.

the city today, thanks to the efforts of generations of popes and other patrons who sought to associate themselves with the majesty of the pharaohs and emperors who originally made or appropriated them. Still others may be admired in Istanbul, Paris, London, and New York (Fig. 2), where they testify to the enduring attraction of the obelisk's pharaonic and imperial legacy. In addition to their symbolic power, the obelisks also posed, at virtually all stages of their history, a daunting challenge to the skill and ingenuity of the engineers and builders who sought to move and re-erect them. In a very real sense the story of the obelisks may be understood, at least partially, as a history in microcosm of engineering and transportation technology in the Mediterranean world (on this point see Engelbach 1921, 1922; Fontana 1987; Parsons 1939: 155–173; Dibner 1950; Carugo 1978).

The modern name obelisk derives from the Greek *obeliskos*, a diminutive that means "little spit." It is from this perhaps deliberately ironic term that the Romans derived the Latin *obeliscus*. Among the Ancient Egyptians, these monuments were called *tekhen* – plural *tekhenu* – which derives from a verb meaning pierce (Iversen 2006, "Obelisk," Grove Art website). The precise meaning of their distinctive shape is also uncertain, although the Roman author Pliny the Elder's report that "an obelisk is a symbolic representation of the sun's rays, and this is the meaning of the Egyptian word for it" may have much to recommend it (Pliny, *NH* 36.14.64). Most scholars associate the obelisk's origin with the ancient solar cult at Heliopolis, and it seems like that its prototype was a much older type of stone monument known as the *ben* or *benben*. These cultic stones, which apparently took a pyramidal form, were dedicated to the sun gods Atum and Re or Re-Harakhti in the sanctuary at Heliopolis. The Egyptians believed that the *benben* originated at the beginning of time, when it provided the seat for the Atum's creation of the universe. The *benben* was also associated with the sacred phoenix or Benu-bird, whose cycle of self-creation and resurrection was associated with the cults of the dead and the rising and setting of the sun (Iversen 1968–1972, 1:11–15; Habachi 1984: 3–6).

Both archaeological and inscriptional evidence make it clear that obelisks of various types were being erected by the rulers of Egypt during the later dynasties of the Old Kingdom (2686–2160 BCE). Among these, perhaps the most notable were a pair of obelisks transported on large ships from southern Egypt to Heliopolis by the sixth Dynasty Pharaoh Pepi II (2278–2184 BCE – Habachi 1984: 40–41). During the preceding fifth Dynasty (2494–2345 BCE) a series of solar temples with obelisk-like centerpieces were erected near the pharaonic cemetery at Abu Sir. These "obelisks" were fashioned not from single blocks of stone, but from masonry blocks and sheathed with fine white limestone in the manner of the pyramid tombs of the time. During the same period, diminutive obelisk-shaped stones began to be erected in pairs at the entrances to tombs. These were generally installed facing east, presumably to present themselves to the rays of the rising sun, which represented the resurrection of the deceased in Egyptian belief. These early funerary obelisks were usually fashioned from limestone and were inscribed on one side with the name of the deceased (Kuentz 1932; Habachi 1984: 41–46).

The earliest surviving large-scale, monolithic obelisk was erected by the 12th Dynasty Pharaoh Senusret I (1985–1956 BCE) in the sacred city of Heliopolis on the occasion of his jubilee year. This was originally one of a pair that was carved from the durable mottled-red granite (or *Syenite*) from Aswan in Upper Egypt, where later obelisks of this size were also quarried. They were shipped up the Nile and erected before a new or rebuilt temple dedicated to the sun god Re-Harakhti. The Heliopolis obelisk, like all succeeding obelisks of the "classical" type, is a four-sided monolith, carved from a single piece of Aswan granite. It stands some 67 ft (20.4 m) high on a squared base and weighs some 120 tons (Habachi 1984: 46–50).

Since no other obelisks datable to the Middle Kingdom have survived, the true successors of Senwosret's monuments are the ones produced by the New Kingdom rulers of the 18th and 19th Dynasties (1550–1186 BCE). This great series of obelisks begins with a pair dedicated to Amun-Ra at Karnak by the 18th Dynasty pharaoh Thutmose I (1504–1492 BCE). One of these, which rises nearly 66 ft (20,016 m) high and weighs an estimated 143 tons, still stands on its original pedestal in the temple precinct (Fig. 3), while the other survives only in fragments. Thutmose I was succeeded after the short reign of his son (Thutmose II) by that king's "royal wife" (and half-sister) Hatshepsut (1473–1458 BCE). Hatshepsut erected no less than four large obelisks at Karnak, in two pairs. Of these, only one still stands intact today (Fig. 4). This great obelisk, which rises to a height 96.78 ft/29.5 m and weighs some 323 tons, is one of the pair set up here on the occasion of her Jubilee. The lower part of its companion stands nearby on its original base, and some fragments can also be seen on site and in various museums. Of the second pair that Hatshepsut erected at the beginning of her reign in the eastern section of the temple, only fragments survive today. But a visual record of their transport is preserved in the relief decoration in the Queen's funerary temple at Deir el-Bahari. Here, the obelisks are shown loaded end to end on a large ship pulled by three rows of boats for their journey "down" the Nile from Aswan to Thebes (Habachi 1984: 56–72).

Hatshepsut's successor Thutmose III (1479–1425) was responsible for the production of at least nine

Obelisks in Ancient Egypt. Fig. 3 Obelisk of Thutmose I, Karnak.

Obelisks in Ancient Egypt. Fig. 4 Obelisk of Hatshepsut, Karnak.

obelisks, including seven erected at Karnak and two at Heliopolis. Of these, only the Lateran colossus (see above), the Heliopolitan pair – which were transferred to Alexandria in Augustan times and are now in London and New York City (for the latter, see Fig. 2) and the Hippodrome obelisk in Istanbul – which stood before the seventh pylon at Karnak until it was removed by Constantine and raised in Constantinople by the Emperor Theodosius (379–395 BCE) – survive today (Habachi 1984: 72–77). During the 19th or Ramesside Dynasty, the Pharaohs Sety I (1294–1279 BCE) and Rameses II (1279–1213 BCE) erected obelisks in a number of locations, including Luxor, Heliopolis, and Piramesse. One celebrated survivor is the so-called Flaminian obelisk (ca. 75 ft/22.84 m, 263 tons), which was quarried by order of Sety I and completed and erected in Heliopolis by Rameses II. It was transported to Rome and set up in the Circus Maximus by Augustus, and re-erected in the Piazza del Popolo by Pope Sixtus V in the late sixteenth century (Fig. 5, and see more below).

During later dynasties obelisks continued to be made, sometimes out of different types of stone and in some cases on a smaller scale. The largest surviving specimen from the later periods is the so-called Montecitorio obelisk (21.79 m, 230 tons in its present, reconstructed form), which was one of a pair raised by the 26th Dynasty pharaoh Psamtek II (664–610 BCE) at Heliopolis and also later taken to Rome (see Fig. 6). The last surviving obelisks commissioned by a native Egyptian pharaoh were a much small pair carved from hard black schist for Nectanebo II (360–343 BCE) of the 30th Dynasty. They were dedicated to the Egyptian god Thoth and presumably set up at that god's temple in the city of Hermopolis. At the end of the Napoleonic campaign in Egypt, two fragments of these obelisks were turned over to British forces by the French and sent to the British Museum, where they may be seen today. A third fragment is in Cairo (Iversen 1968–1972, 2:51–61; Habachi 1984: 101–103).

During the rule of the Macedonian Ptolemaic Dynasty (332–30 BCE), temples and monuments continued to be produced in the traditional Egyptian mode. Among the embellishments for these was the pair of smallish obelisks erected at the Temple of Isis in Philae by Ptolemy IX (107–80 BCE). One of these obelisks (22 ft/6.7 m tall, 6 ton) was discovered in 1815 by the British nobleman and scholar William John Bankes (1786–1855). In 1819 Bankes discovered the lower part of its mate and hired the famous Italian strongman turned explorer–excavator, Giovanni Belzoni, to help remove the obelisks and their bases (inscribed in Greek) to his Kingston Lacy estate in Dorset, England. In 1839, Bankes erected the intact

Obelisks in Ancient Egypt. Fig. 5 Flaminian obelisk of Sety I and Rameses II, Piazza del Popolo, Rome.

Obelisks in Ancient Egypt. Fig. 6 Solarium obelisk of Psamtek II, Piazza di Montecitorio, Rome.

obelisk on its pedestal in the garden of the estate. Its hieroglyphic inscriptions and the Greek ones on its base were among the key documents in the decipherment of the Egyptian hieroglyphic script by Egyptologist Jean-François Champollion (1790–1832) in 1822 (Iversen 1968–1972, 2:62–85; Habachi 1984: 105–108).

Manufacture and Installation

The methods the Egyptians used for the manufacture, transport, and erection of obelisks are not fully understood (for what follows, see Engelbach 1922, 1923; Habachi 1984: 15–37; Arnold 1991: 36–40, 47–52, 57–73). Most of the evidence we have comes from the study of extant monuments, investigation into Egyptian building and stone-cutting techniques, and a few visual representations that survive from pharaonic times. But the richest source of information has come from the archaeological study of a large unfinished obelisk, believed to be of Thutmosid (New Kingdom) date, that still lies in one of the granite quarries at Aswan (Fig. 7). This obelisk, which was originally laid out at a height of 41.75 m (ca. 137 ft), would have weighed about 1,168 tons if extracted. It was abandoned – after an attempt to reduce its length – when it developed irreparable cracks in its upper section. Excavation of the monument by Engelbach in 1921–1922 revealed that the ancient workmen began by cutting test shafts into the rock. Then, after laying out the obelisk's shape on the surface, they began removing the upper layer of uneven stone to expose a suitable piece for excavation. Then came the arduous task of digging trenches on all four sides to provide work areas for the quarrymen to form and separate the block (see Fig. 8). From the evidence of surface marks and tools found on the site, it seems clear that this work was done with ball-shaped tools of ultra-hard dolerite stone (Fig. 9). When the trenches reached the required depth, the workers had to undercut the shaft to extract the obelisk from the bedrock. Then the obelisk had to be pulled or lifted from the quarry bed, smoothed and polished on site (in at least one case, parts of the hieroglyphic inscription were added at this phase) and prepared for transport. At all stages of work, including the carving of hieroglyphic inscriptions, the work was done with stone tools and abrasives like emery, since the copper and bronze tools of the time were not strong enough to cut the hard granite.

Visitors to the site may be surprised to discover that the unfinished obelisk was carved at a considerable angle longwise, with the pyramidion at the highest point on the east side and the bottom much lower on the west. By removing the deposit of granite at the opposite (bottom) end, it seems that the workers could have pulled the great stone out of the quarry with the help of its own

Obelisks in Ancient Egypt. Fig. 7 Unfinished obelisk, Aswan.

Obelisks in Ancient Egypt. Fig. 8 Trench of unfinished obelisk, Aswan.

Obelisks in Ancient Egypt. Fig. 9 Dolerite hand-tool, Aswan.

massive weight. But Engelbach has argued that the failure to remove the rock from the west end, coupled with the removal of stone from the area of the pyramidion on the east side, suggests that the workers planned to lift the obelisk from the bed with the help of large wooden levers and remove it from the front end of the trench (Engelbach 1923: 41–51).

Once the obelisk had been removed, the workmen loaded it onto a large sledge, which was pulled by a team of laborers on a track or ramp to the riverbank for transfer to a specially constructed transport ship. Upon arrival, it was rolled off and dragged in the same manner to the site where it was to be erected. At this stage, the builders faced the difficult (and potentially dangerous) task of raising the monument to an upright position on its pedestal block. Direct evidence for how this was done does not survive, but a number of plausible hypotheses have been put forward. We know that Egyptian builders used three main methods for raising large stones – levering, pulling with ropes, or drawing them up a ramp-like incline. It was the opinion of Engelbach that the workers dragged the monument bottom-end first up a ramp-like incline to a point some height above the base, after which it was pulled upright by ropes and lowered onto the pedestal, where it was positioned by levers and the gradual removal of sand. A version of this method was represented in suitably dramatic terms in the 1956 film, *The Ten Commandments*. A series of attempts to duplicate this method with a modern obelisk finally succeeded in 1999 (see Handshouse Projects 1999; Nova Online: Mysteries of the Nile, http://www.pbs.org/wgbh/nova/egypt/raising/).

Obelisks in Ancient Egypt. Fig. 10 Vatican obelisk, Rome.

Rome and the First Afterlife of the Obelisks

Obelisks continued to be erected, moved, and in a few cases, manufactured anew during the Roman era, which followed the defeat of Cleopatra VII (51–30 BCE) and her ally Marc Anthony by Octavian, who became known as the Emperor Augustus in 28–27 BCE. Egypt became a province of the Roman Empire, and the granite quarries at Aswan came under Roman control, providing a rich supply of monolithic columns and other products for the great building projects of Rome and its empire. The first prefect of Egypt under Augustus, Cornelius Gallus (30–26 BCE), was responsible for laying out a new forum complex, called the *Forum Julium*, at a site near the Ptolemaic capital of Alexandria. As an ornament to this space, Gallus ordered the erection of the so-called Vatican obelisk – the big, 331 ton, 83 ft (25.31 m) colossus that now stands in the Piazza di San Pietro in Rome (Fig. 10). Since it lacks a hieroglyphic inscription, is not known when or by whom this most celebrated of obelisks was originally quarried. Pliny the Elder reports that it had been originally raised in Egypt by the pharaoh "Nencoreus, the son of Sesostris," but it has been persuasively argued (Alföldy 1990) that it was originally quarried by Cleopatra VII as a monument to Julius Caesar and appropriated by Gallus, who added an inscription in bronze letters to the lower-end of the shaft that essentially dedicated the obelisk to himself. The letters were removed after Gallus was forced out of office on charges of corruption and took his own life to avoid prosecution (the fastening holes for the inscription were discovered during analysis of the obelisk's surface in1959). Sometime after this, presumably during the reign of emperor Tiberius (14–37 BCE), a second inscription, now eroded but still visible, was carved on the lower east and west faces of the monument (Fig. 11) which rededicated the monument to Augustus, "son of the divine Julius," and to Tiberius himself (for the Vatican obelisk, see Iversen 1968–1972, 1:19–21; D'Onofrio 1992: 97–185; Alföldy 1990).

In 13–12 BCE, Augustus ordered a pair of obelisks originally raised by Thutmose III (with later inscriptions of Rameses II) in Heliopolis to be transferred to Alexandria, where they were set up – facing the sea – before the so-called Caesareum, a complex dedicated to the cult of Julius Caesar. These had apparently been begun as a mausoleum for Marc Antony toward the end of Cleopatra VII's reign. The obelisks were set on their bases with their corners bronze, crab-shaped astragals – one of which, now in the Metropolitan Museum in

Obelisks in Ancient Egypt. Fig. 11 Latin Inscription, Vatican obelisk, Rome.

New York – was inscribed in both Greek and Latin to commemorate its dedication by Publius Rubius Barbarus, prefect of Egypt. In the later nineteenth century, these obelisks, one of which had fallen but remained intact, were presented as "gifts" from the Egyptian authorities to the British and American governments and transported to London and New York City (Fig. 2), respectively (Gorringe 1882; Iversen 1968–1972, 2:90–147; Habachi 1984: 165–182; D'Alton 1993).

In 10 BCE, 20 years after the defeat of Antony and Cleopatra, Augustus ordered the transport of two large obelisks from Heliopolis. By this time, according to contemporary reports, this great Egyptian city had fallen on bad times, and its marvelous temple had fallen into disrepair. The first, originally carved by order of Rameses II and his father Sety I (and now in the Piazza del Popolo, Fig. 5), was erected on the *spina* of the Circus Maximus (see Iversen 1968–1972, 1:64–75; D'Onofrio 1992: 260–266). The second, the aforementioned obelisk of Psammetichus II (now in the Piazza di Montecitorio, see Fig. 6), became the *gnomon* of a gigantic sundial in the Campus Martius (Iversen 1968–1972, 1:142–160; D'Onofrio 1992: 369–421). Both were capped by gilt-bronze spheres with obelisk-shaped pointers and provided with identical inscriptions on their red granite bases:

> IMP. CAESAR. DIVI. FIL. AVGVSTVS. PONTIFEX. MAXIMUS. IMP. XII. COS. XI. TRIB. POT. XIV. AEGVPTO. IN. POTESTAM. POPVLI ROMANI. REDACTA. SOLI. DONVM. DEDIT.

> When Imperator for the twelfth, consul for the eleventh, and tribune of the people for the fourteenth time, Imperator Augustus, son of the divine Caesar, dedicated this obelisk to the sun when Egypt had been brought under the sway of the Roman People (Iversen 1968–1972, 1:65, 142).

As the inscription makes clear, Augustus' obelisks were intended to commemorate his conquest of Egypt. In both cases, the new installations corresponded to the original Egyptian dedication of these monuments to the sun, but gave this theme a new and distinctly Roman spin. In the case of the Circus Maximus, which was traditionally associated with the solar cult, the obelisk took it its place on the spina or median strip as an embodiment of the sun's power, while the chariots that raced around it came to be considered symbols of the planets moving around it. In the Campus Martius, the Psamtek obelisk was put to use as a solar instrument, as described by Pliny the Elder (1938–1963): (*Natural History*, Ed. Rackham and Eichholz, 10:55–57).

> The one in the Campus Martius was put to use in a remarkable way by Augustus of Revered Memory so as to mark the sun's shadow and thereby the lengths of days and nights. A pavement was laid down for a distance appropriate to the height of the obelisk so that the shadow cast at noon on the shortest day of the year might exactly coincide with it. Bronze rods let into the pavement were meant to measure the shadow day by day as it gradually became shorter and then lengthened again. This device deserves to be carefully studied, and was contrived by the mathematician Novius Facundus. He placed on the pinnacle a gilt ball, at the top of which the shadow would be concentrated, for otherwise the shadow cast by the tip of the obelisk would have lacked definition (Pliny, *NH* 36.14.69–72).

It is unclear from Pliny's description whether this device was designed as a *solarium* (which measured the daily length of the sun's shadow on a meridian) or a *horologium* (a more elaborate device capable of measuring the length of the hours of the day), but his admiration for the device was undiminished by his observation that "the readings thus given have for about thirty years past failed to correspond to the calendar." During the fifteenth and sixteenth centuries, pavements with "lines of gilt metal" and mosaics representing the winds were thought to be remains of the device described by Pliny (Iversen 1968–1972, 1:144–149). In 1979–1981, a section of travertine pavement, with a meridian strip with Greek inscriptions in bronze letters (denoting signs of the zodiac and the Etesian winds), was discovered in the area immediately north of the obelisk, confirming the basic veracity of Pliny's account, although problems of interpretation and function remain (Buchner 1982; Schütz-Tübingen 1990). As for the obelisk itself, it was still standing in the eighth century but was thrown down and broken at some later date and discovered (and reburied) in about 1512. It was finally excavated in 1748, and after several abortive attempts, repaired (with fragments of a large granite column) and re-erected in the Piazza di Montecitorio in 1789 by order of Pope Pius VI. It was intended to lay a modern meridian to track the obelisk's shadow at this time, but the idea was not realized until 1998, when the pavement was restored to designs by the architect Franco Zagari (see Zagari, http://www.francozagari.it/HOME/Piazza%20Montecitorio/montecitorio.htm).

But impressive as these installations undoubtedly were, it was the feat of transporting them across the Mediterranean to Rome that impressed Roman commentators on the subject. Pliny reports that the ship that was specially constructed to carry Augustus' obelisks to Rome was considered such a wonder in its own right that it was placed on display in a "permanent dock" at Puteolis (modern Pozzuoli) to commemorate the achievement – although it was later destroyed by fire. He adds that the ship used by Gaius (Caligula) to move the third (Vatican) obelisk to Rome was likewise preserved until it was filled with concrete and sunk as part of the Claudian harbor-works at Ostia. Excavations in 1957–1960 near Rome's Fiumicino airport near Rome Ostia in 1957–1960 uncovered the concrete core of the Vatican obelisk ship, which preserved a partial "impression" of the vessel that once had borne it. From a reexamination of this and other evidence from Egyptian and Roman sources, Wirsching (2000) has proposed reconstructions of both Egyptian and Roman obelisk and column-carrying ships – and has concluded that both riverine and seagoing vessels used a ballasted double hull to control the level of the ship for loading and unloading the monoliths.

When it came time to transport and raise the obelisks on land, the Romans were able to use a variety of techniques that had not been available to the Egyptians, including iron tools and heavy lifting cranes Employing ropes and pulleys. The most extensive description of the Roman procedure is provided by the fourth century historian Ammianus Marcellinus, in his account of the transport and erection of the Lateran obelisk (Fig. 1) in the Circus Maximus under Constantius II in 359. He reports that upon its arrival in Italy, the obelisk was put on a *chamulcus* (a kind of sled or cradle) and "carefully drawn" through the Ostian gate to the Circus Maximus, where it was raised using a device resembling a "veritable grove" of beams and derricks and powered by an army of men turning wheels "that resembled millstones" (Ammianus, 17.4.14–15; *Ammianus*, Rolfe 1950–1952, 1:325–327). The great stone was gradually raised and lowered on its base on the *spina* of the circus, where it joined (and to a certain extent upstaged) the obelisk erected by Augustus over three and a half centuries earlier. Ammianus' description of the Roman "obelisk-raising" machine corresponds in general terms to the equipment depicted on the base of the Hippodrome obelisk in Constantinople, erected by Theodosius I, 379–395 (Bruns and Krauss 1935: 47–53; Iversen 1968–1972, 2:15–16; Killerich 1998: 69–72). It is also the same basic method that was successfully employed by Domenico Fontana to move the Vatican obelisk in 1586 (see below).

As the story above illustrates, later Roman emperors emulated Augustus' taste for transporting obelisks. The next to be moved to Rome after Augustus (that we know of) was the one in the *Forum Julium* at Alexandria, which was shipped to Rome and raised on the spina of the Vatican Circus by order of Gaius Caligula (37–41 BCE, see more below). These were followed by some 45 others in the three and a half centuries that followed. Among them were at least six small obelisks of 19th and 26th Dynasty vintage that were installed (at an unknown date) in the Roman sanctuary of Isis in the Campus Martius: the Iseum Campense (Iversen 1968–1972, 1:93–114, 174–177; Roullet 1972: 35, 72–77-cat nos. 73–80; Lembke 1994: 202–210-cat nos. 48–53). These include the obelisk now in the Piazza della Rotunda in front of the Pantheon (Fig. 12), which was originally raised in Heliopolis by Rameses II and set up at the beginning of the fifteenth century in the nearby Piazza di San Macuto (which marked the northernmost section of the Isis sanctuary). Its fragmentary counterpart, now in the gardens of the Villa Celimontana in Rome (Fig. 13), had been restored and set up even earlier, during the

Obelisks in Ancient Egypt. Fig. 12 San Macuto obelisk of Rameses II, Piazza della Rotunda, Rome.

twelfth to thirteenth centuries, on the Capitoline Hill. Other obelisks from the Iseum, discovered in the sixteenth to nineteenth centuries, can be seen in other locations in Rome, Florence, and Urbino. The last obelisk to be transported out of Egypt by a Roman emperor was raised in the Hippodrome of Constantinople by Theodosius I in 390 BCE. Originally one of a pair set up at Karnak by Thutmose III, this 30 m, nearly 400-ton colossus (it apparently broke during transport and now stands some 19.5 m–65 ft) was one of at least five obelisks that once stood in the city. Most of these have disappeared without a trace.

In addition to importing obelisks from Egypt, the Romans also produced their own new obelisks when the circumstances required it. Two that may have been produced directly for Roman use are the pair of uninscribed obelisks that were placed before the mausoleum of Augustus in Rome. They were erected at an unknown date (probably the first century BCE) and fell into the debris of the city sometime during the middle ages. In the sixteenth century, one of them was excavated and after years of neglect, was erected by Pope Sixtus V on the Esquiline Hill. In the eighteenth century, the second was discovered and installed in the Piazza del Quirinale by Pope Pius VI (Iversen 1968–1972: 47–54, 115–127).

A more certain case of Roman manufacture is the so-called Pamphilian obelisk, which was inscribed with vignettes and hieroglyphic inscriptions of the emperor Domitian (81–96) in honor of the Egyptian gods. During the fifteenth and sixteenth centuries, this medium-sized and exceptionally slender obelisk (16.54-m tall) lay broken in the ruins of the Circus of Maxentius on the Via Appia outside the walls of Rome. It remained there until the middle of the seventeenth century, when it was repaired and erected as the centerpiece of Bernini's Fountain of the Four Rivers in the Piazza Navona (Fig. 14). It has been proposed that the Pamphilius was originally raised in the central entrance-court of the Iseum Campense when it was rebuilt by Domitian after a fire in 80 BCE, but this is by no means certain. The inscriptions mention Isis and allude to the emperor's restoration of "that which had been destroyed," but the principal dedication is to the sun god Re-Harakhte. It is possible that it was made for another Roman site, or even – as seems to be the case with the obelisk of Antinous (see below) – for dedication in an Egyptian setting, and only later found its way to Rome.

During the reign of Hadrian (117–138), a smaller obelisk was carved in honor of the emperor's late companion Antinous, who drowned in the Nile during an Imperial visit to Egypt and was deified as a kind of modern Osiris in Egypt and elsewhere in the Empire. This obelisk was originally manufactured and, according to most recent theories, probably set up in Egypt

Obelisks in Ancient Egypt. Fig. 13 Capitoline Obelisk of Rameses II, Villa Celimontana, Rome.

Obelisks in Ancient Egypt. Fig. 15 Obelisk of Hadrian and Antinous, Monte Pincio, Rome.

near the site of the unfortunate boy's tomb. But it was eventually brought to Rome and erected in the third century in the Circus Varianus near the Via Labicana, where two fragments of its broken shaft were visible in the fifteenth and sixteenth centuries. These pieces were excavated and partially re-erected by the Saccocius brothers, who owned the property, in 1570. Then, after a period of neglect, the obelisk was purchased by Cardinal Francesco Barberini in 1632, and after some further peregrinations, was installed in Rome's Pincian gardens by Pope Pius VII in the early nineteenth century (Fig. 15).

Obelisks from the Middle Ages to Modern Times

During the middle ages, the obelisks continued to attract their share of interest from learned observers, even while many of them were toppled and otherwise neglected or vandalized in Egypt and Rome. They also acquired new names that continued to emphasize their needle-like shape. The common Medieval (and modern) Arabic word for an obelisk is *mislah* or *missala*, which refers to a "patching needle" and thus, like the Greek *obeliscos*, emphasizes the slender, needle-like shape of these monuments. During the middle ages, the obelisks of Senusret at Heliopolis (along with the Alexandrian pair) were popularly known as *Messalat Far'un* (Needles of Pharaoh). Arabic scholars called the hieroglyphic carvings on the obelisks and other Pharaonic monuments by a variety of names, including "bird's script" (*qalam al-tayr*), "temple-script" (*al-qalam al-birbawi*), and "hieratic" script (*al-qalam al-kahini*) (Habachi 1984: 3–5, 48; Haarmann 1996; El Daly 2003).

In Egypt, then, it is clear that the obelisks, like the pyramids and other monuments, retained their Pharaonic associations into the Medieval period. But the situation was more complicated for the "obelisks in exile" in Rome. It is true that thanks to the writings of scholars like Isidore of Seville the Egyptian origins and traditional name of *obeliscus* was never entirely forgotten in the Latin west (Isidore of Seville, *Etymologiae* 18.28–31). But in the ancient capital itself, as the obelisks fell victim to the indignities of neglect, earthquake, and vandalism, the memory of their Egyptian origins also began to fade, and was superseded by new or alternate associations with Roman history and legend. By the middle of the twelfth century, the only obelisk of great size that was still standing in Rome was the *Vaticanus* (Fig. 10), which by this time was believed to mark the site of the Apostle Peter's martyrdom in the Vatican circus. According to a second tradition set out in the *Mirabilia urbis Romae*, an influential twelfth century guide to the antiquities of Rome, the obelisk had originally been raised as the monument and tomb of Julius Caesar, whose ashes were believed to be interred in the bronze globe at the monument's summit. Although other texts of the time referred to this and other monuments in Rome as pyramids or obelisks, the preferred name for the Vatican monument, and later, for other Roman obelisks, was the *guglia* or "needle" of Caesar (variants of the term include *agulia* and *aguglia*). Derived in part from a misreading of a passage in Suetonius' *Life of Caesar* and the Latin inscription on the monuments' shaft, the association with the "Divine Julius" and the name *guglia* persisted in common parlance long after both the true origin and function of the monument had been established by Renaissance admirers (Iversen 1968–1972, 1:22–28; Curran and Grafton 1995).

By the middle of the fifteenth century, Italian humanists had identified the obelisks in Rome as the Egyptian monuments "in exile" described by Pliny and Ammianus, and had already embarked on the earliest stages of a long and complicated effort to understand and decipher their hieroglyphic inscriptions. In the early 1450s, builders working for the "humanist" Pope Nicholas V (1447–1455) conducted the first archaeological investigation of the Vatican obelisk in relation to the Pope's plan to move the great stone from the remains of the circus on the south side of St Peter's basilica to the piazza in front of it – a distance of some 275 yards. Accounts of the papal architects' claims to have devised machines capable of lifting and moving the great stone spread as far as the northern court of Ferrara, and inspired a host of imaginative obelisk projects – most of them quite impossible to realize, on the part of Renaissance artists and architects (Curran and Grafton 1995: 242–244). But this and other plans to move the obelisk or erect other ones that were discovered in the ruins of Rome were delayed for many years, until 1586, when the transport of the Vatican obelisk was achieved, with great fanfare, by Pope Sixtus V (1585–1590) and his architect-in-charge, Domenico Fontana (1543–1607). To achieve this long-postponed goal, Fontana devised a great obelisk-lifting and lowering machine – called a *castello* – that resembled a wooden siege-tower about 92 ft tall – just tall enough to life the obelisk from its base and lower it to a horizontal position, using a system or ropes and pulleys powered by capstans turned by teams of some 900 men and 74 horses. The obelisk was then transported to the piazza on a specially constructed causeway and raised on its original (albeit restored and elevated) base by reversing the lowering process. The obelisk was solemnly rededicated to the Holy Cross and ceremonially exorcized of all pagan, demonic forces, and Fontana himself was lauded as the hero of the moment and showered with titles and gifts appropriate to his achievement. During the next 3 years, Fontana used his obelisk-lifting machine to raise and repair the broken fragments of three more obelisks – the two large ones excavated from the Circus Maximus (which he raised in the Lateran and the Piazza del Popolo, respectively) and a smaller specimen that had been discovered decades earlier in the ruins of the Mausoleum of Augustus, which was set up on the Esquiline hill, near the apse of the Basilica of Santa Maria Maggiore (for Fontana's account and later studies, see Fontana 1978; Parsons 1968: 155–173; Dibner 1970: 21–43; Iversen 1968–1972, 1:29–40; D'Onofrio 1992: 71–92).

During the later seventeenth and eighteenth centuries, a series of smaller and/or broken obelisks were repaired and re-erected in Rome, including the Obelisk of Domitian (Fig. 14), which was restored under the supervision of the Jesuit polymath Athanasius Kircher (1601/1602–1680) and installed as the centerpiece for Bernini's richly allegorical Fountain of Four Rivers in 1649 (see Iversen 1968–1972, 1:76–92; Preimesberger 1974; Rowland 2001; Parker 2003); and the reconstructed fragments of the Campus Martius sundial obelisk, which was repaired with red granite from the damaged column of Antoninus Pius and set up in the Piazza di Montecitorio by order of Pope Pius VI in 1786 (Fig. 6). It was one of three obelisks re-erected by this pope, whose projects represented the final chapter in grandiose papal appropriation of these monuments (see Collins 2001, 2004). During the nineteenth century, would be European and American obelisk-importers shifted their gaze from Rome to Egypt itself, as the monuments of the country attracted new enthusiasm following the Napoleonic campaign of 1798–1801 and the subsequent decipherment of the hieroglyphic script by Jean François Champollion. The first to arrive in Europe (after the diminutive Philae/Bankes obelisk, see above) was the westernmost of the pair of obelisks inscribed for Rameses II that still stood before the great entrance pylon of the Temple of Amun-Ra at Luxor. Selected as the most beautiful specimen available on the authority of Champollion himself, the 246-ton obelisk was lowered using an elaborate hinged device and loaded onto a specially designed ship for transport to Paris, where it was raised with great ceremony in the Place de la Concorde in 1833 (Lébas 1839; Habachi 1984: 153–164; Porterfield 1998: 13–41; Hassan 2003). The next to arrive was the fallen one of the pair at the Caesareum in Alexandria, which had been offered to the British by the Egyptian authorities early in the century, but arrived only in 1878, after a tragic and nearly catastrophic voyage in a specially designed barge called the Cleopatra. The obelisk was raised on the Thames Embankment on September 13 of that year. The still-standing mate of this obelisk was offered at this time to the United States, and its lowering and transport were supervised by a naval officer and engineer named Henry H. Gorringe, who described his methods in a monumental tome that rivaled the early production of Domenico Fontana. The obelisk was raised with great ceremony in New York's Central Park in the winter of 1881, where it remains today (Fig. 2).

Obscured by trees and mostly ignored by strollers, joggers, and the throngs who crowd the Egyptian collections of the Metropolitan Museum of Art nearby, the New York obelisk provides a somewhat sobering coda for the colorful history of these monuments, whose unique appeal made them the most admired and desired of Egyptian inventions for some 2,000 years.

Observatories in India

Virendra Nath Sharma

India has an ancient astronomical tradition. Information on its observatories is meager, however. It is certain that a number of prominent astronomers, patronized by kings, carried out their own observations, which are mentioned in *karaṇas*, or practical manuals. The places of such observations, if operated for a reasonable period of time, technically could be called observatories. A court astronomer, Śaṅkaranārāyaṇa (fl. 869), mentions such a place with instruments in the capital city of king Ravi Varmā of Kerala. Astronomers of the Islamic school of astronomy, such as ʿAbd al-Rashīd al-Yāqūtī (fifteenth century) report an observatory in the city of Jājilī in India. The Emperor Humayun (d. 1556) is said to have had a personal observatory at Kotah, near Delhi, where he himself took observations.

An ambitious program of building observatories was undertaken by Sawai Jai Singh (Savā'ī Jaya Siṃha), an astronomer–statesman of India. Between 1724 and 1735, Jai Singh built observatories at Delhi, Jaipur, Mathura, Varanasi, and Ujjain. His observatories, except for that of Mathura, still exist today in varying degrees of preservation. Sawai Jai Singh's purpose in building observatories was to update the existing planetary tables. Toward this purpose, he designed and built instruments of stone and masonry. These instruments may be classified into three main categories based on their precision which varies anywhere from ±1′ to a degree. Table 1 presents an inventory of his masonry instruments according to their precision, with the low precision instruments listed first. Table 2 lists instruments added after Sawai Jai Singh's death.

Jai Singh constructed 15 different types of masonry instruments for his observatories. Of these, the Samrāṭ yantra, Ṣaṣṭhāṃśa, Dakṣinottara Bhitti, Jaya Prakāśa, Nāḍīvalaya, and Rāma yantras are his most important instruments.

Samrāṭ Yantra

The *Samrāṭ yantra* or the "Supreme Instrument" is Jai Singh's most important creation. The instrument is

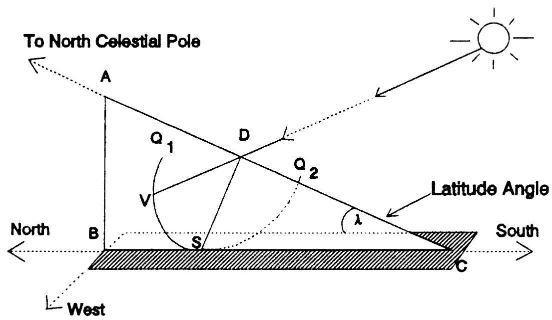
Observatories in India. Table 1 Inventory of Jai Singh's masonry instruments

Instrument	No.	Location
Dhruvadarśaka Paṭṭikā (North Star Indicator)	1	Jaipur
Nāḍīvalaya (Equinoctial dial)	5	Jaipur (2), Varanasi, Ujjain, Mathura
Palabhā (Horizontal sundial)	2	Jaipur, Ujjain
Agrā (Amplitude instrument)	5	Delhi, Ujjain, Mathura
S'aṅku (Horizontal dial)	1	Mathura
Jaya Prakāśa (Hemispherical instrument)	2	Delhi, Jaipur
Rāma yantra (Cylindrical instrument)	2	Delhi, Jaipur
Rāśi valaya (Ecliptic dial)	12	Jaipur
Śara yantra (Celestial latitude dial)	1	Jaipur
Digaṃśa (Azimuth circle)	3	Jaipur, Varanasi, Ujjain
Kapāla (Hemispherical dial)	2	Jaipur
Samrāṭ (Equinoctial sundial)	6	Delhi, Jaipur (2), Varanasi (2), Ujjain
Ṣaṣṭhāṃśa (60 degree meridian chamber)	5	Delhi, Jaipur (4)
Dakṣinottara Bhitti (Meridian dial)	6	Delhi, Jaipur, Varanasi (2), Ujjain, Mathura

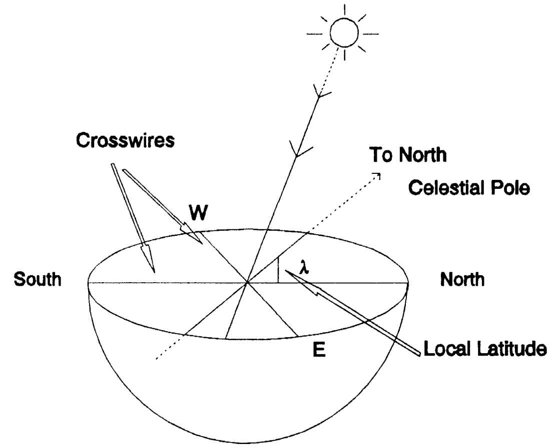
Observatories in India. Table 2 Instruments added after Sawai Jai Singh's death

Instrument	No.	Location
1. Miśra yantra (Composite instrument)	1	Delhi
2. S'aṅku yantra (Vertical staff)	1	Ujjain
3. Horizontal Scale (known as the seat of Jai Singh)	1	Jaipur

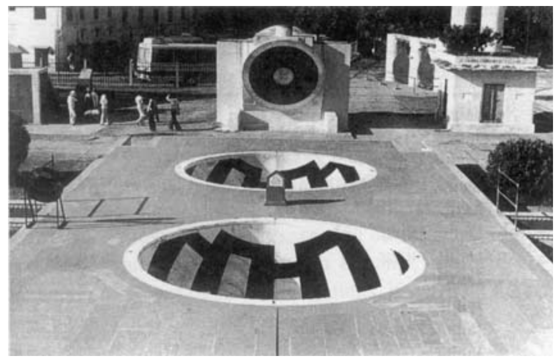
O



Observatories in India. Fig. 1 *Samrāt yantra:* principle and operation.



Observatories in India. Fig. 2 Jaipur Observatory of Sawai Sai Singh.



Observatories in India. Fig. 3 Jaya Prakāśa at Jaipur. The Nāḍīvalaya is in the background.

basically an equinoctial sundial, which has been in use in one form or another for hundreds of years in different parts of the world.

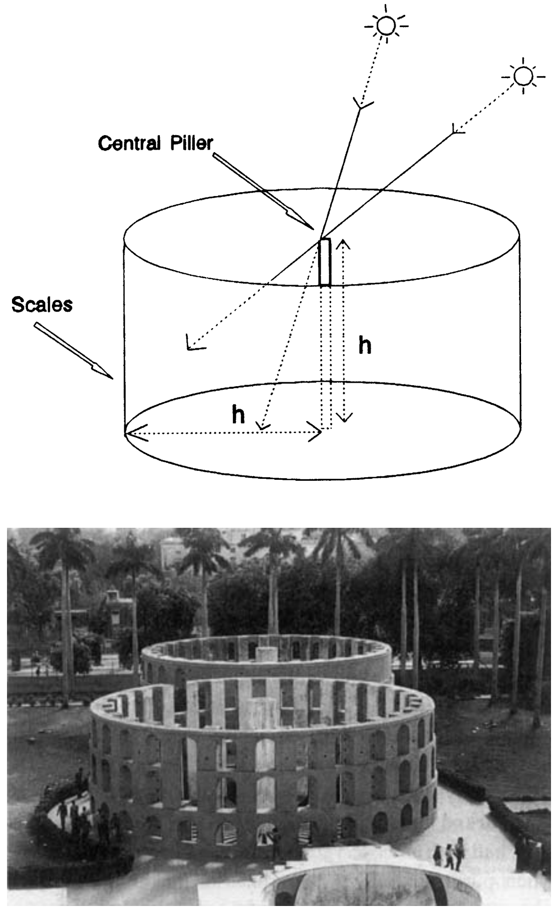
The instrument consists of a meridian wall ABC, in the shape of a right triangle, with its hypotenuse or the gnomon CA pointing toward the north celestial pole and its base BC horizontal along a north–south line. The angle ACB between the hypotenuse and the base equals the latitude λ of the place. Projecting upward from a point S near the base of the triangle are two quadrants SQ_1 and SQ_2 of radius DS. These quadrants are in a plane parallel to the equatorial plane. The center of the two "quadrant arcs" lies at point D on the hypotenuse. The length and radius of the quadrants are such that, if put together, they would form a semicircle in the plane of the equator.

The quadrants are graduated into equal-length divisions of time-measuring units, such as *ghaṭikās* and *palas*, according to the Hindu system, or hours, minutes and seconds, according to the Western system. The upper two ends Q_1 and Q_2 of the quadrants indicate either the 15-*ghaṭikā* marks for the Hindu system, or the 6 a.m. and the 6 p.m. marks according the Western system. The bottom-most point of both quadrants, on the other hand, indicates the zero *ghaṭikā* or 12 noon. The hypotenuse or the gnomon edge AC is graduated to read the angle of declination. The declination scale is a tangential scale in which the division lengths gradually increase according to the tangent of the declination.

The primary object of a Samrāṭ is to indicate the apparent solar time or local time of a place. On a clear day, as the sun journeys from east to west, the shadow of the Samrāṭ gnomon sweeps the quadrant scales below from one end to the other. At a given moment, the time is indicated by the shadow's edge on a quadrant scale.

The time at night is measured by observing the hour angle of the star or its angular distance from the meridian. Because a Samrāṭ, like any other sundial, measures the local time or apparent solar time and not the "Standard Time" of a country, a correction has to be applied to its readings in order to obtain the standard time.

To measure the declination of the sun with a Samrāṭ, the observer moves a rod over the gnomon surface AC up or down until the rod's shadow falls on a quadrant scale below. The location of the rod on the gnomon scale then gives the declination of the sun. Declination measurement of a star or a planet requires the collaboration of two observers. One observer stays near the quadrants below and, sighting the star through a sighting device, guides the assistant, who moves a rod up or down



Observatories in India. Fig. 4 The principle of a *Rāma yantra*.

along the gnomon scale. The assistant does this until the vantage point V on a quadrant edge below, the gnomon edge above where the rod is placed, and the star – all three – are in one line. The location of the rod on the gnomon scale then indicates the declination of the star.

Ṣaṣṭhāṁśa

A *Ṣaṣṭhāṁśa yantra* is a 60° arc built in the plane of meridian within a dark chamber. The instrument is used for measuring the declination, zenith distance, and the diameter of the sun. As the sun drifts across the meridian at noon, its pinhole image falling on the Ṣaṣṭhāṁśa scale below enables the observer to measure the zenith distance, declination, and the diameter of the sun. The image formed by the pinhole on the scale below is usually quite sharp, such that at times even sunspots may be seen on it.

Dakṣinottara Bhitti Yantra

Dakṣinottara Bhitti yantra is a modified version of the meridian dial of the ancients. It consists of a graduated quadrant or a semicircle inscribed on a north–south wall. At the center of the arc is a horizontal rod. The instrument is used for measuring the meridian altitude or the zenith distance of an object such as the sun, the moon, or a planet. According to Jagannātha Samrāṭ, this was the instrument with which Jai Singh determined the obliquity of the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course), to be 23°28′ in 1729.

Jaya Prakāśa

The *Jaya Prakāśa* is a multipurpose instrument consisting of hemispherical surfaces of concave shape and inscribed with a number of arcs. These arcs indicate the local time, and also measure various astronomical parameters, such as the coordinates of a celestial body and ascendants, or a sign on the meridian. Jaya Prakās'a represents the inverted image of two coordinate systems, namely, the azimuth-altitude and the equatorial, drawn on a concave surface. For the azimuth-altitude system, the rim of the concave bowl indicates the horizon. Cardinal points are marked on the horizon, and crosswires are stretched between them. On a clear day, the shadow of the crosswire falling on the concave surface below indicates the coordinates of the sun. Time is read by the shadow's angular distance from the meridian along a diurnal circle.

The instrument is built in two complementary halves, giving it the capacity for night observations. In the two halves the area between alternate hour circles is removed, and steps are provided in its place for the observer to move around freely for his readings. The space between identical hour circles of the two hemispheres is not removed, however. The sections left behind in the hemispheres complement each other. They do so in such a way that, if put together, they would form a complete hemispherical surface. For night observations the observer sights the object in the sky from the space between the sections. The observer obtains the object in the sky and the crosswire in one line. The coordinates of the vantage points are then the coordinates of the object in the sky. Jai Singh built his Jaya Prakās'as only at Delhi and Jaipur. These instruments survive in varying degrees of preservation. The instrument at Delhi has a diameter of 8.33 m and that at Jaipur, 5.4 m.

O

Nāḍīvalaya

A Nāḍīvalaya consists of two circular plates fixed permanently on a masonry stand of convenient height above ground level. The plates are oriented parallel to the equatorial plane, and iron styles of appropriate length pointing toward the poles are fixed at their centers. The instrument Nāḍīvalaya is, in fact, an equinoctial sundial built in two halves, indicating the apparent solar time of the place.

The Nāḍīvalaya is an effective tool for demonstrating the passage of the sun across the celestial equator. On the vernal equinox and the autumnal equinox the rays of the sun fall parallel to the two opposing faces of the plates and illuminate them both. However, at any other time, only one or the other face remains in the sun. After the sun has crossed the equator around March 21, its rays illuminate the northern face for six months. After September 21, it is the southern face that receives the rays of the sun for the next six months. Jai Singh built Nāḍīvalayas at each of his observatory sites except Delhi.

Rāma Yantra

The *Rāma yantra* is a cylindrical structure in two complementary halves that measure the azimuth and altitude of a celestial object, for example the sun. The cylindrical structure of Rāma yantra is open at the top, and its height equals its radius. The accompanying figure illustrates its principle and operation. To understand the principle, let us assume that the instrument is built as a single unit as illustrated.

The cylinder, as in the figure, is open at the top and has a vertical pole or pillar of the same height as the surrounding walls at the center. Both the interior walls and the floor of the structure are engraved with scales measuring the angles of azimuth and altitude. For measuring the azimuth, circular scales with their centers at the axis of the cylinder are drawn on the floor of the structure and on the inner surface of the cylindrical walls. The scales are divided into degrees and minutes. For measuring the altitude, a set of equally spaced radial lines is drawn on the floor.

These lines emanate from the central pillar and terminate at the base of the inner walls. Further, vertical lines are inscribed on the cylindrical wall, which begin at the wall's base and terminate at the top end. These lines may be viewed as the vertical extension of the radial lines drawn on the floor of the instrument.

In daytime the coordinates of the sun are determined by observing the shadow of the pillar's top end on the scales, as shown in the figure. The coordinates of the moon, when it is bright enough to cast a shadow, may also be read in a similar manner. However, if the moon is not bright enough, or if one wishes to measure the coordinates of a star or planet that does not cast a shadow, a different procedure is followed. To accomplish this, the instrument is built in two complementary units.

The two complementary units of a Rāma yantra may be viewed as if obtained by dividing an intact cylindrical structure into radial and vertical sectors. The units are such that if put together, they would form a complete cylinder with an open roof. The procedure for measuring the coordinates at night with a Rāma yantra is similar to the one employed for the Jaya Prakāśa. The observer works within the empty spaces between the radial sectors or between the walls of the instrument. Sighting from a vacant place, he obtains the object in the sky, the top edge of the pillar, and the vantage point in one line. The vantage point after appropriate interpolation gives the desired coordinates. If the vantage point lies within the empty spaces of the walls, well above the floor, the observer may have to sit on a plank inserted between the walls. The walls have slots built specifically for holding such planks.

Observatories in the Islamic World

GREGG DE YOUNG

The observatory in Arabic/Islamic civilization underwent considerable elaboration from its beginning as a follower of earlier Greek observational posts. The observational instruments used must have been versions of Ptolemaic (Greek) equipment:

- The meridian armillary, for determining solstice points and the obliquity of the ecliptic
- The plinth, used for the same purposes
- The equinoctial armillary, to determine equinox points
- The "parallactic instrument" (or "Ptolemy's Rulers") to determine elevation in relation to the zenith, when heavenly bodies reach culmination
- The armillary or spherical astrolabe, for measuring positions of heavenly bodies relative to fixed or known celestial objects

In the centuries that followed, the physical equipment of observatories underwent continuous evolution. Arabic/Islamic observers required precision in their work and usually tried to obtain it by increasing the size of instruments. Large instruments had to be carefully fixed in place and required skilled craftsmen for their construction and maintenance, as well as a staff of observers and mathematicians skilled in reducing the observational data to mathematical models. In general, observation programs were initiated for correcting or improving the accuracy of existing astronomical tables (*zīj*). The production of a zīj was useful, not only for astrological/astronomical predictions, but also for encouraging the collection of data that could support alternative cosmographical schemes that avoided the embarrassment of Ptolemy's equant theory, especially in centers such as Marāgha.

Most observatories, because their operation involved production and use of large and expensive instruments, were supported by state funds, although there is some evidence that private institutions existed as well, such as the observatory of al-Battānī (d. 317 AH/AD 929) at Raqqa. The majority, however, survived at the mercy of their royal patrons. It was very rare for an observatory, such as the institution at Marāgha, to be assigned *waqf* income. Since the waqf was intended to be a grant of property in perpetuity for the sake of generating income for charitable institutions, the observatory at Marāgha (as well as one in Tabriz) must have been seen as providing an essential public service, perhaps through educational programs.

The first true observatories were founded under the patronage of the 'Abbāsid Caliph al-Ma'mūn (198–218 AH/AD 813–833), who also supported numerous translations from Greek into Arabic. The Shammāsiyya (in Baghdad) and Mount Qāsīyūn (near Damascus) observatories operated for a year, it seems. Although the sites may have lacked purpose-built structures, both employed permanent observational staff and instrument makers and technicians. Their purpose appears to have been the collection of accurate observations of sun and moon only, although there are some records of other observations. These observations were presented in the *Zīj Mumtaḥan*.

Sharaf al-Dawla (372–378 AH/AD 982–989) built an observatory in the garden of his Baghdad palace. It was housed in a purpose-built structure and equipped with instruments, some of which seem to have been quite large. This institution marks an advance in several respects (1) it had a specific physical structure, (2) it had as director/administrator, Abū Sahl al-Qūhī, a famous geometer and astronomer, in addition to a staff of astronomers and technicians, and (3) its research program involved collecting data on the motions of all planets. Its activities began with great fanfare, but seem to have died out quickly, perhaps due to the death of the royal sponsor.

The observatory at Marāgha, founded by the Mongol conqueror-prince, Hūlāgū, was one of the biggest and best equipped observatories prior to the modern era. Founded in 657 AH/AD 1259, the construction was overseen by Mu'ayyad al-Dīn al-'Urḍī, from whose autobiographical account we learn many details about the observatory and its operation. The physical plant included several purpose-built structures and an extensive collection of instruments, many of them large. There are also reports of an extensive library. The staff, under the direction of Naṣīr al-Dīn al-Ṭūsī, included a number of leading mathematicians and astronomers from all parts of the Islamic world and beyond. (There are even reports of Chinese astronomers visiting and assisting at this observatory.) Once again, the purpose was to acquire the most accurate observational data in order to correct earlier astronomical tables. The result was the *Zīj Ilkhānī*, completed in 670 AH/AD 1271. After completion of these tables, work on the site seems to have slowed, although the institution continued to exist for at least three more decades.

Another major observatory was founded in 823 AH/AD 1420 in Samarqand by Ulugh Beg, governor of Khurasān, who was himself well versed in mathematics and astronomy. Like the Marāgha observatory, it had a staff of mathematicians, observational astronomers, instrument makers, and technicians, although it seems to have been a more compact operation. The most famous of its instruments was a huge meridian arc enclosed within a large masonry structure. The observatory enjoyed the active support and participation of Ulugh Beg until his assassination in 853 AH/AD 1449. Thus, it functioned for nearly 30 years, during which time the *Zīj-i Jurjānī*, which was widely circulated in Arabic, Persian and Turkish, was produced. Not only was this one of the longest-lived of all Islamic observatories, it was also the site of the most extensive collection of data on the fixed stars ever attempted in the Arabic/Islamic world.

In 983 AH/AD 1575, Taqī al-Dīn Muḥammad al-Rashīd ibn Ma'rūf, with the support of the Ottoman Grand Vizier, successfully petitioned the Sultan for permission to build an observatory in Istanbul in order to produce a new set of astronomical tables, the older tables being inaccurate and in need of revision. His request was successful and, in 985 AH/AD 1577, the Istanbul Observatory, with Taqī al-Dīn as its head, began operations. Like its predecessors, this institution had a permanent building housing observational instruments, a staff of astronomers and support personnel, and a library. Three years after its inception, the observatory was demolished. Contemporary reports differ on whether this action was undertaken with or without the support and encouragement of Taqī al-Dīn. Debate also continues about the possible influence of his account of observatory organization and instrument construction on Europe's greatest naked-eye observer, Tycho Brahe.

With the destruction of the Istanbul observatory, the great premodern period of observatory construction came to an end. The observatories of Jai Singh II, Maharaja of Jaipur (AD 1686–1740) at best represent the dying embers of the tradition. These five observatories (located at Jaipur, Delhi, Benares, Ujjayin, and Mathura) contained enormous masonry instruments, many still extant today. Jai Singh's *Zīj-i Muḥammad Shāhī*, named after the emperor to whom it was dedicated, was largely patterned after the earlier work of Ulugh Beg. This has prompted some to conclude that these late observatories mark a period of decadence and derivative astronomy. This judgment is probably too harsh. These observatories, begun nearly a century after the founding of the Paris Observatory (which marks the beginning of a new era in astronomical technique and organization in support of a new interpretation of celestial phenomena) stand today as monuments to a brilliant, but now abandoned, intellectual, and social tradition within the history of science.

Optics in China

JINGUANG WANG, CAIWU WANG

Before AD 1911, optics in China went through four stages. The first stage was from remote antiquity to the Spring and Autumn Period (770 BCE), the second ended in AD 220 (end of the Dong Han Dynasty), the third ended in AD 1380 (end of the Yuan Dynasty), and the fourth stage ended in 1911 (end of the Qing Dynasty).

In the first stage, the Chinese began to develop a philosophy of nature. The ideas of optics were in their infancy. In remote antiquity, the Chinese germinated basic knowledge of light sources, vision, shadow formation, and reflection. In addition, there were some inventions such as artificial light sources and reflectors. The artificial light sources or fire source were obtained from striking stones, drilling wood, and focusing sunlight. The reflectors included water mirrors which were plane mirrors (Fig. 1) and bronze mirrors which were plane mirrors and convex mirrors. Even though all these achievements were superficial, they laid foundations for later studies on shadow formation and optical images.

The second stage took place within an important period for Chinese science and technology. During that time, optical technology developed very rapidly. As an example, techniques to make mirrors matured. Numerous studies led to deep understandings of light reflection and rectilinear propagation as recorded in the *Mo Jing* (Mohist Canon), which was written between 450 and 250 BCE. There were eight sections in the book:

1. Processes of shadow formation and vanishing
2. Umbras and penumbras

Optics in China. Fig. 1 Water mirror. The water surface was utilized as a reflecting surface. Such a water mirror was called *Jian*.

3. Rectilinear propagation of light and pinhole image
4. Sunlight reflection and formation of an inverted shadow
5. Changes of shadow sizes (length and width)
6. Image formation and symmetries due to plane mirrors
7. Two image variations from concave mirrors (erect image and inverted image)
8. One type of image formed by convex mirrors

These eight propositions systematically described theories in geometrical optics. Technically, *Mo Jing* had achieved a level very similar to that of Euclid's *Optics*.

During the third stage, Chinese scholars discovered various optical phenomena. For example, aspects of atmospheric optics were studied in detail, including halo maps and rainbow formation. Since image formation had been a hot subject in Chinese optics, it was further advanced during this stage. Most of the records can be found in a book called *Mengxi Bitan* (Meng Xi Essays) by the scientist Shen Guo (1032–1096), in the Song Dynasty (960–1279). Among hundreds of sections in the book, there were more than ten dealing with optics. Sections 44 and 330 are the most important. In Section 44, Shen discussed image formation by pinhole and concave mirrors in terms of a terminology called *ai*, or pinhole and focal point. He named such mathematical generalization *ge shu*. In Section 330, Shen discussed light penetrating mirrors, which were also called *tou-guang jian* or "magic mirrors." There were more than 20 characters inscribed on a magic mirror. When sunlight shone on the mirror, all the characters were clearly projected on to a wall. There were three magic mirrors in Shen's family. He also saw other mirrors in his friends' homes. However, some other extremely thin mirrors did not allow sunlight to pass through. The magic was in the inscription of faint lines on the back side of the mirror. (Based on Shen's descriptions, modern Chinese shops are able to reproduce such magic mirrors by several techniques.) Besides those two sections, Shen presented quantitative relationships between image sizes and curvatures of convex mirrors. He introduced a postmortem examination method in which a red light was utilized. He also attributed rainbows to the shadows of the sun during rain.

After Shen's work, another scientist, Zhao Youqin, carried out a famous optical experiment. Zhao lived in the thirteenth century, and recorded this experiment in his book, *Ge-Xiang Xin-Shu* (New Astronomy). In a chapter entitled "Pinhole Image," Zhao detailed a systematic study carried out in a two story house. There were two rooms on the first floor, one on the left and one on the right. To make two light sources in these two rooms, two boards were "planted" with thousand of candles. On the top of each light board, an additional covering board was placed. There was a hole in the center of the additional board. If the candles were lit, light could pass through the hole and then was projected on to a screen. The screen was either the fixed ceiling or an adjustable screen suspended from the ceiling so that the distance between the light source and the screen could be adjusted. The following observations were made in the experiment:

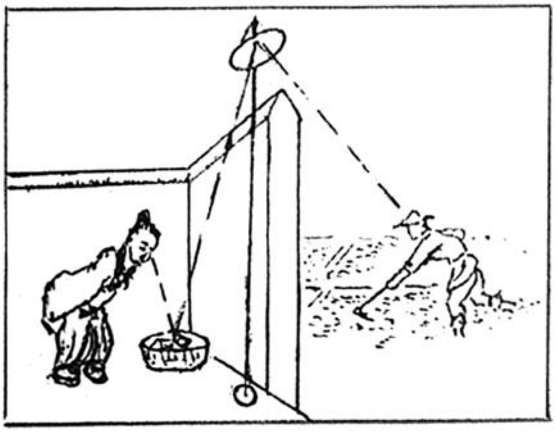
1. Shapes of the pinhole images are independent of the shapes and sizes of the small hole in the covering board.
2. The brightness of the image depends on the size of the hole. The larger the hole, the brighter the image.
3. When the source strength (number of candles) increases, the brightness of the image increases.
4. When the distance between the light source and the image screen increases, the image brightness decreases.

Zhao's experiment provided a lot of information on pinhole images. From the experiment, he proposed this idea. On the image screen, there was a light spot corresponding to a single candle. If a thousand candles were lit on a source board, there would be a thousand images of the candles. These images would overlap each other. The final appearance of the image would depend on the distribution of lit candles. In addition to basic optics, Zhao utilized his pinhole image theory to study eclipses of the sun and the moon and other astronomical phenomena.

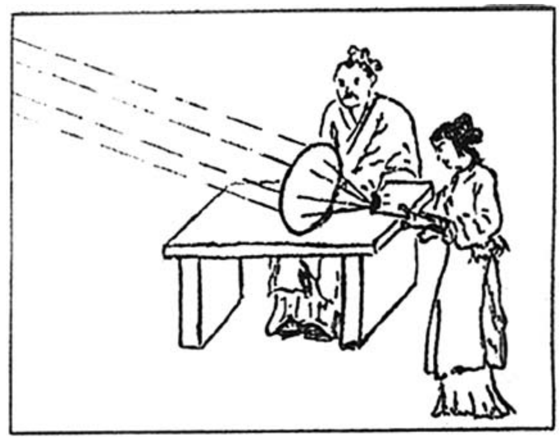
The fourth stage marked the end of traditional Chinese optics. The new trend both continued the Chinese system and adapted the Western system imported from Europe. During this period, Fang Yizhi (1611–1671) wrote a book called *Wuli Xiaozhi* (Small Encyclopedia of Physical Principles). In the book, Fang pointed out that light travels in wave forms, and he carried out an experiment to study the diffraction of light.

Several books and many articles on optics were translated from Western languages to Chinese languages, such as *Yuan Jing Shuo* (Telescopium) by the Germany Missionary Johanna Adam Schall Von Bell (1591–1666), and *On Optics* by Zhang Fuxi (d. 1862) and Englishman Joseph Edking (1823–1905). Another book entitled *Six Lectures on Light*, written by English physicist John Tyndall (1820–1893), was translated by Card T. Kreyer and Zhao Yuanyi in 1876.

Several monographs on optics were written by Chinese authors. In a book entitled *Jingjing Lingchi* (Treatise on Optics by an Untalented Scholar) by Zheng Fuguang (b. 1780), geometric optics was systematically introduced. In another monograph entitled *Geshu Bu* (Supplement to Geometric Optics) written by Zou Boqi (1819–1869), optical theorems and principles were discussed.



Optics in China. Fig. 2 Open-tube periscope in Han Dynasty. This illustration is based on a description in *Huai Nan Wan Bi Shu*, a book published in Xi Han Dynasty. By hanging a big mirror on the top of a pole and using a water-reflecting surface, one could watch a neighbor's actions. The object outside of the wall would form the image in the mirror, which in turn would form another image by reflecting. In this illustration, a person inside is watching a farmer outside of the wall. This is actually the earliest periscope in the world.



Optics in China. Fig. 3 Ice lens experiment. In *Huai Nan Wan Bi Shu*, there was a "miracle" experiment using an ice lens. One would make a spherical lens with a piece of ice by polishing both sides. Facing the lens to the sun and placing a piece of *moxa* at the focal point of the lens, one could light this piece of *moxa*.

Several different kinds of optical instruments or devices were improved. For instance, an optical expert, Sun Yunqiu (seventeenth century), made spectacles, telescopes, microscopes, and distorting mirrors.

The Chinese achieved high levels of understanding in optics, as illustrated by *Mo Jing*, *Mengxi Bitan*, and *Gexiang Xinshu*. The ancient Chinese paid attention to both theories and applications. A unique characteristic of Chinese optics is related to experimental approaches. All eight propositions in *Mo Jing* were based on experimental observations. Between the Qing and Han Dynasties, the Chinese mastered the concept of "focal distance" when they ignited fires from a spherical mirror. They created several novel devices such as the open-tube periscope and ice lens. Both devices were recorded in a book entitled *Huai Nan Wan Bi Shu*, published in Xi Han Dynasty. The open-tube periscope consisted of a big mirror, a basin filled with water, and a pole. As shown in Fig. 2, by hanging the big mirror on the top of the pole, one could watch the actions of the neighbors with the water surface. To make a spherical ice lens, one would use a piece of ice and grind it into a proper shape. As shown in Fig. 3, one could hold the ice lens toward the Sun and place a piece of *moxa* (mugwort, or *artemesia vulgaris*) at the focal point. Thus, this piece of *moxa* could be lit. Chinese observed similarities among rainbows, waterdrop dispersion, and crystal dispersion. Several Chinese scientists conducted high level experiments during their times, such as the "spherical mirror images" experiment by Shen Guo, and the "pinhole images" experiment by Zhao Youqin. The ancient Chinese optics system was based on empirical observations, which was short of theoretical abstraction and quantitative description. For example, no laws of reflection were proposed even after the phenomena of reflections had been observed for 2,000 years. As Western optics was imported to China, the entire foundation of traditional Chinese optics was changed.

Optics in the Islamic World

Elaheh Kheirandish

The science of optics entered the Islamic world primarily through Greek sources, during the ninth century transmission of ancient scientific and philosophical texts. As such, it was unlike other mathematical sciences such as astronomy and algebra, which being based on Indian and Persian sources as well, involved a "non-Western" intellectual and practical dimension, in addition to physical and cultural settings. As further distinct from these and other fields, what emerged as the so-called science of "aspects" or "optics" from a subdivision of Greek geometry, transformed its parent field quickly and significantly, starting with the translation of the relevant texts (Kheirandish 1996, 1999, 2001a). Indeed, if one field were to be singled out in the Islamic world for having left the most influential mark on the development of a discipline, this might be *ʿilm al-manāẓir*, as Greek *optika* came to be called in Arabic. During the earliest phases of the discipline, a decisive theory about the nature and manner of vision, which was the main subject of optics for some time, developed after a long period of debate. The domain of the field also expanded from a geometrical study of vision to one into which not only theories of light, mirrors, rainbows, and shadows, but also the psychology of visual perception, were integrated as common subjects of investigation. Some of these added inquiries produced impressive results, but as the field turned from a branch of mathematics into a discipline closer to physics, its methodology also left the purely geometrical world to enter an experimental realm.

Works that represent some highlights of these developments include the *De aspectibus* of Yaʿqūb al-Kindī (d. AD 870) (Rashed 1997, Adamson 2006), the *Kitāb al-manāẓir* of Ibn al-Haytham (d. AD 1039), and its rich commentary, *Tanqīḥ al-manāẓir* of Kamāl al-Dīn Fārisī (d. AD ca. 1320) (Schramm 1963, Sabra 1989, 1994, 2002).

A supplementary list of optical works by these and other authors, composed in both Arabic and Persian, from the early ninth century all the way to about hundred and fifty years ago, are representative of the quantitative developments of the field (Kheirandish 1998, 2001b, 2002, 2004).

Disciplinary Developments

One would expect the science of optics to have embraced a variety of phenomena from light and shadows, halos and rainbows, mirrors and burning instruments, some observable from the beginning of human history. But this was not always the case even in ancient and medieval times. For ancient Greek scholars, from mathematicians such as Euclid (ca. 300 BCE) and Ptolemy (second century AD), to philosophers and physicians like Aristotle (ca. 400 BCE) and Galen (second century AD), the focus of what was called *optika* and classified under geometry was vision, not light. Greek optics was primarily concerned with theories of vision, as the close association of the term *optika* with the eye indicates, and in the case of the geometrical tradition in optics – the only tradition treating the subject in independent works with that title – the proposed theories of vision were even expressed in terms of visual rays (*opseis*) extending from the eye to the object. Greek writings did go beyond the realm of direct vision, to include reflection from a polished surface (as in Euclid's *Optics*, or Hero of Alexandria's *Catoptrics*) or refraction through a different medium (as added in Ptolemy's *Optics*). But works titled *Optika* still dealt primarily with vision – leaving the domain of the field largely determined by the relevancy of its subjects to what was long considered the "most noble of the senses."

Early Islamic scholars inherited this particular orientation, which initially determined the focus of their own optical inquiries, even the classification and study of related subjects concurrently received from ancient sources, from reflection and refraction to shadows, rainbows, colors, sighting instruments, and burning mirrors. But there was soon a considerable change in optics' scope and profile. With the *Optics* of Ibn al-Haytham (also known as Alhacen or Alhazen, ca. eleventh century AD) the extended disciplinary boundaries left an immediate trace on subsequent developments of a field, now called *Perspectiva*, one that was largely carried over to the seventeenth century when optics acquired its current name and general character.

The change in the scope of *ʿilm al-manāẓir*, which occurred alongside other theoretical and methodological developments, was itself a gradual process. Major works on optics proper, often identifiable by the term *al-Manaẓir* in their titles (corresponding to the *Optika* in the titles of Euclid's and Ptolemy's texts), slowly came to expand the meaning of the study of vision. Works from the *De aspectibus (Ikhtilāf al-manāẓir?)* of Yaʿqūb al-Kindī (d. AD 870) and *Kitāb al-manāẓir* of Ibn al-Haytham, to *Tanqīḥ al-manāẓir* of Naṣīr al-Dīn al-Ṭūsī (d. AD 1274) and *Tangīḥ al-manāẓir* of Kamāl al-Dīn Fārisī (d. AD 1320), spanning a period of about 500 years, well represent the changing disciplinary boundaries. Al-Kindī included in his *De aspectibus* surviving only in Latin a range of related discussions from shadows and mirrors to the clarity of perception,

O

but left a number of others out. Ibn al-Haytham discussed in the seven books of his *Kitāb al-Manāẓir* a wide range of other subjects: the properties of light (and color) (Book 1), visual perception and visual illusions (Books II and III), and reflection and refraction (Books 4–7), but wrote separately on burning instruments, halos and rainbows, or *camera obscura*. Kamāl al-Dīn Fārisī's critical study of this same work, supplemented by a few of Ibn al-Haytham's independent optical writings (*On the Quality of Shadows, On the Form of the Eclipse*, and *On Light*), together with an examination of his own treatises (*On Burning Sphere* and *On the Rainbow and Halo*), expanded the topical range of his *Tanqīḥ al-manāẓir* to include all but the study of burning mirrors. The disciplinary developments are also reflected through a variety of related sources. Al-Fārābī's (d. AD 950) *Iḥṣā' al-'ulūm* (Enumeration of the Sciences) describes *ʿilm al-manāẓir* as including not only the science of mirrors (*'ilm al-marāyā*), but also such topics as the vision of distant objects and the application of vision in surveying. At the same time as the combination of the subjects of mirrors, or even burning mirrors with that of vision was not so uncommon, treatments of what are now considered optical problems often appeared in their own "proper place." Thus theories of light and perception were treated in philosophical works (following Aristotle), as in the related works of Ibn Sīnā (Avicenna, d. AD 1037), or Ibn Rushd (Averroes, d. AD 1198). Treatments related to the anatomy of the eye appeared in medical treatises (following Galen), as in the works of Ḥunayn ibn Isḥāq (d. AD 877). Such subjects as burning instruments were more commonly treated as part of the respective traditions of Diocles and Anthemius on *Burning Mirrors*, as in the case of Abū Saʿd Ibn Sahl (ca. AD 984). Shadows continued to be treated in books called *kutub al-aẓlāl* (Books on Shadows), as in Bīrūnī's (d. AD 1048) work devoted to this subject, and halos and rainbows often appeared in meteorological and astronomical literature, as in the case of Ibn Sīnā and Quṭb al-Dīn Shīrāẓī (d. AD 1311). It was not until the conscious effort of Shīrāẓī's student, Kamāl al-Dīn Fārisī, that most of these subjects were integrated into optics Sabra 1987a, 1987b, 1989.

Theoretical Developments

At the very beginning of the text which set out to place the science of optics on a new foundation and was instantly recognized and utilized as the most complete work on the subject in Europe, Ibn al-Haytham wrote: "For two opposite doctrines, it is either the case that one of them is true and the other is false; or they are both false,… the truth being other than either of them; or they both lead to one thing which is the truth each of the groups holding the two doctrines must have fallen short of completing their inquiry" (Sabra 1989). Here, Ibn al-Haytham was reflecting on a long controversy in visual theory, which had taken shape between the mathematicians and physicists before him and for which he managed to find a lasting solution.

The Greek mathematicians had explained vision through the assumption of visual rays extended from the eye towards the visual object. The best known among these were Euclid, whose *Optics* represents a geometrical approach to the study of vision, and Ptolemy, who had added an experimental and psychological dimension in his own *Optics*. The Galenic version of the visual-ray hypothesis as contained in *De usu partium* included the anatomical aspects of vision and stressed the role of medium through its own physiological approach. So did, Aristotle's language of the reception of forms which was more adopted by the physicists, or natural philosophers, in matters regarding vision. Islamic theorists writing in the tradition of each of the major Greek philosophers on vision did not always fall strictly into one group or another (Lindgberg 1978). The visual-ray theorists (*aṣḥāb al-shu'ā*) and the upholders of the theory of forms (*aṣḥāb al-inṭibā'*), to which Ibn al-Haytham repeatedly refers in his search for a systematic solution, often consisted of more than one group. The first included in addition to mathematicians (*ta'limiyyūn*), the followers of Plato or Galen or even theologians (*mutakkalimūn*), while its immediate rival, natural philosophers (*ṭabī'iyyūn*) covered both Aristotelians and atomists. The illuminationists (*ishrāqiyyūn*), who proposed an alternative form of perception altogether, had their own forms and variations. Ibn al-Haytham's solution to many complex problems raised by the first two groups was not only an attempt to determine such central questions as the direction of radiation in vision. The significance of his most celebrated work, *Kitāb al-Manāẓir*, goes much beyond treatments of the problems of vision. Having been translated into Latin in the late twelfth or early thirteenth century and then into Italian in the fourteenth century, with a printed Latin version in the sixteenth century, the book had an impact on the epistemology of late medieval Europe, the linear perspective of Renaissance artists, and study of light all the way to the seventeenth century, with a list of figures including Roger Bacon, Witelo, Pecham, Ockham, Oresme, Ghiberti, Snellius, Kepler, Descartes, Barrow, and Huygens. Ibn al-Haytham's contribution to the study of light included the assumption that light requires a body (a medium) for its transmission, that its movement from the object to the eye is not of infinite speed, though too quick to be perceived by sense, and it is "easier" and "quicker" in rarer media. His non-traditional conception of a finite, imperceptible interval of time for the movement of light was defended and advanced by a few in the Latin West, and his appeal to mechanical analogies to explain reflection and refraction were adopted by many later thinkers (Sabra 1962, 1967). The earlier independent researches of the tenth century mathematician Abū Sa'd Ibn Sahl and his anticipation of Snell's law have been the subject of a recent study (Rashed 1993). Earlier developments upon which Ibn al-Haytham's concepts of light and vision are clearly dependent include a principle now referred to as the "punctiform analysis of light radiation" (Lindberg 1976, Adamson 2006). An ancient conception based on rectilinear radiation, it grew on the assumption of a one-to-one correspondence between points on a visible surface and the eye, laying the foundation for the geometry of sight of the Western perspectivists and of Kepler. The principle can already be traced not only in the works of earlier Arabic authors such al-Kindī, but even in the way Euclidean assumptions were translated into Arabic, thereby stretching the period and importance of theoretical developments to the early ninth century. Immediate preoccupation with crucial questions about the exact nature of visual clarity and the structure of the visual cone (the role of central ray, the shape of its base), goes back to this same early period. Sometimes, concepts were positively affected by the adopted Arabic terminology: the expression for visual "clarity," for example (kathrā, also meaning multitude and magnitude), led to questions that were themselves the staring points for many later discussions in medieval Europe. Other times, word choices had an opposite effect: in the case of "refraction", the non-standard adoption of its terminology (in 'itāf) for reflection (in'ikās), led to a particularly problematic treatment of indirect vision (i.e. vision through mediums), in addition to the poor reception of the relevant parts of the *Optics* of both Ptolemy and Ibn al-Haytham in some parts of the Islamic world (Kheirandish 1996, 2004). But the limited understanding of concepts such as "refraction" did not provide a major obstacle for important theoretical developments later, including the correct explanation of the theory of rainbow formation. Explanations of the primary and secondary bows in terms of the refraction of light in raindrops were offered by Quṭb al-Dīn Shirāzī and later refined through experimental means by his own student, Kamāl al-Dīn Fārisī in Islamic Persia, almost at the same time as Theodoric of Freiberg's (d. ca. AD 1310) theory of rainbows was being offered. A major obstacle, however, did prevent proper treatment of inverted images within the eye in direct vision (i.e. vision through air), an obstacle occasioned by physiological shortcomings in Ibn al-Haytham's otherwise "revolutionary" achievements in optics (Sabra, 2002). Kepler's much later treatments provided the necessary breakthroughs in involving upright retinal images and focal properties of lenses; but they are also notable for representing theories of vision and light in a manner that has made their respective treatments viewed as a continuation and break with the past, depending on their perceived stress on vision and light respectively (Lindberg 1976; Smith, 2004). The earlier Islamic authors, both before and after Ibn al-Haytham, have their own share of historical achievements and contributions: they not only changed the face of the theoretical and disciplinary problems in optics, they also lay new methodological standards for optical inquiries.

Methodological Developments

The historical relationship between the sciences of optics and astronomy had a particularly important effect on the development of the methodological dimensions of the field. Euclid's *Optics* was among the Intermediate books (*mutawassiṭāt*), studied after his own *Elements* and before Ptolemy's *Almagest*. But optics was also to borrow from astronomy, though in a markedly different form and pace. The notion of *i'tibār* (experiment) was adopted and transformed by Ibn al-Haytham from astronomical works to be used in optics, as a methodological measure to replace geometrical demonstrations related to light and vision with experimental ones (Sabra 1971, 1994). This, however, occurred only after the old Aristotelian superior–subordinate relationship of disciplines was replaced first by their cooperation (*ishtirāk*) (in the ninth century), and then by their combination (*tarkīb*) (in the eleventh century). So the full service of astronomy to optics came relatively late. The imported experimental dimension was a significant step for the methodological transformation of the science of optics (Sabra, 1989).

Before this transformation, the discipline's methodical guidelines relied heavily on the teachings of Aristotle. For Aristotle, optics was a branch of geometry and one of "the more physical of the mathematical sciences" (*Physics*, 194a 6–11). The method of applying geometrical demonstrations to propositions on vision was adopted by Euclid, and through him more directly by Arabic optical authors. But alternative methodological approaches had already begun with a few early Islamic scholars. Al-Kindī, who reminded the reader in the preface of his *De aspectibus* that "geometrical demonstrations would proceed in accordance with the requirement of physical things," supplied geometrical demonstrations with experimental ones throughout his text. About the same time, Qusṭā ibn Lūqā spoke in a text on optics and its application to mirrors about "the cooperation" of natural philosophy (from which we acquire sense perception) and geometry (for its geometrical demonstrations). Even in the early text of Aḥmad ibn ʿĪsā, specifically titled as being "in the tradition of Euclid," Euclidean examples were sometimes supplemented by "sense-based examples" – those to be set up (Kheirandish 2002).

Ibn al-Haytham would continue to regard experimental optics as a mathematical inquiry. But in the course of his attempt to examine the study of vision and its foundations, the methodology of the mathematical science of optics was to be transformed radically. The synthesis (*tarkīb*) of physics (involving questions concerning the nature of light), and mathematics (dealing with manner of its propagation), following his explicit division between physical (*ṭabī'iyya*) and mathematical (*ta'līmiyya*) inquiries as two separate criteria, was at the heart of a new methodology that was to change the discipline. Ibn al-Haytham's contemporary, Ibn Sīnā, adopted a somewhat different methodological approach when he supplemented his critical remarks on previous treatments of rainbows with detailed observations of his own. Kamāl al-Dīn al-Fārisī, acknowledging the guidance of his predecessor, and inspired by his teacher, Quṭb al-Dīn al-Shīrāzī, added an unmistakably modern experimental touch to such observations. He reproduced an artificial object, such as a spherical globe filled with water to represent raindrops, as part of a conscious shift from traditional explanations of the phenomenon of the rainbow in terms of clouds acting as a concave mirror, to one in terms of the passage of light through a transparent sphere. By this later period, the field not only included subjects and theories more easily associated with optics today; it had also acquired the more modern methodological approach of "controlled" experimentation.

Origami

THOMAS HULL

Origami is the art of folding paper into works of sculpture. No one knows when or where the art of paper folding started, but many scholars believe that the invention of paper in China around 100 BCE (see the Institute of Paper Science and Technology website) had to have coincided with the first attempts at paper folding.

However, while there is evidence of paper folding developing around the world as paper making technology spread, it was the Japanese who embraced the art form as part of their culture. In fact, *origami* is a Japanese word made up of two characters: *oru* meaning "to fold" and *kami* meaning paper. The Japanese language has many homonyms–words that sound the same but mean different things. *Kami* is one such word; in addition to "fold" it also means "god" or "deity." Some people have conjectured that this is not a coincidence, and that this reflects why the Japanese Shinto religion uses folded paper to symbolize the spirits of deceased relatives. However, the Japanese language simply has so many homonyms that this might actually be a coincidence.

Records of ancient Japanese folding are hard to find. Certainly by the Edo period (1603–1867) in Japan numerous paintings and woodcuts can be found depicting upper class women folding the traditional crane, or *orizuru*. Also in the 1800s a few books on recreational origami were produced in Japan. Most references historians have found to origami prior to the 1800s are religious and cultural-based. As far back as the 1600s origami butterflies were placed over the stoppers of sake bottles for wedding ceremonies, and folded paper streamers called *go-hei* were hung in Shinto temples to represent spirits of the dead. Such streamers can still be found in modern Shinto shrines (Fig. 1).

The fact that by the 1800s people in Japan were folding paper recreationally, as opposed to only for ceremonies and religion indicates that origami had grown into a standard art form by this time. It is in the Edo period that one finds references to the classic Japanese crane and frog models (Fig. 2). However, there is also evidence that some Edo-era Japanese

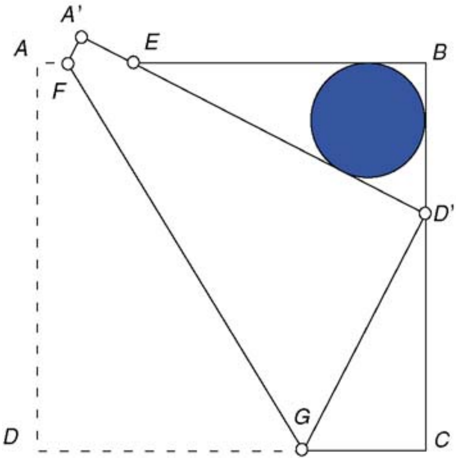
Origami. Fig. 3 The pentagon knot *sangaku*. "Construct a Regular Pentagon by Tying a Knot in a Strip of Paper of Width a. Calculate the Side t of the Pentagon in Terms of a." (Fukawaga 1989: 49)

origamists were exploring the science and mathematics of paper folding–something which modern mathematicians have only been researching in depth for the past 30 years. In Edo-era Japan there was a practice of placing artistically painted geometric problems on small wooden panels in Shinto temples. These tablets, called *sangaku*, were displayed to be read by the temple visitors as challenges to solve. This practice was prevalent throughout Japan, and it indicates some level of public interest and education in geometry–enough to solve such problems recreationally in the same way that people today buy puzzle books for mental challenges. In his book *Japanese Temple Geometry Problems*, Hidetosi Fukagawa describes over 250 examples of *sangaku*, some of which are extremely sophisticated. Two of his examples are based on origami. One, shown in Fig. 3, illustrates how to tie a strip of paper into a pentagonal knot (Fukagawa 1989: 49). The challenge is to prove that this knot makes a regular pentagon (all sides of equal length).

The second example, in Figure 4, shows a much more complicated instance of paper folding geometry. Here we are asked to take a square piece of paper and fold one corner to an arbitrary point on the opposite side. The text of this *sangaku* is more elaborate.

A square sheet of paper $ABCD$ is folded as shown in the figure with D falling on D', which lies on BC, with A falling on A', and $A'D'$ intersects AB at E. A circle is inscribed in triangle EBD'. Show that the radius of this circle is equal to $A'E$ (Fukagawa 1989: 37).

Amazingly, the geometric principles at play in the *sangaku* of Figure 4 were independently discovered over one hundred years later by Kazuo Haga, a Japanese teacher who specializes in origami geometry. In fact, the geometric property that triangles $CD'G$ and BED' and $A'EF$ are all similar is known as Haga's Theorem. That ancient paper folders were exploring the same kind of origami geometry as modern investigators

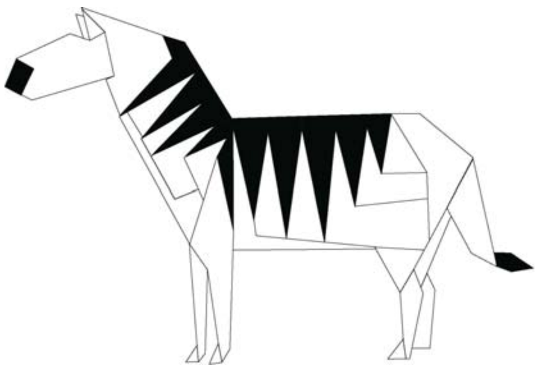


Origami. Fig. 4 A More Intricate Origami *sangaku*.

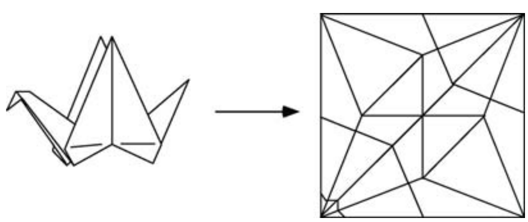
is a testament to the powerful utility of origami as a device for exploring mathematics.

The Meji Restoration (1866–1869) and aftermath saw the decline of a number of classic Japanese arts, including origami. But the practice did continue, and after World War II origami emerged again as an art form. The most influential person in this effort was Akira Yoshizawa, who tried to popularize origami in his country by creating hundreds of new models, holding exhibitions, and creating the International Origami Association. He also began important correspondences with people from other countries, in particular Lillian Oppenheimer of New York, Robert Harbin of the UK, and Gershon Legman of France. This helped spread the art of origami to other countries, and these same people were pivotal in the creation of the organizations Origami USA, the British Origami Society, and the Mouvement Français des Plieurs de Papier.

Partly due to the work of these organizations, origami art went through a renaissance in the late twentieth century. In 1979 American paper folder John Montroll published his first book (Montroll 1979) which contained origami models at a level of complexity never before seen in the origami world. For the first time, paper folders began to see that it was possible to, for example, fold a grasshopper, complete with six legs, wings, abdomen, thorax, head, and two antennae, all from a single square of paper with no cuts involved. The techniques with which he used to do this, which blended methods from classic Japanese models with brand new approaches, were mined by other origamists, starting a wave of complex-level origami design. Among the artists who emerged during this period was Robert Lang, who began systematically, analyzing the mathematics behind such complex designs. In addition, numerous Japanese folders, like Jun Maekawa, Fumiaki Kawahata, and Toshiyuki Meguro, developed their own methods and raised the level of complex origami to new heights (Fig. 5).



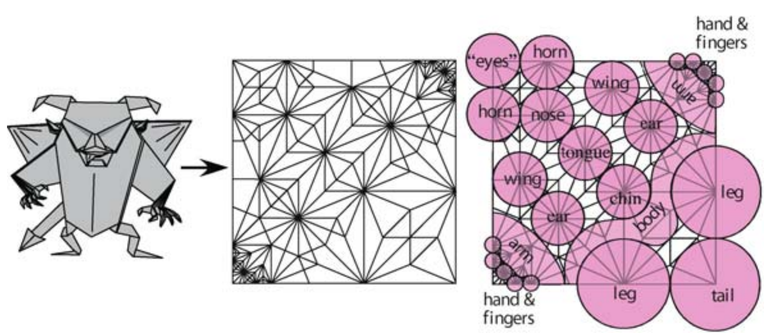
Origami. Fig. 5 John Montroll's Zebra Model (Montroll 1991), Folded from a Square Sheet of Paper, Black on One Side and White on the Other, with no Cuts.



Origami. Fig. 6 The Crease Pattern for the Classic Flapping Bird.

These design methods can be understood by considering the *crease pattern* of an origami model (Fig. 6). This is a diagram of a piece of paper with lines representing the creases used in the final origami model. This can be thought of as a blueprint for the design. In particular, modern origami designers can plan their design by thinking of any appendage that they need, be it the leg of an insect or the head of a horse, as requiring a circle of paper in the square to be devoted to that appendage. In other words, that circle, when folded, can be thought to collapse like an umbrella to create the appendage. This turns origami design into a problem of packing circles of different sizes into a square, and many modern origami designs can be analyzed in this way. Fig. 7 shows a model by Jun Maekawa from the mid 1980s with its crease pattern and circle decomposition.

Complex design methods have been developing and becoming more popular in the origami community since the 1980s, culminating in Robert Lang's compendium on the subject (Lang 2003), where he describes how much of origami design can be done on a computer. Some origami artists have complained that paying such attention to complexity is forcing paper folders to forget the more subtle, artistic expression that origami can achieve. Others have been using computer methods as a quick way to get a design, and then focus on artistry as they try to achieve this design in actual paper. In any case it is clear that origamists today are folding things that people 10 or 20 years ago never would have thought possible.



Origami. Fig. 7 Jun Maekawa's Winged Demon (Kasahara et al, 1983) with its Crease Pattern and Circle. Decomposition.

Pakṣa

K. V. Sarma

Pakṣa (Half) refers, in Indian astronomy, to half the lunar month. The lunar month, which is the interval between two successive new moons (*amāvāsyā*) or full moons (*paurṇamāsyā*), is a visible natural phenomenon, which occurs at regular intervals and, as such, has been used for reckoning time in all ancient civilizations, including that of India. For the people of India of the Vedic times, the two *pakṣas*, one *śukla* (bright) and the other *kṛṣṇa* (dark), provided an easy and most convenient instrument for reckoning time. From actual observation, it was found that a *pakṣa* was completed in 15 lunar days (*tithis*) and these were named after their serial numbers, as *prathamā* (first), *dvitīyā* (second), *tṛtīya* (third), *caturthī* (fourth), etc., up to *caturdaśī* (14th), and the 15th was *amāvāsyā* or *paurṇamāsyā*, according to whether it was the dark fortnight or the bright fortnight.

The moon moves about 13° in its orbit, eastward, in a day of 24 h, but since the sun also moves in the same direction, 1°, during the same period of 24 h, the moon's resultant displacement, which constitutes the *tithi*, is about 12°. A lunar month of 30 *tithis* would be around 29 and a half solar days, and in a solar year of 365 days, the moon would have completed its 12 months in about 354 days, and would have moved further by 11 *tithis*. In order to correlate and bring together the solar and lunar years, the astronomical practice is to expunge and leave uncounted 1 lunar month every 3 years, when the extra 11 *tithis* would have accumulated to 1 month. This expunged month is called *adhika-māsa* or "added" or "intercalary" month.

Time reckoning by *tithi* and *pakṣa* is very much in vogue, even today, among Hindus, for fixing auspicious times for ritual, religious, and social functions, and for horoscopic astrology.

Pāṇini

George Cardona

Pāṇini was a grammarian (Sanskrit *vaiyākaraṇa*) who lived around the early to mid-fifth century BCE in the extreme northwest of the Indian subcontinent. He was native to Śalātura (Cardona 1976: 260–268), and composed a grammar (*śabdānuśāsana*, *vyākaraṇa*, Cardona 1997: 564–572) of early Indo-Aryan. The main part of Pāṇini's work is the *Aṣṭādhyāyī* ("group of eight [*aṣṭan*] chapters [*adhyāya*]"). This consists of approximately 4,000 statements called *sūtra* (Cardona 1997: 4, 6) organized in eight chapters, each of which is further subdivided into four quarter chapters (*pāda*). The corpus of sūtras is complemented by three ancillaries: an inventory of sounds (*akṣarasamāmnāya*), consisting of 14 sets organized in accordance with the manner in which Pāṇini formulates rules of phonology (Cardona 1997: 80–84); an inventory of underived verbal bases (*dhātu*), divided into ten groups in accordance with the manners of forming present stems (Cardona 1997: 85–129); and groups of items – predominantly nominal bases (*prātipadika*) – associated with particular operations and hence recited together with pertinent sūtras (Cardona 1997: 130–135). The rules in question account not only for the language (*bhāṣā*) current in Pāṇini's time and place – conventionally called Sanskrit (*saṁskṛta* "adorned, perfected") – but also for archaic forms proper to earlier stages of Old Indo-Aryan as found in Vedic texts.

Pāṇini accounts for such speech by means of a derivational system from the point of view of a speaker (Cardona 1997: 136–400; Junnarkar 1977–1988). In doing so, Pāṇini continues a procedure known to him from the earlier procedure followed by grammarians who composed analyzed texts (*padapāṭha*, literally "word recitation") corresponding to the continuously recited versions (*saṁhitāpāṭha*) of Vedic texts (see Jha 1987). One of these, the padapāṭha to the *Ṛgveda*, the earliest known Vedic corpus, was definitely known to

Pāṇini, who refers to a dialectal feature observed by Śākalya, the author of this padapāṭha. In addition, Pāṇini formulates phonological rules but assumes a knowledge of phonetics (*śikṣā*).

Pāṇinian rules serve to account for Sanskrit utterances in terms of their being generated from the point of view of a speaker. The derivational process starts with a weak semantics, particular meanings serving as conditions (*nimitta*) for introducing affixes (*pratyaya*) to bases (*prakṛti*), which are either verbal or nominal bases. The meanings in question are of two general kinds: those which Pāṇini can assume known to native speakers from their knowledge of the language and those which require explanation. Among the former are notions such as time references, number, and gender; chief among the latter are categories to which are assigned participants in actions, so that they are given class names such as *kartṛ* ("agent"), *karman* ("object") (see Cardona 1997: 137–139). The general scheme for any simple sentence is thus

(1) $B^n–A^n…B^n–A^n…B^v–A^v$,

in which nominal and verbal bases are to be followed by specified affixes. Moreover, the introduction of postnominal affixes is subordinated to that of verbal affixes, and abstract L-affixes are first introduced, later to be replaced by finite verb endings or participial suffixes. For example

(2a) $B^n–s^1…B^n–am^2…B^v–1$,
(2b) $B^n–ā^3…B^n–s^1…B^v–1$

are schemata for alternating active and passive sentences such that an L-affix is introduced to signify either (a) an agent or (b) an object, consequent upon which differing nominal affixations apply: if (a), a second-triplet nominal ending is introduced to signify an object but no nominal agent-signifying affix is introduced; if (b), a third-triplet nominal ending occurs to signify an agent but an object signifier is not introduced after a nominal. As noted, L-affixes are abstract elements, subject to replacement by finite verb endings and participial suffixes. For example

(3a) devadatta-s^1odana-am^2pac-ti,
(3b) devadatta-$ā^3$odana-s^1pac-ta

are strings such that the specific bases *devadatta* "Devadatta," *odana* "cooked rice," and *pac* "cook" are used. The verb is followed by the endings *ti* and *ta*, which replace the L-affix ***laṭ*** introduced to signify alternately an agent or an object, on condition that the action is referred to current time. Starting with these strings, subsequent operations apply resulting in the final utterances

(4a) *devadatta odanam pacati* "Devadatta is cooking rice."
(4b) *devadatenaudanaḥ pacyate* "Rice is being cooked by Devadatta."

In addition, the same types of derivational procedures serve to derive other, related, utterances such as

(5a) *devadatta odanam pakṣyati* "Devadatta will cook rice."
(5b) *devadatenaudanaḥ pakṣyate* "Rice will be cooked by Devadatta."
(6a) *devadatta odanam apākṣīt* "Devadatta cooked rice."
(6b) *devadatta odanam pakvavān* "Devadatta cooked rice."
(6c) *devadatenaudano' pāci* "Rice was cooked by Devadatta."
(6d) *devadatenaudanaḥ pakvaḥ* "Rice was cooked by Devadatta."

(6a) and (6b) differ in that the former contains the finite verb form *apākṣīt* (third sg. aor. act.) "cooked" and the latter has *pakvavān* (nom. sg. masc.), a form of the agentive past participle *pakvavat-*, itself derived from *pac-tavat-*, with the participial affix *tavat**u*** following the base *pac*. Similarly, (6c) and (6d) differ in that the first has the finite verb form *apāci* (third sg. aor. pass.) "was, has been cooked" and the second contains the passive participle *pakva-* (nom. sg. masc. *pakvaḥ*), from *pac-ta*, with the participial affix ***k****ta* (see Cardona 1997: 144–158, 198).

Further, the selfsame system accounts also for an infinite number of possible correct utterances of Sanskrit. Moreover, this system is recursive in that strings like (1) and constituents within them are the basis for deriving additional elements – derived verbal and nominal bases – which enter into the same derivational system. For example

(7) *ātmanaḥ putram icchati* "… wishes a son of his own (*ātmanaḥ* [gen. sg.] 'self')."

is related to

(8) *putrīyati* "… wishes a son of his own."
(7) contains a form *icchati* (third sg. pres.) of the verb *iṣ* "wish" in construction with the accusative singular *putram* "son." This sentence is derived from an abstract string
(8) ātman-as^6 putra-am^2 iṣ-1(=l**aṭ**).

The constituent *putra-am* of (8) is now allowed optionally to be followed by the affix ***k****yac* to form a derived verbal base *putra-am-ya-* with the meaning of *putra-am* in construction with *iṣ*. The nominal ending *am* of *putra-am-ya-* is dropped and an additional operation applies, yielding *putrīya* – a derived base subject to operations which apply to primitive verbal bases. Again, to a string *rājan-as*^{6} *puruṣa-s*^{1} operations can apply which result in *rājñaḥ puruṣaḥ* "servant (*puruṣaḥ* [nom. sg. masc.])" of the king (*rājñaḥ* [gen. sg.]), as in.

(9) rājñaḥ puruṣaḥ kutra gacchati "Where (kutra) is the king's servant is going?"
(9) derives from an abstract sting
(10) rājan-as^6 puruṣa-s^1 kutra-s^1 gam-1(=l**aṭ**)

Instead of applying the operations that serve to give *rājñaḥ puruṣaḥ*, the related constituents *rājan-as puruṣa-s* can optionally be combined to form a compound (*samāsa*) *rājan-as-puruṣa-s*, the nominal endings included within which are then deleted to give *rājan-puruṣa-*. The status of the original constituent *rājan-as* as a syntactic word (*pada*) is conventionally maintained, so that the final *-n* of this item is dropped, resulting in the compound *rāja-puruṣa-*. Such a derivation accounts for the fact that anywhere one can use a string such as *rājan-as puruṣa-s* one can alternatively use of form of the corresponding compound, as in

(11) rājapuruṣa-s^1 kutra-s^1 gam-1

whence is derived

(12) *rājapuruṣaḥ kutra gacchati* "Where is the king's servant going?"

(9) and (12) contain *kutra* "where," another type of derived nominal base. This is formed from a syntactic constituent *kim-i*^{7}, with the locative singular ending ***ṅi*** following the base *kim* (interrogative pronoun). To this complex, the affix *tra**l*** is optionally introduced, resulting in a derived nominal base *kim-i-tra-*, the ending in which is deleted (→ *kim-tra-*); the base *kim* is itself then replaced by *ku*. The derivate *kutra* alternates with locative forms, e.g., *kutra nagare* "in which town" is a variant of *kasmin nagare*, with the locative singular masculine–neuter form *kasmin*. There are also derivates formed from constituents of strings of the type *aupagava-* "descendent of Upagu." Any form of this derived nominal base alternates with a complex that includes a genitive form of *upagu-* "Upagu" and a term meaning "descendent"; for example

(13) *aupagavam ā nagay* "Bring a descendent of Upagu."
(14) *upagor apatyam ā naya* "Bring a descendent of Upagu."

The derivation of *aupagava-* is comparable to the formation of compounds like *rājapuruṣa-* in that the former is accounted for by introducing an affix *aṇ* after a constituent *upagu-as*^{6} of a sting

(15) upagu-as^6 apatya-am^2 ā^1 nī-loṭ

from which (14) derives. The complex *upagu-as-a* is a derived nominal base in which the affix *aṇ* is considered to have the meaning of a term denoting a descendent, such as *apatya-*, so that *aupagava-x* is equivalent to *upagu-as*^{6} *apatya-X*. Since the derived item is a nominal base, the ending included within it is deleted: *upagu-as → upagu-a- → · · · aupagava-*.

The Pāṇinian system involves the use of rules of different kinds and these must apply in such a manner as to ensure that they account for the proper results, namely possible correct Sanskrit utterances and no incorrect ones. Moreover, Pāṇini's grammar is intended to be understood by native speakers of the language it describes. Accordingly, the metalanguage used is the same as the object language. On the other hand, since he is dealing specifically with grammatical procedures and he must generalize as much as possible, Pāṇini also has both to deviate from established conventions of the object language and to formulate specific practices allowing users to interpret his rules where the native command of usage does not suffice to allow a single unambiguous interpretation. For example, in normal usage a term like go "cow, ox" is used to signify its meaning. In addition, Sanskrit has a quotation particle *iti*, which can be used to show that one is referring to a term and not its meaning: *gav iti* (← *go iti*) refers to the term *go*. In his grammar, Pāṇini reverses the normal convention, so that words other than those used as technical grammatical terms are regularly self-referring: go refers to the term go, not to its meaning. Making use both of the conventions known to any native speaker and of those which Pāṇini states by metarules of his grammar, one can expand and interpret *Aṣṭādhyāyī sūtras* unambiguously (see Cardona 1997: 75–79).

As noted earlier, Pāṇini had predecessors, including the author of the padapāṭha to the *Ṛgveda*. There is no doubt that pre-Pāṇinian grammarians had already recognized some important facts and concepts concerning grammatical procedures. The analyzed text of a Veda presupposes a relation between this text and the continuously recited text with which it is associated. In accordance with authors such as Śaunaka, who composed the *Ṛgvedaprātiśākhya* – a work that includes rules for converting the *Ṛgveda* padapāṭha to the saṁhitāpāṭha of this text – it is appropriate to consider that one text is theoretically derived from the other by rules of phonological change. Such a system involves recognizing classes of entities with respect to operations as well as relations among rules which state these operations. This also involves recognizing the distinction between the use and the mention of linguistic units. Thus, many of the principles which Pāṇini adopts were recognized before him. Pāṇini nevertheless stands as a major innovator. His grammar includes not only a complete phonology, but also goes beyond this to account for Sanskrit syntax. He does not begin, as do padapāṭhas, with words, but with bases, to which affixes are introduced under given conditions to form words. Most importantly, Pāṇini's grammar accounts for a language, not merely for a specific corpus.

Pāṇini's work was the basis of a long commentatorial tradition, including the *Mahābhāṣya* ("great commentary") of Patañjali (mid-second century BCE), which was the basic work for later commentators. Part of this tradition deals with what is generally called philosophy of grammar. A fundamental work in this sphere is the *Vākyapadīya* of Bhartṛhari (fifth century AD; see Cardona 1976: 298–299), which was the basis for later work and influenced not only Pāṇinian grammarians, but also scholars in other fields. Thus, Indian scholars of *Nyāya* (some schools of logic), *Mīmāṁsā* (ritual exegesis and related areas), Buddhism, and Jainism concerned themselves with issues concerning language, semantics, and ontology, and in the course of their discussions make frequent use of Pāṇini's work and the work of later Pāṇinīyas.

Paper and Papermaking

Pan Jixing

Paper is a felted sheet of plant fibers formed from a water suspension using a sieve-like screen. When water escapes and dries, the layer of interwoven fibers becomes a thin-matted sheet and is called *paper*. It is one of the four great inventions of China, along with gunpowder, the compass, and printing. Traditionally, paper was thought to be invented by a eunuch, Cai Lun (ca. 60–121), in the year 105. But according to recent archaeological discoveries, paper made of hemp fibers from rags had already been made in the second century BCE as a new type of writing material. After that papermaking was further improved and popularized in the second to the third centuries in China. During the third to the sixth centuries the raw materials for making paper were expanded. Apart from hemp, paper made from paper mulberry bark and rattan was produced. This marked an important stage in the history of papermaking. Meanwhile, paper converting was developed, such as sizing with starch, coating with white mineral powder, and dyeing with various dyestuffs, especially cork tree bark (*Phellodendron amurens*) which makes paper yellow and moth-proof. Movable types of screens were generally used for making paper. The development of papermaking promoted the flourishing of education, culture, and science. Paper was widely used in daily life to make umbrellas, fans, kites, paper-cuts, toilet paper, and others.

The next important stage (sixth to tenth centuries) was the Tang dynasty (618–907), in which papermaking was greatly developed. In addition to the abovementioned kinds of paper, some new kinds appeared, such as bamboo paper and bark paper made of *Hibiscus mutabilis* and plants of the Thymelaeceae family, such as Daphne. Paper coated with colored wax or powder and wax, as well as that decorated with gold or silver dust, gelatin sized, water-marked, embossed, and marbled were also made in this period. Meanwhile, paper was used for clothing, furnishings, visiting and playing cards, lanterns, armor, window posters, and in commercial activities as a medium of exchange. A large amount of paper was used for ceremonies and sacrificial purposes, as was the so-called "fire paper." The development of block printing also stimulated the manufacture of paper. Another achievement was the production of large-size paper more than 3-m long. The Tang dynasty truly entered the "Age of Paper".

After papermaking was perfect and popularized in China, it was spread in all directions throughout the world. It arrived first in Korea and Vietnam in the third to the fourth centuries, then in Japan and India in the seventh. Paper reached the Arabian world in the mid-eighth century and Africa in the tenth. The Arabs monopolized papermaking in the West for 500 years. Only in the twelfth century was it manufactured in Spain and France, then in Italy in the thirteenth. In the seventeenth century, paper was made in most European countries and even in America; in Australia it was produced in the nineteenth. Thus it took more than 1,000 years for paper to spread from China to almost every part of the world. Paper and other Chinese inventions played a considerable role in the flourishing of medieval Arabic culture and in the development of European society after that. From the eighteenth century during the Industrial Revolution papermaking itself went through a number of technical reforms in Europe. Chemical pulp appeared in Europe in the mid-nineteenth century, although traditional handmade paper persisted by virtue of its artistic value and elegant appearance. It continues to be produced in China, Japan, Korea, and many Western countries including the United States. In fact, China remains the biggest supplier of handmade paper today. Well-known varieties include xuan paper from Anhui, mulberry bark paper from Zhejiang, hemp paper from Shan-xi, and bamboo paper from Sichuan.

Parameśvara

K. V. Sarma

Among Indian astronomers hailing from Kerala, Parameśvara (ca. AD 1360–1465), promulgator of the Kerala Dṛggaṇita School, and author of over a score of works on astronomy and astrology, holds a prominent place. He was a resident of Ālattūr, his house being situated on the northern bank of the river Bhāratappuzha, where he conducted his astronomical experiments and observations for over 55 years.

Parameśvara was a prolific writer. Some of his works still remain in manuscript form, while a few are yet to be found. His works on astronomy are:

1. *Dṛggaṇita* (Computation True to Observation), AD 1431, his magnum opus, a practical manual, in two versions
2. *Goladīpikā* I (Illumination on Spherics), in 302 verses, on spherical astronomy
3. *Goladīpikā* II (Illumination on Spherics), in four chapters, on the same subject as above, but different from it
4. *Grahaṇamaṇḍana* (Ornament on Eclipses), in two versions, of 89 and 100 verses
5. *Grahaṇanyāyadīpikā* (Illuminator on Rationale of Eclipses) in 85 verses
6. *Grahaṇāṣṭaka* (Octad on Eclipses), on the computation of eclipses
7. *Vākyakaraṇa*, on methods for the derivation of several astronomical tables

Parameśvara also commented on several standard works on astronomy that were popular in Kerala. These include: *Āryabhaṭīya* of Āryabhaṭa, *Laghubhāskarīya* and *Mahābhāskarīya* of Bhāskara I, *Mahābhāskarīya-Bhāṣya* of Govindasvāmin, *Laghumānasa* of Muñjāla, *Sūryasiddhānta*, *Līlāvatī* of Bhāskara II, and his own *Goladīpikā* II. All these commentaries except that on *Līlāvatī* have been published.

Although he was primarily an author of astronomical works, Parameśvara also wrote on astrology:

1. *Ācārasaṇgraha*, a popular text
2. *Jātakapaddhati*, in 44 verses
3. Commentary on the *Muhūrtaratna* of Govinda
4. Commentary on the *Jātakakarmapaddhati* of Śrīpati
5. Commentary on the *Praśnaṣ-aṭapañcāśikā* of Pṛhuyaśas
6. *Muhūrtāṣṭaka-dīpikā*, *Vākyadīpikā* and *Bhādīpikā*, mentioned by Parameśvara at the end of his commentary on the *Mahābhāskarīya*

These works are not extant.

In his works Parameśvara evinces a refreshingly scientific outlook. He avers at the beginning of his *Grahaṇamaṇḍana* that he was setting out to compose the work after closely watching the movements and positions of the planets in the skies for a long time. At the beginning of his *Dṛggaṇita*, he says that, in real astronomy, computation should match observation. He enumerates a number of solar and lunar eclipses which he had observed between 1393 and 1432, and gives details about them in his *Grahaṇanyāyādīpikā*. He also points out the error between computed and observed readings and offers corrections and instructs that similar observations should be made at intervals and corrections enunciated for computation and observation to be identical.

Pauliśa

K. V. Sarma

Pauliśa, of Greek origin, is the originator of the *Pauliśa Siddhānta*, one of the five systems of astronomy of the early centuries of the Christian era. These were selectively redacted in the *Pañcasiddhāntikā* of Varāhamihira, the prodigious Indian astronomer–astrologer of the sixth century AD. According to a traditional verse attributed to the sage Kāśyapa, Pauliśa is one of the eighteen originators of Indian astronomical systems. Al-Bīrūnī, the Persian scholar, who sojourned in India from 1017 to 1030, stated that *Pauliśa Siddhānta* was written by Paulus-ul-Yunani, i.e. 'Paulus, the Greek'. Probably the Hindus prepared an Indianized Sanskrit *Pauliśa Siddhānta* on the basis of the Greek work. This original Sanskrit work is no longer available, and neither is the commentary on that work by Lāṭadeva which was referred to by Varāhamihira in *Pañcasiddhāntikā* I.3. However, the redaction of the *Siddhānta* in *Pañcasiddhāntikā* is fairly full and provides ample details about the nature and contents of the work. The Pauliśa system has certain things in common with the *Romaka Siddhānta* and with the *Vāsiṣṭha Siddhānta*, two of the other systems redacted in *Pañcasiddhāntikā*.

The epoch of the *Pauliśa Siddhānta*, which *Pañcasiddhāntikā* says is the same as that of *Romaka Siddhānta*, is the Hindu *caitra-śukla-pratipad* (first day of the bright fortnight of the month of Citrā) in the Śaka year 427 elapsed (*Pañcasiddhāntikā* I.8–10), which corresponds to mean sunset at Yavanapura (modern Alexandria in Egypt), or modern Sunday, March 20, 505. It is interesting that the same moment was adopted by Varāhamihira as the epoch of the *Saura Siddhānta* redacted in the *Pañcasiddhāntikā* (i.e. the old Ś*urya Siddhānta*). The Indian time then was 37–20 *nāḍīs* from mean sunrise in Ujjain, on Sunday, March 20, 505. (*Pañcasiddhāntikā* III.13). In *Pañcasiddhāntikā* III.13, it is stated that the *deśāntara-nāḍīs* (longitudinal difference in terms of time, expressed in *nāḍīs*) from Yavanapura to Ujjain is 7–20, while that to Varanasi is 9. The actual intervals according to modern calculations are 7–38 and 8–50, the difference being 18 *vināḍīs* and ten *vināḍīs*, respectively. One minute being equal to four *vināḍīs*, the difference works out only to 4.5 min and 2.5 min, which is remarkable.

At the commencement of the *Pañcasiddhāntikā* (I.4), Varāhamihira gives a pat to the *Pauliśa Siddhānta* for the accuracy of the *tithi* (lunar day) calculated according to it, though he adds that the *tithi* derived through the *Saura Siddhānta* is much more accurate. In fact, it is these two schools, the Pauliśa and the Saura, one representing the Greek and the other the Indian, that Varāhamihira depicts rather fully in *Pañcasiddhāntikā*, allotting them entire sections. Thus the entire third chapter of *Pañcasiddhāntikā* is devoted to the depiction of planetary computation and allied matters according to the *Pauliśa Siddhānta*, Chapter 5 to the Moon's cusps, Chapter 6 to lunar eclipses, Chapter 7 to solar eclipses, and much of the long Chapter 18 to the motion of the planets. Although the *Pauliśa Siddhānta* was based on a Greek original, the text was painstakingly Indianized, both in the matter of content and presentation.

Pest Control in India

P. Narayanasamy

Field and horticultural crops in India are under threat from many insect pests. Some of them are American bollworm, pink bollworm, spotted bollworm, and white fly on cotton; brown planthopper, green leafhopper, leaf folder, stem borer, and ear head bug on rice; different kinds of stem borers and pyrilla on sugarcane; red hairy caterpillars and leaf miners on groundnuts; leafhoppers and fruit flies on mangoes; green scale on coffee; tea mosquito bug on tea; thrips on cardamom; fruit borers on vegetables and diamond back moths on cruciferous vegetables.

In storage warehouses, food grains are damaged by varieties of insects and non-insect pests. The majority belong to the orders Coleoptera and Lepidoptera, accounting for 60 and 8–9% of the total number of pests respectively. In India, pests like the Angoumois grain moth, rice moth, Indian meal moth, khapra beetle, rice weevil, rust red flour beetle, lesser grain borer on rice and wheat, and pulses beetle on pulses are very important.

Metamorphosis of Pest Control

Pest control techniques in India have undergone sequential metamorphoses during the ancient, medieval, British, and modern periods.

Protohistoric Period

Protohistory has been defined as the period of human history between prehistory, when no written records existed, and history in the strict sense, when records are the main source. In India, the term protohistoric period is applied to the post-Mesolithic and pre-Mauryan cultures, between 3,500 or 3,000 and 600 BCE (Ranjit Pratap Singh 1990).

Following is an account of various kinds of farm pest control practices adopted during the Protohistoric–Neolithic periods.

Grains of primitive wheat species, einkorn, emmer, and spelt have a very tough and sturdy spikelet which does not release the grains in ordinary threshing; such spikelets are beaten to pieces but the grains still remain enclosed in their individual husks. If the spikes are heated however, the solid portion of the spikelet becomes dry and brittle and then it is possible to crush them. Grain drying was a common practice then; it also kept the seed-infesting insects away during storage. The paleoethnobotanical record consisted of mummified and carbonized food grains, imprints of grains on potsherds, silica skeletons, etc.

Harappan Period

Cylindrical pits lined with lime plaster sufficiently wide and deep were likely to have been used for storage of food grains. The lime, besides absorbing moisture, might have deterred the pests.

To the southeast of the pre-Harappan settlement, ploughed furrow marks were still intact in a field with one set of furrows oriented east–west while the other ran north–south. Individual furrows were interspaced at 30 cm in the former and 1.9 m in the latter. Horse gram[1] was grown in short distanced furrows and mustard in the long distanced ones. This prompted the idea of mixed cropping perhaps to manage pest problems.

Terracotta sling-balls were found in all the Harappan excavations. Possibly the farmers used these sling-balls for scaring away pests such as birds, parakeets, or deers. Slings and sling balls are used even now by the farmers of rural India for protecting maize, sorghum, pearl millet, and other crops.

The best evidence of agriculture in the Harappan areas lies in granaries. These granaries, each 50 × 20 ft, were arranged symmetrically in 2 rows of 6, with a central passage, which was 23-ft wide. They were built upon a podium of rammed mud, some 4-ft high, riveted with baked bricks. This kept pest infestation away from the seeds.

Deccan Chalcolithic Period

The wood of *Acacia* spp. was used to fabricate all tillage tools such as ploughs, yokes, and spokes. The wood kept all the timber-infesting pests at bay. This practice existed during 1500–1000 BCE.

Cultivation of two cereals (wheat and barley) and pulses (horse gram, hyacinth bean, lentil, and pea) suggests that the farmers made use of the available water resources very intelligently (Raychoudhary 1964). There was a guide bund and a diversionary channel to support this. This scheme of growing two different species of plants sequentially is called" "crop rotation" and this practice helps to make the next crop free from pest damage.

[1] A small pulse (legume), which is grown as a crop in India, is used as a food for both human and animal consumption. They are small, thin, and oval shaped, which may be light to dark colored in shades of red, brown, and black. When cooked it provides a slightly strong, somewhat earthy flavor. It is consumed as a whole bean as a sprout, or as whole meal when prepared as a side dish or as a main dish with other ingredients. In some regions, the horse gram is boiled and then crushed with salt after which it is allowed to ferment in order to produce a sauce that is used in the same manner as soy sauce. Somewhat similar to the moth bean, which is considered the "poor man's food," horse grams also have the same connotation.

Storage bins had low mud walls 30-cm high, over which was mud plastered with bamboo screens. The structure contained a number of pit silos and round mud platforms for storing different kinds of grains. In some cases, the sides and the bottoms of the pits were lined with lime whereas in others the bottom was full of sand. In both, insect entry was deterred thus saving the grain from damage.

Straw from threshing floors was mixed with moist clay to make mud bricks, which were used to build multiroomed buildings and storage bins. In the storehouse, the silica content of the straw could have acted as a barrier for pest invasion.

Vedic Period

The Vedic literature quotes various laws and instructions regarding protection of crops from damage by insect pests and diseases. The Atharvaveda (Hymn 50 of book VI) describes the destruction of corn by locusts, mice, and borer.

Following are some pest control practices:

In the Rigveda, the cultivators kept birds away from their cornfields by making noise. In Matravagga, scarecrows were used for the purpose.

In Jataka, cultivators set traps and dug pit falls in their fields to protect the crops from wild animals.

Plastering with the powder of Aragvadha, Arista, Kareniya, Saptaparma, Cinnamon, and Vidanga (*Embelia ribes*) dissolved in cow urine and kept over night would destroy the insects that attacked the trees from outside.

Plaster of Vidanga, white mustard, black pepper, long pepper, and dry ginger, ballata and vaca prepared in cow urine, when applied to branches, kills the stem-boring insects and restores the tree to its natural colour.

Plastering with a paste made of cats, jackals, and pigs along with mustard and cow urine kills tree-boring insects.

Paddy seeds were preserved in receptacles like Kathinya (a storage structure) or in well-baked clay pots or in vessels of strong glass or containers woven of ropes and plastered with mud. In this way, the pests were less able to damage the crops.

A pit was dug in the hard earth and provided with descending steps. People were able to store rice seed in it, taking care that it was safe from damp, thieves, parrots, and rats. The sages advocated that presentation of the best kind of seeds conscientiously brought prosperity to their cultivators.

The ancient texts of India – *Bṛhat-saṃhitā* of Varāhamihira (fifth century AD), *Vṛksha Āyurveda* of Lokapakra (ninth century AD) and *Vṛkṣāyurveda* of Sarangadhara saṃhitā (thirteenth century AD) provide instances of plant protection practices based on indigenous knowledge. They provide indication of an integrated approach to control crop pests and diseases through soil, seed, plant, and environmental treatment. Seed treatment with cow dung, milk, juice of *Solanum indicum*, tender coconut water, *Embelia ribes,* and cow ghee were prescribed. Prophylactory pest control measures included soil application of a mixture of *Ferula narthex* Boiss, *Acorus calamus* L., pepper, *Embelia ribes*, cashew seed, *Chelianthes farinosa*, mustard, and cow horn powder in cow urine.

History of Entomology in India

A chronology of events concerning entomological science in India is presented in Table 1 (Atwal and Dhaliwal 2002; Vasantharaj David 2001).

Pest Eradication Era

There were only a few insect pest problems in India during ancient times and when they occurred, they were exterminated by the "slash and burn" concept. Most of the practices involved were traditional. The reason for the success of these measures was that they were all ecofriendly.

Pest Control Era

When the concept of the green revolution came to be regarded as a solution for the duelling population, Indians used high-yielding crop varieties under intensive and extensive types of cultivation. Misuse of the chemical pesticides damaged the environment, and the pests' natural enemies were also at risk. In some cases, insect pests in many crops warranted consumption of more pesticides. This led to a change from the pest eradication to pest control. The pest problems could be curtailed or controlled with various strategies including pesticides with economic return. This happened during 1940–1970.

Pest Management Era

In the aftermath of using chemical pesticides for pest control, many pest species became immune to many of the pesticides used. Many actually resisted and resurged which ultimately increased the pest population manifold. This population upsurge became uncontrollable with then available pesticides, thus culminating in complete crop failure. This pest situation existed from 1970–1985, forcing Indians to change their efforts from pest control to pest management.

Integrated pest management

Integrated pest management (IPM) is a broad ecological approach which employs cultural, mechanical, physical, genetic, and biological methods, including application of chemical pesticides as a last resort, in a harmonious and compatible manner with a view to suppress the pest population below the economic injury level. IPM is a dynamic approach and process, which

Pest Control in India. Table 1 Events in Entomology 1758–1939

Year	Scientist or organization	Contributions
1758	Linnaeus	Included 12 insects from India in his 10th edition of *Systema Naturae*.
	Dr. J. G. Koenig (Tamil Nadu, South India)	Published first scientific work on insects in India.
1779	Koening	Published an account of termites of Thanjavur (Tamil Nadu).
1782	Dr. Kerr	Published a special publication on the lac insect.
1785		Asiatic Society of Bengal was formed.
1791	Dr. J. Anderson, Physician General to East India Company at Madras	Published a monograph on the cochineal insect.
1800	Buchman	Wrote on cultivation of lac in India and silkworms in South India.
	Denovan	Published *Natural History of Insects*, covering insects of Asia (later revised by Westwood in 1842).
1840	Rev. Hope	Presented a paper, "Entomology of the Himalayas and India" in the *Madras Journal of Literature and Science*.
1847	Westwood	Made a cabinet of Oriental Entomology and *Arcana entomologica.*
1875		Indian Museum was founded at Calcutta.
1883		Bombay Natural History Society was established.
1887	Baltour	Published *Agricultural Pests of India and Eastern and Southern Asia* and *Indian Ants*, the first case of biological control in which a small red ant kept away white ants. Government of India commenced the publication of the *Fauna of British India* series.
1889–1903	Indian Museum Calcutta	Published Indian Museum Notes on Economic Entomology.
1892	Hampson	Issued four volumes on Moths of India.
1905		Imperial Agricultural Research Institute was established at Pusa, Bihar State.
	Lionel de Nicevelle	Appointed as the first Imperial Entomologist.
	Indian Tea Association	Commenced entomological work.
1906	Prof. Harold Maxwell–Lefroy	Second Imperial Entomologist (1903) Published two books, *Indian Insect Pests* and *Indian Insect Life* in 1909. Punjab was first to initiate work on agricultural entomology followed by Tamil Nadu (1906), Uttar Pradesh (1906), Karnataka (1908).
1914		Government of India enacted "Destructive Insect Pests and Diseases Act." T. B. Fletcher, first Government Entomologist of the then Madras State became the third Imperial Entomologist (1913–1932).
1916	Zoological Survey of India	Founded Indian Museum.
1921	Indian Central Cotton Committee	Funded projects on cotton pests in Uttar Pradesh.
1925		Indian Lac Research Institute, Ranchi was founded.
1926–1932		The Locust Plague led to the establishment of a "Locust Warning organization" in 1939.
1937		Entomological Society of India was inaugurated in Calcutta.
1938	Dr. T. V. Ramakrishna Ayyar	Published *Hand Book of Economic Entomology for South India.*
1939		Indian Journal of Entomology was launched.

varies from area to area, time to time, crop to crop, and pest to pest. It aims at minimizing crop losses with consideration to human, animal, and environmental health and safety.

Current Pest Management in India

Herbal Pesticides

Use of plant products has attained importance and practical utility in pest management. More awareness has been created among the farmers to use herbal-based pesticide preparations. Plant species like Neem (*Azadirachta indica* A.), Indian privet (*Vitex negundo* L), (Fig. 1) Adhatoda (*Adhatoda vasica* Nees), Holy basil (*Ocimum sanctum* L), Sweet flag (*Acorus calamus* L), Turmeric (*Curcuma domestica* L), Wild chilli (*Capsicum frutescens* L), Onion (*Allium cepa* L) a conifer, Cycas revoluta (Thumb) (Fig. 2) and Garlic (*Allium sativum* L) are used increasingly in pest management. Indian pesticide markets trade in numerous herbal pesticides, especially from plants like neem.

Pest Control in India. Fig. 1 *Vitex negundo L.*

Pest Control in India. Fig. 2 *Cycas revoluta*.

Traditional Knowledge

In recent times, there has been increased awareness of indigenous pest control practices. Concerted efforts are being made to document and revalidate pest control knowledge. Scientific institutions and non-governmental organizations play vital roles in applying the indigenous pest control knowledge with the goal of diminishing consumption of the chemical pesticides. Traditional pest management packages have been created for specific pests in crops such as rice and some vegetables (egg plant) bhendi, and tomato (Narayanasamy 1999). Application of indigenous tribal knowledge in pest control has enabled us to fabricate rat traps (Fig. 3) for rice and other crops (Kathirvelu et al. 2004).

Pest Control in India. Fig. 3 Tribal rat trap.

Biological Pest Suppression

The Project Directorate of Biological Control at Bangalore has developed strains of an egg parasitoid, *Trichogramma chilonis*, with physiological tolerance to Endosulphan 0.07% and high levels of temperature.

The Bhabha Atomic Research Center, at Mumbai, has identified a new variety of *Bacillus thuringiensis* var *kenyae*.

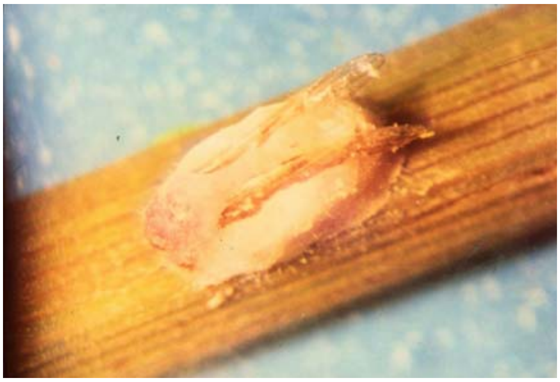
Muralirangan et al. (1996) recorded new species of microsporidians such as *Nosema locustae, N. acridophagus, N. cuniatum, Perezia dichloroplusae* and a recent discovery of Cephalogregarine and Gregarine species on nymphs and adults of 15 species of grasshoppers.

Applications of Nucleopolyhedro viruses infecting *Amsacta albistriga, Spodoptera litura,* and *Earias vittella* have been standardized for various crops.

Thirty groups of fungal pathogens have so far been recorded on key pests in rice, which included *Pandora delphacis* (Hori). Humber on brown planthopper (BPH) (Fig. 4) and green leafhopper (GLH), *Zoophthora radicans* (Brefeld) Batko on leaf folder and *Nomuraea rileyii* (Farlow) Samson on cutworm. A Mycoinsecticide 70% wettable powder with sorghum grains as a carrier has been developed with spores of *Pandora delphacis* and found effective against BPH and GLH (Narayanasamy 2001). Recently for the first time, infection of adult moths of lepidopterous insects of rice ecosystem with certain fungal pathogens including Fusarium moniliformae (Fig. 5) has been reported (Yasodha and Narayanasamy 2004).

Pheromones

Pheromones act as potential tools for monitoring, surveillance, predicting population threat levels, and thresholds for applications of control measures for pests such as *Helicoverpa armigera, Pectinophora gossypiella* in cotton, *Spodoptera litura, Plutella xylostella*, *H. armigera* in vegetables, and *Lymantria pomonella* in apple.



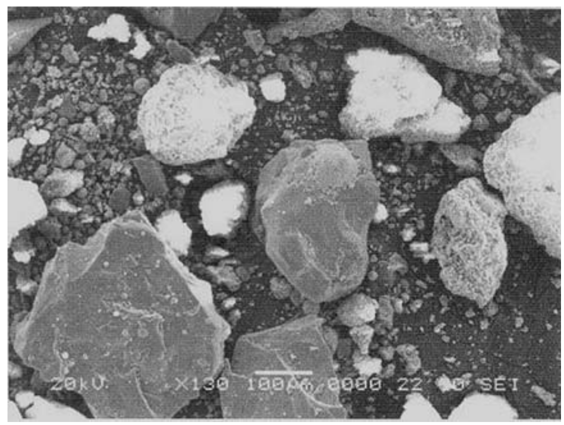
Pest Control in India. Fig. 4 Rice BPH adult infected by *Pandora delphacis*.

Pest Control in India. Fig. 5 Rice yellow stem borer infected by *Fusarium moniliformae*.

Biotechnological Innovations

- Attempts to develop transgenic maize, wheat, cotton, brassica, mungbean, potato, apple, broccoli, walnut, and alfalfa are underway.
- The International Crops Research Institute for the Semi-Arid Tropics (ICRISAT), in Hyderabad is in the process of testing GM pigeon pea, sorghum, pearl millet, and groundnut for the first time (Sharma et al. 2002).
- Transgenic rice with resistance to insect pests and pathogenic viruses are being tested. They include Bt genes like Cry 1 Ab, Cry 1 Ac, conferring resistance against stem borers and leaf folders or GNA (*Galanthus agglutinin*) gene, conferring resistance against sucking pests and potato protease inhibitors for insect resistance (Mishra 2004).
- Entomotoxin gene(s) from *B. thuringiensis* has been transferred to tobacco, rice, cabbage, cauliflower, eggplant, and chick pea (Bhatia 1996).
- Cowpea trypsin inhibitor (CpTI) gene, which also provides a high degree of resistance against many insect pests, has been isolated and transferred to tobacco (Bhatia 1996).

Pest Control in India. Fig. 6 Coal flyash.



Pest Control in India. Fig. 7 Lignite flyash.

Agenda for the Future

If the green revolution is to sustain itself, it is necessary to adapt to the ecology-based IPM strategy for various crops. In this context, the traditional wisdom of agricultural practices should be the foundation and the modern advancements of science the superstructure to usher in a sustainable food security system. It is of interest to note that flyash (Figs. 6 and 7), a waste from coal or lignite based thermal power plants would be a potential dust insecticide and a carrier in pesticide formulations for tomorrow's agriculture.

Acknowledgements

The author expresses his gratitude to the authorities of the Annamalai University for providing facilities and permission for the studies and research projects undertaken. Thanks are also due to various funding agencies. Grateful regards are due to Dr. Richard A. Humber, Insect Mycologist, USDA Entomopathogenic Fungal Museum, Ithaca, New York, Commonwealth Agricultural Bureaux International, International Institute of

Entomology, London, Division of Mycology and Plant Pathology, Indian Agricultural Research Institute, New Delhi and other institutions for help in identification of insect specimens and pathogens.

Physics

Julian A. Smith

Most histories of the exact sciences consider "physics" to have begun with the ancient Greeks, especially with the work of Aristotle (384–322 BCE). Classical physics is usually said to have been developed during the European "Scientific Revolution" by figures like Galileo Galilei (1564–1642) and Isaac Newton (1642–1727), and modern physics is commonly introduced with accounts of the discovery of relativity and quantum mechanics around 1900. Few histories of physics consider developments outside Europe; and of those that do, non-Western physics is often presented as "derivative" of European work.

However, recent scholarship has made it clear that this European view is incomplete, and that numerous non-Western cultures, including those of China, India, the Islamic world, and others, developed sophisticated physical theories independently of Europe. In this expanded view, physics began in prehistoric times. From its origins in Africa, China, and India, physics developed to a surprisingly advanced level before its incorporation into the European scientific tradition.

Very little historical research into prehistoric African physics has so far been done, but the development of mathematics and astronomy has been dated back to very early times by archaeoastronomers such as Alexander Marshack. The bone tool handles of the Ishango culture of Lake Edward are inscribed with various collections of notches suggesting knowledge of abstract mathematical operations, and knowledge of astronomical events like new and full moons. These bones have been dated anywhere from 8500 to 25000 BCE. American physicist John Pappademos argues for a similar early start to African physics. He argues that the earliest dynamical experiments began with prehistoric African inventions like the spear and the bow and arrow, and that "the practical mastery of the principles of mechanics – the oldest branch of physics – grew as man learned to make flint weapons, tools, dwellings, boats, etc." Similar arguments, of course, have been made concerning the prehistory of physics in other early cultures.

Pappademos further argues, based on archeological, linguistic, and historical evidence, that "ancient Egypt was essentially an African civilization," and upon this basis he ascribes priority to African cultures for the early development of astronomy, geometry, and measurement. "To the Egyptians," he concludes, "we owe the concepts of most of the fundamental physical quantities: distance, area, volume, weight, and time. Europe is indebted to Egypt for the invention of standards, units and methods for accurate measurements of all these quantities." If this view is correct, it sheds new light on the development of the sciences among the ancient Greeks, whose indebtedness to Mespotamian astronomy and Egyptian geometry has long been acknowledged.

China

A similar "prehistoric origin" may be claimed for physics in China, whose history has been dramatically advanced with the publication of Joseph Needham's multivolume *Science and Civilisation in China*. Needham argues that traditional Chinese interest in physics was not particularly strong. Yet despite this, Chinese physics developed several interesting and original insights into various physical phenomena.

Chinese physicists, Needham says, were hampered by their lack of an atomic theory, used with great success by both early Greek and Indian, as well as later European scientists. However, their view of the physical universe as a "perfectly continuous whole" rather than as a collection of atoms meant that Chinese scholars were pioneers in understanding action-at-a-distance, and the connection of various forces. Chinese physics tended to emphasize waves rather than particles, and this dominance led to several early discoveries in magnetism, optics, dynamics, acoustics, and many other fields.

Among the earliest Chinese texts on physics are the writings of the Mohist schools of philosophy in the Warring States Period (480–221 BCE). Followers of philosopher Mo Zi (ca. 479–381 BCE), the Mohists made pioneering discoveries in statics and hydrostatics, dynamics, and especially optics, many of which are described in the *Mo Jing* (third–fourth centuries BCE).

One of the areas of physics most successfully tackled by the Mohists was the field of optics. Now while Chinese optics never reached the theoretical level of medieval Arab sources, it is clear that optics in the East was at least as advanced as parallel developments in Ancient Greece.

The propositions of the *Mo Jing* tell us that Mohist physicists made considerable experimentation in their efforts to construct a coherent theory of light and optics. Mohist physicists clearly understood that light travels in straight lines, and by using fixed light-sources, screens with pinhole apertures, and possibly the camera obscura, were able to study the formation of inverted images and the idea of the focal point. The camera obscura is certainly known from the eighth century AD onwards, and is mentioned in the ninth century *Yuyang Za Zi* (*Miscellany of the Yu Yang Mountain Cave*), though the theoretical explanation of its operation is incorrect. By the *Meng Qi Bi Tan* (*Dream Pool Essays*) of Shen Gua in AD 1088 we see an active interest in experiments involving pinhole apertures in screens to pass cones of light into darkened rooms.

Back in the Warring States period, by examining combinations of plane mirrors, Mohists also studied the phenomenon of lateral inversion (left becoming right in an image). They measured refraction in different media by examining the apparent bending of a stick in a glass of water. In addition, they used concave and convex mirrors to determine the properties of real and inverted images, and to differentiate between what we now know as the center of curvature and the focal point.

Concave mirrors were also used by ancient Chinese physicists to start fires by sunlight. Bronze mirrors are described as far back as 672 BCE; surviving dated mirrors occur from AD 6 to 10, and many exist from later Han times. Multiple reflections were studied in the second century BCE, and Han accounts of concave "burning mirrors" in the *Huai Nan Zi* (Book of Huai-Nan) of 120 BCE demonstrate they knew of the focal point of a concave mirror. Besides starting fires, concave mirrors were used with the moon in the later Han era to collect dew.

An interesting development of the fifth century AD was the use of "light-penetrating mirrors". These "magic mirrors" were inscribed on their backs with written characters; when held to the light, these otherwise-invisible letters would "shine through" the mirror and become legible. A 1932 investigation revealed these mirrors were made of more than one curvature, with the designs on the back imposing unequal strains on the mirror. The mirror would differ imperceptibly in thickness from place to place, with the convex reflecting surface on the front varying in curvature, and thicker areas having flatter curvatures than thinner areas. They were described in the eleventh century AD by Shen Gua.

Alongside mirrors, early Chinese opticians made considerable experiments with lenses. Glass was known to the Zhou dynasty, which began several hundred years before the Warring States period. A glassmaking industry began around 500 BCE, and by the AD 83 *Long Heng* (Discourses Weighed in the Balance) of Wang Chung, there are descriptions of glass lenses used to bring sunlight to a focus to start fires. In the third century AD *Bo Wu Zhi* (Notes on the Investigation of Things), burning lenses of rock crystal are mentioned. Finally, the 940 *Hua Shu* (*Book of Transformations*) of Tan Qiao describes the various real and inverted images produced by all four types of lenses, the planoconcave, planoconvex, biconcave, and biconvex.

There also appears to be some evidence for an independent Chinese development of the telescope by Bo You and Sun Yun Qiu in the early seventeenth century. However, as for spectacles, though they are often considered a Chinese invention, they in fact originated in Europe, and were imported overland into China soon after their invention around AD 1286.

In mechanics, the Mohists performed many experiments to determine the properties of levers and balances. They defined forces and weights, knew the laws of levers, balances, and pulleys, and developed a simple version of what came to be known in Europe as the "Atwood's machine" (named after English physicist George Atwood in 1780). They also invented the steelyard, and used it in weights and measures. Mohists seem to have been familiar with the "parallelogram of forces", and may have been in possession of the full theory of equilibrium (ca. 287–212 BCE).

Early Chinese physicists did not discuss theoretical centers of gravity, but they do appear to have done some practical research on centers of gravity in their "trick vessels", that is, jugs which incline or sway depending on the amount of water they contain. Trick vessels were known to Confucius (551–479 BCE), and were explicitly described in texts of the third century BCE. Siphons were constructed since antiquity, and were used for irrigation around the end of the Eastern or Later Han dynasty (AD 25–220). They were later employed (ca. 450 AD) by Daoist scientists and inventors like Li Lan in their balanced clepsydra, or water-clocks. Clockmaking is an ancient art among the Chinese, and attained great precision in the eleventh century mechanical and astronomical clocks of Su Sung (AD 1090).

As for specific gravity, it was known to the ancient Chinese, and was discussed by the philosopher Mencius (374–ca. 291 BCE), cofounder of Confucianism and one of the students of Confucius' grandson. "Archimedes' Principle" appears to have been known to Han technicians (AD 221–264), according to accounts in the *Zhou Li* (Record of the Institutions of the Zhou Dynasty). Han physicists and engineers also knew how to measure specific gravities in liquids, and were familiar with the use of the principle of bouyancy to weigh heavy objects.

Mohists approached the atomic theory in their discussion of the strengths of materials, but never articulated it clearly or developed its consequences. In the explanation of why a fiber breaks under tension, Master Lieh, in the *Lie Zu* book, argues the fiber is composed of unequally strong or cohesive elements, so that a breaking-plane forms somewhere in the fiber. This view is in essence a particulate theory of matter, but Lie uses the example to argue for a continuous universe.

The *Mo Jing* contains some remarkable statements about the study of motion. Though Chinese physics did little theoretical dynamics, they did consider forces in some detail, and appear to have come remarkably close to the principle of inertia as stated by English physicist Isaac Newton (1642–1727) as the first law of motion in his *Principia Mathematica* of 1687. Newton stated that "every body continues in a state of rest, or uniform motion in a right (straight) line, unless it is compelled to change that state by forces impressed on it." According to Joseph Needham, the Mohists argued that

> motion is due to a kind of looseness [the absence of an opposing force]… the cessation of motion is due to the [opposing force] of a 'supporting pillar' [a force that changes the moving body's otherwise-permanent state of motion]… If there is no [opposing force] of a 'supporting pillar', the motion will never stop… If there is [some kind of] 'supporting pillar' [some other force interfering with the motion], and nevertheless the motion does not stop [it may still be called motion but it will not be a straight-line motion because there will have been a deflection].

Mohist Chinese physicists also investigated the relativity of motion, and motion along inclined planes or slopes; they also studied particular problems of moving spheres.

As for Chinese acoustics, its history extends back more than two millennia. Second century BCE philosopher Dong Zhongshu studied sympathetic resonance in musical instruments; indeed the entire history of Chinese acoustics is intricately tied up with musical instruments, especially lutes and bells. Chinese physicists first classified sounds based on the four materials (stone, metal, bamboo, and skin) which made up the musical instruments producing them; later, they extended their classification to an eightfold scheme tied to the eight directions of the wind. Chinese musicians used resonance phenomena to tune their instruments, and were well aware of the fact that sound was caused by vibrations. Chinese military strategists even used resonance in the fourth century BCE to construct primitive geophones to listen for the tunneling of an enemy besieging a city.

Chinese investigation of magnetism and electricity is similarly ancient, but is better known in the West than acoustics. Almost all physics textbooks note Chinese priority in the magnetic compass. Lodestones and magnets are mentioned in the third century BCE *Lo Shi Chun Qiu* (Master Lu's Spring and Autumn Annals), as well as in the later *Huai Nan Zi* (Book of (the Prince of) Huai-Nan). By the fifth century, Chinese physicists knew of the directive property of the lodestone, and had begun to measure magnetic forces; and by the eighth or ninth centuries, they had discovered both magnetic polarity and variation. Engineer–astronomer Shen Gua discussed both in his *Dream Pool Essays*; his descriptions indicate considerable experimentation on the magnet. As for the magnetic compass, it is clear that the Chinese were using it for geomancy and divination by the first century AD. Their earliest use of the compass in navigation is unclear; the first datable references occur in about the eleventh century, but it is certain that Chinese mariners used compasses many years earlier. As in Europe, Chinese physicists used both "wet" and "dry" compasses; the former were made by floating magnetized needles in bowls of water whose rims were inscribed with directions, and the latter by carefully mounting the needle on an upright pivot.

What about the physics of surface phenomena? As in the West, its study was long delayed in China. Of course, knowledge of friction was very old among both cultures. Ancient Chinese, for example, knew how to use friction to make fires; and the friction of wheels was discussed in the *Han Zou Li*. By the Tang dynasty (AD 618–906), prince Li Kao studied the fit of smooth surfaces, and in the thirteenth century, Zhou Mi studied monomolecular films. And, during the Sung dynasty (AD 960–1279) Zhang Shi-Nan's 1233 treatise, *Yu Huan Zhen Wen* (Things Seen and Heard on My Official Travels), discusses the ring-test to determine the quality of lacquer. The ring-test was a method of quality control for centuries; it was not until 1878 that it was applied to measuring surface tension by finding the force to break the surface.

In China as in Europe, heat and combustion were a comparatively late interest. Making heat and sparks by rubbing wood and striking flint were techniques known to the ancient Chinese, and medieval texts give priority to the Chinese in the invention of the match (Northern Qi, AD 577). Candles were known to the Mohists in the Warring States period, and lamps since ancient times. But by the early eighth century AD, Chinese lamp-makers had cleverly designed an oil-cooling water reservoir below the lamp to reduce evaporation. The use of natural gas for fuel goes back to the first few centuries BCE, and Chinese inventors applied this knowledge on an industrial scale.

Some knowledge of the practical principles of steam power may go back as far as the second century BCE, based on a passage in the undated Daoist alchemical and technical recipe book, the *Huai Nan Wan Bi Shu* (Ten Thousand Infallible Arts of the Prince of Huai-Nan). Interest in spontaneous combustion is also very old, and is discussed in accounts of the third century AD. Chinese physicists also looked at successive boiling phases of liquids (particularly water for tea).

On the theoretical side, Li Shizhen's sixteenth century *Bencao Gangmu* (Great Pharmacopoiea) of 1596 attempts to classify types of fire. Fire is of two varieties, *Yin* and *Yang*, with many subdivisions; in general, it has *qi* (energy) but not *chi* (matter). Shizhen could not classify luminescent "fires" like fluorescence, phosphorescence, electro-luminescence, and piezo-luminescence.

Electro-luminescence was described by Chinese physicists of the third century AD. The *Bo Wuzhi* (Record of the Investigation of Things), of approximately AD 290, describes sparks created by contact with charged objects, such as drawing combs through the hair. As for other electrostatic phenomena, the ability of amber to attract objects when rubbed was known very early. Amber was first described by first century AD philosopher Wang Chong, and its properties were discussed in more detail around AD 500 by alchemist–physician Tao Hong Jing. But there was little progress in electrostatics until the eighteenth century. Meanwhile, piezo-luminescence, caused by rubbing certain types of crystals, was known in the Tang dynasty. Artificial phosphors may have been studied in the Sung period; the eleventh century *Xiangshan Yelu* (Rustic Notes from Xiang Shan) of monk Wen Rong explains the making of a phosphor from oyster shells. Some of these crystals and phosphors may have been imported overland from Arabic cultures, Needham argues; and if so, they may well have similarly influenced Indian physics on the way.

India

There is still much historical research to be done on the growth and development of science in India. Hindu scientists have been justly celebrated for their early contributions to mathematics (including the Hindu–Arabic number system, the use of zero, trigonometry, series summation, algebraic operations, and so on) and astronomy (elaborate computational techniques to determine the positions of celestial objects), but until recently little has been written on their physics, which is both sophisticated and extensive.

Early Indian physics is concerned with the "doctrine of the five elements" (*pannĩcamahabhūtas*); that is, the interplay between the elements of earth, water, fire, air, and a nonmaterial substance (*pṛthvī, ap, tejas, vāyu and ākāśa*, respectively). Among the earliest treatises of the Ṛgveda period (2000–1500 BCE) we see the emergence of primeval water as the "first cause" of all other elements, rather like the simple cosmologies of ancient Greek scientists like Thales (ca. 624–545 BCE) and Anaximander (ca. 611–575 BCE).

The five element theory was later developed by the Vaiśeṣika School of about 700–600 BCE, which also began the study of atomism. The introduction of Buddhism and Jainism brought new inquiries into the problems of atomism, matter, and motion (ca. 600–200 BCE); this was followed by the systematic formulation of atomic theories among Indian physicists between 200 BCE and AD 400. Indian science made its greatest advances between the period AD 400 and 1200, especially among the Jaina and Buddhist schools, as well as the Nyāya-Vaiśeṣika commentators. These medieval Indian physicists refined atomic theory, and made detailed investigations into gravity, motion, and impetus.

Physicists first began to explain the natural world in terms of atomic theories after 700 BCE. For the Vaiśeṣika School, atoms were eternal or indestructible, indivisible, and infinitely small. These atoms (*pramāṇus*) had vibratory and rotational motions, along with inherent impulses to form binary molecules (*dvyaṇuka*). Various combinations of atoms made up all the diverse substances in our world. Interestingly enough, this theory explained chemical reactions by supposing that these substances were broken up into their original atoms (the *pramāṇu* state) before they could be recombined to make a new material.

Physical and chemical change, meanwhile, was closely linked to the theory of heat. The first century AD philosopher Vātsyāyana argued that chemical change occurs as a result of either internal or external heat; moreover, during combustion, heat trapped inside the fuel in a latent form is released, allowing chemical reactions to proceed. The *Kiranāvali* of Udayana ultimately traced all forms of heat back to their source in the Sun.

Ancient Hindus believed that both heat and light were composed of streams of infinitely small particles radiating in all directions from sources like the sun. These particles move at inconceivably high speeds, and, when they strike molecules, break them down into smaller atoms, promoting chemical change. This theory was described in detail in the eleventh century AD *Nyāyamanjari* of Jayanta.

Other factors governing matter and physical change included gravity (*gurutva*), fluidity (*dravatna*), viscosity (*sigdha*), and elasticity (*sthitishāpaka*). For the Vaiśeṣika, gravity was seen as a causal factor resulting in the fall of bodies; it is not a force in the modern sense. Moreover, only earth and water possess it. The later Nyāya-Vaiśeṣika school of physicists (ca. 400–1200) add that gravity could be cancelled out by the effects of conjunction (a object supported on a stand) or impetus (an arrow flying through the air). They argued that gravity is eternal for primeval atoms, but temporary for compounds.

Fluidity was of two types, natural and incidental, with the former reserved to water, the latter to water, earth, and fire. Viscosity governs cohesion and smoothness, and is a property of water, preventing particles in it from dispersing. Elasticity is a quality of earthy substances.

How did Indian physicists handle the problem of matter in motion? The Vaiśeṣika held that matter was naturally static or stationary. It could be moved by some physical quality, like gravity in a falling body, but this motion would be temporary; and perpetual motion was impossible. Interestingly enough, it seems that gravity was only required to set the falling object in motion. Once it had started moving, impetus is generated, which keeps it falling without any additional help from gravity.

The fifth century AD philosopher Praśastapāda made a detailed study of motion and impetus in his *Pradārtha dharma saṁgraha*, a revision of the much older *Vaiśeṣikasūtra*. He divided motion into five categories: *utkṣepaṇa, avakṣepaṇa, prasāraṇa, ākuñcana*, and *gamana*, or, respectively, lifting up, throwing down, expansion, contraction, and action (gyrations, evacuations, quivering, and the like). Motion can be caused, says Praśastapāda, by six things: gravity, fluidity, volitional effort, conjunction (such as impact or striking), impetus or unseen causes. His use of impetus (*vega*) is rather close to our modern momentum, and is illustrated by the examples of throwing a heavy shot or firing an arrow. When the shot is thrown, the first impelling push begins its motion; then the shot's internal impetus takes over, and maintains its motion. Once the impetus is exhausted, the shot falls back to the ground.

Praśastapāda also had a relatively modern conception of sound. He realized sound was produced by vibrations in air, and added that these vibrations travel "like a series of water-ripples… or a series of waves" to the ear.

Indian physicists had many contacts with Chinese developments in the East, but they were equally well connected to Arabic work in the West. The relations between Indian and Islamic science in the Medieval period has recently been the focus of much scholarly work (Needham, Chin, Filliozat, Sen).

Islam

Islamic physicists, mathematicians, and astronomers such as Ibn Sīnā, Ibn al-Haytham, al-Bīrūnī and al-Kindī have long been known to Western historians for their influences on scholastic science in the Medieval Latin West. Arabic scientists frequently criticized and extended the physics of Aristotle, Archimedes (ca. 287–212 BCE), and other ancient physicists and often provided the original roots for many physical ideas, such as force and momentum.

In mechanics and dynamics, Muslim physicists developed several important concepts. Ibn Sīnā or Avicenna (980–1037) invoked the idea of *mayl* (Latin *inclinatio*, or inclination) to explain projectile motion; this theory was further developed by al-Baghdādī before its transmission to the Latin West. Ibn Sīnā and Ibn-al-Haytham developed the concept of momentum, and did pioneering research into the theory of gravity. Muslim philosophers knew that falling bodies accelerated independently of their mass, and that the attractive power between two objects increased as their masses got larger, but decreased with their separation.

Arabic physicists extensively studied the theory of weights, densities, buoyancy, and measures. They were familiar with the law of the lever and Archimedes' principle, and developed the balance as a scientific instrument to study topics such as specific weights. Thābit ibn Qurra (836–901) worked extensively on the law of the lever, and his ideas were later quite influential in the West. Meanwhile, al-Khāzinī's (fl. 1115–1130) celebrated *Kitāb mizān al-ḥikmah* (Book of the Balance of Wisdom) developed formulae for the specific and absolute weights of various alloys. Al-Khāzinī's work also discusses centers of gravity, hydrostatics, and other physical concepts.

Many Islamic scientists extended the theory of simple machines. Among these researchers were Baghdad's Banū Mūsā, and the many Arabic scientists involved with the development of various mechanical gadgets, automata, trick devices, and other complex machines. This branch of physics, called *ʿilm al-ḥiyal*, was developed by the Banū Mūsā, the school of Ibn Sīnā, Ibn-al-Sāʿāti, and many more. It reached its climax in the famous *Kitāb fī maʿrifat al-ḥiyal al-handasiyyah* (Book of Knowledge of Ingenious Mechanical Devices) of al-Jazarī.

Among the most influential researches of Muslim physicists were their pioneering inquiries into light and optics, which virtually established this branch of physics as an organized discipline. Al-Kindī's (fl. 790–866) early treatises introduced Euclidean optics to the Medieval Latin West. His theories of vision influenced Islamic writers for several centuries, including al-Fārābi (d. 950), al-Ṭūsī (1201–1274), and many more.

Opticians such as Ibn Sīnā and al-Bīrūnī (973–ca. 1050) studied particular problems like the speed of light from ancient sources, usually declaring it to be finite. Meanwhile, doctors like al-Rāzī or Rhazes (ca. 854–935) and Ḥunayn ibn Isḥāq inquired into human eye physiology, making their own contributions to the theory of vision. However, the most significant figure in Muslim optics was the Egyptian physicist Ibn al-Haytham (ca. 965–1039), better known in the West as Alhazen.

Many historians consider Ibn al-Haytham to be the most important optician between Euclid and Johannes Kepler (1571–1630). Historian of science David C. Lindberg argues that "Alhazen was undoubtedly the most significant figure in the history of optics between antiquity and the seventeenth century." This is because Ibn al-Haytham successfully integrated not only competing mathematical and physical approaches to light in his new intromission theory of vision, but also harmonized his views on sight with the anatomical work of earlier Muslim physicians. A prolific writer, Ibn al-Haytham is credited with more than 200 treatises on all branches of the sciences, including almost two dozen dealing with light and optics.

Ibn al-Haytham's most important optical work was his *Kitāb-al-manāẓir* (Book of Optics), which was translated into Latin as *De Aspectibus* or *Perspectiva*. This treatise had a profound effect on optics in the Latin West, influencing the work of Witelo (ca. 1230/5–1275), Roger Bacon (ca. 1220–1292), John Pecham (fl. 1250–1292), and many more. Traces of Ibn al-Haytham's theories are even found in the seventeenth century optical writings of Kepler and Newton.

Alongside his intromission theory, Ibn al-Haytham also studied various celestial and atmospheric phenomena such as twilight, refraction, atmospheric thickness, and optical illusions. He also contributed to the theory of catoptrics and dioptrics and extensively researched the laws of parabolic and spherical mirrors. "Alhazen's problem", which he solved geometrically, involved taking a spherical mirror and placing an object before it so that its image was reflected in the mirror; to find the point of reflection, one must solve the equivalent of a fourth degree equation. Ibn al-Haytham also demonstrated various reflection laws, including the significant finding that incident, normal and reflected rays all lie in the same plane. In his study of refraction, he discovered the equivalent of Pierre de Fermat's (1601–1665) "principle of least time": that a ray of light always takes the shortest and easiest path. Much of Ibn al-Haytham's work in this area was based on direct experimentation; glass cylinders immersed in water revealed refraction laws, and homemade lenses helped him determine the laws of magnification. Ibn al-Haytham even did early research into the camera obscura.

Islamic optics declined after Haytham's synthesis, though there was a revival of interest during the rise of the *ishrāq* (School of Illumination) in the thirteenth century. Al-Shīrāzī extended Ibn al-Haytham's account of the rainbow, arriving at essentially our modern understan that its colors are due to a combination of light reflection and refraction through suspended water droplets. Al-Shīrāzī's explanation was confirmed experimentally by his student, al-Farīsī (d. ca. 1320). But by the fifteenth century, leadership in optics had passed to the West, and by the following century, European scientists were making discoveries in physics, astronomy, and mathematics that were to usher in the "Scientific Revolution".

Physics in China

R. A. Uritam

An account of physics, as well as of any other science, in a prescientific revolution era or civilization does not present a meaningful picture without an understanding of the views of nature that are embedded in various natural philosophies that develop in each civilization and that are the most comprehensive account of natural phenomena before "physics" as a distinct discipline existed. In the West most of these natural philosophies had their origins in Greece, and included Pythagoreanism, Atomism, Platonic idealism and dualism, and Aristotelianism, each of which introduced distinct elements into Western science. However, they largely agreed that the final ground for understanding physical reality was substance, or "stuff." Additionally, in due course, rational proof, Euclidean geometry, reductionism, mechanistic materialism, and atomism became principal determinants of Western science.

In a similar way at about the middle of the first millennium BCE various schools of natural philosophy arose in China. These included Daoism, Naturalism, Mohism, Legalism, and (much later) Sung Neo-Confucianism. The central concept of Daoism, systematized by Laozi (a contemporary of Aristotle) is the *Dao* (the way), the "way the universe works." It is the unifying principle of the universe, akin to the "One" of Parmenides. This natural, noncoercive, nonanthropomorphic principle encompasses all phenomena, and invites study of all aspects of nature. Human standards are irrelevant in nature; one is to subject oneself to the harmonies of nature (*wu wei*).

Naturalism, represented by its early proponent, Zou Yan (fl. 300 BCE) introduced the doctrines of *Yin* and *Yang* and the *Wuxing* (Five Elements or Phases). Yin and Yang are the two fundamental forces, the expression of the basic dualistic principle, two forces existing not in conflict, but in a balance or a cooperative tension of opposites. Yang represents light, heat, dryness, hardness, activity, heaven, sun, and south. Yin stands for dark, cold, wetness, softness, quiescence, earth, moon, and north. The Five Elements invite comparison with the four elements of Empedocles. In China the five are water, fire, wood, metal, and earth, representative less of substances than of processes of nature. The elements are further arranged into the Mutual Production Order: wood, fire, earth, metal, water, wood, etc., where each element produces the subsequent one. In the Mutual Conquest Order, each element dominates over the subsequent one.

The less prominent school of Mohism introduced more formal, abstract, and geometrical notions such as a dimensionless geometrical point in space and time. Somewhat in the same vein, the Legalists discussed formal logical propositions, paradoxes, and syllogisms. Curiously, modern Chinese writers during the Cultural Revolution were fond of heaping fulsome praise on the Legalists for their supposed kinship to the scientific materialism of Marxism.

Mohism and Legalism waned in importance, and after centuries of evolution indigenous Chinese natural philosophy reached its most mature form in the twelfth century AD in the Sung neo-Confucian synthesis, best represented by the natural philosopher Zhu Xi (AD 1131–1200). This school combined the attention to nature present in Daoism and Naturalism with the heretofore society-centered official Confucianism that governed human conduct and interaction. In this way the human world and the world of nature were unified and investigation progressed at each "level of integration" from inanimate to human. The synthesis introduced two other fundamental principles of *qi* and *li*, roughly similar to Aristotelean matter and form.

The picture or model of nature that emerges is quite different from the Western one. It is not mechanistic, legalistic, geometrical, linear, or even materialistic. The leading twentieth century student of Chinese science, Joseph Needham, described that picture of nature in China as being one of a harmoniously functioning organism, an interconnected, interdependent whole. Reductionism and analysis into parts will not yield an understanding of nature because each entity is defined by the role it plays in relation to the pattern it fits into, by the web of relationships it has. The principal element of explanation is not substance but relation and pattern. As in Chinese society, so also in nature there is "order without law". The legal metaphor is absent in statements about nature ("laws" of nature); the order of nature is not as that of citizens subject to universal law but as that of musicians in an ensemble or dancers in a pattern. For these reasons, traditional Chinese thought found no problem in retroactive causality, since temporal succession is unimportant compared to the interdependence of the system as a whole, as a pattern in space and time.

With a world picture so different from the Western one, it is difficult even to match traditional Chinese activity in some realm with "physics", itself a term that acquired a recognizable meaning only fairly recently. Nathan Sivin has proposed the following divisions for Chinese science: medicine, alchemy, astrology, geomancy, natural philosophy and physical studies, mathematics, harmonics and acoustics, and mathematical astronomy. Present-day "physics" corresponds to parts of "physical studies" and "harmonics." Also, the strong and weak branches of physics are reversed in China and in the West. There was no Chinese achievement in mechanics, dynamics, or kinematics, nothing at all to rival Aristotle or the medieval precursors of Galileo. This is consistent with the absence in China of geometrical, corpuscular, and mechanistic ideas. Instead the preference was for continuum theories, pneumatic models, waves, vibrations, and resonances, all consistent with interrelation, pattern, and meaning only for a system as a totality. Thus, the highest achievements in indigenous Chinese physics were in the areas of optics, acoustics, and magnetism. Of the three, optics was the weakest, and ironically, its best practitioners were the Mohists, a school generally atypical of Chinese scientific philosophy. Although, lacking Greek geometry, Chinese optics never attained the level of medieval Islamic optics, it began at least as early as its Greek counterpart, with an account of light-sources, mirrors, and, later, lenses.

The fourth-century BCE Mohist text *Mo Jing* describes shadow formation, the distinction between umbra and penumbra, and discusses the dependence of the size of the shadow on the position of the object and of the source of light. Properties of light passing through a pinhole are discussed, including the definition of a focal plane and the inversion of the image. Reflection from a plane mirror and from a combination of plane mirrors is treated. Refraction of light at the plane boundary between air and water is described, including the resulting phenomenon of the apparent reduction in depth of an object in water. Also, the formation of images by spherical concave and convex mirrors is discussed in some detail.

Of even greater antiquity in China was the practical use of burning-mirrors for igniting fires from the sun's rays. The earliest such mirrors, made of bronze, date from the Chinese Bronze Age, in the seventh century BCE. A more difficult technological achievement was the production of lenses and burning-lenses. Rock-crystal, i.e., pure transparent quartz (SiO_2) was used; glass was produced as early as the sixth century BCE, and lenses were in use from the time of the Han dynasty of the first century AD. By the tenth century AD the four fundamental types of lenses (plane-concave, biconcave, plano-convex, and biconvex) were produced and their properties analyzed. Eye-glasses and spectacles, as well as magnifying glasses were in use by the fifteenth century AD.

Progress in the fields of sound and acoustics followed naturally from the fundamental orientation of Chinese natural philosophy. The alternation between Yin and Yang implies a cyclic, recurring process between opposites, reminiscent of harmonic oscillation or wave motion. Also, sound was likened to waves in a pool, caused by friction, and to a resonance in the fundamental neo-Confucianist substance, *qi*.

In the description and classification of musical sound and in the construction of instruments, the Chinese displayed their characteristic tendency to emphasize the whole and the complex, instead of isolating the simple. To Western thought the primary attributes of sound are pitch (frequency) and loudness (amplitude). By contrast, Chinese acoustic theory concentrated from the beginning on timbre (the overtone structure) as the primary attribute or parameter describing sound. Sounds were classified according to timbre according to the "eight sources of sound." metal, stone, earth-clay, skin, silk-thread, wood, gourd, and bamboo. As can be expected, these timbres were correlated, like the five elements, with seasons, compass points, and, naturally, musical instruments.

The influence of the concept of pattern and organic unity was at work in the ready acceptance of the spontaneous resonances of two musical instruments, this being merely a corroboration of a resonance in the cosmic organism. In a similar vein, sounds were not classified by pitch; rather, the names of notes in the early five-note scale arose from the mutual arrangement of musical instruments in archaic ceremonies.

A distinctive later achievement of Chinese acoustic theory is less closely related to the organic view of nature. In the sixteenth century AD, Zhu Zaiyou (b. AD 1536) provided the earliest solution to the classic problems of rendering melodies in several keys on one musical instrument, without retuning the pitches. The natural scale is one where the frequencies of the sounds, and the associated lengths of strings in a musical instrument are in "just intonation," following Pythagorean ratios (e.g., 2 : 1 for octave to tonic, etc.). If the ratios are true for one scale they cannot be so for a scale that begins one note higher. Zhu's solution was to have frequencies of all adjacent notes, differing in pitch by half a tone in a twelve-note scale, differ by a ratio $2^{1/2}$ to 1. This system of equal temperament, in use on a modern piano, was introduced considerably later in Europe, becoming popular only in the eighteenth century, and is familiar to music lovers from early examples of its use by composers, such as in Johann Sebastian Bach's *Well-Tempered Klavier*.

The most prominent achievement of traditional Chinese physics, however, was in magnetism. That phenomenon is totally harmonious with a model of the world as organism, with resonances and intangible influences on the parts from the pattern as a whole. Also, China, not knowing the Aristotelian concepts of natural place, natural and enforced motion, did not have to explain magnetic phenomena, as did the West, as deviations from this scheme. Even more to the point, action at a distance, or the concept of a field, was no problem in China, whereas Cartesian mechanicists saw these as throwbacks to scholasticism when used to account for gravitational, electrical, and magnetic phenomena.

Historically, the discovery of every significant magnetic phenomenon – attraction, directivity, polarity, thermoremanence, declination, as well as application to a working compass – considerably antedates comparable advances in the West. Chinese texts of the third century BCE describe the simplest effect, the attraction of iron by natural magnetite (lodestone). The directional, north–south seeking property of the lodestone was observed about the first century AD and first demonstrated by a lodestone placed on a very smooth bronze surface. (Modern replicas of this arrangement have verified that friction can be made low enough to display the effect.) Subsequently, the lodestone was balanced on a pin, or floated on wood in water. In the early centuries of the first millennium AD the directive property of the lodestone was transferred to iron by rubbing. By the eleventh century AD the more sophisticated method of magnetization, thermoremanence, was in use, consisting of allowing a red-hot piece of iron to cool rapidly through the Curie point while it is oriented along the earth's magnetic field.

By about AD 1100, a useful magnetic compass was in use in navigation, although the traditional inward-looking agrarian economy and dependence on river, rather than ocean, transportation did not thereby lead to extensive global exploration. Beginning in the ninth century AD magnetic declination was observed. Subsequent recordings of declination chronicle a variation of declination over time, for example, the declination being to the east prior to about AD 1050, and to the west after AD 1050.

Philosophers of science differ on whether the fundamental concepts of Chinese natural philosophy, such as relation, pattern, and organism could have furnished an alternative but adequate basis for a model of scientific explanation. On this question, in his extensive writings, Needham has probably overstated the case in favor of the Chinese potential for doing this.

In terms of transmissions from China to the West, the technological contributions are well-known; printing, gunpowder, and the magnetic compass are always at the head of the list. Many scholars also attribute to Chinese science a role in promoting the development, after Newton, of nonmechanistic concepts in physics, such as field, wave, fluids such as caloric and ether, to say nothing of the loss of distinction between matter and energy in relativity and between wave and particle in quantum mechanics.

Physics in India

William T. Johnson

Early Indian thinkers developed a number of theoretical systems which centered around two main themes: elements and atoms. Based upon a relatively broad review of the ancient philosophies, we will discover a rich scientific tradition in India.

Ancient India (2000 BCE–AD 800)

Early Indian explanations about the physical makeup of the universe were religious and philosophical in nature. The oldest literary record of this period, the *Ṛgveda*, presents several fundamental concepts related to physical science such as *ap* (primeval water), which was considered the basic element of matter. Gradually, the doctrine of five fundamental elements emerged, as seen in the Upaniṣadic literature of around 700 BCE. The five elements were *pṛthvī* (earth), *ap* (water), *tejas* (fire), *vāyu* (air), and *ākāśa* (a nonmaterial substance). The Sanskrit terms have a wider connotation than the English translation, so it is essential to present the original terms.

Much of this early literature was concerned with the attributes associated with each of these elements. They had both common as well as distinctive attributes, many coincident with the five senses, as follows: *pṛthvī* (earth) sound, touch, color, taste, and odor; *ap* (water) sound, touch, color, and taste; *tejas* (fire) sound, touch, and odor; *vāyu* (air) sound and touch; and *ākāśa* (nonmaterial) sound. Different combinations of these five elements yielded certain products. The human body is a good example. The human embryo has energetic principles which are separated into form by *vāyu* (air). *Tejas* (fire) subsequently transforms the embryo. *Ap* (water) maintains moisture while *pṛthvī* (earth) gives it shape and size. Finally *ākāśa* expands the embryo and develops it.

Many of today's scholars question the notion that scientific inquiry only found fertile ground in the minds associated with the Greek tradition. In fact, a number of diverse systems of scientific inquiry were developing in India coincident with the Greek philosophies by 500 BCE. Those which presented five fundamental elements were the *Sāṃkhya, Nyāya*, and *Vaiśeṣika*. The *Jaina, Bauddha*, and *Cārvāka* schools, like many of the Greek thinkers, presented four fundamental elements. It is difficult to say with certainty which school or culture developed these ideas first, therefore who influenced whom, or if they developed independently.

The *Nyāya-Vaiśeṣika* school, prominent among early Indian systems, was popularized by an individual who came to be known as Kaṇāda. He and his followers extended the concept of five elements and built a comprehensive theory of atoms. The first four elements of this system (*pṛthvī, ap, tejas*, and *vāyu*) were material and considered either eternal or temporal. The fifth element, *ākāśa*, was considered eternal only. The eternal form consisted of imperceptible atoms, while the temporal form arose when these atoms joined to create perceptible products. This view of five elements was part of a much larger conceptual picture, that of *dravya* (substance). There were nine types of substances. In addition to the five elements or substances already mentioned, there was *dik* (space), *kāla* (time), *ātman* (self), and *manas* (mind). Each of these substances was considered inseparable from its respective set of attributes. In other words, they were one and the same.

The word used for atom was *aṇu* or *pramāṇu*. The *Nyāya-Vaiśeṣika* school held that the atom was indestructible, indivisible, without magnitude, spherical, and in constant motion. Two atoms of the same substance could join to form a dyad. Atoms of different substances could not join together, yet they could play a supportive role in the combination of materially compatible atoms. The dyad was regarded as too small to be perceived. The smallest visible structure was a triad (three dyads). This structure was referred to as *trasareṇu* or *tryaṇuka* which was about the size of a speck floating through a sunbeam. The principle of causality was crucial to the *Nyāya-Vaiśeṣika* school. Atoms were the material cause for the dyad, the effect. The dyads were the cause for the production of a triad which was another effect. The individual atoms lost their causative property once the triad was formed. The reason for atoms joining in the first place was attributed to *aḍṛṣta*, an unseen force.

Jaina philosophers held that atoms were both cause and effect. They theorized that atoms joined to form aggregates in response to attractive and repulsive forces which were inherent characteristics of the atoms themselves. Jaina atoms were all of one class. There was no distinction, qualitatively, or quantitatively, between types of atoms such as earth-atoms, water-atoms, etc. According to the Buddhists, the atom was indivisible, unable to be analyzed, invisible, inaudible, unable to be tested, and intangible. Neither were these atoms eternal. The Buddhists did not speak of atoms in terms of particles. They thought of them as a force of energy.

The *Nyāya-Vaiśeṣika* school was distinct from other Indian schools in that it placed much more emphasis on the attributes of matter. There were five general qualities possessed by all nine substances: number, dimension, distinctness, conjunction, and disjunction. Other qualities, more closely associated with modern physics included, *gurutva* (gravity), *dravatva* (fluidity), *sigdha* (viscosity), and *sthitishāpaka* (elasticity). Gravity, or the cause of falling, was not considered a force but a quality which resided in a whole object. No apparent correlation between gravity and the mass of a particular object was presented. Fluidity was a quality of only three substances – earth, water, and fire – and was of two kinds. Natural fluidity was a specific quality of water. Incidental fluidity was associated with fire in the case of some melted substances. Viscosity was specific to water, causing cohesion and smoothness. Elasticity was only a quality of earthy substances as in the branch of a tree which was caused to return to its original condition if displaced. Another fundamental concept considered by ancient Indian thinkers was that of motion.

The *Nyāya-Vaiśeṣika* concept of karma (motion) was represented by three actions: *utkṣepaṇa* (throwing upward), *avakṣepaṇa* (throwing downward), *prasāraṇa* (going). Only one kind of motion was considered possible at a time and a substance experienced motion only for a moment. This motion was subsequently destroyed or rendered ineffective once completed. The motion of free atoms made possible by *aḍṛṣta* (unseen force) caused the material world to be formed.

Among Indian physical concepts, that of *ākāśa* should not be overlooked. Its special quality was sound. Though considered a nonmaterial substance, it was believed to play a role in the formation of material objects. A modern physics concept which some have equated with *ākāśa* is that of ether, which is conceived to be a vast expanse or continuum. Sound moved through *ākāśa* like ripples across the surface of a pond. Unlike the ripples, sound moved through *ākāśa* in a succession of points. The first sound caused the second, and once the second sound was created, the first was destroyed.

Heat and light were understood in relation to one of the five basic elements, *tejas* (fire). When an object was heated it went through a series of distinct changes, each one lasting a prescribed number of moments. A clay pot for example, if heated, would in the first moment experience the production of atomic motion. The second moment would be characterized by the destruction of the clay's original color. In the third and fourth moments one would find that the color red would be produced followed by the destruction of the atomic motion created earlier. A new type of atomic motion, creative in nature, occurred in the fifth moment. A series of two disjunctions between the atoms and *ākāśa* was followed by a conjunction in the sixth through eighth moments. The final two moments consisted of the formation of a red colored dyad followed by a triad. The ultimate source of all heat was thought to be the sun. Light, though often associated with heat in many modern physical systems, possessed many qualities, distinctive from heat, in the early Indian systems.

Light was thought to consist of rays which emanated from the eyes just as a candle casts its light throughout a room. If an obstruction prevented the rays from touching an object, then that object simply could not be perceived. Mirrors were thought to possess particular attributes of color which caused the light rays from one's eyes to return to one's face upon striking the surface.

Medieval India (AD 800–1800)

It is a common misconception that there was a lack of scientific inquiry during the Middle Ages. While India experienced great change during this time, such as the introduction of Islam, there was a continued advance and assimilation of scientific information with an ever increasing number of collaborators. New cultural influences, changing technologies, and language barriers challenged as well as fostered scientific advances.

Physics was viewed as a distinct branch of study during the early part of the Middle Ages. Though experiments were still quite rare, use of this scientific technique began. A large number of texts were translated into different languages. A scholar named Ḥunayn ibn Isḥāq translated Aristotle's works into Syriac and his son Isḥāq ibn Ḥunayn followed suit, translating Euclid's *Elements*. Ideas were shared, expanded upon, and refined. A number of original inquiries were also initiated.

Among the more notable individuals describing physics research in India as well as Middle Asia at this time was Abū Rayḥān al-Bīrūnī. He authored many books devoted to the scientific achievements of the Indian people.

The latter part of this period experienced an influx of European influences. Educational institutions, scientific journals, and professional societies each played a role in the development of what was to become modern India. New political and economic structures, in the face of new language barriers between the educated few and the illiterate masses, threatened to disassemble the rich scientific heritage of the Indian people. Yet India assimilated the old and the new to emerge strong with an outstanding future of scientific inquiry before it. Much of that future rested in the hands of a few visionaries who understood the significance of science in India's future.

Modern India (AD 1800–Present)

The outstanding efforts of many have contributed to India's rich past and promising future. The following few individuals are some of the physicists who have exemplified the level of achievement found throughout modern India.

Jagdish Chandra Bose (1858–1937) was a biophysicist who explored the response of plants and animals to electrical stimulation. Like many pioneering physicists active at the turn of the century, Bose used instruments of his own design in his work. He was elected a Fellow of the Royal Society of London in 1920. C. V. Raman (1888–1970) investigated optics, including diffraction, molecular scattering of light, and magneto-optics. He was awarded the Nobel Prize in 1930 for the discovery which bears his name, the Raman Effect. This pioneering work described the molecular scattering of light and explained, among other things, why the ocean appears blue. Finally, Jawaharlal Nehru, the first Prime Minister of India, worked hard to foster what he described as a "scientific temper." He believed that for science to succeed in modern India, as it had in its past, there had to be strong support for the scientific enterprise from all segments of society.

The history of physics in India is a vast subject, offering extensive opportunities for further study. It is hoped that this brief presentation has encouraged some to explore the ancient philosophies, medieval refinements, and modern achievements.

Physics in the Islamic World

Timothy J. McGrew

With the rapid expansion of the Arabian tribes into western Asia and northern Africa in the early seventh century, the Islamic world fell heir to the documentary remains of Greek science and mathematics. Scientific research had grounded to a halt in the Byzantine Empire, and in a very real sense the intellectual center of gravity was transferred to the East, where, despite occasional upheavals, learning flourished under a series of enlightened patrons for over five hundred years.

In contemporary usage, the word "physics" denotes an autonomous and highly specialized branch of science which deals with the behavior of non-living systems, bringing them under the scope of the most general natural laws. There was no parallel to this discipline in medieval Islam, yet from the eighth century onwards there was a profusion of translations, commentaries, and learned writings on topics which would today fall under the broad heading of physics.

The contributions of Islamic thinkers to astronomy and mathematics were of the first importance. Optics, which would today be considered a branch of physics, was studied in close conjunction with both geometry and medicine, since various problems regarding vision remained unresolved in the Greek scientific literature. The contributions of Ibn al–Haytham to the problem of refraction are particularly noteworthy.

Astronomy and optics aside, Islamic scholars wrote profusely on the nature of matter, causality, the theory, and practice of mechanics, and dynamics.

The Nature of Matter and Causal Laws

The dominant philosophical school in Islamic physics was the Aristotelians or *Falāsifa*, Prominent members of this school included al–Kindī (d. 873), al–Fārābī (d. ca. 950), Ibn Sīnā (Avicenna, d. 1037), and Ibn Bājja (d. 1138). While the *Falāsifa* held Aristotle in the highest respect, their work was somewhat syncretistic. The Greek philosophical corpus was often taken to be an integrated whole, and diverse elements of Plato and the Neoplatonists found their way into the synthesis of the Arabic Aristotelians. Al-Fārābī went so far as to write a book entitled *Jamʿ bayna raʾyay al-ḥakīmayn Aflāṭūn al-ilāhī wa-Aristūṭalīs* (The Harmony between Plato and Aristotle). Most Arabic scholars who sought to reconcile these strands of thought relied heavily on a work known as the *Theology of Aristotle*, in which Aristotle himself seemed to provide a bridge between his technical and logically rigorous work and the more literary and imaginative work of Plato. But modern scholarship has established that the *Theology* was wrongly attributed to Aristotle and is actually a compendium of the writings of the Neoplatonist Plotinus.

In physics, the doctrine held that every object could be analyzed as a composite of matter, which is the locus of its potency or possibilities, and form, which is the actualization of some of those potencies. Matter, like space itself, was believed to be infinitely divisible. Physical bodies behaved in qualitatively predictable ways because of their innate tendencies. Hence, a stone falls

P

because it seeks its natural place at the center of the earth, and water seeks its lowest level in lakes and oceans because its attraction to the center of the earth is slightly less strong than that of the stone.

The infinite divisibility of space led to some perplexing dynamical difficulties, first noted by the Greek philosopher Zeno of Elea, which induced some Islamic physicists to question the coherence of the Aristotelian concept of space. Al-Bīrūnī (d. after 1050), a prominent critic of Aristotelian physics, posed this dilemma in a letter to Ibn Sīnā: If the sun is west of the moon in the sky, with a definite space between them, then even though the moon moves much faster than the sun, it should never be able to catch it. For the space between them can be conceived as divisible into an infinite number of parts; but how can a body moving with a finite speed cross an infinite number of spaces? In al-Bīrūnī's view, this paradoxical consequence reflected poorly on the Aristotelian concept of the infinite divisibility of space. After all, anyone can see that the moon does in fact overtake the sun.

A competing school of thought was inspired by Sunni theology, with its strict insistence on divine omnipotence. In this view, all bodies consist of a finite number of indivisible atoms, and the behavior of these atoms is not the consequence of any causal relations between them but is governed directly by the divine will. What appear to be causal connections are only regularities which we are in the habit of calling laws; there is no connection discoverable by reason between separate events, and Aristotelian explanations for the behavior of bodies in terms of natural tendencies are therefore hopelessly misguided.

The controversy between the theologians and the Aristotelians came to its climax in the *Tahāfut al-Falāsifa* (Self-Destruction of the Aristotelians) of al-Ghazālī (ca. 1058–1111), in which he maintained that philosophers could not know, for example, that fire causes cloth to burst into flame but only that the combustion of the cloth occurs at the moment that it makes contact with the flame. Ibn Rushd (ca. 1126–1198) responded with a *Tahāfut al-Tahāfut* (Self-destruction of the Self-destruction) in which he claimed that such skepticism regarding the efficacy of reason would undermine itself. In contemporary philosophy of science, a similar controversy is still raging over the nature of causality and our knowledge of causal connections, though the arguments arise not out of theological considerations but rather from Hume's skeptical doubts about induction and the verificationism of the logical positivists.

Mechanics

One of the simplest of mechanical devices, the lever, had been investigated mathematically by the Greek polymath Archimedes, who gave an elegant proof that the forces required to keep the unequal arms of a lever in balance were inversely proportionate to the length of the arms. In the course of his proof, Archimedes assumed that two equal weights located at different points on one arm of the lever produced the same effect as if they were both located at the midpoint between them – an assumption which is intuitively plausible but for which he gave no rigorous justification. Thābit ibn Qurra (d. 901) provided an intriguing argument for this assumption in his *Kitāb al-qarasṭūn* (Book of the Balance).

The balance was investigated very thoroughly in Islam. Al-Bīrūnī worked out a general method for determining the specific gravity of an irregular solid which he published in his *Maqala fī'l-ḥisab allatī bayn al-filizzāt wa'l-jawāhir fī'l-hajm* (Treatise on the Ratios Between the Volumes of Metals and Jewels). In later years, the best-known work on the subject was the *Kitāb mīzān al-ḥikma* (Book of the Balance of Wisdom) of al-Khāzinī (fl. ca. 1115–30), a careful though not very original treatise which covers the theory of balances (relying heavily on the work of al-Bīrūnī), the practical details of their construction, and their use for determining proportions of metals in alloys. In the course of his discussion, al-Khāzinī notes that heat decreases the density of metal objects. The *Kitāb* of al-Khāzinī is among other things a source of alchemical lore, and it is no accident that it became a standard text on the construction of equipment among alchemists in succeeding generations.

Islamic scientists were aware of more complex mechanical contraptions, and a few works described windmills, clocks, and other marvelous devices. The most lavishly illustrated volume on this subject, the *Kitāb fī maʿrifat al-ḥiyal al-handasiyya* (Book of Knowledge of Ingenious Mechanical Devices) of al-Jazarī, describes some fifty mechanical devices including several different types of fountains. But they made no systematic effort to apply the principles utilized in these devices on a broad scale. The knowledge of the principles of mechanics did not generate a technological revolution.

Dynamics

The Aristotelian theory of motion was a source of considerable difficulty for Islamic thinkers. Apart from the "natural motion" by which objects seek their natural place, the Aristotelians viewed motion as the result of the application of a force. In the absence of the force, motion ceases, as a cart grinds to a halt when the rope connecting it to the horse is broken. But this commonsense theory generates serious problems when applied to projectile motion. Why should a flung stone hurtle through the air when it leaves the hand? Why should an arrow continue to fly when it has left the bowstring? Aristotle's own suggestion was that somehow the air rushes around to the rear of the object in a way which prolongs its flight. But this was both vague and apparently irreconcilable with the facts; the flight of a javelin is not appreciately improved by design changes at its back end which would help it to "catch" the air.

In place of this unsatisfactory explanation, Ibn Sīnā and Abū'l-Barakāt al-Baghdādī (ca. 1080–ca. 1165) developed a theory of "violent inclination" which matches very closely the impetus theory first suggested by the Alexandrian Neoplatonist John Philoponus (d. ca. 570) and which was widely held until the seventeenth century. According to this theory, the agent of motion (the hand which flings a stone, for instance) imparts to the object a temporary inclination to continue moving, an inclination which partly counteracts the tendency of the object to seek its natural place and which is gradually dissipated through its flight.

Aristotle's notions regarding free fall also came under critical scrutiny by Islamic thinkers. According to Aristotle (*Physics*, Book 4, chapter 8), the motion of a falling object is directly proportional to its natural inclination (the tendency it has to seek its natural place) and inversely proportional to the resistance offered by the medium through which it moves, an account which strongly suggests the mathematical formulation

$$M \propto \frac{F}{R},$$

where M is motion, F is force and R is the resistance. Ibn Bājja (better known in the West as Avempace), though working within the broadly Aristotelian framework, criticized this view on the grounds that, if Aristotle's account were correct, unresisted motion (such as that of the heavenly bodies) would be instantaneous – which it clearly is not. In place of the Aristotelian law of motion, he suggests the formula

$$M \propto F - R,$$

which has the advantages that motion in the absence of resistance need not be instantaneous but rather proportional to the impressed force, and that when force and resistance are balanced, the result is not motion at all but cancellation of motion. Ibn Bājja's views here closely resemble some arguments advanced earlier by John Philoponus, but it was through Ibn Bājja's writings, preserved in a commentary on Aristotle's *Physics* by Ibn Rushd, that these views were transferred to the west and influenced the early work of Galileo.

Abū'l-Barakāt's reflections on motion in his *Kitāb al-Muʿtabar* (Book of What has been Established by Personal Reflection) are also remarkable as precursors of a radical departure from the Aristotelian view. In explaining the motion of a flung stone, he appeals not only to the dissipation of the violent inclination but also to a compounding of successive natural inclinations which increases the overall strength of the natural inclination during the fall. This idea of the compounding of the force through small intervals represents a serious advance over Aristotle's view that the distance travelled by an object in free fall per unit time is directly proportional to the weight of the object. It appears not to have occurred to Aristotle to consider the question of instantaneous velocity. Abū'l-Barakāt's explanation for free fall is thus one of the first hints that the constant action of a force might produce not merely motion but an acceleration.

Pi in Chinese Mathematics

LAM LAY YONG

In the earliest existing mathematical texts, *Zhoubi suanjing* (The Mathematical Classic of the Zhou Gnomon) and *Jiuzhang suanshu* (Nine Chapters on the Mathematical Art), the ratio of the circumference of the circle to its diameter, or π, was taken to be three. Liu Xin, who lived in the first century BCE and was an astronomer and an expert on calendrical calculations, was mentioned in *Suishu* (Standard History of the Sui

P

Dynasty) as being among the earliest to improve on this value. This arose from the construction of a standard measure called *jia lianghu* which he prepared for Emperor Wang Mang.

In his commentary on a problem concerning a sphere in *Jiuzhang suanshu*, Liu Hui of the third century referred to Zhang Heng's (AD 78–139) empirical deduction which implied a value of $\sqrt{10}$ for pi. The eighth century book, *Kaiyuan zhanjing* (Kai Yuan Treatise on Astrology), expressed Zhang Heng's estimation in the ratio of 736–232. A century later, Wang Fan improved this to the ratio of 142–45.

However, it was Wang Fan's contemporary, Liu Hui, who succeeded not only in attaining a better estimate for pi, but also in writing down the detailed method of how he arrived at the result.

His method commenced with a regular hexagon inscribed in a circle. This was extended to a 12-sided polygon where the length of one side and its area were calculated from the hexagon based on the properties of the right-angled triangle. Next, a polygon of 24 sides was constructed and the length of its side and its area were calculated from the data of the dodecagon. Regular polygons inscribed in the circle were in this manner continuously constructed; the number of sides of one polygon was always double that of the previous polygon and the area of a polygon was formulated as one half the perimeter of the previous polygon multiplied by the radius of the circle. Liu Hui pointed out that if this process was repeated long enough, eventually there would be a polygon whose sides were so short that they would coincide with the circle. He concluded that this explained why the area of a circle was one half the circumference multiplied by the radius. He further pointed out that when the ratio of the circumference to the diameter was taken as 3–1, this value was in fact the ratio of the perimeter of the hexagon to the diameter.

Lui Hui reached a polygon of 192 sides when he calculated pi to lie between 3.14 64/625 and 3.14 169/625. From these figures he deduced an approximate value for pi of 157/50 or 3.14. He gave another value of 3927/1250 or 3.1416 which he said could be verified when calculations reached the polygon of 3,072 sides.

Computations were performed through the rod numeral system which was not only a medium for whole numbers but also one for common fractions and decimal fractions. The knowledge of Lui Hui's method and the rod numeral system would enable the value of pi to be calculated to any desired degree of accuracy. It was therefore not surprising that Zu Chongzhi (AD 430–501), the most distinguished mathematician, astronomer and engineer of his time, found π to lie between 3.1415926 and 3.1415927 and also gave it a value of 355/113. These values were not surpassed until a thousand years later when al-Kāshī evaluated pi correctly to sixteen decimal places. Zu's values were recorded in *Suishu* but no method was given, and Zu's own work had long been lost.

PI in Indian Mathematics

R. C. Gupta

Undoubtedly *pi* or π is the most interesting number in mathematics, and its history will remain a never-ending story. It occurs in several formulas of mensuration and is variously involved in many branches of mathematics, including geometry, trigonometry, and analysis.

The earliest association of π is found in connection with the mensuration of a circle. The fact that the perimeter or circumference of any circle increases in proportion to its diameter was noted quite early. In other words, in every circle, perimeter/diameter = constant, or $p/d = \pi_1$, where π_1 is the same for all circles.

After knowing the perimeter, the area of the circle was often found by using the sophisticated relation

$$\text{area} = \left(\frac{p}{2}\right)\left(\frac{d}{2}\right) = \frac{pd}{4}.$$

But the earliest rules for determining area were of the form area $= (kd)^2$ where k is a constant prescribed variously. Both these methods imply that the area of a circle is proportional to the square of its diameter (or radius r), or area $= \pi_2 r^2$.

We know that π_2 is the same as π_1, but this was not always known. Similarly, π_3 may be defined from the volume of a sphere. In this article, the symbol π is used to denote all the above three values, as well as for their common value, which is now known to be not only an irrational, but also a transcendental number.

Since the Indus Valley script has not been deciphered successfully, we cannot say any final thing about the scientific knowledge of India of that time (about the third millennium BCE). Some conjectures about the value of π used in the *Ṛgveda* (about the second millennium BCE) have been made. Definite literary evidence is available from texts related to *Vedāṅgas*, especially the *Śulbasūtras* which contain much older traditional material. In the *Baudhāyana Śulbasūtra*, the oldest of them, the perimeter of a pit is mentioned to be three times its diameter, thereby implying $\pi_1 = 3$. This simplest approximation is found in almost all ancient cultures of the world. In India, it is found also in classical religious works such as *Mahābhārata* (Bhīṣmaparva, XII: 44), and certain *Purāṇas*, as well as in some Buddhist and Jain canonical works.

Different approximations to π_2 are implied in the various Vedic rules for converting a square into a circle of equal area and vice versa. If r is the radius of the circle equivalent to a square of side s, the usual *Śulba* rule is to take $r = s(2+\sqrt{2})/6$, which implies the approximation $\pi_2 = 18(3-2\sqrt{2}) = 3.088$. Recently, a new interpretation of the *Mānava Śulba Sūtra* has yielded the relation $r = 4s/5\sqrt{2}$, thereby implying $\pi_2 = 25/8 = 3.152$, which is the best *Śulba* approximation found so far.

The ancient Jain School preferred the approximation $\pi = \sqrt{10}$, which they considered accurate and from which they derived the value $\pi = \sqrt{3^2+1} \approx 3 + 1/6 = 19/6$. This value ($\sqrt{10}$) continued to be used in India not only by the Jains but also by others, such as Varāhamihira, Brahmagupta, and Śrīdhara, even when better values were known.

With Āryabhaṭa I (born AD 476), a new era of science began in India. In the *Āryabhaṭīya*, he gave a fine approximation of π_1, surpassing all older values. It contains the rule that the perimeter of a circle of diameter 20,000 is close to 62,832, so that $\pi_1 = 62,832/20,000 = 3.1416$ *nearly*, which is correct to four decimal places, and he still calls it close and not exact.

This value had a respectful place in Indian mathematics and exerted greater influence. How Āryabhaṭa obtained it is not known. It was known in China, but evidence of borrowing lacks documentary support. On the other hand, the two typically Indian values $\sqrt{10}$ and $62,832/20,000$ appear in many subsequent Arabic works.

In India, the Archimedean value 22/7 for π first appeared in the lost part of Śrīdhara's *Pāṭī* (ca. AD 750). A Jain writer, Vīrasena, quotes a peculiar rule in his commentary *Dhavalā* (AD 816). It is equivalent to $\rho = 3d + (16d + 16)/113$. If we leave out the redundant dimensionless number +16 in the brackets, this rule will imply a knowledge of the value $\pi_1 = 355/113$ which was known in China to Zu Chongzhi (AD 429–500). In explicit form, this value is found in India much later, e.g., in the works of Narāyaṇa II, Nīlakaṇṭha, and others. The simplified or reduced form $3,927/1,250$ of Āryabhaṭa's value of π occurs in the works of Pauliśa, Lalla, Bhaṭṭotpala, and the great Bhāskara II.

Most significant contributions on the computations of π were made by the mathematicians of the late Āryabhaṭa School of South India. Mādhava of Saṇgamagrāma (ca. AD 1340–1425), the first great scholar and founder of the School, gave the value $\pi_1 = (2,827,4,333,8,823,3)/(9 \times 10^1)$ as known to the "learned men". This value yields an approximation correct to 11 decimals. Mādhava also knew the series $\pi/4 = 1 - 1/3 + 1/5 - 1/7 + \cdots$ which was rediscovered in Europe in 1673 by Leibniz.

In discovering various series for π and in evolving techniques for improving their convergence, a great theoretical breakthrough was attained in sixteenth-century India.

Pirī Reis

SEVIM TEKELI

Pirī Reis, Muhyī al-Dīn Pirī (1465–1554), was born in Gallipoli, a naval base along the Marmara coast. He was an important admiral, cartographer, and geographer of his time. His fame depends on two world maps and a book named *Kitāb-i Bahriye*.

The First World Map (1513)

In 1929 a map was found in Topkapi Palace, on a piece of parchment 90 × 60 cm in size. It had been drawn in 1513, and later presented to Sultan Selim in 1517 in Egypt. This portion shows only the coast of South Western Europe, West Africa, the Middle East, and Central America. On the map, mountains were drawn in outlines, and the rivers marked with thick lines. Shallow places were indicated by red dots, and rocky places in the sea with crosses. Notes were added concerning different regions, and they were decorated with illustrations of special plants, and animals.

This map is a *portolano*, a navigation manual illustrated with charts, with no lines of longitude and latitude. Instead there are two wind roses, one in the North and the other in the South. Each of these roses is divided into 32 parts, and lines are extended beyond these roses; there are two scales indicating mileage. The lines that are extended from the wind roses and the scales are used in measuring the distances between the ports.

Pirī Reis made use of 34 maps in drawing his own. Of these, 20 had no dates. Eight of them were maps that were called *Jaferiyye* by Muslim geographers. Four were new maps drawn by the Portuguese, and one was the map of Christopher Columbus. Since this last is now lost, the only original document we have today is the map of Pirī Reis. When he was drawing the coasts of America, he remained faithful to Columbus' map, and copied it from several points. The Antilles and Cuba are shown as continents on his map, which was what Columbus believed. When Columbus was near the coast of Cuba in 1494, he had the firm belief that Cuba was a continent. As a result, he had his conviction recorded by the notary public on board, Ferdinand Perez de Luna, and asked all the crew to sign it. Columbus had shown South America as a group of islands. Inspired by this, Pirī too drew lot of imaginary islands opposite Trinidad. This map is a very valuable historical map for two reasons. First of all, it was the most correct and scientific map of the time, and secondly it was the only map which was drawn using Columbus' map, of which neither the original nor the copy exists today.

The Second World Map (1528)

Fifteen years after his first map, Pirī Reis drew a second world map. Today we have only a small portion of it, 68 × 69 cm in size. On this portion, there are the northern parts of the Atlantic Ocean and the newly discovered regions of North and Central America.

The map starts with Greenland, in the north. Toward the south there are two pieces of land. The first is called Baccalo; the second one, further down, is called Terra Nova, and it is mentioned that these were discovered by the Portuguese. Further south there is the peninsula of Florida drawn quite correctly. The pieces of land at the side are the peninsulas of Honduras and Yucatan, discovered in 1517 and 1519, respectively.

Cuba and Haiti are drawn quite accurately. The errors on the previous map were corrected on this one.

There is a slight distortion on the map from the true positions as we know them today. This error was committed because of neglect in not taking into consideration the 10°–13° of difference in angle on contemporary compasses. This error is true for all Western-originated maps.

In this second map, the drawing of the coastlines shows greater improvement when compared with the inaccuracies of the first one. Only the parts of the world that were discovered were shown; the unexplored areas were left blank.

Kitāb-i Bahriye

Pirī made a book of all his notes, revised and expanded it, and in 1525 presented it to Süleyman the Magnificient. He analyzed the geographic works of his time and, with his sharp faculties of observation, he set down everything he came across in his travels. In the preface of his book, he said that his purpose in writing such a book was to give information about ports, coasts, and islands by drawing them on maps known as portolanos in the west. However, he added that no matter how big the scales of maps were, it was impossible to show enough of the vital details on them. This lack of important information made him see the necessity of writing a book to compensate for this insufficiency. This, then, is the novelty *Bahriye* brought to the science of navigation.

Potato: Origins and Conservation of Potato Genetic Diversity

TIMOTHY JOHNS

The Origins and Conservation of Potato Genetic Diversity When the conquistador Francisco Pizzarro and his men overran the Inca Empire in the 1530s they stumbled upon the potato, a vegetable with an annual crop value that today far exceeds that of all the gold the Spaniards ever removed from the New World. While the first potatoes that were taken to Europe in 1537 were regarded suspiciously or as just a curiosity, the potato is now the most important tuber crop globally, exceeded only in its contribution to human subsistence by the cereals wheat, rice, and maize.

What global humanity assumed from the Andeans was not just an important nutrient source, but also several millennia of accumulated empirical experimentation through which Amerindian farmers molded wild species of tuber-bearing members of the genus *Solanum* into the domesticated potato. This is a process determined by biological and environmental forces and by the intelligence and cultural traditions of these people in relation to plant biology and ecology. The Andeans made good use of the natural vegetative propagation method of potato plants, and altered it to their own advantage. They chose those tubers that were most favorable, and by planting the same preferred types year after year maintained their favorable characteristics.

Through time, human selection has resulted in specific changes in the potato plant. In comparing the potato of commerce, *Solanum tuberosum*, with its wild relatives, a botanist might first observe the changes in the length of the underground stems, or stolons, that bear the tubers. These are invariably short in modern cultigens. When wild and primitive plants are pulled up, the stolons are likely to break; tubers from plants with long stolons are more likely to be left in the ground, and less likely to be planted the next year. The result is an unconscious selection for shorter underground stems, and a plant that conveniently produces a mass of easily harvestable tubers close to its base. The typical wild potato is golf ball-sized or smaller. Selection for greater tuber size and plant yield improved the output compared to wild types.

In South America, several thousand different landraces and eight species of potatoes are presently cultivated. Farmers recognize them by differences in color, size, shape, and flavor as well as numerous agronomic traits. Most North American consumers are familiar with two or three colors of potatoes. In the Andes selection by humans has resulted in cultivars in which the skin and flesh color may be black, purple, red, yellow, or white, and spotted combinations of any of these colors. Many wild plants, in order to avoid being eaten by herbivores, produce unpleasant-tasting chemicals. Glycoalkaloids, steroidal nitrogen-containing compounds, are normally found in wild species of potatoes in concentrations high enough to be toxic or potentially fatal to humans or animals. These toxins have posed particular problems for Andean peoples and have been dealt with in various ways, including the selection of genes conferring lower glycoalkaloid content.

Andeans make good use of the knowledge that different potato varieties grow best under different environmental conditions. Even if one type fails due to adverse weather or diseases caused by viral, bacterial, or fungal pathogens, others with specific resistances

P

produce enough tubers to sustain the human population until the next season. Not surprisingly Andean potatoes are a source of invaluable germplasm from which plant breeders obtain sought after traits such as resistance to frost and disease.

Modern potato fields in the high Andes of Peru and Bolivia exist in the very locale from which wild plants were originally taken (the center of diversity for potatoes) and wild plants, growing around fields, or even within fields, hybridize with cultivated plants. This creates a dynamic situation which produces, from seed, new genetic types. These plants will have valuable traits of the cultivated parent and perhaps valuable traits of the wild parent. Some of them will have a combination of characteristics superior to earlier types; they will often grow as weeds in fields and from them farmers continue to choose new varieties that constantly improve the nature of the cultivars.

Essential to this process of crop evolution is the intimate knowledge farmers have of their potatoes. Andean cultivators recognize clones of potatoes for their various qualities and may grow up to 35 different landraces together in one field. Aymara and Quechua Indians know tubers by name, e.g., *laram imilla* (blue girl), and have detailed taxonomies to describe the multitude of types.

The dynamic situation that created this diversity continues to the present day and is an essential resource both for ensuring human survival in the Andes and for maintaining potato genetic diversity. However, commercial interests which supplant this variation with new high-yielding varieties of potatoes, and introduce modern technologies, are bringing rapid change to the traditional agricultural system in the Andes; it is with alarm that scientists view the loss of potato landraces and the farming systems that guarantee the long-term survival of this crop upon which humankind is heavily dependent.

The conservation of biodiversity of both crop and wild species of plants is of global concern. However, the most obvious beneficiaries of the use of plant genes to produce new pharmaceuticals or improved crops are in the industrialized countries of the world. Fewer of the financial benefits derived from patented products are returned to the countries from which the germplasm was obtained. More importantly little recognition or compensation is provided to the communities who maintain the essential indigenous knowledge about plant properties. Indeed with economic development the marginalization of indigenous peoples in society is often increased rather than diminished; while indigenous peoples have traditions of conserving natural resources, changing economic conditions force them to adopt practices that are often destructive to their traditional systems.

In addition to the potato, the first peoples of the Americas were the domesticators of numerous crops including tomatoes, maize, and chili peppers. From their knowledge systems humanity learned the use of traditional medicines such as curare and ipecac which have provided valuable pharmaceuticals. Recognition of the true value of the intellectual property of indigenous people is the first step to settle the debt established in 1537; international governments and institutions need to seek in conjunction with these communities means to conserve in situ the valuable resources that are maintained within their cultural traditions.

Precession of the Equinoxes

K. V. Sarma

Precession of the equinoxes, which in Indian astronomy is called *ayanacalana* (shifting of the solstices), refers to the slow but continuous backward movement of the point of intersection of the ecliptic (which is a fixed circle) and the celestial equator (which keeps on moving backward). This effectively means that the first point of Aries, which is the traditional point of the commencement of the Indian year, is really shifting backward continuously. This shifting is, however, so slow, being a meager 50.2 s per annum that it comes to be noticed only when it accumulates over several years, and takes about 25,800 years to complete one circle.

Such a shift seems to have been noticed in India even during the Vedic times, as is evidenced by the Vedic priests' changing the beginning of their year backward, from the constellation Mṛgaśiras (Delta Orionis) to the next previous constellation Rohiṇī (Alpha Tauri), and again backward, to Kṛittikā (Eta Tauri) in the course of time. But no measurement of it was made. Precession was not apparent during the time of astronomer Āryabhaṭa (AD 499), since at that time the First point of Aries coincided with the equinox. However, later astronomers noted it and also measured its rate. The first Indian astronomer who gave a rule for finding the value of precession seems to be Devācārya, who, in his *Karaṇaratna*, I.36 (AD 689), gives the rate of precession which works out to 47 s per annum. The magnitude of the precession, called *ayana-aṃśa* (degrees of precession) of a celestial body would be the angular distance between its computed longitude and the first point of Aries on the zodiac (which Hindu astronomy takes as fixed).

Hindu astronomers did not conceive the shifting of the equinoxes as a continuously regressing phenomenon, which it really is. They understood it as an oscillatory motion, with the beginning of the Kali era (3102 BCE) as the "zero-precession year", when the Sun and other planets were at the first point of Aries (Aśvinī), i.e., at the end of Zeta Piscium (Revatī). According to the *Sūryasiddhānta*, an oscillation of amplitude 27° to and fro would take 7,200 years to complete. Thus, during the first 1,800 years, the equinox moved forward by 27° and during the next 1,800 years it moved backward, coming back to the zero position at the end of the Kali year 3,600 (which corresponds to AD 499, when Āryabhaṭa composed his work *Āryabhaṭīya*). It will continue to regress for 1,800 years more, till AD 2299, when its forward motion for 1,800 years would commence, again reaching the zero position at the end of 7,200 years, covering, in all, 108°. Certain other texts, such as the *Karaṇaratna* and *Vākyakaraṇa* take the amplitude of the oscillation as 24°, the period for one complete oscillation being 7,380 years. Among Indian astronomers, it was only Muñjāla (AD 932) who conceived precession as a continuous motion.

Proofs in Indian Mathematics

M. D. Srinivas

Alleged Absence of Proofs in Indian Mathematics

Most of the scholarly works on history of mathematics assert that Indian Mathematics, whatever its achievements, does not have any sense of logical rigour. For instance, we may cite the following as being typical of the kind of opinions commonly expressed about Indian mathematics:

> As our survey indicates, the Hindus were interested in and contributed to the arithmetical and computational activities of mathematics rather than to the deductive patterns. Their name for mathematics was *gaṇita*, which means "the science of calculation". There is much good procedure and technical facility, but no evidence that they considered proof at all. They had rules, but apparently no logical scruples. Moreover, no general methods or new viewpoints were arrived at in any area of mathematics (Kline 1972: 190).

While modern scholarship seems to be unanimous in holding the view that Indian mathematics lacks any notion of proof, even a cursory study of the source works that are available in print reveals that Indian mathematicians place much emphasis on providing what they refer to as *upapatti* (proof, demonstration) for everyone of their results and procedures.

Some of these *upapattis* were noted in the early European studies on Indian mathematics in the first half of the nineteenth century. For instance, Colebrooke notes the following in the preface to his widely circulated translation of portions of *Brāhmasphuṭasiddhānta* (ca. AD 628) of Brahmagupta, and *Līlāvatī* and *Bījagaṇita* of Bhāskarācārya (ca. AD 1150):

> On the subject of demonstrations, it is to be remarked that the Hindu mathematicians proved propositions both algebraically and geometrically: as is particularly noticed by Bhāskara himself, towards the close of his algebra, where he gives both modes of proof of a remarkable method for the solution of indeterminate problems, which involve a factum of two unknown quantities (Colebrooke 1817: xvii).

Around the same time, Whish (1835) pointed out that infinite series for π and the trigonometric functions were derived in texts of Indian mathematics much before their discovery in Europe. It would indeed be interesting to find out how the currently prevalent view, that Indian mathematics lacks the notion of proof, obtained currency in the last 100–150 years.

P

The Tradition of *Upapattis* in Mathematics and Astronomy

A major reason for our lack of comprehension, not only of the Indian notion of proof, but also of the entire methodology of Indian mathematics, is the scant attention paid to the source works so far. Much of the methodological discussion is usually contained in the detailed commentaries, whereas modern scholarship has concentrated almost exclusively on translating and analysing the original works, without paying any heed to the commentaries. Traditionally, the commentaries have played at least as great a role in the exposition of the subject as these original texts.

Among the source works available in print, there are about 25 commentaries which present detailed *upapattis* of results and processes in mathematics and astronomy (see References, Primary Sources). Amongst these, the earliest expositions of *upapattis* are to be found in the *Bhāṣya* of Govindasvāmin (ca. 800) on the *Mahābhāskarīya* of Bhāskarācārya I, and the *Vāsanābhāṣya* of Caturveda Pṛthūdakasvāmin (ca. 860) on *Brāhmasphuṭasiddhānta* of Brahmagupta. We find a very detailed exposition of *upapattis* in the works of Bhāskarācārya II (ca. 1150): his *Vivaraṇa* on *Śiṣyadhīvṛddhidatantra* of Lalla (ca. 800) and his *Vāsanā* on his own *Bījagaṇita* and *Siddhāntaśiromaṇi*. Bhāskarācārya notes that the exposition of *upapattis* goes back to the ancient teachers and is handed down by the teaching tradition (Bhāskarācārya II, *Vāsanā* on *Bījagaṇita* 1949: 125–127).

Mathematical Results Should be Supported by *Upapattis*

The following passage from Kṛṣṇa Daivajña's commentary *Bījapallava* (ca. 1600) on *Bījagaṇita* of Bhāskarācārya, clearly brings out the basic understanding of Indian mathematical tradition that citing any number of instances (even an infinite number of them) where a particular result seems to hold, does not amount to establishing that as a valid result in mathematics. Only when the result is supported by an *upapatti* or a demonstration, can the result be accepted as valid:

> How can we state without proof (*upapatti*) that twice the product of two quantities when added or subtracted from the sum of their squares is equal to the square of the sum or difference of those quantities? That it is seen to be so in a few instances is indeed of no consequence. Otherwise, even the statement that four times the product of two quantities is equal to the square of their sum, would have to be accepted as valid. For, that is also seen to be true in some cases. For instance take the numbers 2, 2. Their product is 4, four times which will be 16, which is also the square of their sum 4. Or take the numbers 3, 3. Four times their product is 36, which is also the square of their sum 6. Or take the numbers 4, 4. Their product is 16, which when multiplied by four gives 64, which is also the square of their sum 8. Hence, the fact that a result is seen to be true in some cases is of no consequence, as it is possible that one would come across contrary instances (*vyabhicāra*) also. Hence it is necessary that one would have to provide a proof (*yukti*) for the rule that twice the product of two quantities when added or subtracted from the sum of their squares results in the square of the sum or difference of those quantities. We shall provide the proof (*upapatti*) in the end of the section on *ekavarṇa samīkaraṇa* (Kṛṣṇa Daivajña, *Bījapallava* 1958: 54).

Upapatti for the *Kuṭṭaka* Process

To understand the nature of *upapattis* in Indian mathematics, we have to analyse some of the lengthy demonstrations which are presented for the more complicated results and procedures. We also have to analyse the sequence in which the results and the demonstrations are arranged to understand the method of exposition and logical sequence of arguments. For instance, we may refer to the demonstration given by Kṛṣṇa Daivajña of the celebrated *kuṭṭaka* procedure, which has been employed by Indian mathematicians at least since the time of Āryabhaṭa (ca. AD 499), for solving first-order indeterminate equations of the form $(ax + c)/b = y$, where a, b, c are given integers and x, y are to be solved for integers. The *upapatti* is rather lengthy (Kṛṣṇa Daivajña, *Bījapallava* 1958: 85–99; Srinivas 1987), and we merely recount the essential steps here.

Kṛṣṇa Daivajña first shows that the solutions for x, y do not vary if we factor all three numbers a, b, c by the same common factor. He then shows that if a and b have a common factor, then the above equation will not have a solution unless c is also divisible by the same common factor. Then follows the *upapatti* of the process of finding the greatest common factor of a and b by mutual division, the so-called *Euclidean algorithm*. He then provides an *upapatti* for the *kuṭṭaka* method of finding the solution by making a series of transformations on the *vallī* (column) of the quotients obtained in the above mutual division, based on a detailed analysis of the various operations in reverse (*vyasta-vidhi*). The last two elements of the *vallī*, at each stage, are shown to be the solutions to the *kuṭṭaka* problem for the successive pairs of remainders (taken in reverse order from the end) which arise in the mutual division of a and b. Finally, Kṛṣṇa Daivajña explains why the procedure differs depending upon whether there are odd or even number of coefficients generated in the above mutual division.

Yuktibhāṣā Proofs of Infinite Series for π and the Trigonometric Functions

One of the most celebrated works in Indian mathematics and astronomy, which is specially devoted to the exposition of *yukti* or proofs, is the Malayalam work *Gaṇita-yuktibhāṣā* or *Yuktibhāṣā* (ca. 1530) of Jyeṣṭhadeva. Jyeṣṭhadeva states that his work closely follows the renowned astronomical work *Tantrasaṅgraha* (ca. 1500) of Nīlakaṇṭha Somasutvan and is intended to give a detailed exposition of all the mathematics required thereof. The first half of *Yuktibhāṣā* deals with various mathematical topics in seven chapters and the second half deals with all aspects of mathematical astronomy in eight chapters. The mathematical part includes a detailed exposition of proofs for the infinite series and fast converging approximations for π and the trigonometric functions, which were discovered by Mādhava (ca. 1375); it also includes proofs of Brahmagupta's results concerning the diagonals and the area of a cyclic quadrilateral. Some of the proofs in this part have been studied in recent times, after the pioneering work of Rajagopal and his collaborators over 50 years ago (Marar 1940; Rajagopal 1949; Rajagopal and Venkataraman 1949; Rajagopal and Aiyar 1951; Saraswati Amma 1979; Katz 1995; Paramesvaran 1998; Raju 2001; John 2002; Srinivas 2005). The proofs of *Yuktibhāṣā* have also been expounded in the form of Sanskrit verses (*kārikas*) by Śaṅkara Vāriyar in his commentaries *Kriyākramakarī* (ca. 1535) and *Yuktidīpikā* on *Līlāvatī* and *Tantrasaṅgraha*, respectively.

Upapatti and "Proof"

The Raison D'être Of *Upapatti*

The notion of *upapatti* is significantly different from the notion of "proof" as understood in the Greek and modern Western traditions of mathematics. The ideal of mathematics in the Greek and modern Western traditions is that of a formal axiomatic deductive system. This ideal of mathematics is intimately linked with another crucial philosophical presupposition that mathematics constitutes a body of infallible eternal truths. It is this quest for securing absolute certainty of mathematical knowledge, which has motivated most of the foundational and philosophical investigations into mathematics and has shaped the course of mathematics in the Western tradition, from the age of Greeks to contemporary times.

Indian epistemological position on the nature and validation of mathematical knowledge is very different from that in the Western tradition. This is brought out for instance by the Indian understanding of what indeed is the purpose or raison d'être of an *upapatti*. In the beginning of the *golādhyāya* of *Siddhāntaśiromaṇi*, Bhāskarācārya says (Bhāskarācārya II 1981: 326):

> Madhyādyaṃ dyusadāṃ yadatra gaṇitaṃ tasyopapattiṃ vinā
> prauḍhiṃ prauḍhasabhāsu naiti gaṇako niḥsaṃśayo na svayam
> gole sā vimalā karāmalakavat pratyakṣato dṛśyate
> tasmādasmyupapattibodhavidhaye
> golaprabandhodyataḥ
>
> Without the knowledge of *upapattis*, by merely mastering the *gaṇita* (computational procedures) described here, from the *madhyamādhikara* (the first chapter of *Siddhāntaśiromaṇi*) onwards, of the (motion of the) heavenly bodies, a mathematician will not have any value in the scholarly assemblies; without the *upapattis* he himself will not be free of doubt (*niḥsaṃśaya*). Since *upapatti* is clearly perceivable in the (armillary) sphere like a berry in the hand, I therefore begin the *golādhyāya* (section on spherics) to explain the *upapattis*.

Thus, as per the Indian mathematical tradition, the purpose of *upapatti* is mainly (a) to remove confusion and doubts regarding the validity and interpretation of mathematical results and procedures; and (b) to obtain assent in the community of mathematicians. Further, in the Indian tradition, mathematical knowledge is not taken to be different in any "fundamental sense" from that in natural sciences. The valid means for acquiring knowledge in mathematics are the same as in other sciences: *Pratyakṣa* (perception), *Anumāna* (inference), and *Śabda* or *āgama* (authentic tradition).

The Limitations of *Tarka* or Proof by Contradiction

An important feature that distinguishes the *upapattis* of Indian mathematicians is that they do not generally employ the method of proof by contradiction or *reductio ad absurdum*. Sometimes arguments, which are somewhat similar to proof by contradiction, are employed to show the non-existence of an entity, as may be seen from the following *upapatti* given by Kṛṣṇa Daivajña to show that "a negative number has no square root":

> The square-root can be obtained only for a square. A negative number is not a square. Hence how can we consider its square-root? It might however be argued: 'Why will a negative number not be a square? Surely it is not a royal fiat'... Agreed. Let it be stated by you who claim that a negative number is a square as to whose square it is; surely Not of a positive number, for the square of a positive number is always positive by the rule... not also of a negative number. Because then also the square will be positive by the rule... This being the case, we do not see any such number whose square becomes negative... (Kṛṣṇa Daivajña, Bījapallava 1958: 19).

Such arguments, known as *tarka* in Indian logic, are employed only to prove the non-existence of certain entities, but not for proving the existence of an entity,

P

whose existence is not demonstrable (at least in principle) by other direct means of verification.

In rejecting the method of indirect proof as a valid means for establishing existence of an entity whose existence cannot even in principle be established through any direct means of proof, the Indian mathematicians may be seen as adopting what is nowadays referred to as the "constructivist" approach to the issue of mathematical existence. But the Indian philosophers, logicians, etc., do much more than merely disallow certain existence proofs. The general Indian philosophical position is one of eliminating from logical discourse all reference to such *aprasiddha* entities, whose existence is not even in principle accessible to all means of verification (Srinivas 1986). This appears to be also the position adopted by the Indian mathematicians. It is for this reason that many an "existence theorem" (where all that is proved is that the non-existence of a hypothetical entity is incompatible with the accepted set of postulates) of Greek or modern Western mathematics would not be considered significant or even meaningful by Indian mathematicians.

Upapatti and "Proof"

We now summarise the classical Indian understanding of the nature and validation of mathematical knowledge:

1. The Indian mathematicians are clear that results in mathematics, even those enunciated in authoritative texts, cannot be accepted as valid unless they are supported by *yukti* or *upapatti*. It is not enough that one has merely observed the validity of a result in a large number of instances.
2. Several commentaries written on the major texts of Indian mathematics and astronomy present *upapattis* for the results and procedures enunciated in the text.
3. The *upapattis* are presented in a sequence proceeding systematically from known or established results to finally arrive at the result to be established.
4. In the Indian mathematical tradition, the *upapattis* mainly serve to remove all ambiguity and doubts and obtain assent for the result among the community of mathematicians.
5. The *upapattis* may involve observation or experimentation. They also depend on the prevailing understanding of the nature of the mathematical objects involved.
6. The method of *tarka* or "proof by contradiction" is used occasionally. But there are no *upapattis* which purport to establish existence of any mathematical object merely on the basis of *tarka* alone.
7. The Indian mathematical tradition did not subscribe to the ideal that *upapattis* should seek to provide irrefutable demonstrations establishing the absolute truth of mathematical results. There was apparently no attempt to present the *upapattis* as a part of a deductive axiomatic system. While Indian mathematics made great strides in the invention and manipulation of symbols in representing mathematical results and in facilitating mathematical processes, there was no attempt at formalisation of mathematics.

The classical Indian understanding of the nature and validation of mathematical knowledge seems to be rooted in the larger epistemological perspective developed by the *Nyāya* school of Indian logic (Bhattacharya 1987; Mohanty 1992). Some of the distinguishing features of *Nyāya* logic, which are particularly relevant in this context, are:

1. That it is a logic of cognitions (*jñāna*) and not "propositions".
2. That it has no concept of pure "formal validity" as distinguished from "material truth".
3. That it does not distinguish necessary and contingent truth or analytical and synthetic truth, that it does not admit, in logical discourse, premises which are known to be false and terms that are non-instantiated.
4. That it does not accord *tarka* or "proof by contradiction", a status of independent *pramāṇa* or means of knowledge, and so on.

Towards a New Epistemology for Mathematics

Mathematics today, rooted as it is in the modern Western tradition, suffers from serious limitations. First, there is the problem of "foundations" posed by the ideal view of mathematical knowledge as a set of infallible eternal truths. The efforts of mathematicians and philosophers of the West to secure for mathematics the status of indubitable knowledge has not succeeded, and there is a growing feeling that this goal may turn out to be a mirage.

Apart from the problems inherent in the goals set for mathematics, there are also other serious inadequacies in the Western epistemology and philosophy of mathematics. The ideal view of mathematics as a formal deductive system gives rise to serious distortions. Some scholars have argued that this view of mathematics has rendered philosophy of mathematics barren and incapable of providing any understanding of the actual history of mathematics, the logic of mathematical discovery and, in fact, the whole of creative mathematical activity. There is also the growing awareness that the ideal of mathematics as a formal deductive system has had deleterious consequences on the teaching of mathematics.

Notwithstanding all these critiques, it is not likely that, within the Western philosophical tradition, any radically different epistemology of mathematics will emerge and so the driving force for modern mathematics is likely to continue to be a search for absolute truths and modes of establishing them, in one form or the other. This could lead to "progress" in mathematics, but it would be progress of a rather limited kind.

If there is a major lesson to be learnt from the historical development of mathematics, it is perhaps that the development of mathematics in the Greco-European tradition was seriously impeded by its adherence to the cannon of ideal mathematics as laid down by the Greeks. In fact, it is now clearly recognised that the development of mathematical analysis in the Western tradition became possible only when this ideal was clearly given up during the heydays of the development of "infinitesimal calculus" during sixteenth, seventeenth and eighteenth centuries. As a historian of mathematics notes:

> It is somewhat paradoxical that this principal shortcoming of Greek mathematics stemmed directly from its principal virtue – the insistence on absolute logical rigour … Although the Greek bequest of deductive rigour is the distinguishing feature of modern mathematics, it is arguable that, had all the succeeding generations also refused to use real numbers and limits until they fully understood them, the calculus might never have been developed and mathematics might now be a dead and forgotten science (Edwards 1979: 79).

It is of course true that the Greek ideal has gotten reinstated at the heart of mathematics during the last two centuries, but it seems that most of the foundational problems of mathematics can also be perhaps traced to the same development. In this context, study of alternative epistemologies, such as that developed in the Indian tradition of mathematics, could prove to be of great significance for the future of mathematics.

Putumana Somayāji

K. V. Sarma

Putumana Somayāji (ca. 1660–1740), author of the work *Karaṇapaddhati* (Methodology for Astronomical Manuals) was a *nampūtiri* (the appellation of the Brahmin community of Kerala in South India), who belonged to a family which bore the name Putu-mana (New House). He was of Ṛgvedic denomination, and secured the surname Soma-yāji by having performed the Vedic *Soma* sacrifice. His real name remains unknown. The date of Soma-yāji is surmised on the basis of the chronogram which gives the date of completion of his *Karaṇapaddhati* (as 17,65,653) of the Kali era, stated in the *kaṭapayādi* notation of expressing numerals, which is in the year AD 1732. Again, in the concluding verse, Somayāji states that he hailed from the village named Śivapura, which has been identified as Covvaram in Central Kerala, where his descendants still reside.

Somayāji was a prolific writer, mainly on astronomy and astrology, his only work in a different discipline being *Bahvṛcaprāyaścitta*, a treatise which prescribes expiations (*prayāścitta*) for lapses in the performance of rites and rituals by Bahvṛca (Ṛgvedic) Brahmins of Kerala. In addition to his major work, Somayāji is the author of several other works. In *Pañca-bodha* (Treatise on the Five), he briefly sets out computations at the times of *Vyatipāta* (an unsavory occasion), *Grahaṇa* (eclipse), *Chāyā* (measurements based on the gnomonic shadow), *Śṛṅgonnati* (elongation of the moon's horns), and *Mauḍhya* (retrograde motion of the planets), all of which are required for religious observances. His *Nyāyaratna* (Gems of Rationale), available in two slightly different versions, depicts the rationale of eight astronomical entities: true planet, declination, gnomic shadow, reverse shadow, eclipse, elongation of the moon's horns, retrograde motion of the planets, and *Vyatipāta*. Three short tracts on the computation of eclipses, including a *Grahaṇāṣṭaka* (Octad on Eclipses), are ascribed to Somayāji. He also composed a work called *Veṇvārohāṣṭaka* (Octad on the Ascent on the Bamboo), which prescribes methods for the computation of the accurate longitudes of the moon at very short intervals. A commentary in the Malayalam language on the *Laghumānasa* of Muñjāla is also ascribed to him. On horoscopy, Somayāji wrote a *Jātakādeśa-mārga* (Methods of Making Predictions on the Basis of Birth Charts), which is very popular in Kerala.

The *Karaṇa-paddhati*, in ten chapters, is his most important work. The work is not a manual prescribing computations; rather it enunciates the rationale behind such manuals. Towards the beginning of the work, the author states that he composed the book to teach how the several multipliers, divisors, and R sines pertaining to the different computations and the like are to be derived. Thus, the work is addressed not to the almanac maker but to the manual maker. All the topics necessary to make the daily almanac are not treated in *Karaṇapaddhati*, whereas several other items not pertaining to manuals are dealt with. The work takes as its basis the parameters and postulates of the Parahita system of astronomy promulgated by Haridatta, except for the section on eclipses, where the more accurate system from the *Dṛgganịta* of Parameśvara is taken as the basis.

In Chapter I, the *Karaṇapaddhati* sets out the planetary parameters, the computation of the mean planets, and the corrections to be applied thereto. Chapter II is devoted to the derivation, by means of pulverization (*kuṭṭaka*), of the multipliers and divisors necessary for planetary computations. Chapter III is concerned with various aspects of the computation of the moon, and Chapter IV deals with miscellaneous matters relating to the determination of suitable epochs for commencing computations. Chapter V mentions methods for correlating observed results with computed results, while Chapter VI depicts such matters as the circle and the circumference, and the R sines pertaining to various entities for different purposes. Chapter VII is devoted to the rationale of the derivation of the mnemonics relating to the epicycles, their R sines, and allied matters. Chapter VIII describes varied derivations using the gnomonic shadow. Chapter IX is devoted to stellar declination and latitudes. The last chapter is concerned with certain derivations from the shadow of the gnomon.

As a work on astronomical rationale and exposition of the logic of several practices, the *Karaṇpaddhati* is highly important. A very significant statement made by the Putumana Somayāji, towards the close of Chapter V, is that the conception of eons and eras, the measures therefore, and the various derivations based on them are not really true; they are only a means to compute the positions of celestial bodies and matters related to them. What is really important is the correlation of computation with observation, and to effect the same a practical astronomer is authorized to make changes as necessary. This is a highly significant statement, maybe even revolutionary, which was made in a forthright manner by an orthodox Hindu astronomer.

Pyramids in Egypt

GREGG DE YOUNG

The pyramids of ancient Egypt still stand beside the Nile, bearing mute testimony to the civilization that constructed them nearly 5,000 years ago. Considering the magnitude of the effort expended, it seems surprising that no information about their planning or construction has been preserved. Such mysteries have generated an incredible array of hypotheses and suppositions concerning both construction techniques and cultural implications of the pyramid.

History

The origins of pyramid construction are obscure. The stepped pyramid of Third Dynasty Djoser (ca. 2667–2648 BCE) at Saqqara appears to be an elaboration of earlier funerary architecture, combining First Dynasty *mastaba* (low, flat mud brick, or stone superstructure above a subterranean burial vault and storage compartments) forms with large, mud-brick walled funerary enclosures of the Second Dynasty. This pyramid appears to be a first experiment in large-scale stone construction. Beginning as a mastaba, it was enlarged horizontally several times before building upwards, perhaps because the original low mastaba was not visible behind the wall surrounding the complex. A passage on the north led to a subterranean burial chamber with 11 subsidiary burial chambers. The adjoining of storage chambers and corridors were decorated with blue faience tiles and relief sculptures of Djoser.

P

The Step-Pyramid is only the most obvious structure on the site. Also inside the enclosure wall were a complex of temples, pavilions, mastaba-like tombs, chapels, as well as extensive storage structures. Most important of these was the mortuary temple, possibly in imitation of the offering chapels attached to archaic mastabas, where offering on behalf of the dead Pharaoh might be made, placed on the northern side of the pyramid. (In later pyramid complexes, this mortuary temple was typically moved to the eastern side.)

The experiment in stone construction must have been regarded as a success, for the pyramid was rapidly developed in the Fourth Dynasty. The Pharaoh Sneferu (ca. 2613–2589 BCE) erected two pyramids at Dahshur, south of Saqqara. The Bent Pyramid's distinctive outline, with its shift from 54° to 43° showed the necessity for a solid foundation. Built with much larger stones than the Step Pyramid of Saqqara placed directly on the desert surface, subsidence, combined with carelessly laid core blocks, soon introduced internal stresses that caused fissures to appear in the structure. Learning from experience, Sneferu's architects constructed the Red Pyramid somewhat to the north of the Bent Pyramid. These early Fourth Dynasty pyramid complexes reveal the basic features of most later attempts. The pyramid is the focal point of an east–west oriented rectangular enclosure, which also contains an offering temple on the east side of the pyramid, and often one or more subsidiary pyramids. A causeway, usually covered, led from the pyramid complex down to a valley temple.

Following on these early experiments, the great pyramids of Giza were constructed. The largest was created by Sneferu's son, Khufu (ca. 2589–2566 BCE). Two somewhat smaller pyramids belong to his successors, Khafre (ca. 2558–2532 BCE) and Menkaure (ca. 2532–2503 BCE). These mark a high point in terms of sheer physical size and engineering prowess. The Fifth Dynasty pyramids at Abu Sir are often held to represent the highest development architecturally of the pyramid complex and associated valley temple, although they are distinctly smaller in size. They also reveal a significant decline in workmanship, perhaps paralleling the decline of centralized authority in the state. Their interior blocks were scarcely shaped, and the removal of the limestone casing blocks has left most of them looking like little more than piles of rubble.

Royal burials between the Sixth and Twelfth Dynasties largely abandoned the pyramid form. When it was revived in the Twelfth Dynasty (ca. 1895–1795 BCE), construction techniques had changed considerably. The interior structure often consisted of little more than stone cross walls to give solidity and rigidity to the mud brick or rubble-filled structure. The pyramids continued to be faced with high-grade limestone, however, and so would externally have looked very similar to earlier pyramids. They would have been more economical to build, however, since they require a considerably smaller work force, as well as utilizing cheaper building materials.

By the end of the Thirteenth Dynasty, pyramid building had once again been abandoned for royal burials. In the New Kingdom, however, there is evidence that the pyramid structure was reduced to a decorative architectural element of the superstructure of the funerary chapels for nonroyal burials. Important examples appear in the cemetery associated with Deir el-Medina, the town housing the workers who constructed the tombs in the Valley of the Kings and Valley of the Queens, the new royal necropolis on the west bank of the Nile across from Thebes.

Nearly a 1,000 years passed before the pyramidal form was reclaimed for royal burials by the Nubian kings. These pyramids are constructed from blocks of local sandstone. They have steep sides (approximately 70°) and are relatively small. Their apex is often flat. The burial chamber was not constructed inside or underneath the pyramid. Rather, the burial chamber, often decorated in Egyptian style motifs, was constructed and then the pyramid was erected above it. The pyramid fields at Nuri and el-Kurru (above the fourth cataract) were constructed mainly between 770 and 400 BCE. Meroe (between the fifth and sixth cataracts) was an active necropolis until nearly 350 AD. These sites contain more pyramids than have been discovered in the Nile Valley.

Construction Techniques

The pyramid of Khufu involved quarrying nearly 2.5 million blocks of limestone weighing on average between two and three tons, transporting them to the building site, and raising them into place. If the report of Herodotus, that the pyramid was completed in 20 years, is to be believed, this would require moving a block into place roughly every 3 min – a remarkable achievement indeed.

There is ample evidence to suggest that these pyramids were carefully planned, taking into account what had been learned in earlier construction attempts. The builders constructed a level foundation directly on the bedrock. The early suggestion that the site was leveled through surrounding the entire site with a low mud wall, filling the enclosure with water, and digging a series of trenches at uniform depth below the surface of the water (the intervening material could easily be removed later) no longer appears credible, but the precise technique remains rather mysterious. Most probably it was done by adjusting the foundation stones to provide a flat plane on which to build.

These pyramids are also remarkable for their accurate alignment with the four cardinal directions.

This alignment must have involved some sort of astronomical technique, since the Egyptians did not know the magnetic compass. One suggested technique involved bisecting the angle between the rising and setting point of a star in order to determine true North. Even this simple-sounding method would require the construction of an artificial level horizon and very precise observations in order to obtain the observed accuracy of alignment. A somewhat easier technique would require erecting a gnomon perpendicular to the surface of the earth and a circle constructed about it with some convenient radius. It is then necessary to mark the two points during the day when the shadow of the gnomon touches this circle, connect these two points to the gnomon and bisect the angle so produced in order to determine true North. Although requiring simpler equipment, the observations must still be made with careful accuracy in order to produce the orientation we observe in Khufu's pyramid.

Large quantities of stone had to be quarried and transported to the building site. Extracting blocks of relatively soft local limestone for use in the core of the structure posed no technical difficulty for the ancient Egyptians. The stone block could be defined using bronze tools and separated from the rock matrix with wedges. Facing blocks of higher-grade limestone were brought from Tura, on the other side of the Nile. Granite used in facing the corridors and chambers within the structure had to be quarried in Aswan and transported to Giza. A very hard Plutonic stone, it required use of dolerite stone tools to work, since copper and even bronze were too soft to be effective.

Once separated from the bedrock, the core blocks were transported to the building site on wooden sledges pulled by teams of men. The sledges could travel across firm surfaces using sets of wooden rollers as a kind of primitive wheel. If it were necessary to transport the blocks over sand, friction might be reduced by constructing a kind of roadway, embedding timbers in the surface on the pattern of railway ties. When wet, the wooden sledge would slide quite easily across these wooden beams. There is still no conclusive evidence to indicate whether dressage occurred at the quarry sites or at the construction site.

Once at the pyramid site, the blocks had to be raised into position. The most prevalent view is that this involved recourse to a system of ramps, although there is no agreement on straight or helicoidal ramps spiraling around the exterior of the pyramid. Either proposal requires considerable construction of an ancillary structure that would later need to be removed. Opponents of ramps question where the evidence is for removal of such large-scale ramps. The most common alternative suggestion has been the use of some form of jacking mechanism, either directly through levering or indirectly through use of "cradles" equipped with rockers that could be pushed to one side or the other while wooden planks were placed under the elevated side to raise the structure. (Examples of such rocker cradles have been found near construction sites.) In practice, however, raising blocks to the level of about a meter is difficult because the supporting structure becomes less stable with increased height.

More recently, a suggestion has been made that the "cradles" were not intended for rocking the stone upward, but that four cradles, attached to the faces of the block, might function as a kind of primitive wheel. A few preliminary tests indicate that such a configuration might work to move stones up a ramp. Another recent suggestion does away with both jacking and ramps, arguing that the blocks were simply pulled up the side of the pyramid mounted on their sledges and lubricated with water. Such an hypothesis would explain why there is little evidence of ramps surviving at the work site. It would also presuppose that the finished casing blocks must have been put in place immediately on completion of each course of core blocks. It also leaves open questions about the upper courses, where men would have had less room for maneuvering while raising the blocks a longer distance. Each theory has some merit to recommend it, as well as difficulties in application. It is likely that there was no single method used in every pyramid; probably an array of techniques was employed to solve these technical problems in various contexts.

In addition to the physical problem of raising heavy stones to a considerable height, it was necessary to control the shape of the pyramid in order to avoid deformations. Once again, we do not know exactly how the ancient Egyptians solved such problems. One of the simple-sounding techniques would be to measure the sides at each course of stone to make sure they are still square (assuming that one had successfully laid out a square base), perhaps checking by sighting across the pyramid on the diagonals. But actually carrying out such operations might prove difficult. Measurement would require either the repeated application of a measuring rod, which would allow small errors to cumulate over long distances, or by use of a measuring rope, which would be subject to stretching or sagging and so also allows for incursions of significant error. Again, we have no conclusive direct evidence. In this case, too, it is possible that various techniques were tried in various combinations on each pyramid that was constructed.

From very early dynastic times, there was a clear concern for security of tombs (including burial chambers within or below pyramids). Considerable treasure was interred with royalty, and wealth inevitably attracts robbers. Already at the construction of the Fourth Dynasty Bent Pyramid, we find use of a portcullis system by which large usually granite blocks could be lowered to block passages leading to the burial chamber. Sometimes these portcullis blocks came with a kind of locking device to prevent robbers from lifting them with levers: a short rod would be placed in a small shaft at the side of a portcullis channel of the same height and angled so that when the portcullis was lowered, the wooden rod would protrude into the channel, thus blocking any attempt to raise the portcullis. In practice, such devices rarely delayed robbers long. They simply tunneled around or over the portcullis. No more effective were the efforts to provide a means to block entrance tunnels with great blocks of granite drawn into the passage from the side or the use of gravity to slide granite blocks into a passageway, blocking access to the door to the burial chamber. Again, robbers were likely simply to tunnel past these obstacles. The lure of riches left no pharaoh undisturbed for long.

Pyramids of Mesoamerica

Geoffrey McCafferty

The construction of monumental architecture is one of the archaeological hallmarks of social complexity. It involves the ability to mobilize and coordinate labor; it requires surplus manpower and material; it implies sophisticated knowledge of architecture and engineering; and it assumes a fair degree of administrative control. In evolutionary terms, monumental architecture appears when there is a fairly high degree of complexity, with multitiered political organization in what can be characterized as "chiefly" or "stratified" society. In pre-Columbian Mesoamerica, this level of complexity first appeared in the Early Formative period, ca. 1200 BCE, among the Olmecs of the southern Gulf Coast. In time other cultures also adopted monumental architecture for primarily religious purposes but also as a legitimation of political authority.

The most typical form of monumental architecture used in Mesoamerica was the pyramid. Pyramids were often perceived as artificial mountains, and they represented attempts by the ruling elites to construct a symbolic landscape. Most pyramids were built to correspond to cosmological principles, such as astronomical orientation. They also represented the recreation of an *axis mundi*, a world axis where the pyramid became the cosmic center around which the rest of the universe revolved both vertically and horizontally. Mesoamerican pyramids were literally a "stairway to heaven" where a select few could rise above the mortal plane to communicate with deities of the multitiered heavens in temples on top of the pyramid platforms. Similarly, many pyramids were constructed over natural springs, caves, or artificially created portals into the underworld for access to the deities residing there. A pyramid, therefore, was a conduit linking the three planes of the cosmos, where powerful ruler/priests could communicate with the gods and petition them for supernatural assistance. In part because of this symbolic centrality, Mesoamerican pyramids were often rebuilt by encasing the old structure within new layers of fill and façade to enhance the cosmic significance with a connection to the ancestral past, and thereby adding a temporal dimension as well.

Pyramids were fairly basic in their architectural form, with simple mounds of packed earth as the most simple style. Others were made of mounded earth and rubble, sometimes segregated in cells for internal integrity. The most elaborately built pyramid was the Great Pyramid of Cholula, where the internal structure is made up of stacked adobe bricks to create a remarkably stable interior. Note that with very few exceptions the interior of pyramids was solid, lacking inner chambers. The importance of a Mesoamerican pyramid was as a platform for one or more temples located on top.

Despite the relatively simple internal construction, however, Mesoamerican pyramids were often elaborately decorated on the exterior. The staircase was a natural focus of the building program, since it was the means of ascending to the temple. Staircases were often quite steep, making a direct vertical climb difficult, particularly for heavily robed priests. One speculation is that ascent was made in a serpentine fashion, moving up diagonally. Priests in colorful robes and elaborate feathered headdresses, climbing in procession, would appear to spectators below as a polychrome feathered serpent undulating up to the inner sanctum of the temple. As will be discussed below, the Feathered Serpent god was a unifying theme of Mesoamerican religion, particularly as it relates to political legitimation and priestly knowledge.

Pyramid façades were generally finished in cut stone and covered with layers of stucco. Particularly in the Maya area they were often elaborated with symbolically significant carvings, often depicting powerful deities. The temples themselves were occasionally decorated with the image of the earth monster whose open mouth formed the temple entrance, a portal into the underworld. Maya temples also featured elaborate roof combs of stone rising high above the temple itself, created in lattice format to depict further cosmological images visible from great distances (Fig. 1). The Maya temples were constructed using the corbeled vault technique so that the weight of the roof and roof comb was transferred to the thick walls, in what was the crowning achievement of Maya structural engineering.

Mesoamerica, consisting of central and southern Mexico, Guatemala, Belize, Honduras, and parts of El Salvador, Nicaragua, and Costa Rica, is a culturally complex region that, during the pre-Columbian era, was often characterized by overarching similarities. Religious beliefs were one of these, and the use of pyramids was common to Mesoamerican cultures for over 2,500 years. Other commonalities included the calendar system, ritual ballgame, maize/beans/squash as dietary staples, and human sacrifice to appease the gods. Nevertheless, due to the cultural diversity some regional and temporal variations arose. The following is a brief survey of some of the important pyramids of Mesoamerica within their cultural contexts.

The earliest clear pyramid is known from La Venta and corresponds to the Olmec culture of the Middle Formative period (900–500 BCE). The pyramid itself is just one manifestation of a massive landscape modification as the ruling elite transformed the ceremonial center into a cosmogram that constructed their capital as the center of the universe. The pyramid itself is made of packed earth, and has been compared to an effigy volcano. The Olmec heartland is in the swampy lowlands of the Gulf Coast, so this pyramid may be a reference to the volcanic Tuxtla Mountains to the north, from which much of their building stone was imported. A more revealing monumental construction was intentionally buried beneath the plaza in front of the pyramid, where thousands of imported jadeite bricks were formed into a mosaic image of the jaguar-like earth monster and then covered by layers of imported, colored clays to symbolize the layers of the underworld. Taken as a meaningfully constructed building program, the La Venta ceremonial center represents the symbolic relationship between the three levels of the cosmos, as well as a major investment in labor and resources.

In the Maya lowlands, sites such as Uaxaxtun, Nacbe, and El Mirador demonstrate monumental architecture during the Late Formative period. El Mirador features the El Tigre pyramid complex, one of the earliest Maya pyramids that was also the largest in terms of volume at 380,000 m^3. Another early Maya pyramid is found at Cerros, where elaborate building façades are interpreted as representations of astronomical passages as the sun traveled from east to west on its daily journey. A symbolic reading of this again suggests that the universe revolved around the Cerros pyramid. This probably relates to both religious beliefs as well as political propaganda, as jadeite jewelry cached at the site has been interpreted as an indication of the creation of a Maya *ahaw*, or king, suggesting a new level in political complexity.

Monte Albán, located in the southern highland valley of Oaxaca, represents another example of monumental architecture that was begun in the Late Formative period (500 BCE–200 CE), though modifications continued through the Classic period (200 CE–800 CE). Located on a ridge high above the valley floor, Monte Albán's acropolis was created first by flattening the ridge top

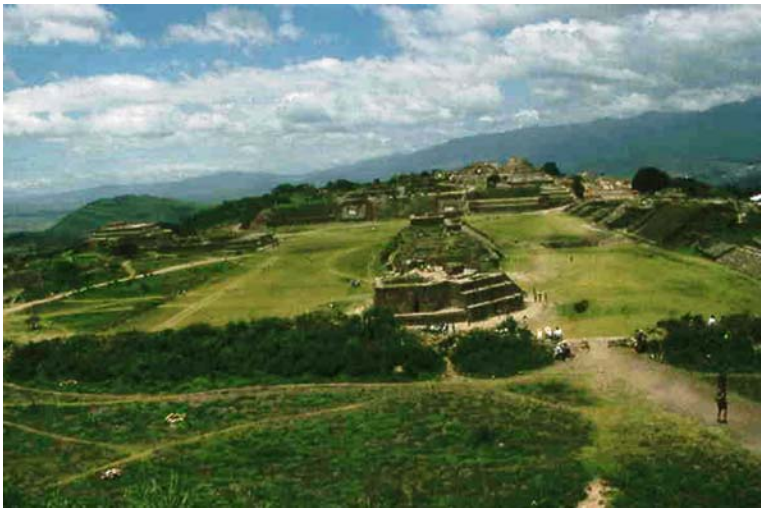
P

Pyramids of Mesoamerica. Fig. 1 Example of a Maya temple with roof comb (Palenque).

to form a level surface, then by building numerous large buildings around a rectangular plaza (Fig. 2). The largest pyramid is the South Platform, that in its final manifestation consisted of a massive platform with a smaller pyramid located on top. While religious practices were probably paramount on this structure, numerous carved stone slabs depict political scenes including captives and an emissary from Teotihuacan, emphasizing the interwoven nature of Mesoamerican religion and politics. The North Platform is even more massive, but probably had a more secular function. A wide staircase leads to a plaza where public rituals were likely held, before smaller passageways lead to a more restricted area that may have been the royal residence. Other smaller pyramids delimit Monte Albán's plaza, which is clearly outlined on the horizon and visible from the valley floor as a sort of "Big Brother is watching" political message.

In central Mexico the great urban center of Teotihuacan arose in the Late Formative period, and around 100 CE embarked on a major urban renewal program that included a rigorous grid system based on its Avenue of the Dead. The Avenue is oriented at 16° east of North, with a pecked cross marker in the bedrock of Cerro Gordo mountain as a datum point for aligning the Avenue. At the northern end of the Avenue is the Pyramid of the Moon, framed by Cerro Gordo behind it and actually designed to mimic the form of the mountain (Fig. 3). To the south is the Pyramid of the Sun, the largest of Teotihuacan's pyramids, and it too mimics the shape of Otumba mountain in the distance. A third pyramid in the western part of the city is similarly set in relation to the natural landscape, perhaps as an intentional cosmogram in which the hills and the pyramids represent the three hearth stones symbolic of symbolic centrality.

Excavations beneath the Pyramid of the Sun discovered a long passageway, excavated into the volcanic bedrock for building materials but then modified into an artificial cave where rituals were performed. The form of the inner chamber resembles the flower shape of Chicomoztoc, the cave of origin



Pyramids of Mesoamerica. Fig. 2 Acropolis of Monte Albán.

Pyramids of Mesoamerica. Fig. 3 Teotihuacan's Pyramid of the Moon.

Pyramids of Mesoamerica. Fig. 4 Serpent/Axolotl on façade of Teotihuacan's Feathered Serpent Pyramid.

from later Aztec mythology, suggesting that later peoples may have continued to worship in the artificial cavern at Teotihuacan. The entrance to this tunnel is beneath the west facing staircase onto the Avenue of the Dead, and therefore faces 16° north of west, the orientation of the setting Pleiades constellation which marks the beginning of the rainy season. It is possible, therefore, that the entire urban renewal program around the Avenue of the Dead makes Teotihuacan an elaborate celestial almanac relating to the all-important rains.

Recent investigations into Teotihuacan's Pyramid of the Moon, as well as the Pyramid of the Feathered Serpent, have discovered sacrificial burials of warriors, perhaps as dedicatory offerings to the lords of the underworld. These burials are clustered in groups of 9, 13, and 20, numbers symbolic of cosmological principles including the sacred 260-day calendar. The stone façade of the Feathered Serpent Pyramid features a long rattlesnake body (covered in feathers) undulating in profile but with a front-view head surrounded by more feathers (Fig. 4). This image is generally identified as a "feathered serpent" but is also similar to the *axolotl*, a species of salamander that lives in the lakes of central Mexico and has feathery gills that encircle the head. On the back of the serpent is an elaborate mosaic headdress representing political office (a similar scene adorns the mosaic façade of the Nunnery Compound at the Maya site of Uxmal). Curiously, the west façade of the Pyramid of the Feathered Serpent was covered over by later construction to obscure, and thereby unintentionally preserve, this iconographic program.

Pyramids dot the Classic Maya landscape where, because of the prevalence of textual evidence on carved stone markers, they can occasionally be related to the particular ruler who commissioned their construction. Some of the most impressive pyramids come from Tikal, the capital of a Maya "superpower" of the sixth through ninth centuries. For example, Temple I reached 52 m in height, with its temple structure and roof comb reaching above the current jungle canopy (Fig. 5). Contemporaneous with these is the Temple of the Inscriptions from Palenque, where extensive hieroglyphic texts record the lineage history of King Pakal. A trapdoor in the floor of the temple led to a passageway down through the pyramid itself to a subterranean chamber where Pakal's sarcophagus was

Pyramids of Mesoamerica. Fig. 5 Tikal Temple I.

found (Fig. 6). This use of a pyramid to enshrine a ruler is unusual in Mesoamerica. Other pyramids at Palenque include the Cross Group, where three small temples represent the three hearth stones, a Mesoamerican metaphor for the cosmic center. Another major Maya center was Copán, located in modern Honduras. It is famous for its elaborately decorated architecture and the many carved stone stelae that recount dynastic histories. Its largest pyramid was Temple 26, known for its hieroglyphic staircase representing the longest known text in the Mayan language; unfortunately early explorers stripped the carved stairs from their original position before randomly replacing them out of order so attempts at decipherment are still furtive.

Following the collapse of Teotihuacan and Monte Albán at the end of the central Mexican Classic period (ca. 700–800 CE), Maya influences in the central highlands of Mexico resulted in architectural innovations that affected pyramids at sites such as Xochicalco, Cacaxtla-Xochitecatl, and Cholula. Similar to Monte Albán for the scale of modifications to the natural hilltop, Xochicalco is best known for its Temple of the Feathered Serpent. Large feathered snakes curl around the walls of the pyramid base, with Maya-style lords seated within the curves of the serpent's body (Fig. 7). Glyphic inscriptions in a non-Maya – and as yet undeciphered – script likely describe conquests and/or political alliances. Cacaxtla boasts beautiful polychrome murals, again in Maya style, on the walls of Building B at the north end of its acropolis. The murals depict the aftermath of ethnic conflict between an army with Maya costume and physiological traits, who have been defeated by another group. As a result of this battle the female war-chief of the Maya group is

Pyramids of Mesoamerica. Fig. 6 Palenque's Temple of the Inscriptions, indicating passage to a subterranean crypt.

Pyramids of Mesoamerica. Fig. 7 Temple of the Feathered Serpent at Xochicalco.

Pyramids of Mesoamerica. Fig. 8 Great Pyramid of Cholula with church to the Virgin of the Remedies on top.

captured, perhaps to become the founding queen of a new, united lineage. On the adjoining hill of Xochitecatl, the Pyramid of the Flowers was likely dedicated to a goddess cult. The staircase is made up of basalt grinding stones, an artifact closely associated with female domestic practice. On top of the pyramid, caches contained dozens of female figurines depicting different phases of the female life cycle, especially motherhood, and also hundreds of clay spindle whorls, another characteristic of female practice.

The largest pyramid in Mesoamerica is at Cholula, located in the Puebla/Tlaxcala valley east of Mexico City. It was built in successive stages over a period of over 1,000 years (Fig. 8), and it remains an important religious site with its Colonial church dedicated to the Virgin of the Remedies perched on top and attracting tens of thousands of pilgrims annually. The Great Pyramid of Cholula is known as *Tlachihualtepetl*, literally an artificial mountain. Its construction history has been studied using 8 km of tunnels cut through the adobe brick construction to reveal at least four major construction stages. The final stage measured at least 400 m on a side, and 65 m in height (although the construction of the Colonial church undoubtedly destroyed the uppermost levels). The Great Pyramid was oriented toward the setting sun at summer solstice, the longest day of the year, so that the temple on top of the pyramid would have been the last place illuminated by the setting sun.

The relationship between Maya and central Mexican architecture is particularly strong at the sites of Chichen Itza, in northern Yucatan, and Tula, located far to the west. Chichen Itza features Puuc style architecture with elaborate stone mosaic work to create geometric patterns and visages of deities (Fig. 9). But it also has other architecture with distinctive features that have traditionally been labeled "Mexican" following ethnohistorical accounts that Toltecs from central Mexico invaded the region. This interpretation has been challenged, however, with new dates that suggest that Chichen predates Tula, the highland capital of the Toltecs. Numerous decorative features from both Chichen Itza and Tula are virtually identical, including the use of reclining Chacmool thrones, feathered serpent columns, and colonnaded areas. The close similarities between the two sites has led many to suspect that the two were eastern and western capitals of an extensive Toltec empire, but a near total lack of related elements in the intervening territory adds to the enigmatic status of the two sites. The large pyramid at Chichen Itza is notable because of the feathered serpents that flank the radial staircases (Fig. 10). The pyramid is oriented so that, at the spring equinox, shadows formed by descending serpents appear to undulate down to earth; this phenomenon is a popular tourist attraction drawing thousands to witness the illusion, including living Maya who continue to revere the site. At Tula, north of modern Mexico City, the ceremonial center has a nearly identical plan (albeit 90° off from Chichen Itza). Pyramid B closely resembles Chichen Itza's Temple of the Warriors, with stone warriors as building columns that must have supported the roof (Fig. 11).

The Gulf Coast site of El Tajín does share some iconographic characteristics with Chichen Itza, especially in the use of elaborately carved columns and ball court. Narrative qualities of the carvings seem to relate to political legitimation and alliance building, again emphasizing the ideological content of the built environment. The major pyramid at El Tajín is known as the Pyramid of the Niches, named for 365 empty niches that decorate the façade (Fig. 12). Conceivably these would have originally held idols of gods associated

P

Pyramids of Mesoamerica. Fig. 11 Pyramid B from Tula, showing warrior columns.

with different days of the solar year. Large slabs at the base of the pyramid were drilled with holes where banners representing conquests or forged alliances would have been raised.

The final pyramid to be discussed is also the best known, though ironically it is almost invisible today. When the Spanish entered the Aztec capital of Tenochtitlan in 1519, the Great Temple was the ceremonial center of the Aztec empire. Spanish conquistadors described the temple and associated rites of sacrifice, and artists in the early Colonial period illustrated the Temple. Typical of Aztec pyramids, the Great Temple featured two temples atop a single pyramid base. These were dedicated to Huitzilopochtli, the patron god of war, and Tlaloc, god of storms and rain (Fig. 13). However, shortly after the Spanish defeated the Aztecs they tore down the Great Temple to build their own Colonial capital. Fortunately for later archaeologists the lowermost levels of the pyramid were preserved beneath the rubble (Fig. 14). When utility workers dug at the site in the 1970s they chanced upon a massive carved stone representing the dismembered moon goddess Coyolxauhqui, and based on this discovery a monumental excavation project was begun by the Mexican government to expose the remains of the Great Temple. According to Aztec myth, the Great Temple represented the serpent mountain, Coatepec, where Huitzilopochtli killed his sister, Coyolxauhqui, while defending his mother, Lady Serpent Skirt/Coatlicue. This mythico-historical drama was played out at the Great Temple, which featured serpent head iconography to make it "Serpent Mountain," while the dismembered moon goddess lay at the base of the staircase. Archaeologists have found hundreds of ceremonial offerings at the Great Temple that further emphasize the symbolism of the site. For

P

Pyramids of Mesoamerica. Fig. 14 Excavated Great Temple of Tenochtitlan.

example, stone boxes contain layered dioramas of the three-tiered cosmos represented by successive layers of sea, land, and sky creatures. Sacrificial victims climbing the steps of the pyramid, only to have their hearts removed and their bodies hurled back down the bloody steps, were themselves participating in the mythic drama of creation and rebirth.

The Pyramids of Mesoamerica are among the most visible monuments of the ancient cultures of the region, and the stories that they tell are important clues to the belief systems of the people. Modern tourists marvel at the grandeur of these structures, built using Stone Age technology and without the benefit of draft animals or complex engineering. In fact, the pyramids of Mesoamerica are relatively simple mounds of rock and rubble, albeit decorated with often elaborate stucco façades. What is truly remarkable about these monuments is the meaning content that they embody, as cosmograms reenacting and centering cosmic forces, and as political narratives to legitimize the ruling elite. These pyramids encode important messages about Mesoamerican belief systems, and the critical yet imaginative interpretation of these monuments reveal the mythstories of the Mesoamerican world.

Qāḍīzāde al-Rūmī

Gregg De Young

Qāḍīzāde al-Rūmī was born in Bursa, in Turkey, about 765 AH/AD 1364. His talent for scholarship was early recognized, and he was recommended to continue his studies of mathematics and mathematical astronomy among the scholars of Transoxiana (a portion of Central Asia that corresponds today with parts of Uzbekistan and Kazakhstan), then a major center of scholarship. Consequently, about 814 AH/AD 1410, he went to the court of Ulugh Beg, governor of Samarqand (in what is now Uzbekistan) and serious amateur astronomer, and joined his retinue.

In 824 AH/AD 1421, 4 years after establishing a major *madrasa* (school of advanced studies), Ulugh Beg decided to establish an observatory in Samarqand in order to complete and improve the data collected by Naṣīr al-Dīn al-Ṭūsī and his assistants in the *Zīj al-Ilkhānī*. Al-Rūmī, along with his younger contemporary, Ghiyāth al-Dīn Jamshīd al-Kāshī (d. 832 AH/AD 1429), played an important role in both institutions. When al-Kāshī died, al-Rūmī succeeded him as director of the observatory. The work was still incomplete at the time of al-Rūmī's death in 840 AH/AD 1436. It was finally completed under ʿAlī Kushjī under the title *Zīj-i Jurjānī*. In addition to his role in producing these tables, al-Rūmī authored *Sharḥ Mulakhkhaṣ fī'l-Hay'a* (Summary Commentary on Hay'a/Mathematical Cosmography), an influential commentary on ʿUmar al-Jaghmīnī's (d. ca. 745 AH/AD 1345) compendium of cosmography.

In the field of mathematics he is best known historically for his commentary on al-Samarqandī's *Ashkāl al-Taʾsīs* (Fundamental Theorems). His *Risālat al-Jayb* (Treatise on the Sine) displays a greater independence of thought, but even here he relies on the iterative techniques developed by al-Kāshī in order to find the sine of one degree.

Qanat

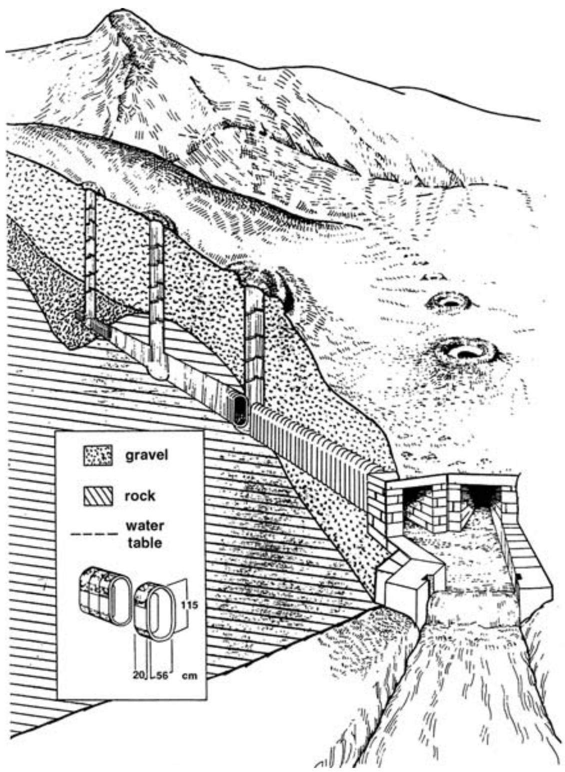
Arnold Pacey

The *qanat*, invented in Iran, is a tunnel that allows a well in hilly country to supply water to users on lower ground by gravity flow.

Once the well has been sunk and has proved to be a good source of water, the route of the tunnel is carefully surveyed, and a series of further wells or guide shafts is dug, each one about 300 m from the next. Excavation of the tunnel begins at the intended outlet and proceeds from the foot of one guide shaft to another. The depth of these shafts has previously been set, so that when the tunnel links them all together, it will have an even gradient of about 1:500. The head well may be anything from 15 to 100 m deep, and tunnels are frequently 2,000 m or more in length (Fig. 1).

As Andrew Watson points out, the history of the qanat can be clearly illustrated by a distribution map showing where water supplies of this kind are to be found. Before the time of Alexander the Great, i.e., before 330 BCE, about the only qanats known to have existed were in Iran. A thousand years later, around AD 700, qanats had been constructed in the Arabian Peninsula and Syria as well as in Persia. But then the Islamic people took up the qanat in a big way. Books were written on the subject in AD 840, and by al-Ḥasan al-Ḥāsib around AD 1000. Knowledge of the technique spread east to Afghanistan and west through North Africa to Morocco, Mauretania, and Spain.

Qanats continued to be developed in later centuries. By the sixteenth century, potteries were making earthenware rings for lining the tunnels where they passed through soft ground. In 1960, three-quarters of all water used in Iran came from qanats, with Tehran



Qanat. Fig. 1 Two qanat tunnels in a typical landscape, where rainwater running off mountains replenishes groundwater beneath the sand and gravel of the lower slopes. (Water-bearing gravel is shown darker than the dry gravel layer above.) The ground penetrated by one of the qanats is shown in cut-away section to demonstrate how the tunnel gives access to water trapped by impervious rock. The section also shows how the tunnel is lined with earthenware rings when passing through sand or gravel layers which might otherwise cave in. Qanat tunnels were excavated from the bottoms of a series of well shafts, with the "mother well" at the upstream end dug first to prove the existence of water. The tunnels were sometimes several kilometers long with their route evident on the surface from the line of well shafts, as on the right of the picture. (Illustration by Hazel Cotterell based on sketches by Arnold Pacey. Reproduced from Pacey 1990: 86.)

alone having 36 of them bringing water from hills several miles away.

The word "qanat" in Arabic is said to be the source of the English word "canal," which was initially used to mean a pipe or tube or tunnel carrying liquid; it retains that usage in anatomy – hence, alimentary canal.

Qi

Steven Klarer, Ted J. Kaptchuk

In Chinese culture, *qi* is the common denominator that underlies all being and all behavior and that allows for their interaction and their interpenetration. *Qi* enables seeds, air, and soil to become plants, a mountain range to produce good fortune, or a human being to cultivate wisdom and human kindness. It is what makes possible the processes of chemistry and the researches of the alchemists. *Qi* is the fundamental Chinese articulation of what underlies the universe, what is the universe, and what is the reality of the universe.

Given the key position the concept of *qi* holds in explaining the process of change in Chinese scientific, medical, psychological, and spiritual thought, one is tempted to assume that it is one of the oldest and most central concepts in the Chinese world view. A look at the history of both the character and the concept shows otherwise.

The oldest inscriptions in Chinese, the bones used in the Shang dynasty oracle, are concerned with understanding the process of change in such uncertain areas as agriculture and illness. Nowhere in the more than 200,000 known extant oracle bones can one find the character *qi* or anything which might be its close antecedent or relative. Throughout the oracle bone inscriptions we see that, in Shang culture, change was brought about by the actions of spirits rather than by naturalistic forces.

The character *qi* is composed of an element which signifies vapors which rise to form clouds and another element which means grain. The character may mean vapors arising from cooked food or simply steam. At this level of the character's history *qi* is a simple notion. *Qi* is what makes the lid on a pot of boiling water rattle.

In the course of its development Chinese thought began to look for the origins of change in sources other than the spirits. For a time change, especially illness, was understood to come from the winds of the eight directions, each of which was responsible for causing particular diseases at particular seasons and each of which was personified as a deity. Although this model of change brought about by wind is a step toward a world of naturalistic causality and away from a world of spirit causality, it still has a strong component of the latter. It is probably, however, a major step in the development of the concept of *qi* which later comes to permeate all of Chinese thought.

By the time of Confucius (551–479 BCE), the word *qi* appears in literature but it is rare and its meaning is confined to purely human qualities. The *Analects*, the record of Confucius' teachings, use the word four times, each of which is distinctly related to some aspect of human behavior, such as appetite, tone of voice, breath, and physical stamina. In none of these does it refer to anything beyond a specific physical quality of human life. At this stage in its history *qi* still shows its origin as a common, ordinary term.

The several centuries following Confucius were a critical time of change in Chinese culture. One of the key concepts to emerge at this time was *qi*. Mencius (371–289 BCE), the follower of Confucius, refers to *qi* 19 times and each time it is a concept of major philosophical import. *Zhangzi*, between 399 and 295 BCE, a major Daoist text, refers even more frequently to *qi*. In this text we see one of the earliest and clearest uses of *qi* to refer to a natural force, something which, although an attribute of human beings, is also a power which makes things happen in the world. We see this conceptualization of *qi* (although still connected to wind) as a moving power in the universe in a famous passage from the *Zhangzi*.

> The great clod belches out breath (*qi*) and its name is wind. So long as it doesn't come forth nothing happens, but when it does, the ten thousand hollows begin crying wildly.

Here *qi* is a conceptual model for explaining and understanding the process of change in the observable world. The Shang world of a supernatural spirit causality which had developed into the world of semisupernatural wind causality has now become a world of natural causality. The *qi* model explains the process of change and development in a naturalistic way which is conducive to the expansion of philosophic and scientific thought and inquiry.

By the late third century BCE we see *qi* becoming a concept used throughout Chinese thought. This conceptualization/experiential model is used to explain the qualities of plants and animals, the uses of herbs, and the influences of climate, weather, and geographic location on people. From its use to explain the process of disease and illness comes psychological insights into character and personality types. Eventually, through philosophers such as Wang Yangming (1472–1529), *qi* becomes an essential quality which enables all change since, no matter how they seem to differ, all things share the same *qi*. It also becomes a moral spiritual quality allowing for the oneness of all being.

In recent times, possibly under the influence of Western thought, *qi* has frequently been identified with the Western concept of energy. Westerners are by no means the only ones to make this equation. To characterize *qi* as energy is to invoke a worldview which the Chinese never had, a worldview in which matter and energy are different things. While it is true that modern scientific theory no longer holds that matter and energy are separate entities the words have come, through several centuries of use, to connote, in common parlance, distinct, and separate entities. To the Chinese matter was never inert; it always had dynamic and teleological properties.

As Western concepts of physics have caused some to think of *qi* as energy, nineteenth century western concepts of vitalism have caused it to be identified, especially in medicine, as some form of vital force, distinguishing living things. Historically, however, *qi* has been as much an attribute of a rock or river as of a person or animal. To call *qi* energy or life force is as erroneous as it is to call it matter. It is all and it is neither. *Qi* is the fundamental Chinese articulation of the interconnectedness of the universe, of what the Chinese call the 10,000 things. *Qi* is the cause, process, and outcome of all activity in the cosmos.

Qianjin Yaofang

Richard Bertschinger

The *Qianjin Yaofang* (Remedies Worth their Weight in Gold), and its sequel the *Qianjin Yifang* (More Remedies Worth their Weight in Gold), were written by the physician and alchemist Sun Simiao (also called Sun Simo) in 652 and 682, respectively, during China's Tang dynasty.

These books are especially valuable for the breadth of their content. They described the medicine of the day, both the systematic acupuncture and herbal tradition, and the less organized folk tradition. Unfortunately neither has as yet been translated into a Western language.

Sun built on the work of Zhang Zhongjing's earlier *Shanghan Lun*, especially in advocating the careful selection, picking and preparation of herbs. In acupuncture he devised the system of *ahshi*! (ow! that's it!)

points, or needling at the tender muscle nodules. These books also contained the author's newly verified and drawn charts of the channels and points on the body, with front, side, and back views – the earliest-known point charts to have been produced. The 12 channels were shown in five colors, while the eight extraneous channels were depicted in green.

Many of Sun's ideas were closer to Western notions of common sense. For instance he put disease down more to incorrect diet than to the influence of evil ghosts and spirits. He advocated general cleanliness to protect against the development of sores and ulcers, and he urged rinsing the mouth out several times after a meal to keep the teeth healthy and the breath fresh. During childbirth he said not more than two or three people should be allowed into the delivery room, to keep the mother quiet and the atmosphere calm, and he excluded anyone who had recently survived a fatal illness. He thus showed an awareness of complications arising in labor through the nervousness of the mother, and of infection spreading to the mother or newborn child. He also advocated the use of gentle exercise in imitation of animals in order to prevent disease and combat the process of aging. He introduced the treatment of night-blindness with goat or ox liver (which is rich in Vitamin A), the use of the thyroid glands of sheep or deer (equally rich in iodine) for a swollen thyroid, and abstaining from salt in cases of edema.

He innovated a clear ethical stance on medical practice, urging the doctor to be vigorous in investigating the disease and finding a suitable treatment. Many of his methods are in line with modern thinking. His work was equally valued in both Japan and Korea and works in these countries quote extensively from his tracts.

Qibla and Islamic Prayer Times

MOHAMMAD ILYAS

Ṣalāt (prayer) is one of five pillars of Islam. Islam requires all adult sane, healthy, and able-bodied Muslims to perform five daily prayers. The corresponding time intervals are commonly known as "Islamic prayer times."

Muslims are enjoined to face the *Kaᶜba* in Mecca during their prayers. It is believed that *Kaᶜba*, the cubical shaped edifice, was built by the Prophet Abraham. The direction to the *Kaᶜba* from a place is known as its *qibla* direction. Mosques are built with a clear pointer in the qibla direction. Knowledge of the qibla direction is also important for certain other acts, including the call to prayer (*Adhān*), the ritual slaughter of animals for food, and burial of the dead. Muslim astronomers from early times dealt with the determination of the *qibla* and produced highly sophisticated trigonometric and geometric solutions.

The time intervals of the specified daily prayers are clearly specified. The intervals are exclusive of each other; the end of one time interval marks the beginning of the next. Besides regular prayers, there are supplementary prayers, and some of these follow specific time intervals. There are also certain periods of the day during which prayers are prohibited. All this reflects the need for a clear understanding of diurnal phenomena and the proper determination of the time of day. The way in which the various Islamic prayers are distributed throughout the day further emphasizes the treatment of day and night as a single time unit, in contrast to the practice of earlier civilizations in treating them separately. Also, the mutually exclusive time intervals for each regular prayer, which depend upon the specific (local) positions of the sun, introduced a new way of dividing the day.

The Islamic prayer times are so defined that they can be easily ascertained by observation on a clear day. However, under cloudy conditions, one has to resort to some sort of a time clock and mathematical computation. Since the performance of regular prayers within the specified time intervals is a most serious matter, advance determination of the intervals is of great importance. From the very beginning, Muslim scientists were engaged in mastering the techniques of positional and observational astronomy, including instrumentation, and went on to develop this and allied fields. It is not surprising to find that almost all major astronomical works during that period of 500 years incorporated a discussion relating to the Islamic prayer times, which came to be known as *ᶜIlm al-mīqāt* or the times of "fixed positions" of the sun. Closely associated with the Islamic prayer times is the matter of determining the direction of Mecca. Elaborate tables showing the direction of the *Kaʾba* from different parts of the world became an integral part of Islamic astronomical works.

The demarcation of various time intervals is based on the guidelines contained in the *Qurᶜān* and elaborations given in the *Ḥadīth* (Traditions) of Prophet Muḥammad. Based on these, the time intervals were subsequently translated into more precise definitions by the theological jurists of the early centuries of Islam. Muslim astronomers helped to translate these into equivalent astronomical definitions.

In Islam, the day begins at sunset and the time for the first prayer (*maghrib*) begins after the sun has set. The second (*ʿishāʾ*) and third (*fajr*) prayers then follow, the latter ending before the sun begins to rise. The fourth prayer (*ẓuhr*) is performed after midday and is followed by the fifth and last obligatory prayer (*ʾaṣr*) in the afternoon. The optional prayers performed after midnight (*tahajjud*) and a little after sunrise (*chasht*) have special importance. The time durations during which the sun rises, sets, and crosses the local meridian are prohibited times and no prayers are generally allowed during these periods. Thus, one has to determine the various portions of the day in a sequential and somewhat symmetrical way.

As we know, the "true" solar day-length keeps changing through the seasons. Therefore, on a 24 hour civil clock, the solar phenomena, such as midday and midnight, keep moving backward and forward. However, as the Islamic time intervals are related directly to the true natural (solar) phenomena and not to the day length, it simply boils down to the daily determination of the times of various astronomical phenomena according to whatever day-time system is used, e.g., time-hours or time-degrees would be equally applicable. This situation obviously laid down strong foundations for mathematical–dynamical astronomy. Also we can recognize that the "day-time" length depends upon the season and the latitude and varies from a winter minimum to a summer maximum. For Islamic fasting, which is done from dawn to sunset, some countries are favored (shortest duration) in one season and others in a different season. In Islam, this situation has been fully taken care of through the rotation of the Islamic (lunar) months through the seasons.

Muslim astronomers during the medieval period made considerable efforts to construct tables of Islamic prayer times according to the defined solar positions. The data on the solar position (azimuth) at different altitudes was also used for observationally determining the direction of the *qibla*. It was important to present the prayer times in the form of basic universal tables which would remain unchanged over a long time. These tables could then be used through secondary and smaller tables which could be recomputed if necessary.

These tables were universal, since the Muslims used a purely lunar calendar independent of solar calendar dates. For each new day/date, one simply needed to ascertain the solar longitude by direct measurement or through the simultaneous measurement of positional parameters at meridian passage.

Muslim astronomers' interest in regulating daily time went beyond the determination of prayer times to include overall time measurement. Their tables contained information on various time parameters, such as length of daylight and duration of the fasting period (from morning twilight to sunset), auxiliary tables on various functions needed in computations, and special tables on parameters such as the solar azimuth and solar altitude in certain azimuths for use in *qibla* determination, besides supplementary information on such parameters as horizontal refraction. The prayer tables were generally produced with great computational skills and care and in a comprehensive way. A study of Cairo's tenth-century astronomer Ibn Yūnus' *Kitāb Ghayat al-intifa' fi ma.'rifat al-da'ir wa-faḍlihi wa-l-samt min qibal al-irtifāʿ* (Very Useful Tables for Finding the Time since Sunrise, the Hour Angle, and the Solar Azimuth, from the Solar Altitude), one of the major *mīqāt* tables, shows that Ibn Yunūs' values were, in general, very carefully computed. The tabular works incorporating *ṣalāt* times and other auxiliary tables were prepared for various major localities of the Muslim world, such as Cairo, Mecca, Medinah, Jerusalem, Damascus, Tripoli, Aleppo, Tunis, Istanbul, Baghdad, and towns in West Africa, Andalusia and the Indian subcontinent. Later work by a Damascus astronomer, al-Khalīlī (fourteenth century), greatly expanded the dimension of *mīqāt* tables by latitude and longitude degree of the globe. David King's comparison of al-Khalīlī's data with modern calculations shows his work to be remarkably accurate. Al- Khalīlī's tables may thus be considered to present the first global data set on the *qibla*.

We noted how, through the ingenious use of solar longitude, the Tables were made time-invariant and independent of the solar calendar, and the computational system was further expanded to determine the solar altitude for a specific solar azimuth, giving the direction to Mecca. In this way, an accurate astronomical method was developed to meet an additional need. The remarkable achievements in mathematical astronomy mark the high points of Islamic astronomy.

In the period after the introduction of the mechanical clock, a 24-equal-hour civilian day took over from the 12-hour daytime and 12-hour nighttime day which had dominated civilian timekeeping systems well into the fourteenth century. Although Muslim scientists had started to utilize an Islamic equal hour day, the use of true solar time and sundials prevailed in non-European and Islamic countries for quite a while. The detailed tables of Islamic prayer times constructed for specific localities of the Muslim world in the early centuries have remained in effective use right into modern times.

We are aware that as we go toward the higher latitudes, the usual cycle of daylight, twilight, and night begins to change during certain parts of the year. First, the night gets shorter and shorter with the increasing latitude, until the evening twilight merges with the morning twilight. In other words, the clear distinction of the end of the evening twilight from the beginning (or end – depending how one looks at it) of morning twilight no longer exists, and the determination of times for the beginning of *ishā*, *fajr*, and fasting cannot be done through the conventional solar position basis. As one moves toward the higher latitudes, even the twilight period gets shorter, to the extent that the end of the day merges with the beginning of the day, so that the sun does not set (or rise) but remains continuously above the horizon. In a situation like this, with 24 hours of daylight, how is one to determine the times of *fajr* and *maghrib* prayers and how is one to fast a "nonending daylight" day? This is one of the questions that needs to be tackled within the theological rather than the scientific arena.

Qin Jiushao

Ulrich Libbrecht (Revised By Andrea Eberhard-Bréard)

Qin Jiushao is one of the few mathematicians in China of whom we have fairly detailed biographical data, since he held subsequent positions in government administration. Although not mentioned in the biographies of the official Song dynasty historical annals, numerous references to Qin Jiushao can be found in local monographies or writings by his contemporaries.

Qin was in all probability born in 1202 in Puzhou (now Anyue in Sichuan province). In his youth he was commander of the "patriotic soldiers", an armed force outside the regular military establishment, in his native place. In 1224–1225 his father was given an appointment in the capital of Southern Song, Hangzhou. In the preface to his *Shushu Jiuzhang* he says, "In my youth I was living in the capital, so that I was able to study in the Board of Astronomy; subsequently, I was instructed in mathematics by a recluse scholar". According to analysis of his mathematical work he must have studied the *Jiuzhang suanshu*. In 1226 he was staying with his father in Tongchuan (now Santai in Sichuan province). When the Mongols began their conquest of Sichuan and destroyed its capital Chengdu in 1235, Qin was at the frontier as a military official.

According to his own preface it was during this period of distress that his mind went back to the mathematical studies started in his youth. He escaped calamities by going to the southeast. He was appointed subprefect in Qizhou (now Qichun in Hubei), where he behaved badly, causing a military revolt. Later he was appointed prefect in Hezhou (now Hexian in Anhui), where he was responsible for the salt trade and sold salt illegally to the people, so that he left the southeast as a rich man, settling in Huzhou in Zhejiang. In 1244, he was named Court Gentleman for Comprehensive Duty in the prefecture of Jiankang (now Nanjing in Jiangsu). After three months he resigned because of his mother's death and returned to Huzhou. It was during this 3-year mourning period that he wrote his mathematical work, which appeared in 1247. As a consequence he was recommended to the throne on account of his calendrical science, and he was allowed to take part in the examinations. We can only suppose that something went wrong, as we find him as consultant of the Directorate of Military Affairs in Jiankang from 1253 until 1259. However, after that he resigned and went back to his native place. He paid a visit to chancellor Jia Sidao, and he got an appointment as prefect of Qiongzhou (now Qiongshanxian) in far Hainan. But after a few months he had to leave Qiongzhou because he was impeached for corruption and exploitation of the people. He followed his friend Wu Qian, who was a naval officer in the district of Yin in Zhejiang, and in 1259 he was appointed assistant in the Court of the National Granaries there. Wu Qian subsequently became a minister, but when he was disgraced in 1260, chancellor Jia Sidao also collected data about Qin, and put him away in Meizhou (now Meixian in Guangdong), where he died in 1261 at the age of 60.

Quadrant

RICHARD P. LORCH

The quadrant is an instrument which was used for measuring angles and for making astronomical calculations. Apart from those for the accurate observation of altitude, known to us almost entirely from written descriptions, the quadrants of the Arabic Middle Ages were portable. They fall into three categories: those carrying a projection, or two-dimensional representation, of the celestial sphere (the imaginary sphere containing the stars and celestial circles); those designed for astronomical calculations; and horary quadrants, i.e., those used specifically for telling the time by the altitude of the Sun. Most have a thread fixed at the vertex carrying a movable bead for transferring distance from the vertex from one point of the instrument to another. Of the first type the best known is the astrolabe quadrant, invented before 1100. These are essentially the plate and rete of a standard astrolabe overlaid on one another. The motion of a star (or the Sun) is imitated by the motion of the bead, which has been set by putting it over the representation of the star, about the vertex. In the *shakkāzīya* plate associated with the name of ʿAlī ibn Khalaf (eleventh-century Toledo) and taken over by al-Zarqāllu (Arzaquiel), celestial coordinates may be converted (e.g., ecliptical coordinates into equatorial) either by moving one projection over another or by using one twice and transferring one set of coordinates to the other by means of the thread and bead.

The second type of quadrant is closely related to graphical solutions of astronomical problems by ruler and compasses, the function of the compasses being taken over by the string and bead (or ruler) fixed at the vertex. Many astronomical calculations involve the use of sines of arcs in a standard circle (a sine is half the chord spanning double the arc) and these may be drawn as lines parallel to one side of the quadrant. Multiplication may be achieved by the help of scales and the thread and bead. The sine quadrant is well attested in the tenth century and was probably known in ninth-century Baghdad.

The horary quadrant was a quadrant on which "hour-lines" were represented on the face of the instrument by circular arcs issuing from the vertex. The altitude of the Sun is taken by using sights on one side of the instrument and seeing where the thread, weighted with a plumb-bob, falls on the markings. When the position of the bead has been set for the day (e.g., by the noon altitude and the corresponding hour-line), the time can be read off from its position among the hour-lines. In some forms of the instrument a ruler or alidade takes over the functions of the thread and bead. The hours measured by the instrument are "seasonal" hours, for which 1 h = 1/12 time of daylight. The instrument, which is universal, is inaccurate in high latitudes. Underlying the instrument is an approximate formula, which probably came from India, used for calculating tables and also applied to a type of sine quadrant. Horary quadrants and related instruments were often provided with a cursor, or sliding plate carrying markings to facilitate the initial placing of the bead.

There were several further varieties of quadrant – e.g., horary quadrants for fixed latitudes – and also numerous mixed forms. Much of our knowledge of the rarer forms comes from the encyclopedic treatises of al-Marrākushī (thirteenth-century Cairo) and Ibn al-Sarrāj (fourteenth-century Aleppo). The "new" quadrant of Jacob ben Machir (thirteenth-century France), with its combination of horary quadrant and astrolabe projection, appears not to be of Arabic origin.

Quarries in Harappa

Paolo Biagi

It is surprising to note that one of the most important raw materials exploited by the III millennium BCE Bronze Age Harappans of the Indus Valley and its related territories was flint. Although the importance of this siliceous stone has never been pointed out even in the most recent publications on the subject (see for instance Lahiri 1992), nevertheless the research carried out mainly during the last 20 years in the Rohri Hills (Biagi 1997) and also in the artisan workshops of the metropolis of Mohenjo-daro (Vidale 2000) have shown the fundamental role played by flint in the wider context of this highly developed urban civilisation of the Indian subcontinent.

Although the Rohri Hills have been known since the end of the 1980s as a raw material source, systematic surveys and excavations in the region were undertaken only in the 1990s by the Ca' Foscari University of Venice (Italy) and the Shah Abdul Latif University, Khairpur (Sindh, Pakistan; Biagi and Shaikh 1994). The first to report the presence of flint artefacts from this region was Blandford (1880: 103), who, in his *Geology of Western Sind*, describing the flat tops of the Rohri Hills south of Rohri, wrote that, "the surface of the limestone consists in general of a series of low slopes, corresponding in direction to the dip of the rock. The flints weather out and cover the surface throughout a large area; cores and flakes split from them being scattered about in abundance in some places" (Fig. 1). The same author mentions the recovery of "some flint cores, from which flakes have been chipped, obtained from Lieutenant Twemlow, R. E., in the bed of the Indus. The cores were remarkable for their regularity" (Blandford 1880: 20). These latter cores were first illustrated by Evans (1886: 28) who was "superintendering excavations connected with a canal, near Shikarpoor, in Upper Scinde". Furthermore Blandford (1880: 20) reports that "large quantities of flint cores have been found near Sukkur and Rohri, and there is a good collection in the Geological Museum Calcutta" (Figs. 2 and 3).

Quarries in Harappa. Fig. 2 The Indus at Rohri.

Quarries in Harappa. Fig. 3 Fishermen flat-bottomed boats in the Indus at Sukkur.

Apart from the re-discoveries made by Cousens (1929) and De Terra and Paterson (1939), Allchin (1976: 477) of the University of Cambridge visited the northernmost edge of the hills, near Sukkur and Rohri, in December 1975. Here she noticed "extensive Harappan working floors on the top of several of them", which were illustrated by the same author in another of her papers (Allchin 1979), where she describes each of them as "an area large enough for a man to sit cross-legged", which "had been completely cleared of stones" (Allchin et al. 1978: 276).

Before the complete destruction of this important archaeological area, due to industrial quarrying, the limestone mesas south of Sukkur were visited by the present author in April 1985 and again in 1986, when groups of large flint quarries were discovered by the present writer and Professor M. Cremaschi of Milan University in the Shadee Shaheed region (Figs. 4–6).

The Rohri Hills

The Rohri Hills, which are some 40 km long and 16 wide, extend in a north–south direction between the course of the Indus and the cities of Sukkur and Rohri, in the north, and the westernmost fringes of the Thar Desert, in the south (Fig. 7), which, in this part of the country is very rich in salt-lake basins (Figs. 8 and 9). The hills consist of fossiliferous limestone rocks of the Brahui formation attributed to the Middle Eocene/ Early Oligocene period, very rich in seams of good quality flint, which attracted the prehistoric populations from the Early Palaeolithic onwards (Biagi and Cremaschi 1988) (Fig. 10). They separate two very different environmental regions, the Indus Valley to the west and the Thar Desert to the east. Their eastern fringes are lapped by the Nara Canal, which flows inside the old bed of the Hakra–Ghaggar River. The hills are limestone mesas (Fig. 11), dissected by erosion and

deeply incised by old river courses (Fig. 12) (Biagi 2004).

As mentioned above, the surveys carried out in 1986 led to the discovery of groups of Harappan flint quarries and workshops in the Shadee Shaheed area of the hills (Biagi and Cremaschi 1991). Here the most impressive structures were located along the edges of the limestone plateau (Fig. 13). From the surface the quarries consisted of almost circular empty areas, representing the quarry–pits, filled with aeolian sand, blown from the Thar Desert dunes, and heaps of limestone block, deriving from the prehistoric mining activity (Fig. 14). All around these structures flint workshops were noticed (Fig. 15), represented by scatters of flint flakes and blades among which were typical Harappan-elongated blade cores and characteristic bullet cores with very narrow bladelet detachments (Fig. 16). During the same survey, it was possible to observe that large areas of this part of the hills had already been highly damaged by illegal activities carried out by limestone quarriers (Figs. 17 and 18), and that even wider devastations were in progress by modern industrial quarrying (Fig. 19). Nevertheless it was possible to notice that the area covered by the

Quarries in Harappa. Fig. 13 Professor Cremaschi positioning the first Harappan flint quarries at Shadee Shaheed in January 1986.

Quarries in Harappa. Fig. 14 Aerial view of part of the main system of Harappan, flint quarry-pits on the hills near Shadee Shaheed.

presence of groups of prehistoric quarries was very wide and extended all over the central-western region of the hills. Harappan quarries were discovered also in the valleys of the internal mesas (Fig. 20).

The Excavation of Quarry–Pit 862

The excavation of Quarry–pit 862 was carried out between 1995 and 1998. This quarry lies along the western edge of the Shadee Shaheed Hills, some

Quarries in Harappa. Fig. 15 Very wide, circular concentration of Harappan debitage flakes near Shadee Shaheed.

Quarries in Harappa. Fig. 20 An internal region of the central part of the Rohri Hills rich in groups of Harappan flint quarries and workshops.

(Starnini and Biagi 2005: 1). The quarry was surrounded by several flint scatters and workshops (Negrino et al. 1996), one of which was connected with the production of narrow bladelets from typical bullet cores (see Fig. 16). As mentioned above, the

Quarries in Harappa. Fig. 21 The beginning of the excavation of the Harappan flint quarry pit 862 in the Rohri Hills.

excavation was carried out during four fieldwork seasons. It was aimed at the understanding of the quarrying techniques employed by the Harappan workers and the understanding of its chronological attribution. Thanks to the discovery of two small pieces of *Zyzyphus* cf. *nummularia* charcoal it was possible to obtain an AMS radiocarbon date of the main quarry–pit. It gave the result of 3,870 ± 70 uncal BP (GrA-3235), which attributes the structure to the Mature Harappan Civilisation (Biagi 1995). The excavation covered an area of some 60 m^2 down to a depth of 1.5 m, where the floor reached by the Harappan workers was found (Fig. 22), inside which dozens of extractive holes containing flint nodules still in situ (Figs. 23 and 24) were discovered (Starnini and Biagi 2005, Fig. 4). The excavation did not yield any metal or other extractive tool which might have been employed for breaking the fissured limestone and reaching the flint seam. In contrast it produced a huge amount of flint debitage (Fig. 25) and several hammerstones and cores from the same material. On the basis of the field observations, "the preparation of the precore rough-outs was most probably performed inside the quarry trench, or along its edge, as many decorticating flakes, pre-forms and typical crested blade-like-flakes found inside the ditch fill should indicate" (Starnini and Biagi 2005: 5).

The Daphro Hill

The surveys carried out on the Daphro Hills, south of Hyderabad, in Lower Sindh, led to the discovery of other flint extractive quarries also in this region (Biagi 2006). At least three different points of this hill revealed the presence of flint extractive systems similar to those observed along the western mesas of the Rohri Hills in Upper Sindh (Figs. 26 and 27). Apart from ditches excavated along the edges of these limestone mesas, the surveys revealed the presence of flint

Quarries in Harappa. Fig. 22 The flint seam reached by the Harappan quarries during the mid III millennium BCE with many nodules still *in situ*, ready for extraction at quarry-pit 862.

Quarries in Harappa. Fig. 23 A large flint nodule discovered in the bottom layer of the excavation carried out at quarry-pit 862.

Quarries in Harappa. Fig. 27 Three parallel, Harappan flint extraction trenches opened along the edge of the Daphro Hill.

workshops (Fig. 28), undoubtedly attributable to the Harappan Civilisation, as indicated by the occurrence of characteristic elongate, subconical, flint cores with long blade detachments (Fig. 29). At Daphro, the presence of large-sized pre-cores (Fig. 30), already prepared for being transported, is of major interest.

Quarries in Harappa. Fig. 28 A long Harappan flint extraction trench excavated along the edge of the Daphro Hill.

Quarries in Harappa. Fig. 30 Harappan flint pre-core already oval-shaped for its exportation to one of the Harappan urban centres of the Indus Valley.

Quarries in Harappa. Fig. 29 Harappan elongated core for the production of long, narrow flint blades with parallel edges.

Single pre-core specimens have been found at Mohenjo-daro, the Rohri Hills and Kahiro Bhandari near Badin, close to the Runn of Kutch. This discovery is particularly important because it indicated that not only the final products, such as well-defined types of blades and bladelets were transported to the major centres of the Harappan Civilisation for being transformed into instruments for craft production around the middle of the III millennium BCE, but also complete, large blocks of flint already prepared for their transport.

Considerations

The discoveries made in the Rohri and Daphro Hills have demonstrated that flint was still extremely important during the flourishing of the III millennium BCE Harappan Civilisation. Flint was extracted not only from the Rohri Hills quarries, but also from Daphro and possibly other outcrops during this period and traded over long distances at least as far as Harappa, to the north, and the cities located along the north Arabian Sea coast, to the south. The complicated extractive system, which undoubtedly involved a great number of workers and knappers, and the extraordinary great number of quarries discovered on the Rohri Hills indicate that this raw material was of primary importance at least during the Mature Harappan Civilisation. Although the extraction systems have not been fully understood and the trade routes are still badly known, there is no doubt that the role played by this raw material has so far been underestimated by archaeologists.

Furthermore the damage to a more comprehensive knowledge of the Harappan Civilisation caused by the systematic devastation, for illegal industrial activities, of both the aforementioned archaeological areas of Upper and Lower Sindh is remarkable.

Quipu

MARCIA ASCHER, ROBERT ASCHER

Quipus were the logical–numerical recording devices of the Incas, a civilization that dominated western South America from about 1400 to 1560. In almost every respect, the Incas are comparable to other early civilizations. They maintained a highly developed bureaucracy with strong centralized authority. They built an extensive road system, maintained a state religion, and supported a large mobile army. They constructed and regulated irrigation systems, built storage facilities, and organized distribution networks, and they forged communications linking cities and villages, up, down, and across a terrain that included mountains, tropics, desert, and seacoast.

The Incas differed from other early civilizations in one crucial respect – they had no writing as we generally understand the term. We generally understand writing to be a system based on the sounds of speech. But writing can also be based on units of meaning. This latter form, called *concept writing*, is used, for example, in chemistry and choreographics. Quipus are no doubt the most highly developed and widely applicable known use of concept writing (Ascher 2002). In Inca civilization, quipus served the important ends that sound-based writing served elsewhere. Quipus were, for example, used to keep track of agricultural yields and population sizes. There is good reason to believe that they were used to follow astronomical events. Also, they may have been used for planning purposes, such as laying out structures to be built or scheduling amounts and types of goods to be moved from one location to another.

The Inca state had existed for about 100 years when the Spanish arrived to conquer. A short time after that, Inca civilization collapsed. Knowledge of quipus was largely lost with the conquest. We have no sure way, for example, to assign a specific meaning or usage to a particular quipu. What we can know now comes from two sources: writings in Spanish, mostly by the conquerors; and quipus that were already in graves and then excavated at a much later date. Both sources pose problems of interpretation, but studies of the quipus themselves have proved most fruitful. Some 475–500 quipus are now located mostly in museums spread across three continents. About 400 of these have been studied and 200 recorded in detail (Ascher and Ascher 1978, 1988). These extensive, detailed descriptions are available at ►http://instruct1.cit.cornell.edu/research/quipu-ascher/.

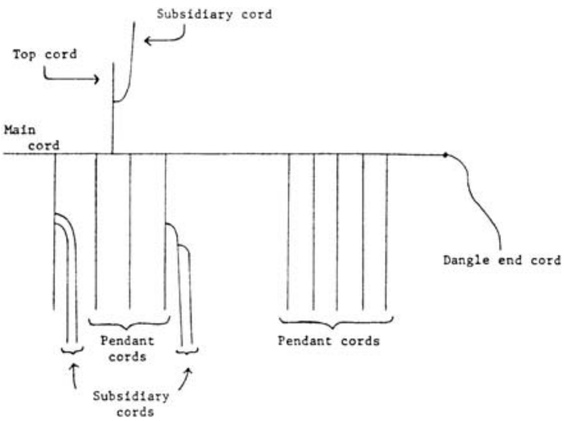
The generalizations that follow are based largely on this quipu corpus.

A quipu is a spatial array of multicolored knotted cords. In general, a quipu has a main cord from which other cords are suspended. Most of the suspended cords fall in one direction (pendant cords); sometimes a few fall in the opposite direction (top cords). Often other cords (subsidiary cords) are suspended from some or all of the pendant or top cords. And, there can be subsidiaries of subsidiaries, and so on. (Notice in Fig. 2 that the first pendant has two subsidiaries on the same level while the fourth pendant has two levels of subsidiaries.) Occasionally there is a single cord distinctively attached to the end of the main cord (dangle end cord). A quipu can be made up of from as few as three cords or as many as 2,000. On some, there are as many as ten levels of subsidiaries and, on others, as may as 18 subsidiaries per level. All cord attachments are tight so that the spacing between cords is fixed and serves to group or separate the cords. Color is another important means of associating or differentiating cords within a single quipu. For example, ten cords can be formed into two groups by having five yellow pendants followed by five red pendants, or by a five-color sequence repeated twice. In the latter case, each cord is not only associated with its group, but also with the like-colored cord in the other group. In all, a complex logic of associations and distinctions is created by combining cord type, cord spacing, cord level, and cord color.

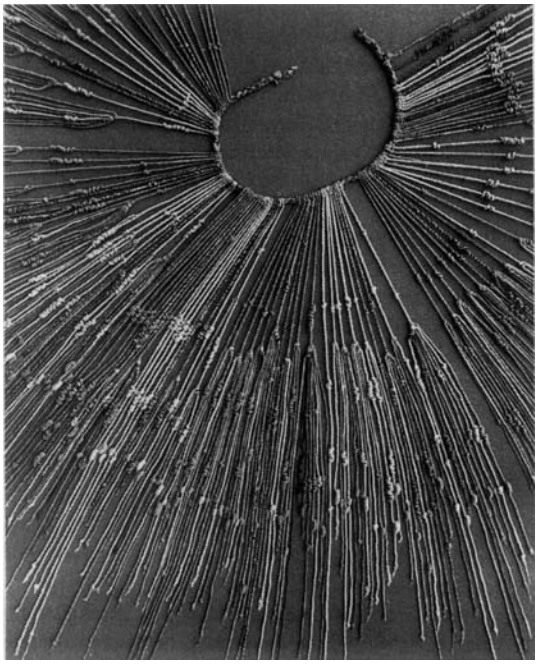
Within this logical array, numbers are represented by spaced clusters of knots on the cords. Only three types of knots appear: simple overhand knots, long knots of two or more turns, and figure-eight knots. Depending on the knot types and relative cluster positions, each cord can be interpreted as one number or multiple numbers. If it is one number, it is an integer in the base 10 positional system. Each knot cluster represents a digit and each consecutive cluster, starting from the free end of the cord, is valued at one higher power of 10. The units position is always a long knot or a figure-eight knot; all other positions are clusters of simple knots. When, instead, the cord carries multiple numbers, they are still base 10 integers, but each of the interspersed long knots or figure-eight knots signals the start of a new number (Fig. 1–4).

Crucial to a base positional system is the concept of zero, namely that "nothing" is identified in some way. On the quipus, careful knot cluster alignment from cord to cord makes evident a position with no knots within a number. This is further supported by the identification of the units position by knot type. What is more, the color coding of the cords enables the distinction between a cord with value zero and an intentional omission or blank.

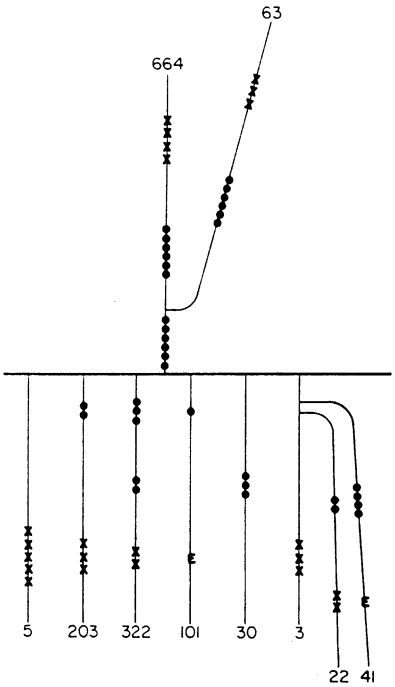
In Fig. 3, the top cord carries the sum of the pendant cord numbers. When top cords appear, that is generally their role. This relationship between cord types and cord values was first observed by Locke (1923),



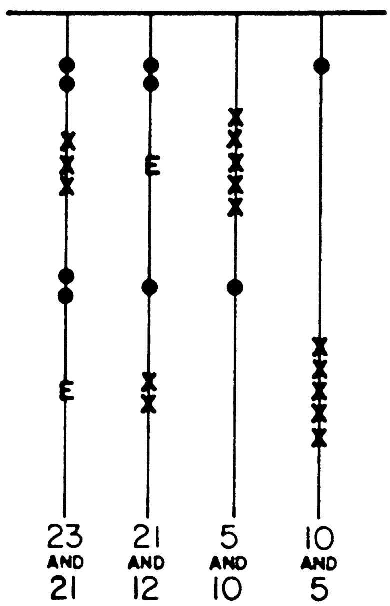
Quipu. Fig. 2 A schematic of a quipu.



Quipu. Fig. 1 A quipu in the collection of the Museo Nacional de Anthropología y Arquelogía, Lima, Peru (photo by Marcia and Robert Ascher).



Quipu. Fig. 3 A schematic showing numbers represented by knots (● = simple knot; x = one turn of a long knot; E = figure-eight knot).



Quipu. Fig. 4 A schematic showing multiple numbers represented by knots (● = simple knot; x = one turn of a long knot; E = figure-eight knot).

corroborating the numerical interpretation of the knots. Consistent with the structural indicators of cord type, color, and placement, many arithmetic relationships are found on quipus. There are, for example, groups that sum values in other groups which, in turn, are summed elsewhere, and sets of values with consistent ratios. There are even numerical relationships that involve several linked quipus. Some of the data structures are analogous to spreadsheets, matrices, and tree diagrams. But what makes the quipus a general recording device is that numbers are used as labels as well as magnitudes. This usage of numbers has recently become prevalent in our culture where, for example, 1-207-667-4854 identifies a type of phone call, a geographic region, a locale within that region, and a specific telephone within that locale.

The logical–numerical system of the quipus was sufficiently standardized to be read and interpreted by the community of trained quipu-makers. The quipus were not ad hoc personal mnemonic devices; they were the means of communication and record keeping of a large bureaucratic state. Both quantitative and nonquantitative information are a part of these records. Most recently the nonquantitative aspects are receiving more scrutiny (Ascher 2002; Brokaw 2003; Quilter and Urton 2002). And there is a unique case where apparently Inca period quipus are venerated in a contemporary Andean community (Salomon 2004). In a very real sense, quipus are the quintessence of, or metaphor for, Inca civilization. Like the civilization itself, quipus emphasize regularity, spatial arrangement, and portability, and their construction is highly methodical and conservative.

Q

Qusṭā ibn Lūqā

E. Ruth Harvey

Qusṭā ibn Lūqā is one of the important figures in the transmission of Greek scientific writings to the Muslim world and subsequently to the Latin west. The ancient Arab biographers say that he was a Christian of Greek origin from Baalbek (Heliopolis) in Lebanon; he visited the Byzantine empire and brought back Greek texts which he then translated into Syriac and Arabic. He worked for the Caliph al-Mustaʿīn (862–866) in Baghdad, where he may well have known al-Kindī and Thābit ibn Qurra; he died in Armenia (ca. AD 912/300 AH) where he had been an honored guest of the ruler Sanharib.

Qusṭā is important both for his translation and for his original works. The transition of Greek science and philosophy into the Arab world resulted in the development and preservation of traditions largely lost to the west. Most western medieval science owes a great debt to the Arab scholars who kept alive this vital link with ancient learning. Qusṭā provided versions of Diophantos' *Arithmetica*, Hypsícles' *Liber…de ascensionibus*, Autolycus' *De ortu et occasu*, Theodosius of Bithynia's *De sphaeris*, and Hero of Alexandria's *Mechanics*; Qusṭā's Arabic version of this last work is the only text extant today. He is credited with other translations, notably some of the works of Aristotle with the commentaries of Alexander of Aphrodisias and John Philoponos, but they do not appear to have survived.

The biographers provide a list of over 60 original works by Qusṭā; the titles suggest that most are medical, but some are clearly works on mathematics, astronomy, logic, and natural science. Sezgin provides a list of the medical works of Qusṭā which are known to survive in manuscript. Very few of them have been printed, although interest in Qusṭā's treatises is increasing. His little monograph on infection (*Kitāb fī al-iʿdāʾ*) explains in terms of the medicine of the day how some diseases are contagious, and his *Viaticum*, explaining various principles of health and hygiene for travelers are both now available. His work on sex has been published in Germany, but is not readily obtainable. A work on the efficacy of amulets is extant only in the Latin translation of Arnald of Villanova (called both *De physicis ligaturis* and *De incantatione*); the Arabic text of his work on the celestial globe still exists and there are in addition medieval translations of the treatise in Latin (*De sphaera solida*), Hebrew, Spanish, and Italian.

Probably the most famous and influential of all Qusṭā's works is the short treatise on the difference between the spirit and the soul (*Kitāb fī 'l-farq baina 'l-nafs wa 'l-rūh*), which, in the Latin translation of John of Seville, was used as an authority by almost all medieval Western physicians and by some of the philosophers. It distinguishes carefully between the immortal soul and the bodily "spirit of life" within man. The idea that a material but gaseous substance existed inside the human frame and made possible the functions of life, sensation, and motion was an essential part of medical doctrine in the days before the discovery of electricity. Qusṭā's lucid explanation was received as a kind of gloss or commentary on Aristotle's *De anima*. It was frequently misattributed to Constantine the African.

Rainwater Harvesting

Arnold Pacey

Throughout history people have lived in areas where there are few rivers and where the direct collection of rainwater from roofs, paved courtyards, hillsides, or rock surfaces is one of the best available methods for securing a water supply. By extending this principle to provide water for crops, early civilizations practiced agriculture much further into the semidesert areas of Arabia, Sinai, North Africa, India, and Mexico than has been possible in modern times – and this is not explicable by changes in climate.

Agriculture in the Old World originated in climatically dry regions in the Middle East and may have depended to some degree on rainwater running off nearby slopes almost from the start. Evidence is lacking until a later period, however, when some of the most striking applications of rainwater harvesting were related to crop production in the Negev Desert between 200 BCE and AD 700. One technique would be to dig a channel across a hillside to intercept water running downslope during storms. The water would be directed onto fields which, in the Negev, were carefully leveled and enclosed by bunds (an embankment or dike). Further west, steeper hillsides were used in Morocco, with cultivation on flat terraces formed behind stone retaining walls. In Tunisia, French travelers in the nineteenth century noted fruit trees being grown at the downslope end of small bunded rainwater catchment areas or microcatchments.

In India, one common technique is simply to build a bund across a gently sloping hillside, so that runoff flows originating from rainfall collect behind the bund, where water is left standing until the planting date for the crop approaches; then the land is drained, and the crop sown. This land behind the bund which is seasonally flooded and then later planted with a crop is known as an *ahar* in Bihar, or a *khadin* in Rajasthan. Although some *ahars* may be only one hectare in extent with a bund 100 m long, others are very large and account for 800,000 ha of cultivation in Bihar state. In desert areas of Rajasthan, there are many *khadins* of 20 ha or more, some of them having been first constructed in the fifteenth century AD.

In North America, research on the modern potential of runoff farming methods has been stimulated by the realization that people living in what is now Mexico and the southwestern United States prior to European settlement had methods of directing rainwater from hillsides on to plots where crops were being raised, thereby making productive agriculture possible in an otherwise unpromising semiarid environment. On lands occupied by the Hopi and Papago peoples in Arizona, fields were predominantly on alluvial valley soils below hillsides or gullies from which water could flow to the crops during rainstorms. Sites were chosen so that only minimal earthworks were needed to spread the water over the fields. These were short lengths of bund referred to as spreader dikes.

Ramanujan

Bruce C. Berndt

Srinivasa Ramanujan was born on 22 December 1887 in the home of his maternal grandmother in Erode, India, a small town located about 250 miles southwest of Madras. Soon thereafter, his mother returned with her son to her home in Kumbakonam, approximately

160 miles south–southwest of Madras. Ramanujan's father was a clerk in a cloth merchant's shop, and his mother took in local college students to augment the family's meager income.

Ramanujan's mathematical talent was recognized in grammar school, and he won prizes, usually books of English poetry, in recognition of his mathematical skills. At the age of 15, Ramanujan borrowed G. S. Carr's *Synopsis of Pure Mathematics* from the local Government College in Kumbakonam. This unusual book, written by a Cambridge tutor to teach students, contained approximately 5,000 theorems, mostly without proofs, and was to serve as Ramanujan's primary source of mathematical knowledge.

With a scholarship, Ramanujan entered the Government College in Kumbakonam in 1904. However, by this time, he was completely absorbed with mathematics and would not study any other subject. Consequently, at the end of his first year, Ramanujan failed all of his exams, except mathematics. He lost his scholarship and therefore was unable to return to college.

For the next 5 years, working in isolation, Ramanujan devoted himself to mathematics. He worked on a slate, and because paper was expensive, recorded his mathematical discoveries without proofs in notebooks. During this time, he attempted once more to obtain a college education, at Pachaiyappa College in Madras, but his singular devotion to mathematics, and illness, deterred him again.

Having married Janaki in 1909, Ramanujan sought employment in 1910. For over a year, he was privately supported by Ramachandra Rao, as he gradually became known in the Madras area for his mathematical gifts. In 1912, Ramanujan became a clerk in the Madras Port Trust Office, and this was to be a watershed in his career, for the manager, S. Narayana Aiyar, and the Chairman, Sir Francis Spring, took a kindly interest in Ramanujan and encouraged him to write English mathematicians about his work.

On 16 January 1913, Ramanujan wrote to the famous English number theorist and analyst, G. H. Hardy. He and his colleague J. E. Littlewood examined the approximately 60 mathematical results communicated by Ramanujan and were astounded by his many beautiful and original claims. Hardy strongly encouraged Ramanujan to come to Cambridge, so that his mathematical talents could be fully developed. At first, Ramanujan was reluctant to accept the invitation, because of orthodox Brahmin beliefs that crossing the seas makes one unclean, but on 17 March 1914 Ramanujan sailed for England.

During the next 3 years Ramanujan achieved worldwide fame for his mathematical discoveries, some made in collaboration with Hardy. However, in the spring of 1917, Ramanujan became ill and was confined to nursing homes for the next 2 years. Tuberculosis, lead poisoning, and a vitamin deficiency were among the many diagnoses made, but a more recent examination of Ramanujan's symptoms points to hepatic amoebiasis. In 1919, he returned to India with the hope that a more favorable climate and more palatable food would restore his health. However, his condition worsened, and on 26 April 1920, Ramanujan passed away.

After Ramanujan's death, Hardy strongly urged that Ramanujan's notebooks be edited and published with his Collected Papers. Two English mathematicians, G. N. Watson and B. M. Wilson, devoted over 10 years to proving the approximately 3,000–4,000 theorems claimed by Ramanujan in his notebooks, but they never completed the task. It was not until 1957 that an unedited photocopy edition of Ramanujan's notebooks was published. In 1977, Berndt, with the help of Watson and Wilson's notes, began to devote all of his research efforts toward editing the notebooks, and in 1998 he completed the task with the publication of his fifth volume on the notebooks. In 1976, Andrews discovered a sheaf of 140 pages of Ramanujan's work, now called the "lost notebook," in the library at Trinity College, Cambridge. In 2005, Andrews and Berndt published their first volume on Ramanujan's lost notebook.

Ramanujan made many beautiful discoveries in several areas of number theory and analysis, in particular, the theory of partitions, probabilistic number theory, highly composite numbers, arithmetical functions, elliptic functions, modular equations, modular forms, q-series, hypergeometric functions, asymptotic analysis, infinite series, integrals, continued fractions, and combinatorial analysis. His influence can be traced to many areas of contemporary mathematics; this is evident in the proceedings of major conferences commemorating Ramanujan on the 100th anniversary of his birth. Although much of Ramanujan's work is quite deep, many of his original discoveries can be understood with a background of only high school mathematics. In particular, his several results on solving systems of equations, representing integers as sums of powers, and approximating π are elementary. In the past few decades, as more of Ramanujan's results have been unearthed, his already great reputation has soared even more.

Most biographical sketches of Ramanujan's life rely chiefly on the obituaries written by Seshu Aiyar and Ramachandra Rao, and the writings of Hardy. However, Robert Kanigel's biography is by far the most complete and detailed description of Ramanujan's life. Much can also be learned from Ramanujan's letters to Hardy, his family, and friends.

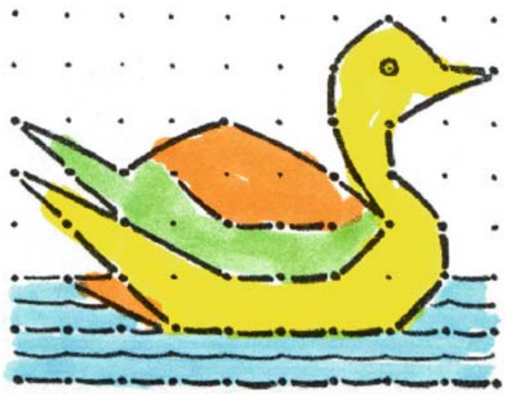
Rangoli: Versatile Domestic Art

JYOTSNA KAMAT

The art of rangoli (also known as alpana, saaz, muggu, kolam, zuti, mandana, and by many other names in India) is a traditional art of decorating courtyards and walls of Indian houses, places of worship and sometimes eating places as well. The powder of white stone, lime, rice flour, and other cheap paste is used to draw intricate and ritual designs. Each state of India has its own way of painting rangoli (Fig. 1).

Women's Art

One characteristic of rangoli is that commoners paint it, without much background in geometry, fine arts or mathematics. Women use their bare fingers or a homemade brush to create various designs from sandstone powder or grain flour. Sometimes colors and petals are used in addition to flour paste. Some women are so skilled with their fingers that they can create figures of deities, chariots, temples, etc., on the finely layered floor. Petals of various flowers, such as oleanders, cosmos, zinnia, chrysanthemums, and green leaves provide the artist with the ability to work out various patterns and colors. Most of the rangoli designs are motifs of plants, flowers, leaves such as coconut, lotus, mango, and ashwath (peepal), animals such as cows, elephants, and horses, and birds like eagles and swans. There are geometrical designs as well. When drawn with the fingers, these acquire different dimensions of their own (Fig. 2).



Rangoli: Versatile Domestic Art. Fig. 1 Example of a Rangoli Design (illustration by K. L. Kamat).

Rangoli: Versatile Domestic Art. Fig. 2 Rangoli to welcome God (photograph by K. L. Kamat).

R

The rangoli art is practised as a ritual to welcome the goddess of prosperity, Lakshmi, into the home. Hence the first duty for housewives and young girls in the morning is to sweep the courtyard clean and draw rangoli patterns. Old and young alike participate in this ephemeral domestic art which changes every day. We see that rangoli is predominantly a ritual performed by women. Men draw rangolis in temples and in public places.

History of Rangoli

The history of rangoli is quite ancient. Early rock paintings have symbols and figures of wild animals, hunting scenes, etc., to ward off evil and wish success in hunting expeditions. By the time of the Indus valley civilization (3000 BC), symbols like triangles, circles, and *swastikas* were used to represent supernatural powers. During the Vedic period, places to seat guests and sacrificial altars were decorated with floral designs. By the use of the hand and deft movement of the fingures, rangoli has developed into a fine art over centuries. At times, a simple homemade brush is used (Fig. 3).

Complex Geometry and Philosophy for Common Folk

Almost all of the rangoli patterns involve dots (*bindu*) and lines (*rekha*); joining these creates innumerable patterns. A spot suggests power or life. A line suggests the flow of life. A circle represents the universe and a triangle signifies woman's power or fertility. The swastika stands for the sun's movement. Some interpret that it represents fourfold achievements for householders as laid down by sacred texts. These are *dharma* (virtuous life), *artha* (earning livelihood), *kama* (creature comforts), and finally *moksha* (renunciation in old age). The four corners of the swastika are supposed to symbolize these ideals.

Rangoli: Versatile Domestic Art. Fig. 3 Women joining dots to make complex designs (photograph by K. L. Kamat).

The sun, the moon, the stars, conches, and lotus are considered sacred figures in rangoli. Animals like elephants, cows, horses, tortoises, and birds like parrots, peacocks, and swans, along with plants and creepers, are often included in this art that combines geometry with philosophy and devotion with beauty.

Rangoli in Contemporary India

Festivals dedicated to different gods provide change in the daily routine of rangoli. During Naga panchami, symbols of serpents will appear. On Deepavali, the festival of lights, small earthen lamps will be drawn. On Sankranti festival day, sugarcane, paddy, and wheat sheaves, which are fresh at that time, will find a place of honor in the front door rangoli. Usually every Hindu house has a platform built round the sacred plant of Tulasi. On festival days, this place will also get a special design in addition to the daily ones. Patterns of flowers are popular. Innovative artists paint Christmas and New Year's greetings also in the form of rangolis, depicting Santa Claus and nativity scenes.

During Car festival, the entire village or townspeople will decorate the paths with colorful rangoli designs through which the deity's car (chariot or *ratha*) will pass.

With smaller flats in cities, this temporary and renewable art is disappearing. More and more households find it convenient to decorate their houses with permanent paints; however, they continue to use traditional rangoli designs.

Rationale in Indian Mathematics

K. V. Sarma

Rationale in Hindu mathematics and astronomy is expressed by the terms *Yukti* and *Upapatti*, both meaning "the logical principles implied". It is characteristic of the Western scientific tradition, from the times of Euclid and Aristotle up to modern times, to enunciate and deduce using step by step reasoning. Such a practice is almost absent in the Indian tradition, even though the same background tasks of collecting and correlating data, identifying and analyzing methodologies, and arguing out possible answers, have to be gone through before arriving at results. However, in the final depiction, only the resultant formulae would be given, and that too in short, crisp aphoristic form, leaving out details of all the background work. Commentaries generally content themselves with explaining the text of the formulae and adding examples. This tendency toward selective depiction of results has resulted not only in blacking out the background, but also in not understanding the mental working of the Indian scientist. It also throws into oblivion the methodologies that had evolved. For this reason, many Indian advances have been branded as unoriginal and borrowed.

The situation is, however, relieved to some extent by the presence of a few commentaries which took pains to explain elaborately the methodologies adopted by the original author and also set out the rationales of the formulae he enunciated. Among such commentaries might be mentioned:

Siddhāntadīpikā on Govindasvāmi's *Mahābhāskarīya-Bhāsya* by Parameśvara (1360–1465)
Āryabhatīya-Bhāsya by Nīlakaṇṭha Somayāji (b. 1444)
Yuktidīpikā on Nīlakaṇṭha Somayạji's *Tantrasaṅgraha* by Śaṅkara Vāriyar (1500–1560)
Vāsanābhāṣya on Bhāskarācārya's *Siddhāntaśiromaṇi* by Nṛsiṃha Daivajña (1621)
Marīcī, again on Bhāskarācārya's *Siddhāntaśiromaṇi* by Munīśvara (1627)

A few texts devoted solely to the depiction of rationale are also known, such as the *Yuktibhāṣā* (Mathematical "Rationale in Language" Malayalam) by Jyeṣṭhadeva (1500–1610), *Jyotirmīmāṃsā* (Investigations on Astronomical Theories) by Nīlakaṇṭha Somayāji (b. 1444), *Rāśigolasphuṭānīti* (True Longitude Computation on the Sphere of the Zodiac) by Acyuta Piṣāraṭi (1600), and *Karaṇapaddhati* (Methods of Astronomical Calculations) by Putumana Somayāji (1660–1740).

However, what is more significant is the occurrence of a number of short tracts giving mathematical and astronomical rationale which are available, some in print and several others in the form of manuscripts. These tracts take up individual topics of importance, analyze the technical principles involved therein, compare the procedures adopted in different texts, and often suggest revisions. To cite an example, the work *Gaṇitayuktayaḥ* (Rationales of Hindu Astronomy) contains a set of 27 tracts providing rationalistic exegeses on several topics including parallaxes of latitude and longitude, elevation of the moon's horns, constitution of epochs for new astronomical manuals, planetary deflections, and equation of the center. It is also noteworthy that some of these exegeses establish the originality of the methodologies and formulae depicted by Indian scientists.

Rationality, Objectivity, and Method

David Turnbull

Rationality, objectivity, and method are three words that capture the essence of science and at the same time provide its mythic structure. Science has become the authoritative form of knowledge in the world today. The proof of its superiority lies in the ever-expanding body of knowledge we have about reality. We can predict where, when, and how meteorites will collide with Jupiter, and we can build interplanetary spacecraft to send back signals recording the event. We can explore the atomic structure of chemicals and design new ones to suit whatever purpose we have in mind, ecstasy or health. We can map the human genome. We can explain the origins of everything in the universe down to the first few nanoseconds. The source, according to the myth, of this unparalleled success lies in science's embodiment of the highest form of rationality and objectivity in the scientific method. This mythical underpinning of science also provides the rationale for the celebration of modernity and the current domination of the West. This view is unselfconsciously exemplified by the philosopher Ernest Gellner who claims, "If a doctrine conflicts with the acceptance of the superiority of scientific-industrial societies over others, then it really is out" (cited in Salmond 1985).

Therein lies the first set of intrinsic problems and contradictions the myth conceals. Modernity is supposedly synonymous with development and social

R

improvement, but it has become apparent in recent times that science and technology are no longer unalloyed agents of progress. They now seem to contribute significantly to the difficulties we are facing in environmental degradation, pollution, climate change, and waste disposal. The other equally difficult emergent problem for the mythological account of science is that it has been seen as quintessentially Western and as absent in the developing countries or an undeveloped possibility in the Islamic, Chinese, and Indian cultures. This can no longer be accepted as a simple fact, but has now to be seen as an ideological marker in the creation of the "other." We have then a joint problem. On the one hand "the future is not what it used to be," courtesy of the negative effects of science and technology, but we will nonetheless have to call on them for their problem solving capacities. On the other hand it is becoming apparent that the grand project of modernity – a universal scientific culture – has failed and ought to be relinquished in favor of encouraging cultural diversity. Just as biological diversity has become recognized as an ecological necessity so too has our cultural survival come to be seen as dependent on a diversity of knowledge (see knowledge systems). Consequently "the central problem of social and political theory today is to decide the nature of communicatory reason between irreducibly different cultures" (Davidson 1994). Given this double difficulty we need to ask ourselves if science can be reconstituted.

Rationality

It is in trying to explicate rationality, objectivity, the scientific method and the nature of science that the myth of science's transcendental supremacy really comes undone. Rationality is a deeply problematic concept. It is profoundly embedded in the hidden assumptions of late twentieth century occidentalism about what it is to be a knowing, moral, sane individual. Indeed it is so embedded that to be anything other than rational is to be ignorant, immoral, insane, or a member of an undifferentiated herd. Hence rationality cannot be treated as simply an epistemological concept about the conditions under which one can know something; it also carries ideological overtones, privileging certain ways of knowing over others. Rationality is a constitutive element in the moral economy.

Yet despite, or perhaps because of, this central role of rationality, there are no fully articulated rules or criteria for being rational in the acceptance of beliefs or in the pursuit of knowledge, nor is there a single type of rationality. This sense of incoherence in the concept reaches total intransigence in the recognition that ultimately there can be no rational justification for being rational. Nonetheless critical rationalism as advocated by Karl Popper has a primal persuasiveness in contemporary Western society. Mario Bunge has captured some of that self-evidentiality and variability in his seven desiderata for rationality:

1. Conceptual: minimizing fuzziness, vagueness, or imprecision
2. Logical: striving for consistency, avoiding contradiction
3. Methodological: questioning, doubting, criticizing, demanding proof, or evidence
4. Epistemological: caring for empirical support and compatibility with bulk of accepted knowledge
5. Ontological: adopting a view consistent with science and technology
6. Valuational: striving for goals which are worthy and attainable
7. Practical: adopting means likely to attain the goals in view

Indeed seeing them set out like this makes their denial seem irrational.

From a relativist's perspective there are no universal criteria of rationality, and even if the claim for rationality's governing role is weakened to talk of desiderata as Bunge does, Wittgenstein's and Godel's point prevails: all formal systems are necessarily incomplete, no body of rules can contain the rules for their application. Rationality consists in the application of locally agreed criteria in particular context or as Foucault puts it, forms of rationalization are embedded in systems of practices (Foucault 1979: 47). Hence it should be acknowledged that science, rather than exemplifying some transcendental rationality, has developed its own rationalities that have in turn served to create a great divide between science and traditional beliefs. There is of course a middle ground, the so-called bridgehead argument which calls for the recognition that all humans have some minimal forms of practical rationality in common. Though this recognition has produced no universal truths and no universal criteria, it nonetheless provides the grounds for a commonality sufficient for partial communication and understanding across linguistic, ontological, and cultural differences.

There is a philosophical tendency to talk of rationality as if it were a problem with no historical or sociological dimensions. This is to ignore the fact that the concept of the individual as a rational actor that is now so basic to Western ways of thought is not derived from first principles; it arose in conjunction with the development of modern science in the seventeenth century. This was a period which saw great debates over the appropriate forms of rationality between the Cartesian rationalists and the Baconian empiricists. Whether true knowledge was to be derived deductively from self-evident first principles or by observation and experiment, it had already been accepted that the acquisition of such knowledge was within the capacity of human individuals. The recognition that human reason and experience was not inherently limited and could be a source of knowledge re-emerged in the twelfth and thirteenth centuries in the West with the separation of the church from the state and with the development of secular law from the accompanying canon law (Berman 1983). The development of this conception of rationality was not universal. For example it was not paralleled in Islamic society where men were denied rational agency; they were held to lack the capacity to change nature or to understand it. Knowledge was instead to be derived from traditional authority. This is not to claim that there has been no Islamic science or any Islamic discussion of rationality (Huff 1993). On the contrary, there have been major achievements in Islamic science but in a radically different moral economy.

While the notion of the rational actor as unconstrained by circumstance or authority and moved only by logic and evidence has become embedded in our legal, economic, and scientific presuppositions, such an idealized conception is at variance with our lived reality both at the societal and the individual level. At the societal level, modern Western capitalism has become a bureaucratic system that, as Weber pointed out, relies on a calculative rationality (Weber 1979). The administration and perpetuation of this system is crucially dependent on a system of rules from which legal and administrative calculations can be derived by professional, objective, experts. Hence modern science and capitalism are interdependent; they were coproduced on the basis of a calculability derived in part from rational structures of law and administration. In Weber's view it is the specific and peculiar rationalism of western culture that makes science unique to the west. Even if Weber was right, what needs further examination is how specific and peculiar that calculative rationalism is. That form of rationality has a number of interwoven components, for example the acceptance of written documents as evidence as opposed to oral testimony. This transition also occurred in the twelfth and thirteenth centuries but required the development of a "literate mentality" before it became self-evident that records and archives were more worthy of belief than the word of "twelve good men and true" (Street 1984). Some, like Goody, have further argued that the accumulation of knowledge and the possibility of criticism and hence rationality are only possible in a literate culture. Similarly vision had to be rationalized to provide grammar or rules for the relationship between the representation of objects and their shapes as located in space. Yet another component of the form of rationality we equate with science was the acceptance of the validity of experimental evidence. Shapin and Schaffer have argued in The Leviathan and the Air Pump that Thomas Hobbes was able to dismiss Robert Boyle's experiments on the vacuum as private, local, and artifactual until Boyle was able to introduce a range of social, literary, and technical practices that enabled the knowledge produced in the isolation of the laboratory to be "virtually witnessed" and reproduced for other audiences and in other laboratories (see Knowledge Systems).

Rationality is not a particular human capacity. Rather there are forms and compounds of rationality which at the societal level, as Foucault has shown, are dependent on particular social and historical institutions, constituted through the interwoven practices, techniques, strategies, and modes of calculation that traverse them. However, at the individual level we do not behave like the ends/means optimization calculators that economic rationalism would have us believe we are. We are at least as interested in meaning, significance, and personal values as we are in economic concerns. Nor are we quite the rational agents basing our knowledge on direct experience that the legal and philosophical theorists claim. A vast preponderance of our knowledge derives not from personal experience but from books, newspapers, journals, teachers, and experts. In other words our knowledge comes, directly or indirectly, from the testimony of others, in particular from those we trust. Thus our individual lived rationality is based in a range of social practices, traditions, and moralities that are suppressed and concealed in the portrayal of rationality as an ahistorical, universalistic form of reasoning exemplified by science.

Objectivity

Much the same can be said of objectivity. Objective knowledge is held to be the product of science that has established methods to ensure that individual, institutional, and cultural biases are eliminated. On closer examination objectivity is not characteristic of one special kind of knowledge – science. Rather it is the result of whatever institutionalized practices serve in a particular culture to create self-evident validity. Objective knowledge, in modern terms, is held to contrast with subjective knowledge. It is knowledge that is not local, that is not contingent on the circumstance, authority, or the perspective of the individual knower. However, the concept of objectivity, like that of rationality, is not immutable; it is an historic compound. In the seventeenth century objectivity meant "the thing insofar as it is known." The concept of aperspectival objectivity emerged in the moral and aesthetic philosophy of the late eighteenth century and spread to the natural sciences only in the mid-nineteenth century as result of the institutionalization of scientific life as a group rather than an individual activity.

This characterization of objectivity as the "view from nowhere" (Nagel 1986) represents one of the essential contradictions of scientific knowledge production. Knowledge is necessarily a social product; it is the messy, contingent, and situated outcome of group activity. Yet in order to achieve credibility and authority in a culture that prefers the abstract over the concrete and that separates facts from values, knowledge has to be presented as unbiased and undistorted, as being without a place or a knower.

Objectivity, like democracy, is at best a worthy goal but one that is never capable of achievement. Since knowledge is the product of social processes it can never completely transcend the social. Objective knowledge cannot, for example, simply be knowledge which is unaffected by nonrational psychological forces, since scientists always have motivations even if they pursue knowledge for its own sake. Nor can objectivity be restricted to the avoidance of dogmatic commitment, because there have been scientists like Kepler whose obsession with regular solids and cosmic harmony led to his derivation of the laws of planetary motion. While it may be possible to avoid personal idiosyncrasy this can only be achieved through the establishment of communal or public knowledge. If knowledge is a communal product, then the question of how the community should be constituted arises. Should the scientific community be an essentially western institution? Consequently objective knowledge cannot simply be "value free" knowledge because what is counted as knowledge is itself a value. Similarly the criterion of practical effectiveness cannot determine objectivity since it too is based in community standards.

The only remaining possibilities for objective knowledge lie in the notions of correspondence with reality and experimental verification. There are well known difficulties here, since correspondent theories of truth and verification are dependent on empiricism and the scientific method, both of which have been subject to powerful criticism in the last half century or so. Essentially, what philosophers like Duhem, Quine, and Wittgenstein have argued is that our ways of knowing about the world are riddled with indeterminacies; which is to say that there is no set of procedures sufficiently powerful to determine which knowledge claims are absolutely true and certain, nor is there a certain way of grounding such claims. There are uncertainties inherent in all our ways of knowing that have to be bridged by a variety of practical and social strategies. Popper and Kuhn have argued that neither deduction nor induction is capable of providing true and certain knowledge. Furthermore observations and theories are interrelated and hence neither can be an independent foundation for the other. Both Popper and Kuhn recognize that observations have point and meaning within the context or framework of a theory: we do not simply observe natural phenomena, we observe them in the light of some theory we already have in mind, or minimally with some set of expectations about what is interesting or what to look for. In this sense our observations of the world are "theory dependent" or "theory laden."

As Duhem points out, all theories are enmeshed in a web of other theories and assumptions. The apparent conflict between an experimental result and a particular hypothesis cannot conclusively lead to the rejection of that hypothesis, since the strongest conclusion that can be drawn is that the hypothesis under test and the web of theories and assumptions in which it is embedded cannot both be true. Since the experimental result by itself is insufficient to tell us where the flaw lies, we can always maintain a theory in the light of an apparently falsifying experiment if we are prepared to make sufficiently radical adjustments in the web of our assumptions. Conversely it is the case that for any given set of facts there is an indeterminably large number of possible theories that could explain them.

In addition to the problematic relationship of theory and observation there is a difficulty concerning the language in which our claims about the world are expressed. All propositions or observation statements contain descriptive predicates which imply a classification or categorization of the world based on postulated essences or natural kinds. We are stuck with some degree of circularity since we gain our knowledge about natural kinds from theories which are in turn based on observations. There is no neutral observation language; our only option is to recognize and acknowledge the conventional character of our linguistic classifications.

Scientific Method

Despite all these difficulties scientists are able to reach firm conclusions about the natural world. How is this possible? Many would claim that even though it may be logically true that there are an indefinite number of possible explanations for a given body of facts, in a given case there are typically a very restricted set of alternatives and there are adequate means of selecting the right theory, or at least the best possible theory in the circumstances, given the application of certain criteria. For example, we obviously desire theories which are internally coherent, consistent with other accepted theories, and simple rather than complex. However coherence, consistency, and simplicity as well as other criteria like plausibility have all proved notoriously difficult to express in a way which can be used to measure all theories in all circumstances. It is, none the less, very tempting from our twentieth century standpoint, imbued as we are with the scientific ethos, to suppose that there must be a particular set of rules, procedures, and criteria to which all scientists adhere. Taken together they should constitute the scientific method, and by diligent application of this method we should be able to arrive at all the scientific discoveries of our age. However, Paul Feyerabend in *Against Method*, for example, argues that no proposed set of rules and procedures has survived criticism or has been universally adopted by all scientists in all circumstances. Likewise he claims that in no case can it be shown that the success of science can be solely attributed to its adherence to the scientific method.

There can of course be endless debates about such claims, but so far no one has been able to identify the one scientific method which has been adopted in all the sciences. Compare for example theoretical physics (mainly mathematical) and biology (mainly observational). Nor is there a method which has been unilaterally accepted in a particular discipline. Compare again, Newton's espoused methodology ("I feign no hypotheses") with Einstein's (bold hypotheses and deductive tests). Further, particular instances of scientific practice under close examination reveal a pragmatic willingness to suspend or modify any particular version of the scientific method if necessary, as Feyerabend has shown in his analysis of Galileo and Copernicus. It seems then that there is no "single, invariant methodology of science." Instead there are series of complex interactions between method and practice. As science and technology develop, so the practitioners develop and negotiate the rules for doing them in a local and contingent fashion. New methodologies are propounded in order to provide support and credibility to a newly preferred scientific theory.

Scientific Practice

It could be argued that the indeterminacies of science and the lack of a specific scientific method are merely philosophical and theoretical problems, and that science is firmly grounded in experimental practice. The best way to know whether a particular knowledge claim about the world is true or false is to subject it to experimental test and then have somebody else repeat the experiment.

There are two kinds of related difficulties with this empirical approach. Experiments are inevitably performed on a simplified, artifactual, and isolated portion of reality. Hence the universal generalizations drawn from them are not indubitable. Cartwright (1983) goes so far as to claim that the Laws of Physics are, in effect, lies. Equally the effectiveness of experimental replication as the litmus test of truth is somewhat undermined by the role of skill or tacit knowledge in scientific practice. "The problem being that, since experimentation is a matter of skillful practice, it can never be clear whether a second experiment has been done sufficiently well to count as a check on the results of the first. Some further test is needed to test the quality of the experiment – and so forth" (Collins 1985). This result in what Collins calls "the experimenter's regress." In the normal course this is resolved by social processes in which the judgment about whether to accept a particular result is based on the relevant community's evaluation of the skills of the experimenter in question. It becomes deeply problematic when the existence of the phenomenon itself is at issue, as in the case of gravity waves. An experiment showing the existence of such waves was followed by others seemingly denying their existence, or at least failing to detect them. Which was correct? The existence of gravity waves turns on the judgment of the community about competently performed experiments, and those judgments of competence are based on the accepted community knowledge about the nature of gravity waves. Replication then is not the test of their existence; rather it reflects the ability of the experimenter to achieve community standards of experimental practice.

Thus it would seem that conceptions of rationality, objectivity, and the scientific method cannot be derived from self-evident epistemological principles. They are instead embedded in the historically contingent processes of scientific practice, whereby the resistances and limitations of reality are encountered and accommodated. Science is a social activity that is essentially dependent on community and tradition, and the practice of science is governed by concrete, discrete, local traditions which resist rationalization.

The notion of a great divide between Western and so-called primitive knowledge systems has turned crucially on the question of rationality of science. If, as the arguments above suggest, science has a rationality of its own, but not one that is especially privileged, how do we both account for and deal with similarity and difference between cultures? How is it, on the one hand, that the peoples of the world are sufficiently alike to have universally developed complex languages, and yet those languages and their accompanying knowledge systems have produced profoundly different cultures? On the other hand, how are we to ensure communication and preserve cultural diversity?

In the entry on local knowledge it is claimed that the common element in all knowledge systems is their localness, and that their differences lie in the way that local knowledge is assembled through social strategies and technical devices for establishing equivalences and connections. It is no small reflexive irony that this entry on rationality and science and the encyclopaedia itself are dependent on unspoken assumptions concerning their credibility and authority which constitute a form of rationality. The encyclopaedia is based on the assumption that widely disparate knowledge can be meaningfully assembled into a volume without loss of coherence due to incommensurability. Furthermore it is assumed that the individual articles, dependent as they are on evidence, analysis, and argument, are capable of being read, understood, and utilized by readers from all cultures. In other words there is a strong resemblance between this encyclopaedia and the practice of science. Science is dependent on the assemblage of heterogeneous inputs, but that assemblage is not achieved by the application of logical and rational rules or conformity to a method or plan. Indeed it is not even dependent on a clearly articulated consensus. Rather the assemblage results from the work of negotiation and judgment that each of the participants puts in to create the equivalences and connections that produce order and meaning. Perhaps then it has to be acknowledged that there is a minimal rationality assumption, and that links between rationalities can either be created or ignored by common human endeavor. So, given the lack of universal criteria of rationality the problem of working disparate knowledge systems together is one of creating a shared knowledge space in which on the one hand equivalences and connections between differing rationalities can be discursively constructed; and on the other hand where no common ground can be created, agreement can be sought to work with the creative tension of difference. A good example of such competing rationalities in tension is the irrigation system of Bali. Stephen Lansing's analysis shows the crucial role of the symbolic system of water temples in managing the flow of the waters, a role that classic Weberian forms of rationality have in the past simply dismissed as irrational (Lansing 1991). Yet the role of the water temples was revealed by Lansing's anthropological and computer-based analysis. Communication, understanding, equality, and diversity will not be achieved by others adopting Western information, knowledge, science, and rationality, it will only come from negotiating ways to work together in joint and multiple rationalities.

Religion and Science in China

Weihang Chen

"Religion and science in China" is a controversial topic which requires some clarification before the discussion can begin. Because the first serious efforts to bring Chinese classical study to the Western academic world were initiated by Jesuit missionaries in the seventeenth century, it became a Western tradition to look at many Chinese cultural phenomena from a religious point of view and categorize them accordingly. For a long time in the West, the three main *Jiao* (systems of teachings and beliefs) of Chinese traditions, Confucianism, Daoism (Taoism), and Buddhism, were called three religions. However, since the reconstruction of Chinese classical study early in this century, Chinese scholars generally consider Confucianism and Classical Daoism philosophies, popular Daoism a religion, and Chinese Buddhism both a religion and a philosophy. Today in the West there is no consistent way of using these terms. All three are called either religions or philosophies or both, according to the idea or method or focus of the researcher. Furthermore, it is common practice to include other beliefs and activities in the study of religion, such as myths, rituals, customs, popular superstitions, and court divination rediscovered through mythological, linguistic, or archeological findings. These new studies are in fact turning the topic of "religion and science" into a much broader topic of "culture and science."

On the other hand, the concept of "Chinese science" is even more uncertain. There is a strong tendency both in the West and in present-day China to question the possibility of a different kind of science. The underlying implication is the belief that there is only one science for one universe – The Science, which is objective and universal. With this belief in mind, explicitly or implicitly, historians of science generally consider Western modern science as the best approximation of The Science, and use it as a measure to search for relevant materials in Chinese ancient relics and texts. By using the same measure, Chinese ancient ideas, theories, studies of nature, and activities dealing with nature are accordingly classified into "scientific subjects" and thereby evaluated. The same belief also provides criteria for distinguishing nonscience from science. The danger of this viewpoint is that it will miss many of the real merits in cultures other than Western ones. One example is that the deep-set dichotomy of "body and soul (mind)" in the Western culture is typically a Greek tradition and may not be shared by other cultures. This difference will show itself especially in the different medical traditions.

For those who do not accept the idea of The Science, it becomes crucial to establish a reasonable or practical criterion for nonscience and science. Research efforts in this regard have not been successful either. Another confusion comes from the fact that in ancient China achievements in technology and in science are not easily distinguishable. There are doubts about if it makes sense or even if it is possible to define these two concepts separately in the context of Chinese ancient culture.

With all these ambiguities in the main concepts and differences in the basic positions, the interaction between religion and science in China has not been formed into a regular study subject. In this article we will acknowledge that the concepts "religion" and "science" are both Western concepts used in a Chinese context. "Religion" means a system of beliefs and "science" means knowledge, especially theoretical or systematic knowledge about nature, human beings, and life, but not about human beliefs, activities, and relationships. Thus we will be able to achieve some clarity in our discussion.

The question of why the scientific revolution did not take place in China has drawn much attention during recent decades. A generally accepted conclusion is still far away, and may not even be important. In this article we will explore the influence exerted by the main Chinese ideologies on the nature and development of Chinese science. Here "main Chinese ideologies" means Confucianism and Daoism. Also, "Chinese science" means and includes Chinese ideas, theories, and knowledge about nature (including humans as natural beings) which were accepted by Chinese scholars or professionals in corresponding historical periods.

In the West in ancient times, science was under the strong influence of religions, and in modern times, religions were under the influence and pressure of the development of science. In China, science went along a different road; it started under the decisive influence of early Confucianism and philosophical Daoism. These two traditions governed the development of Chinese science. There were no serious conflicts between these governing ideologies and Chinese science until China began to bring in Western science on a large scale in the late nineteenth century. The conflict between Confucianism and Western science at that time has been a much studied topic.

After Buddhism was introduced into China around the first century, it gradually became the primary organized religion. However, little can be found in the development of Chinese science that was affected by the development of Chinese Buddhism. One explanation of this phenomenon is that the characteristics of Chinese science, its subject matter and method, had been firmly established before the Qing dynasty (221–206 BCE). The nature of that science is quite compatible with the philosophy and practice of certain kinds of Indian Buddhism. On the other hand, together with Confucianism and Daoism, Chinese science might have exerted a strong influence upon the development of Chinese Buddhism, especially the Chan sect (the origin of the Japanese "Zen"). Little research has been done on this topic.

Our main concern will be the influence of ancient Confucianism and Daoism on Chinese science. We will begin with ancient cosmological beliefs and the methodology associated with these beliefs. As Confucianism and Daoism are the two schools that have been most influential in the making of Chinese culture, have preserved a great quantity of texts and historical records for their teachings, and have been thoroughly studied, the common features of these two schools will provide a good starting point in searching the origin of Chinese science. After this, we will also discuss how the difference between these two schools influenced the development of Chinese science in their own way.

Chinese Ancient Cosmological Beliefs

It is important to examine the basic concepts that were used in both Confucian and Daoist texts. Those that concern Chinese science are the concepts of Heaven, Earth, Human, *Dao*, *Te*, and Fate. Though Chinese classics do not provide definitions for these concepts, we can study the way they were used in their textual contexts and interpret their meaning approximately by using Western concepts as follows: Heaven and Earth form the natural world that Human lives in. Heaven is the part that is farther away from Human but is more fundamental in the sense that it ultimately governs and decides everything that happens to Earth and Human. Earth is the part of the natural world that surrounds and interacts with Human directly. Human is the concept for every human being, who has a life that has a beginning, a growing process, and an end. The distinction between Heaven and Earth is of great importance in the interactive mechanism between Human and Nature. Human can act directly on Earth and change it and use it for his own purposes, but not on Heaven. Earth is governed by Heaven and not by Human; therefore, the way Human deals with Earth (e.g., agriculture and irrigation) can either be right or wrong according to whether it follows or violates Heaven's way. This sounds quite like the Western idea of natural law and it seems compatible with modern scientific views, but there is a crucial difference. The Chinese "Heaven's way", which is called *Dao*, governs not only Earth, but also Human's life and society, and therefore it is a moral matter whether one follows or violates it. To follow the *Dao* is not only a matter of what to do to achieve a certain purpose, like what science tells us in the West, but also what purposes one should have in all his/her activities including governmental, social, familial, and individual activities. Thus, *Dao* as the most fundamental principle or cosmological law is objective and natural, and governs the whole world which in Western categories splits into the natural world, society, and individual life.

To know *Dao* and therefore to act according to *Dao* is the goal of ancient Chinese study. The result of this study is to gain *Te*. *Te* is both knowledge in the sense of knowing what is right, and virtue in the sense of practicing what is right. Like knowledge and virtue in the West, *Te* can be both innate and acquired. That is, people are born with *Te*, to a greater or less degree, and can acquire and accumulate *Te* through study and practice in their lives. However, unlike the Western concepts of knowledge and virtue, *Te* can neither be defined by a general relationship, either functional or quantitative, nor be abstracted or theorized from its special context – the human conditions which define the reality of the individuals concerned.

The reality of an individual is his/her Fate, which is basically determined by Heaven. That means it is out of human reach to change or control it. On the contrary, Fate is the realization of *Dao* in each individual's life. It can be known either through study and practice, or by divination. Ancient Chinese divination, like a certain kind of Greek oracle, does not tell what will happen in the future but answers if actions are right or wrong according to Heaven's way. Therefore, the concept of "good fortune" is not defined by positive results to individual purposes, nor satisfaction of natural or whimsical human desires, but by the realization of the *Dao*. Therefore, ancient Chinese divination, typically represented by the *Yijing* (I Ching, Book of Changes), has a close relation with the ancient Chinese value system and moral principles as well as understandings of *Dao*, and thus exerts great influence on the development of Chinese science.

Now when we look back at these beliefs, the following conclusions are apparent:

1. Because of the wide variety of its governed phenomena, and because of its moral nature, *Dao* is not a deterministic regularity which decides in every detail what happens in the world. Maybe it is, on the whole and in the long run, but certainly not in the form of an instant causal relationship in everyday phenomena which are available for measurement and observance. *Dao* is not a natural law which is impossible to violate.
2. If *Dao* is ultimately deterministic, it can be seen in history. Therefore, to keep historical records is tremendously meaningful and important for the Chinese, and to study these records, what is called historiography in Western terminology, is especially so.

3. If *Dao* is indeterministic in details, and can be violated by people for their wrong purposes, then it makes no sense to study *Dao* by mechanical experimenting, nor by searching underlying regularities in the observable movements of stars in heaven and things on earth. In other words, one cannot study *Dao* through instant causal relationships, because in these relationships there are no observables which indicate whether what happened was on the *Dao* or against the *Dao*.
4. Chinese divination has a nature of empirical knowledge which comes from generalization of phenomenological and historical observations, and a nature of theoretical knowledge which employs mathematical representation to calculate functional relations in the change of affairs. Not only does it exert great influence on the later development of Chinese science in its conceptual system and methodology, but also it could be looked upon as the earliest achievement of Chinese science.

Confucianism

Confucianism is the English word for *Ru Jia* (the School of Scholars), which was founded by Confucius (551–479 BCE), the first private teacher in China. Confucius is the Latinized form of *Kong Fuzi*, a respectful way of addressing the master. *Kong* was his family name. He lived in a time when the empire was being broken up into numerous feudal states. It was a time of change, disorder, and degeneration of the old moralities. When he started as an officer and political reformer, Confucius' ideas of personal cultivation and moral government failed to attract the rulers of his time. So he turned to teaching and taught a large number of private students, preparing them to be good court ministers as well as good teachers. Thus, he managed to exert an influence by establishing a tradition of individual learning and private education. In the second century BCE his ideas and teachings were made authoritative by the Han emperors, and the Classics Confucius edited and used in teaching became the only official textbooks in China until the beginning of the twentieth century.

Confucianism is *the* Chinese ideology. From the second century BCE to the beginning of the twentieth century, it has been the orthodoxy. In a way, it is the Chinese religion, because it provides a system of beliefs (or disbeliefs) and values which calls for faith and acceptance from students, and also because it is more a way of life for students to follow than a body of knowledge for them to master. There are always scholars who spend their lives studying the text of Confucian Classics, but it is not through these studies that Confucianism exerts its influence on Chinese society and culture. In this regard, Confucianism is more comparable to Western religions than philosophies.

However, Confucianism is not a religion in the Western sense, because it has neither doctrine nor reference to the supernatural. It gives no promise, no reward, and no consolation to its followers either in or beyond this life. It has no God, no church, and no organization. It is only a teaching. It teaches the follower how to be a noble man (a *Junzi*) living a noble life in his special social context.

The ultimate goal of Confucius' teaching, and therefore the goal of Confucian learning, is the benefit of the people. The essence of Confucianism lies in these two doctrines (1) a moral government, i.e., governing by moral examples and education instead of by rules, law, and punishment, is the solution to social disorder and is to the highest benefit of the people; and (2) the cultivation of a group of *Junzi* (noble men) in a society is a practical road toward moral government.

A *Junzi* is an elite scholar. He is elite because he has higher moral standards and is therefore a better person than a common man (*Xiaoren*, the small men); but he is not an elite in the Western sense, because his higher moral standards require that he has no social privileges but only duties and obligations. To be a *Junzi* is both to lead a noble life and to have a noble personality; it is a lifelong task of self-cultivation without personal gains. One will choose to be a *Junzi* because he knows it is his fate.

To be a *Junzi* is the immediate goal for a Confucian. Because Confucians believe that people's benefit will be served best by bettering the government, people are left alone to deal with their own material needs, their production, and their struggle with the natural surroundings. Confucians take it for granted that common people are naturally wise enough to deal with all that and take care of their own needs, and it is not *Junzi's* task to learn and develop knowledge and ability in this regard. Confucians believe that a moral society would naturally become prosperous.

The *Analects*, a basic Confucian classic, recorded that Confucius once refused to teach his student agricultural knowledge, saying the elder farmers and gardeners were better than he in this regard. This shows that *Junzi's* learning should be limited to the scope of human relationships, and science or scientific knowledge has no value to *Junzi's* task of self-cultivation.

This Confucian attitude toward scientific knowledge has its roots in the belief that the world Human lives in is governed by the *Dao*, and the best thing Human can do is to follow the *Dao*. In Chinese cosmology it is a Human choice, therefore a moral matter, to follow or to go against the *Dao*. Therefore, the Western task of changing the world according to man's ideas, or reforming the world to suit man's needs, would sound absurd and dangerous to the ancient Chinese, for it advocates going against the *Dao*. Human is a part of the universe, and not the governing part. Man is not the lord of the earth and cannot give orders to Nature. This is not to say that ancient Chinese did not make efforts to better their living conditions, but it does mean that they did not give these efforts high priority on the scale of social urgencies.

After Confucianism was made authoritative by Chinese emperors in the second century BCE nearly all Chinese intellectuals became Confucians, who formed an elite class in Chinese society. Generally speaking, Confucians looked down on technical and scientific knowledge and achievements because these neither had any use in self-cultivation, nor helped in turning the government into a moral one. This attitude left the development and preservation of scientific knowledge in the hands of professionals, many of whom were illiterate and kept their skills and knowledge as a family tradition. With the exception of astronomy, mathematics, and medicine, Chinese ancient technological and scientific achievements were seldom recorded or their records preserved. When the British scientist and historian of science Joseph Needham started to search extensively through the extant texts for these records, and began to publish the results of his search in the multivolumed *Science & Civilisation in China* (1954–), it shocked the world to see that Chinese themselves did not remember what they had achieved. Certainly the ancient Confucians would not value these "achievements" as much as modern Westerners do.

There is no doubt that this Confucian devaluation of scientific activity, knowledge, and achievements has been a significant hindrance to the development of Chinese science. However, Confucians did value the study of astronomy, mathematics, and medicine, though the former two were not necessarily as urgently needed by the people as the knowledge for agricultural production. The reason Confucians accepted them as a proper scholarly study is for their use in divination. Confucianism included divination in the basic teaching of *Li* (rites). Astronomy and mathematics were needed in making calendars, which were important for the agricultural economy. Medicine was an early tradition and developed into such a complicated system that it became an intellectual profession even before Confucianism gained its orthodox position.

Confucianism did allow for scientific and technological knowledge to grow among the professionals. The Confucian attitude toward science is to leave it alone. Science and technology are not Confucians' proper concerns, but they never go against them. Under the reign of Confucianism there were no known cases in which scientists and innovators were persecuted because of their ideas or inventions. Confucianism created unfavorable social attitudes and conditions for scientific and technological development in China, only because Chinese rulers made Confucianism orthodox and turned the intelligentsia into Confucians. But we cannot oversimplify this situation and accuse Confucianism of smothering a scientific revolution which would otherwise have happened in China. When we study the three branches of science Confucianism valued, and compare them to Western ones, it can be seen that they are metaphysically and methodologically different. What Confucianism did to Chinese science was external and only confined to social factors.

Daoism

The term *Daoism* in English has several meanings. In its basic meaning it is a translation of the Chinese *Dao Jia* (the School of *Dao*), which was represented by two Daoist classics: the *Lao Zi* and the *Zhang Zi*. In this sense, Daoism (also called Classical Daoism or Daoist philosophy) is an ancient philosophical tradition. In its second meaning Daoism is a translation of the Chinese *Dao Jiao* (the religion of *Dao*, or Popular Daoism). It includes a variety of later organizational developments of the Daoist religion, mostly imitating the form of imported Buddhism but incorporating the ideas of the *Lao Zi* and *Zhang Zi*. It was often involved in political issues, sometimes was used to organize and mobilize peasants' uprisings, occasionally was used to seek favors from the court, and was thereby supported by Chinese emperors. It was a folk religion and Confucians looked down on it as low culture and superstition. In its third and very broad meaning, it is a vague concept that includes Classical Daoism, Popular Daoism, and some other schools that were similar to Classical Daoism. These other schools include the School of *Yinyang* and the School of *Huang-Lao* (the School of the Yellow Emperor and *Laozi*). It is in this last sense that we are now using the term Daoism.

Generally speaking Daoists emphasize individual happiness rather than social welfare. They believe in *Dao*, in cutting down one's desires and wants, in living a simple, secluded, and natural life, and in cultivating spiritual as well as physical immortality. In the last aspect it is mysticism from a modern scientific point of view, but the method it uses in seeking the way of immortality, which according to Daoism should be realized in this life on earth, is very much empirical and congenial with the Western development of geography, health care, and elixir alchemy. Thus, the influence of Daoism on the development of Chinese science is substantial.

The central idea that exerts a strong impact on the development of Chinese science is the search for immortality in this life on earth. We do not know what the origin of this idea is and when its practice started. There are three approaches: the first is by cultivating one's *Qi*, the second by making special drugs such as the elixir of life, and the third by going deep into mountains or on the seas to find living immortals to learn from. The concept of *Qi* is one of the most ancient Chinese concepts about nature and life. It was used, in the sense of vitality, in the works of the warring-states philosophers, such as Mencius, Xun Zi, Zhuang Zi, and Lüshi Chunqiu in the fourth and the third centuries BCE. The earliest extant text that mentioned elixir drugs is *Hanfei Zi*, which was in the third century BCE. *Shi Ji* (Records of the Historian, compiled during the second and the first century BCE) recorded that in the fourth and third century BCE the rulers of Chu and Yan states sent envoys sailing to learn about the ways of immortality.

These three approaches led to three developments of Chinese science. The first is Chinese medicine, including health care techniques and *Qigong*. *Qigong* is an Eastern exercise which is based on the theory of interaction between body and spirit and the possibility of controlling one's mental state by manipulating one's body. The second is somewhat connected with the development of Chinese pharmacology, but more so with that of chemistry which led to the invention of gunpowder. The third helped to preserve ancient myths and legends, and initiated the need to exploit the outside world which Confucians neglected. The earliest Chinese geographical work, *Shan Hai Jing*, is basically the result of this effort.

The Daoist influence on Chinese science is more congenial with the criteria of modern science. Daoists believe in the power of true knowledge for their own purpose of immortality and that knowledge can be sought by experimenting or by learning from those who know. They accept that the truthfulness of that knowledge should be tested by the results of its applications. With their beliefs of *Yinyang* and *Wuxing* (Five Phases), which are not religious but ontological and methodological, Daoism is the Chinese system of belief that led to the flourishing of Chinese medical theory and health care practices, which might be considered the highest achievements of Chinese science.

Religion and Science in Islam I: Technical and Practical Aspects

David A. King

In Islam, as in no other religion in human history, the performance of various aspects of religious ritual has been assisted by scientific procedures. The organization of the lunar calendar, the regulation of the astronomically defined times of prayer, and the determination of the sacred direction toward the Kaʿba in Mecca are topics of traditional Islamic science still of concern to Muslims today, and each has a history going back close to 1,400 years. But the techniques advocated by the scientists of medieval Islam on the one hand and by the scholars of religious law on the other were quite different, and our present knowledge of them is based mainly on research conducted during the past 30 years on one small fraction of the vast literary heritage of the Muslim peoples. To understand Muslim activity in this domain we must realize that there were two main traditions of astronomy in the Islamic Near East, folk astronomy and mathematical astronomy.

The Regulation of the Lunar Calendar

The Islamic calendar is strictly lunar. The beginnings and ends of the lunar months, in particular of the holy month of Ramadan, and various festivals throughout the 12-month "year," are regulated by the first appearance of the lunar crescent. Since 12 lunar months add up to about 354 days, the 12-month cycles of the Islamic calendar begin some 11 days earlier each year, and the individual months move forward through the seasons.

R

For scholars of the sacred law, the month began with the first sighting of the crescent moon. This observation is a relatively simple affair, provided that one knows roughly where and when to look and the western sky is clear. Witnesses with exceptional eyesight were sent to locations that offered a clear view of the western horizon, and their sighting of the crescent determined the beginning of the month; otherwise they would repeat the process the next day. If the sky was cloudy, the calendar would be regulated by assuming a fixed number of days for the month just completed. Also, the crescent might be seen in one locality and not in another. Unfortunately the historical sources contain very little information on the actual practice of regulating the calendar.

Medieval astronomers, on the other hand, knew that the determination of the possibility of sighting on a given day was a complicated mathematical problem, involving knowledge of the positions of the sun and moon relative to each other and to the local horizon. The crescent will be seen after sunset on a given evening at the beginning of a lunar month if it is far enough away from the sun, and if it is high enough above the horizon not to be overpowered by the background sky glow. Conditions required to assure crescent visibility on most occasions can be determined by observations, but the formulation of a definitive set of conditions has defied even modern astronomers. The positions of the sun and moon must be investigated to see whether the assumed visibility conditions are satisfied, but, even if they are, the most ardent astronomer can be denied the excitement of sighting the crescent at the predicted time if clouds or haze on the western horizon restrict his view.

The earliest Muslim astronomers adopted a lunar visibility condition which they found in Indian sources. It was necessary to calculate the positions of the sun and moon from tables and then to calculate the difference in setting times over the local horizon. If the latter was 48 min or more, the crescent would be seen; if it was less, the crescent would not be seen. In the early ninth century the astronomer al-Khwārizmī compiled a table showing the minimum distances between the sun and moon (measured on the ecliptic) to ensure crescent visibility throughout the year, based on this condition and computed specifically for the latitude of Baghdad. During the following centuries Muslim astronomers not only derived far more complicated conditions for visibility determinations but also compiled highly sophisticated tables to facilitate their computations. Some of the leading Muslim astronomers proposed conditions involving three different quantities, such as the apparent angular separation of the sun and moon, the difference in their setting times over the local horizon, and the apparent lunar velocity. Annual ephemerides or almanacs gave information about the possibility of sighting at the beginning of each month.

The Regulation of the Five Daily Prayers

The times of the five daily prayers in Islam are defined in terms of astronomical phenomena dependent upon the position of the sun in the sky. More specifically, the times of daylight prayers are defined in terms of shadows, and those of night prayers in terms of twilight phenomena. They therefore vary with terrestrial latitude, and unless measured with respect to a local meridian, also with terrestrial longitude.

Because the months begin when the new moon is seen for the first time shortly after sunset, the Islamic day is considered to begin at sunset. Each of the five prayers may be performed during a specified interval of time, and the earlier during the interval the prayer is performed, the better. The day begins with the *maghrib* or sunset prayer. The second prayer is the *ishāʾ* or evening prayer, which begins at nightfall. The third is the *fajr* or dawn prayer, which begins at daybreak. The fourth is the *ẓuhr* or noon prayer, which begins shortly after astronomical midday when the sun has crossed the meridian. The fifth is the *ʿaṣr* or afternoon prayer, which begins when the shadow of any object has increased beyond its midday minimum by an amount equal to the length of the object casting the shadow. In some medieval circles, the *ẓuhr* prayer began when the shadow increase was one-quarter of the length of the object, and the *ʿaṣr* prayer continued until the shadow increase was twice the length of the object.

In the first few decades of Islam, the times of prayer were regulated by observation of shadow lengths by day and of twilight phenomena in the evening and early morning. Precisely how either the daylight or the nighttime prayers were regulated is unfortunately not clear from the available historical sources. Muezzins who performed the call to prayer from the minarets of mosques were chosen for their piety and the excellence of their voices, but their technical knowledge was limited.

On the other hand, the determination of the precise moments (expressed in hours and minutes, local time) when the prayers should begin, according to the standard definitions, required complicated mathematical procedures in spherical astronomy, that is, the study of problems associated with the apparent daily rotation of the celestial sphere. Accurate as well as approximate formulae for reckoning time of day or night from solar or stellar altitudes were available to Muslim scholars from Indian sources and these were improved and simplified by Muslim astronomers. Certain individual astronomers from the ninth century onward applied themselves to the calculation of tables for facilitating the determination of the prayer times. The earliest known prayer-tables were prepared in the ninth century by al-Khwārizmī for the latitude of Baghdad. The first tables for finding the time of day from the solar altitude or the time of night from the altitudes of certain prominent fixed stars appeared in Baghdad in the ninth and tenth centuries. The extent to which these tables deriving from mathematical procedures were used before the thirteenth century is unknown. The earliest examples are contained in technical works which must have had fairly limited circulation; the muezzins certainly had no need of them. Only a professional astronomer could use the tables, together with some kind of observational instrument for measuring the sun's altitude and reckoning the passage of time.

It was not until the thirteenth century that the institution of the *muwaqqit* appeared in mosques and madrasas. These professional astronomers associated with a religious institution not only regulated the prayer times, but constructed instruments, wrote treatises on spherical astronomy, and gave instruction to students. In thirteenth-century Cairo, new tables were available, and these set the tone for astronomical timekeeping all over the Islamic world in the centuries that followed. In medieval Cairo there was a corpus of some 200 pages of tables available for timekeeping by the sun and for regulating the times of prayer; in numerous copies the tables are associated with Ibn Yūnus.

Impressive innovations in astronomical timekeeping were made in other medieval cities, especially Damascus, Tunis, and Taiz, although by the sixteenth century Istanbul had become the main center of this activity. Highly sophisticated tables of special trigonometric functions were compiled to solve problems of spherical astronomy for any latitude. Tables for finding the time of day from the solar altitude at any time of year were compiled for Cairo, as we have mentioned, and also for Damascus, Tunis, Taiz, Jerusalem, Maragha, Mecca, Edirne, and Istanbul. Medieval tables for regulating the times of prayer have been found for a series of localities between Fez in Morocco and Yarkand in China. Such tables have a history spanning the millennium from the ninth century to the nineteenth.

Astronomical tables for regulating the prayer times had to be used together with instruments; only in this way could one ascertain that the time advocated in the table had actually arrived. The most popular of these instruments were the astrolabe and the quadrant. Hundreds of Islamic astrolabes and several dozen quadrants are preserved in the museums of the world, only a small fraction of the instruments actually made by Muslim astronomers. An alternative means of regulating the daytime prayers was available to the Muslims in the form of the sundial. Many mosque sundials from the later period of Islamic astronomy survive to this day, though most are now nonfunctional.

The Determination of the Sacred Direction

The Kaʿba in Mecca was adopted as the focal point of the new religion since the *Qurʾān* advocates prayer toward it. For Muslims it is a physical pointer to the presence of God. Thus since the early seventh century Muslims have faced the Sacred Kaʿba in Mecca during their prayers. Mosques are built with the prayer-wall facing the Kaʿba, the direction being indicated by a *miḥrāb* or prayer-niche. In addition, certain ritual acts such as reciting the *Qurʾān*, announcing the call to prayer, and slaughtering animals for food, are to be performed facing the Kaʿba. Also Muslim graves and tombs were laid out so that the body would lie on its side and face the Kaʿba. (Modern burial practice is slightly different but still Mecca-oriented.) Thus the direction of the Kaʿba – called *qibla* in Arabic and all other languages of the Islamic commonwealth – is of prime importance in the life of every Muslim.

During the first two centuries of Islam, when mosques were being built from Andalusia to Central Asia, the Muslims had no truly scientific means of finding the qibla. Clearly they knew roughly the direction they had taken to reach wherever they were, and the direction of the road on which pilgrims left for Mecca could be, and, in some cases, actually was used as a qibla. But they also followed two basic procedures, observing tradition and developing a simple expedient. In the first case, some authorities observed that the Prophet Muḥammad when he was in Medina (north of Mecca) had prayed due south, and they advocated the general adoption of this direction for the qibla. This explains why many early mosques from Andalusia to Central Asia face south. Other authorities said that the Quranic verse quoted above meant standing precisely so that one faced the Kaʿba. Now the Muslims of Meccan origin knew that when they were standing in front of the walls or corners of the Kaʿba they were facing directions specifically associated with the risings and settings of the sun and certain fixed stars. They knew that the major axis of the rectangular base of the edifice points toward the rising point of Canopus, and the minor axis points toward summer sunrise and winter sunset. These assertions about the Kaʿba's astronomical alignments, found in newly discovered medieval sources, have been confirmed by modern measurements.

In addition Arabic folklore associates the sides of the Kaʿba with the winds and rain. These features and associations cast new light on the origin of the edifice, and in a sense confirm the Muslim legend that the Kaʿba was built in the style of a celestial counterpart called *al-bayt al-maʿmūr*: indeed it seems to have been an architectural model of a pre-Islamic Arab cosmology in which astronomical and meteorological phenomena are represented. The religious association was achieved first by a number of statues of the gods of the pagan Arabs which were housed inside it. With the advent of Islam, these were removed, and the edifice has for close to 1,400 years served for Muslims as a physical focus of their worship.

R

The corners of the Kaᶜba were associated even in pre-Islamic times with the four main regions of the surrounding world: Syria, Iraq, the Yemen, and "the West." Some Muslim authorities said that to face the Kaᶜba from Iraq, for example, one should stand in the same direction as if one were standing right in front of the north eastern wall of the Kaᶜba. Thus the first Muslims in Iraq built their mosques with the prayer-walls toward winter sunset because they wanted the mosques to face the north eastern wall of the Kaᶜba. Likewise the first mosques in Egypt were built with their prayer-walls facing winter sunrise so that the prayer-wall was "parallel" to the north western wall of the Kaᶜba. Inevitably there were differences of opinion, and different directions were favored by particular groups. Indeed, in each major region of the Islamic world, there was a whole palette of directions used for the qibla. Only rarely do the orientations of medieval mosques correspond to the qiblas derived by computation. Recently some medieval texts have been identified which deal with the problem of the qibla in Andalusia, the Maghrib, Egypt, Iraq and Iran, and Central Asia. Their study has done much to clarify the orientation of mosques in these areas. In order that prayer in any reasonable direction be considered valid, some legal texts assert that while facing the *actual* direction of the Kaᶜba (*ᶜayn*) is optimal, facing the *general* direction of the Kaᶜba (*jiha*) is also legally acceptable.

In various texts on folk astronomy, popular encyclopedias, and legal treatises, we find the notion of the world divided into sectors about the Kaᶜba, with the qibla in each sector having an astronomically defined direction. Some 20 different schemes have been discovered recently in the manuscript sources, attesting to a sophisticated tradition of sacred geography in Islam.

The earliest schemes of Islamic sacred geography date from the ninth century, but the main contributor to its development was a Yemeni legal scholar named Ibn Surāqa, who studied in Basra about the year 1000. Ibn Surāqa devised three different schemes of sacred geography, with the world arranged in 8, 11, and 12 sectors around the Kaᶜba. Each sector of the world faces a particular section of the perimeter of the Kaᶜba. Simpler versions of his 12-sector scheme occur in such popular geographical works as the *Taqwīm al-buldān* of Yāqūt al-Rūmī (ca. 1200) and the *Āthār al-bilād* of al-Qazwīnī (ca. 1250) as well as the encyclopedia *Ṣubḥ al-aᶜshā* of al-Qalqashandī (ca. 1400). From the fifteenth century to the nineteenth, we find a proliferation of schemes with different numbers of divisions between eight and 72 divisions of the world around the Kaᶜba.

Muslim astronomers from the eighth century onward concerned themselves with the determination of the qibla as a problem of mathematical geography. This activity involved the measurement of geographical coordinates and the computation of the direction of one locality from another by procedures of geometry or trigonometry. The qibla at any locality was defined as the direction of Mecca along the great-circle on the terrestrial sphere.

Muslims inherited the Greek tradition of mathematical geography, together with Ptolemy's lists of localities and their latitudes and longitudes. By the early ninth century observations were conducted in order to measure the coordinates of Mecca and Baghdad as accurately as possible, with the express intention of computing the qibla at Baghdad. Indeed, the need to determine the qibla in different localities inspired much of the most sophisticated activity of the Muslim geographers (see below).

Once the geographical data are available, a mathematical procedure is necessary to determine the qibla. The earliest Muslim astronomers who considered this problem developed a series of approximate solutions, all adequate for most practical purposes, but in the early ninth century, if not before, an accurate solution by solid trigonometry was formulated. The accurate formulae derived by the Muslim astronomers from the ninth century onward are impressive, and are mathematically equivalent to the modern formula. Muslim astronomers also compiled a series of tables displaying the qibla for each degree of latitude and longitude difference from Mecca, based on both approximate and exact formulae, the first of these being prepared in Baghdad in the ninth century.

Over the centuries, numerous Muslim scientists discussed the qibla problem, presenting solutions by spherical trigonometry, or reducing the three-dimensional situation to two dimensions and solving it by geometry or plane trigonometry. They also formulated solutions using calculating devices. But one of the finest medieval mathematical solutions to the qibla problem was reached in fourteenth-century Damascus: a table by al-Khalīlī displays the qibla for each degree of latitude from 10° to 56° and each degree of longitude from 1° to 60° east or west of Mecca, with entries correctly computed according to the accurate formula. This splendid table (rediscovered only in the early 1970s) was not widely known in later Muslim scientific circles. *Muwaqqits* of later centuries wrote treatises about the determination of the qibla but did not mention this Syrian table. By the fourteenth century the correct values of the qibla of each major city had long been established (correct, that is, for the medieval coordinates used in the calculations). Simple qibla-indicators fitted with a magnetic compass and a gazetteer of localities and qiblas became common, and the modern variety represents a continuation of this tradition.

Some of the most important Muslim contributions to mathematical geography are to be found in a series of treatises by the early eleventh-century scientist al-Bīrūnī. In one treatise he set out to determine for his patron the qibla at Ghazna (in what is now Afghanistan), first establishing the necessary geographical coordinates and then calculating the qibla by different procedures. Since 1989 three Persian qibla-indicators, made in Isfahan about 1675, have became available for study. They bear a cartographic grid so devised that one can read the direction and distance to Mecca directly. Mecca is at the center of the grid and one has only to lay the diametrical rule over any city marked on the map (between Spain and China, Europe and the Yemen) to read off the qibla on a circular scale around the grid and the distance on the diametral rule. The origin of this remarkable device is still under investigation; but the underlying mathematics is described in two treatises on conic sections, one from tenth-century Baghdad and the other from eleventh-century Isfahan. The tradition behind the Isfahan world maps represents the most sophisticated contribution to mathematical geography known between Antiquity and the Renaissance.

The alignment of medieval mosques reflects the fact that the astronomers were not always consulted on their orientation. But now that we know from textual sources which directions were used as a qibla in each major locality, we cannot only better understand the mosque orientations but also recognize numerous cities in the Islamic world that can be said to be qibla-oriented. In some, such as Taza in Morocco and Khiva in Central Asia, the orientation of the main mosque dominates the orientation of the entire city. In the case of Cairo various parts of the city and its suburbs are oriented in three different qiblas. The new Fatimid city of al-Qāhira, founded in the tenth century, faces winter sunset, which was the qibla of the Companions of the Prophet who erected the first mosque in Egypt in nearby Fustat some three centuries previously. The later Mamluk "City of the Dead" faces the qibla of the astronomers. The predominant orientation of architecture in the suburb of al-Qarāfa is toward the south, another popular qibla. The splendid Mamluk mosques and madrasas built along the main thoroughfare of the old Fatimid city are aligned externally with the street plan, and internally with the qibla of the astronomers: one can observe the varying thickness of the walls when standing in front of the windows inside the mosque overlooking the street outside. This is an area of the history of urban development in the Islamic world which has only recently been studied for the first time, not least because, prior to the discovery of the textual evidence, it was by no means clear which directions were used as qiblas; even if a qibla at variance from the true qibla was clearly popular, it was not known why. The first accurate longitude values of localities in the Islamic world become available only with the systematic scientific cartographic surveys of the eighteenth and nineteenth centuries. Thus most of the accurately computed qiblas of the medieval astronomers could be judged as being in error by a few degrees anyway.

Other Applications of Science to Daily Life

The Islamic laws of inheritance, based on prescriptions in the *Qurʾān*, are complicated, and their application involves some skill in arithmetic. Both legal scholars and certain mathematicians wrote on this subject, but only two or three simple works by legalists have been studied and until recently no research of consequence had been conducted on the large number of available sources. There is also a vast corpus of literature on weights, measures, and arithmetical techniques.

Muslims also developed geometric designs for the decoration of religious architecture and also secular artifacts. The acceptability of such ornamentation is discussed by various legal scholars, but their writings have yet to be properly studied. Only two Muslim mathematicians are known to have included remarks on geometric design in their writings, a fact which confirms the suspicion that this was an art passed down amongst the practitioners. Some years ago a manuscript of an artisan's manual with guidelines for generating numerous patterns is now published.

The legal scholars of medieval Islam used methods for regulating the calendar and prayer times and for finding the sacred direction which were simple and adequate for practical purposes. Their ingenuity in coping with differences of opinion never lost sight of the basic purpose of Quranic and Prophetic injunctions. Some of the greatest of the Muslim scientists dealt with the calendar, prayer times, and the qibla, and in these areas, as in others, their mathematical creativity and their quest for greater accuracy was impressive. In later centuries (after the thirteenth), competent astronomers were appointed to the staffs of major mosques in order to advise on these specific subjects. But the solutions developed by Muslim scientists were invariably too complicated for widespread application in the medieval milieu. Although the scholars of the sacred law and the scientists proposed different solutions for the same individual problem, there are few records of serious discord between the two groups in the medieval sources. The legal scholars criticized mathematical astronomy mainly insofar as it was used by some as the handmaiden of astrology, which was an anathema to them. The scientists seldom spoke out against the simple procedures adopted by the legal scholars.

Religion and Science in Islam II: What Scientists Said About Religion and What Islam Said About Science

Anton M. Heinen

The interaction between religious life and scientific enterprise in the culture that evolved under the impact of Islam is one of the predominating themes in today's discussions and writings of Muslims all over the world. It has continued to be such ever since the beginning of the last century, when European forces, with their newly developed technological means, extended their rule over large areas with Muslim populations until then concerned only with the traditional values of their preindustrial communities. Today's revivalist Muslim leaders, themselves often engineers or trained scientists and not theologians, fight for a new society based on a harmonious practice of Islam and science. Or governments build mosques with technological showpieces (e.g., minarets with laser beams as indicators of the *qibla*, the direction of Mecca, as recently in Morocco), and museums and universities dedicated to the "Islamic sciences". The scientific achievements of the West are considered to be the inheritance of great Muslim sages of the Middle Ages. Thus modern technology cannot be a dangerous evil because it belonged to the Muslims first. But it has been alienated by the West, truncated from its heart, which is the recognition of Allāh, the Creator of all beings. This was the view of the influential leader of the Muslim Brothers, Sayyid Qutb (1906–1966). Although he was executed under Nasser's government in Egypt in 1966, his brief sermon on *This Faith, Islam* is still representative of some sections of opinion in the Muslim community.

Observers from the outside world, where the dispute between religion and science has largely turned into a relic of the past, if it does not lead into ethical discussions about the effects of scientific and technological progress on human values, find it difficult to do justice to this preoccupation of their Muslim neighbors, which they usually interpret in analogy to apparently similar ideologies in their own realm, such as fundamentalism in America's "Bible Belt". However, the religious as well as the scientific realities involved differ greatly on both sides. Instead, the insights of the history of science as well as that of religion should be drawn upon when the relationship between the two fields is to be treated objectively. As the history of science has brought to light a whole spectrum of changing methods and conceptualizations that over the centuries have been interpreted as "science", so also "religion" has been described by its historians as being practiced variously by just about every people, culture, time, or even individual. Generalizations about the religious factor in human activities, in the West always identified with dogmatic teachings, are just as false as those about an unhistorically monolithic science, but even more widespread. The surprisingly bitter reaction to the attack of some European powers and individuals will be more readily understood if the interaction of science and Islamic religion, from the outset centered on increasing knowledge, is rightly appreciated.

The case of scientific technology probably was chosen as a favored battlefield because the Western critics, proudly flying the flag of enlightenment, had previously used it as a weapon against the Islamic religion. Thus, cultural and technological back wardness became a religious issue for Muslim intellectuals. Curiously enough, it was the philosophical and scientific work of Ibn Rushd (Latin Averroes, 1126–1198), who as "the Commentator" (namely of Aristotle) had been accepted as master by the European scholars throughout the Middle Ages, which stood in the center of this modern attack on Islam. That he had not been able to influence his co-religionists in the Islamic world to the same extent as the Jewish and Christian schoolmen in Europe was the main reason that Islam in the last century was made responsible for the worst obstruction against scientific progress. The main exponent for this attack was Ernest Renan's *L'Islam et la science*, written in 1883; the Arabic writings of Faraḥ Anṭūn in the journal *Al-Jāmiʿa* (Cairo, 1902–1903), easily accessible for Egyptian intellectuals, made this attack on Islam even more effective. From then on, the relationship between science and religion, both seen in the crystallized and almost ahistorical notions of that time, was turned into the most crucial question for any global view of Islam in human history. The question was raised on more general grounds: "Why did the Muslims fall back, while the others made progress?" The more general and fundamental questions have stood in the foreground; the more particular ones, e.g., the Islamic position *vis-à-vis* alchemy, astrology, geocentric vs. heliocentric astronomy, or such consequential medical questions as anatomical dissections, preventive measures against epidemics, abortion, birth control, etc., have been strangely pushed into the background, although numerous treatises over the centuries have been written on them.

In defense, the beginnings of the spread of scientific activity in Islamic culture, and then its high period, were chiefly taken for reference, not the obvious stagnation in the later Middle Ages. The latter phenomenon has hardly been studied, and almost no convincing explanations have ever been proposed. But it is revealing that no responsibility for such an intrusion into scientific development has been assigned to the Islamic religious authorities, as has been the case of the Inquisition trials in Christian countries.

But, in confrontation with medieval historians centered on Europe, it was not easy to reclaim the scientific heritage for the Muslims, for this heritage was primarily seen as that of the ancient Greeks whose works had been translated into Arabic. And since these works, some centuries later, were again translated from Arabic into Latin, the Arabs apparently were assigned the humble role of transmitters only, like the merchants in an import and export business. For Renan, the cultural role of Islam was actually limited to the preservation of ancient culture for and transmission to Europe, where it would be revived. That such translations from pre-Islamic Hellenistic culture involved a heavy indebtedness was not denied by Arab historians. However, in their view this ancient heritage was integrated into an already established Islamic society. As it is today, with more sources to judge by, the roots of the scientific movement in Islam itself are more generally recognized as having exerted a stimulating influence on the introduction of the more complete scientific heritage of pre-Islamic cultures: the *Qurʾān* and its exegesis, jurisprudence, philology, etc.

The first line of defense was taken up by such rationalist reformers as Shaykh Muḥammad ʿAbduh (1849–1905). He argued that Quranic religion was in no way opposed to, but on the contrary totally in harmony with science. The guidelines of his argument were taken from the apologetic discussions about the necessity of miracles as testimonials for the true prophet: miracles supposedly revealed the divine nature of Jesus, the Son of God, while the Prophet Muḥammad had only referred to the factual evidence of the Arabic *Qurʾān* in support of his divine message. (Miracles like the splitting of the Moon by the Prophet, as they were described in popular literature, were apparently not considered in this argumentation of modernist theology.) That the fact of revelation, divine speech entering the limits of creation, or the *Qurʾān* as an inimitable revealed book, were proposed by the Prophet as the decisive miracle, or that creation and recreation after death were described as miracles permeating the whole of human existence, all these truly "miraculous" events apparently were not considered to interfere with the course of nature.

Unfortunately, ʿAbduh's apologetic argumentation was later exaggerated by his disciple Rashīd Riḍā (1865–1935) who claimed science for Islam. In his commentary of the revealed book, all knowledge was traced to the *Qurʾān*, even modern technological and medical inventions. For example, the Arabic *Jinn* were identified with the microbes of contemporary medicine. But progress soon let such hasty identifications appear outdated, and today this unhealthy spirit of "Islamization" is much less prevalent.

More common, and truer to the revealed Quranic texts, is the derivation of an original Muslim science from the so-called "sign-verses," i.e., those verses that prescribe the inquiry into such signs in creation as the sun, moon, stars, earth, and sea, life in all its forms, in fact whatever enters the realm of human experience. Corresponding texts can be found in the works of Muslim scientists throughout Islamic history, in the *Taḥdīd nihāyāt al-amākin* (The Determination of the Coordinates of Positions for the Correction of Distances Between Cities) of the mathematician and astronomer al-Bīrūnī (973–1051), in the *Faṣl al-maqāl* (On the Harmony of Religion and Philosophy) of the philosopher Ibn Rushd (1126–1198), or the interviews of the living Nobel prize winner Abdus Salam. Such an inquiry, as should be noted against a frequent misunderstanding of Western scholars, was not to lead to higher developed proofs for the existence of God, for it would be contrary to the faith of Islam that such proofs should be needed. But Muslims of all times have interpreted the Quranic counsels of "considering the wonders of creation" as the most effective promotion of scientific research. The results were not predetermined; not even the existence of the Creator was imposed as the logical consequence of a binding argument. But the faithful scientist was to find himself placed in the more overwhelming presence of a personally approachable God Almighty. The inner spiritual motivations for an Islamic science, not the passing discoveries, were of the greatest significance.

How far along the way of an open and progressive science a Muslim scholar could be led by the sign-passages of the *Qurʾān* is best illustrated by Ibn Rushd's treatise *Faṣl al-maqāl*. Even though he was a high functionary of Islamic law at the court of the strict Almohad administration, Ibn Rushd wrote this work as a legal defense of objective and universalist scholarship. Beginning from the Quranic injunctions to respond with thought and inquiry to the wonders of creation, he gradually moved on to the defense of gradual progress beyond incomplete scientific results, relying in the process on the heritage of pre- and non-Islamic sages. Hence, the great lawyer could even accept preliminary results, teachings known to include errors. To tolerate such partially erroneous theories, while always proceeding toward deeper insights, was for him a basic consequence of the human condition. While not denying prophetic revelation as the source of the Islamic religious movement, Ibn Rushd with this open system may be said to have reached the highest peak of the Islamic scientific worldview.

It cannot be surprising that natural research on the background of the Quranic finding of the Creator, whose inner nature is above all human speculation, in the signs he had placed for humanity into his creation, has sometimes been understood along Pantheistic lines. Knowledge did seem to acquire a higher character for salvation, or even a certain participation in the unitarian nature of the One God. Influential theologians like al-Ghazālī (1058–1111), but also leading scientists up to Abdus Salam in present times, insisted on Allāh's personal nature as Creator. Scientific disciplines, therefore, were to be used only for specific human purposes, and no one but God himself granted his highest blissful knowledge to the faithful who had clung to the fulfillment of his revealed will. Since God himself as Creator was also the author of all instruction, the growth of knowledge and the production of new inventions were not really possible for man restricted to his own created capacities.

But, as heir to a tradition of scholars who already had worked at filling a still Hellenistic science with Islamic spirit, al-Ghazālī also proposed the method of *Tafakkur*, a kind of meditation on the various phenomena of creation, which could lead to greater insights and more extensive knowledge, under the constant guidance of the Almighty. Such a method may have been at the root of the widespread mysticism of nature in Islam. As S. H. Nasr has observed, some of the greatest scientists in Islam (e.g., Quṭb al-Dīn al-Shīrāzī, AD 1236–1311) are known to have practiced Sūfism as well. But *Tafakkur* also presents a corrective for the unitarian view of Islamic science described above, Muslim thinkers asserted God's unity in all spheres of reality, thus reducing the multiplicity of created phenomena into a forced monism. The contrary can also be said, because by always keeping the spiritual goal of *taʿẓīm Allāh* (Magnification of God) in mind, the Muslim researcher, instead of closing it, would instead turn more and more leaves of Allāh's grand book of nature. The linguistic particularity of the Arabic language, always concentrating on individuality (*shawādhdh*), naturally could enforce this tendency.

It has become a standard argument that Islam needed such sciences as astronomy, mathematics, and geography for ritual obligations like the pilgrimage to Mecca, the establishment of the *qibla* (direction to Mecca) of new mosques, or even any prayer according to the traditional prescriptions. But some scholars feel this point should not be overstressed: even a legal authority like Abū Hanīfa (d. 767) warned that spatial orientation was not essential for the submission of the worshipper to the Creator, and numerous religious leaders maintained a quite relaxed attitude when confronted with greater mathematical exactness in the setting of the *qibla*. On the other hand, quite simple devices were sufficient for these needs. The number of treatises on the mathematical problems of the *qibla* are not necessarily in proportion to its importance for the Muslim community.

Of greater significance, and easily demonstrable, is the promotion of mathematical works by the theological principles of Islamic law. As the mathematician and astronomer in the Biblical tradition was encouraged by the saying that God had created the whole world with numbers (Wisdom 11,20), so the Muslim was convinced that the divine lawgiver had left nothing to the arbitrary decisions of sinful mankind, not even the shares of inheritance to be distributed among the members of a family: "…the male shall receive the portion of two females…" (Sūra 4, 175 ff). The natural consequence was the discovery and perfecting of algebraic rules which future lawyers had to learn for the administration of bequests; in other words, some mathematical instruction even entered legal schools usually blamed for having marginalized the rational and natural sciences. There it achieved full recognition as the respectable "science of shares" (*ʿilm al-farāʾid*).

The most characteristic and generally applied argument in support of orthodoxy and orthopraxis in Islamic intellectual history has certainly been the principle of *Sunna*. With carefully examined traditional reports it had to be established that questionable teachings or practices were sanctioned by words or actions/omissions of the Prophet himself or his Companions, or, in the case of Shiite Islam, the Imams. As this had already been done for the concepts and arguments of the theologians and jurists, the procedure did not stop at science, where it would seem to have been singularly inappropriate. Thus one of the most copied treatises of the Middle Ages, an indicator of its popularity, was the *al-Hayʾa al-sanīya fī al-hayʾa al-sunnīya* by al-Suyūṭī (1445–1505), a cosmographical work totally made up of well-attested traditional fragments of early theories.

The apparently simplistic view that truth can only be what has been taught or practiced by respected members of the Muslim community, testified to by an interrupted chain of trustworthy witnesses, may have been grounded in the deeper conviction that all values are sanctioned by the harmony with the laws of a well-established community. Scientific progress cannot be judged good and sane if it does not fit into the proven structures of a justice-oriented society or a healthy environment. In Islam this social order and the harmony with a God-created nature are directly derived from religion; hence, their demands on the work of the scientists belong to the religious, not the ethical or secular, realm.

Jurisprudence, no doubt, has been the most important discipline in the intellectual formation of the Muslims throughout their history. Some historians, considering the numerical superiority of law teachers and their students at the colleges and universities in Muslim lands, have blamed the lawyers for having pushed the sciences to the margins of academic institutions. On the other hand, hardly any other religious community has been so deeply formed by the ideal of realizing all its vital functions according to the principles of justice. The work of the scientists has not remained unaffected by this ideal. Thus long before Simon Stevin in his *Weeghconst* (Theoretical Statics, 1586) prepared the "democratization of science", which eventually gave it a special measure of vitality in Western nations, his Arab predecessor al-Khāzinī (fl. first half of the thirteenth century) had published in the *Kitāb mīzān al-ḥikma* (Book of the Balance of Wisdom) a remarkable memorandum on science's being rooted in an all-encompassing justice. This is, however, an aspect of the interaction of science and faith in Islam which has hardly been studied, in spite of its significance for the appropriation of technology by widely spread popular organizations, guilds, and Sūfi brotherhoods, or the stagnation up to modern times.

Religion and Science in the Native Americas

Åke Hultkrantz

If science may be said to be concerned with "observation, description, definition, classification, measurement, experimentation, generalization, explanation, prediction, evaluation, and control of the world," as it is in the *International Encyclopedia of the Social Sciences*, it is easy to conclude that all these practices have occurred among American Indians, mostly within a religious and mythological perspective. Some scholars presuppose that American Indians have lived in a natural–supernatural continuum where the distinction between this and the other world (however we care to define it) practically falls down. Others, including this author, are under the impression that the indigenous people postulated two experimental worlds, the natural world around them in everyday life, and the mysterious world of myth and religion which occasionally breaks into the natural world, for instance in dreams and rituals. In the long run this mysterious (supernatural) world seems to constitute the real, true world; at least some religious Native thinkers believe this is the case. It is not impossible that many Indian visionaries believed this without verbalizing their beliefs.

In any case, Indian observations and explanations have, in their own thinking, been linked to religious evaluations. Everyday reality was mostly experienced from a profane point of view where experiences followed each other in a foreseen way. Where this was not the case, or uncertain courses of events and unknown places are met, the other dimension is resorted to. Since the latter dimension is the most difficult to understand, and rules humankind's life, the interpreters of that world, medicine men, shamans and priests, and artisans that catch symbols and spiritual realities, are more important than experts on the everyday world. We can state that in Native America the range of spiritual experts has been much wider than that of technological experts.

The anthropologist Paul Radin has shown that there exists what he calls "two general types of temperament" among, in particular, American Indians: "the man of action and the thinker, the type which lives fairly exclusively on what might be called a motor level and the type that demands explanations and derives pleasure from some form of speculative thinking." It is characteristic that in order to describe the thinkers and their accomplishments he turns to the specialists on religion (and then a bit arbitrarily joins "historians," i.e., mythological raconteurs, with such specialists of experimental religion as medicine men and shamans). American Indians are on the whole not skeptics, since dreams, hallucinations, and traditions of visits to the other world by eminent spiritualists give strength to their religious beliefs. Collective rituals give these beliefs a realistic stamp. Only when different religions collide and a relativism of values ensues do religious brooding, skepticism, and indifference take over. There is thus little space for other than religiomythical incitements in penetrating the marginal recesses of the empirical world.

The dominance of religious thinking in what science today would call secular matters is obvious in the fields of cosmology and medicine. There are two great world pictures in America. One is certainly the older one, with Paleolithic–Mesolithic origins and connections with the hunting tribes in the Old World. It depicts a Universe where the world pillar or the world tree forms the axis which connects heaven and earth. It is often said that this pole or tree is situated in the middle of the world; its roots are fixed in the underworld and nourished by subterranean rivers or a well. Its top reaches the sky that rests on it. Sometimes the world column stretches through several skies until it reaches the highest sky. Symbols of the different species of animals living on different levels are supposed to dwell on the tree: lowest down snakes or fishes, on the earth level deer and buffalo, highest up birds like eagles and falcons. Some tribes relate that unborn souls inhabit the crown of the world tree. Other tribes believe that the world tree, that often has a forked top, is identical to the Milky Way which is "the backbone of the sky" and the road taken by the souls to the hereafter. The world has also formed the passageway downward for the gods when they cared to visit the ground and upward for the shamans when in their séances their souls went to the supernatural world to receive information of the gods (and, in some cases, to release a diseased person's captured soul from the realm of the dead). The world tree is ritually modeled in the middle pole of ceremonial structures, such as the Plains Indian Sun Dance hall, which is itself a ritual reproduction of the cosmos. The Sun Dance ceremony is a repetition of the cosmic creation.

The world tree expresses an inclination for a heavenly world. American high culture supplants the tree or pillar symbol with a temple mound, mostly a pyramid. On the top of this pyramid the gods have their habitats (read: statues), and many pyramids enclose the bodies of deceased princes. The sacred temple areas in Mexican pre-Columbian cities are modeled after the supposed heavenly geography.

The other world picture which has been distributed in agricultural areas has its parallels in the agrarian civilizations of the Old World. In this case the attention on the supernatural world is, at least partly, directed downward, to the underworld. Here is the place from which man, like the plants, once in mythic time came up, often climbing on a reed. Myths even talk of four successive underworlds, one darker than the other, or qualified through different colors. Inundating waters or other difficulties started the evacuation. Myths tell us that valuable animals, like the buffalo in North America, also came up from the nether world. Men and animals appeared from a grotto which ever since has been said to be the center of the world. After death the living beings returned to the underworld, like the plant returns to it when it withers. The underworld realm of the dead is mostly the place to which shamans send out their soul to retrieve the lost soul of a sick patient. Some divinities, be it the lord-lady of the dead or the spirits of vegetation, may be found in the underworld.

These world pictures are supposed to be stable, as when the Lenape (Delaware Indian) Supreme Being with his hand holds the upper part of the world pole.

However, in earthquake areas this is not the case. According to anthropologist Lowell J. Bean, the Cahuilla of Southern California believed

> that all matter was subject to unpredictable change… For example, dramatic changes in topography are vividly and frequently recalled…This instability was true from the beginning. Creation of the earth and life itself was fraught with indecision, mistakes, and conflicts of power between the creator brothers.

This is a neat example of how environmental changes are referred to mythical incidents.

Also in another topic, medicine and medical practice, religion outbids what we might consider a more “scientific” approach. Certainly, there is, even behind supernatural gestures, the beginning of a systematic and naturalist treatment of sick persons in a simple hunting milieu. The herbalists who supply herbs, cobwebs, sap, or leaves for wounds, or handle internal medicine for the patient, follow what they have learnt or what their own experiences have taught them. Observation and practice over the years thus guided their use of natural medicine, and today’s science of laboratory medicine can sometimes corroborate the positive medical properties of these medicines. If anything the choice of useful medicaments points out the scientific endeavors of American Indians.

However, there are other doctors as well, and their curing is considered more important. Medicine men and shamans invoke supernatural powers in order to deliver the sick from a serious disease (or a disease which they comprehend as serious). Gods and spirits are then thought to be the active medical powers, and the disease itself may be a demoniac being. In other words, the more serious the disease is, the more frequently supernatural powers have to be invoked. Of course, even simple herbalist methods may be accompanied by religious blessings.

Such a continuum between this world and the other world may, superficially seen, seem to make the distinction between them invalid, but this is not so. American Indians have had recourse to systems which would not satisfy Western logic; their logic is often created from the needs of the situation. In religion, completely reciprocally exclusive belief chains may be resorted to, depending on the situation. In the same manner, Indians may interpret phenomena as derived from this world or the other world, but also, in single cases, see a continuous line between them.

As a further example of such thinking the hierarchy of biological masters may be mentioned. In many places in both Americas animals and plants are supposed to be controlled by masters who rule over them and own them. These masters may be animals of some sort, or supernatural beings. The Mataco in Argentina and Bolivia believe that herbs and trees are subordinated to their “owners,” certain animals and birds. Thus, the wild red pepper is owned by the red-eyed dove. The dove in its turn obeys a lord of the forest who is also the lord of honey. We learn that the latter is a supernatural being, whereas the dove is a natural bird. In this connection it should be pointed out that in many places, scholars have observed a folk classification of natural plants and animals. Indian tribes have constructed taxonomies with a series of hierarchical levels. In these cases it seems that only natural species have been segregated. It is another matter when Plains Indian medicine men arrange their guardian spirits, which appear in animal disguise, in an order according to their efficiency: they are ranked as spirits, not as animals, and may be included in a hierarchy. It is a remarkable fact that this hierarchical thinking occurs in societies which are otherwise characterized by their equality.

We have seen how the world picture, or the view of the Universe, is arranged according to religiomythical models in original Native American thought. In addition to what was said above it can be noted that stars and planets are also included in these models. The sun and moon may be understood as divinities or symbols of divinities; the sun is often a manifestation of the Supreme Being, the moon a manifestation of Mother Earth, or the god (goddess) of vegetation. The planets and stars incarnate other supernatural beings, often the culture hero and hunting spirits. The Blackfoot and other tribes tell myths according to which the main actors are transformed into well-known stars when their adventures have finished. Among the Pawnee all dominant gods are stars, the chief one among them being the high god Tirawa who is identified as the North star. Thus, the stars are supposed to be living, spiritual beings, something which is also demonstrated in their movements over the sky. Such a portrait of the star charter is the presupposition of astrology. In the classical antiquity of the Old World some supreme power, or fate, ruled the star movements; in America, the prime movers could be the stars themselves, or some power behind the stars. In both worlds omens and policies were dictated by these powers, and thus what some call a pseudoscience, astrology, took form to find out the nature of these dictates.

Among the high civilizations, such as the Maya of Southern Mexico and Guatemala, parts of the clergy made observations of the sky for astrological purposes. It has been said that in Mesoamerica and South America people tracked the positions of the stars in order to know how they themselves should behave, when they should plant, and when they should perform sacrifices, whereas in North America the signs from the heaven were an aid to good living, not frightening information. This distinction is probably too exaggerated. In North America there was great fear when, during eclipses of the sun or the moon, the celestial body was supposed to be swallowed up by some monster.

Astrology has, all over the world, paved the way for astronomy; this is also true in North and South America. The great annual festivals, the fertility ceremonies, and other occasions for ritual celebrations could begin when star constellations were favorable. The Tapirape Indians of the Amazonian forest know that when the Pleiades disappear in the west the rainy season is over. The prehistoric northern Plains Indians constructed medicine wheels on mountain tops (or, if there were no mountains in the area, on the open plains) which archeologists and astronomers interpret as calendar monuments, used for the determination of the summer solstice. For instance, the famous Medicine Wheel on the ridge of the Bighorn Mountains in Wyoming has the form of a wheel with a central cairn united with the peripheral stone ring through 28 spokes of stone. Other cairns are situated close to the periphery. From one of the latter cairns one can perceive the sun over the central cairn on Midsummer's Day. There are reasons to assume that the structure also had cultic functions. Its ground plan mirrors the world picture with the world pillar in the middle of the world, as was described earlier. Among other things, the 28 spokes correspond to the 28 roof poles of the Sun Dance lodge. This might also correspond to the 28 lunar mansions in Chinese, Islamic, and Indian astronomy.

In the matter of astronomical calculations the Maya were the masters. In order to arrive at exact computations they developed mathematics, used multiplication tables, and calculated the days of the year. With these means the Maya priest-astronomers managed to bring the Venus cycle into relation with the year, and they were also able to construct a table for predicting solar eclipses (although the latter were not always visible in the Maya area). Such eclipses were considered to be dangerous. The foreknowledge of the times they would appear made it possible for the priests to take action to help the threatened human beings.

Thus it appears that the beginning of science was motivated by its use for religious and ritual purposes. The Maya scholar, Eric Thompson, has this to say about the Maya intellectual achievements:

> It is remarkable that the intellectual successes of the Maya were not (from our point of view) practical; they were the outcome of spiritual needs. The Maya astronomers strove for knowledge, not as an end in itself, but as a means of controlling fate, a kind of astrology. There was, he felt, an orderliness in the heavens to which the gods conformed; once that was learned, he could predict the future through exact knowledge of which gods held sway at any given time, and influence it by knowing when and whom to propitiate.

It is also possible that the Maya writing with its multivalent hieroglyphs was first developed to serve sacerdotal ends. In any case, during the Classic Period, the Maya texts deal with astronomy, the connections between stars and gods, and associated ceremonies.

We could of course argue that there was in aboriginal America an appreciation of knowledge and learning that had no religious causation; but it can be scarcely understood as a scientific ambition. Skills in technology, and inventions (Inca road building, Maya corbelled vaults, Mexican wheel toys, etc.), rarely deserve this designation either. Inuit coast maps are a wonder of precision and may pass for art. Truly profane science was not part of the American Indian world.

Rice Fields Reclamation in Southern India

K. T. Rammohan

Backwaters are large water bodies that are receptacles of rivers but contain saline water as they are connected to the sea. The Vembanad backwater system in far southern India covers an area of over 21,000 ha, measures 96.5 km in length, and is 3 to 8 m deep. Designated as a Ramsar site in 2002, the Vembanad is the largest estuarine system on India's western coast and as a transitional ecotone between land and sea, offers protection to innumerable living organisms, including clams and waterfowl (Nair 2003). Population expansion and economic pressures of commercial agriculture and tourism, however, have put pressure on the backwater causing it to considerably dwindle over time (Narayanan 2003).

While reclamation of Vembanad backwater for habitation and cultivation has a history that dates back many centuries, the scale of operation was small until the nineteenth century. From this period, Travancore was rapidly drafted into the world economy as a source of varied goods: coffee, tea, coconut oil, coir, and later rubber. It was crucial for the export economy to be price-competitive in the international market. Export production was labour intensive. To keep prices low, wages had to be kept low. This in turn required keeping food prices under check. However, the demand for rice was rising and its supply was falling. Besides normal demographic expansion, the immigrant workforce in the plantations marked new demand. The relocation of agricultural workers to coir weaving factories in the coastal urban centres also possibly raised the demand for rice. Earlier, in the countryside, their food comprised some rice and a large share of tubers. In the town, lacking access to tubers that were not a marketed commodity, people substituted rice. As demand for rice rose, its supply fell. This was mainly due to the decline of hill cultivation of rice consequent to the setting up of plantations (Rammohan 1996).

The princely government of Travancore sought to address the growing mismatch between supply and demand of rice in three ways: import of rice from Bengal, Burma, and Siam; propagation of cassava as a rice substitute; and encouraging the creation of new rice lands by reclaiming the Vembanad backwater. Large-scale reclamation began towards the late nineteenth century, with the princely government granting short-term exemption from tax on reclaimed lands and extending loans at concessional rates to the cultivators. Even with cheap and servile labour, reclamation was expensive. Usually one person was given permission, but he carried out reclamation by forming partnerships with a few others. Networking was mostly confined within a caste or community or among castes and communities of similar social status. Nayars and Christians, jointly and severally, floated most of the partnerships. Lower castes and communities lacking financial resources and influence in government could not undertake reclamation. Workers of Pulaya and Paraya castes, considered 'untouchable' by their higher caste landlords, did most of the work. The technology of reclamation also is indebted to these castes, especially Pulayas, who had long resorted to reclaiming shallow backwaters for cultivation, as they owned no land themselves.

Reclamation occurred during the summer when water level in the lake dipped. It involved two major operations: building a circular dyke (outer main dyke or ring dyke or *mata*) to enclose the backwater area proposed to be reclaimed and draining water out from the enclosed area. Dykes had to be built where water was 8 to 10 ft deep. This involved several stages. First, coconut palm trunk piles in two parallel lines were driven into the bed of the backwater area to be reclaimed. These were fenced with bamboo screens on either side. The space enclosed by the bamboo screens was then tightly packed with clay, sand and brushwood. Clay had to be lifted from the lakebed at a depth of 10 to 12 feet and transported by country boats to the site. The dyke-enclosed area was then drained by using an array of waterwheels of different sizes, mounted one upon the other, operated day and night. After draining the area, usual agricultural operations could be commenced. With high water levels surrounding the field and the lake being prone to tides, constant vigil had to be maintained against any breach in the dyke. Land and water management was central to cultivation. All operations, including ploughing, sowing, weeding and harvesting, were dependent on timing and any delay could ruin the crop.

Rice cultivation in reclaimed lands was highly labour-intensive and its success depended on the availability of a captive workforce round the clock. Male workers built and maintained the dykes, and ploughed the field; the rest of the operations were mostly done by women. These workers were initially slaves and their masters were mostly members of upper castes like Brahmins and Nayars and communities like Syrian Christians. From the mid-nineteenth century, with the abolition of slavery, they were partially liberated but were still attached to the masters and their land. As land changed hands they had new masters. Some of them were settled in thatched mud huts in the master's homestead so that their services could be had anytime in the day or night. Others were settled on or near the dyke so that they could keep vigil over the dyke in times of heavy rains and act immediately if a breach occurred. The ring dykes demarcated individual fields while most fields were protected by outer dykes, built and maintained jointly by the farmers.

During the early years of reclamation, water was drained by using waterwheels made of wood. With the introduction of mechanical pump sets towards the end of the nineteenth century reclamation activity received a further boost. While earlier, only small blocks of 40–60 acres used to be reclaimed, large blocks of hundreds of acres could now be reclaimed. Over 5,000 acres were newly reclaimed. The first pump sets that were introduced during the late nineteenth century were worked by producer gas and those introduced in the early decades of the twentieth century were run by kerosene or diesel. A British engineering firm based in Cochin, Geo Brunton Company, boat builders and operators of steamboats, introduced the first pump sets. The company hired these out to farmers. The company's men, many of them Anglo-Indians, operated the pump sets. With increase in demand, new suppliers like Marshall Sons and Company of Edinburgh operating through its branch at Madras also entered the scene (Rammohan 1996).

Agricultural operations in the reclaimed tracts began in January or February. The field was ploughed using bullocks or oxen as draught animals. The soil of the reclaimed backwater was acidic and to neutralise it, lime was applied. The field was then flooded by opening the sluices in the dyke. The field remained submerged throughout the south western monsoon (June to August). By August when the water receded the field was again ploughed. This was a difficult operation as the worker had to wade through waist-deep and muddy water with the draught bullock or buffalo. Following this, the outer dykes were repaired and waterwheels set up at different points. The wheel was mounted vertically on a horizontal axle. The wheels were of different sizes; the number of spokes was usually in multiples of 6 and ranged from 6 to 36. To drain large areas an array of waterwheels, arranged in ascending order of size was used. The wheels were operated by gangs ranging from 8 to 10 workers, who perched themselves on bamboo scaffolding and pedalled the water away. This was hard labour and work was carried out in four shifts. The workers ascertained the time by looking at the sun, moon and stars. Alternatively, a half shell of coconut with a fine hole pierced at its bottom was used like an hourglass with water substituting for sand. The shell was placed in water and when water entering from below filled it entirely it was reckoned as a unit of time. Drainage operations were conducted for many fields at a time. As water levels receded, the inner dykes and irrigation channels were repaired. The soil was then raked with a harrow, weeded and worked into a soft puddle. Water was then let into the field up to knee-depth. Sowing was done in October or November after the monsoon subsided. Seeds, sprouted in screw-pine bags, were broadcast in water. The field was then completely drained and kept dry for a week. Water was then let in, and when seedlings were about a month old, some transplanting was done to reduce the unevenness resulting from broadcast sowing. The field was completely drained after transplanting and manure – cow dung, green leaves, hay, and ash – applied. Pesticides were not used. The most common pest was a worm. As water level in the field rose, the worm crawled up and positioned itself on the edge of the leaf-blade. The worms were swept away into a basket using a stick or a broom. Water was let into the field at regular intervals till the harvest, which occurred in February or March. The ear heads were garnered with sickles and threshed with feet. The grain was winnowed and sun-dried on the threshing floor and conveyed to the granaries in country canoes. The grain was boiled, sun-dried and pounded by hand into rice. In certain parts of reclaimed areas, a deep-water variety of rice was cultivated. Its ear heads floated on the surface of water and were harvested from the canoes (Pillai and Panikar 1965; Tharamangalam 1981).

Road Networks in Ancient Native America

Rubén G. Mendoza, Gretchen W. Jordan

Pre-Columbian road networks in ancient America – specifically, the Southwestern United States, Mesoamerica, and Peru – provide a point of departure for exploring current issues in the study of non-Western technology. It should be noted that other major road networks have been documented for the Mississippian complex of eastern North America, Casas Grandes in Chihuahua, Mexico, and the Maya sacbe road networks of the Maya lowlands of Mesoamerica. These networks are currently the subject of ongoing investigations.

The three primary road networks of concern here are those of the North American Chaco Anasazi or Ancestral Pueblo of west-central New Mexico, Mesoamerican road networks centered on La Quemada and Xochicalco, Mexico, and the Inca system of Peruvian South America. These networks vary in scale, with the La Quemada complex representing a highly integrated, valley-wide network, dating to the period between AD 700 and 900. The Chaco network covers a circuit of over 300 linear miles of ground-verified constructed road segments and features spanning the period from AD 920 to 1140. The Inca road network was expanded in a vigorous campaign to integrate all pre-existing road segments in the period between AD 1438 and 1532. This system incorporates over 2,000 linear miles of roads into the single most massive archaeological feature in the Americas (Hyslop 1984).

The American Southwest

The formalized road network of Chaco Canyon, New Mexico, connects the canyon core with peripheral pueblo communities lying at relatively great distances from the core area. Over 500 miles of roads are indicated through the analysis of aerial photographs; however ground survey data are as yet incomplete, leaving unresolved the question of continuity in the network. The sociopolitical complexity of the Anasazi of the San Juan Basin is closely tied to the problem of road network continuity (Vivian 1990). If the road network was contiguous throughout, this would support the contention that Chaco served an administrative function as the center of a regional system extending from Southwestern Colorado to Southeastern Utah, into Western Arizona and Northwestern New Mexico. Lack of continuity in the road network indicates a less integrated system, and a more autonomous character for the outlying communities.

Functional aspects of the Chaco road system are as yet unclear. Functional considerations center on the nature and control of goods transported as well as with the degree of interaction between core and peripheral communities. Proposed interpretations include (a) a defensive role for outlying pueblos, (b) protection of trade routes, (c) ceremonial functions, (d) political administration, and (e) the transport of subsistence-related goods. It has also been suggested that outlying pueblos served as rural sustaining communities directly affiliated with representative groups of the canyon core (Kincaid 1983).

Chacoan road construction exhibits several characteristic features. Most notable is the absolute linearity of the roads, despite potential topographic obstacles. The great North Road deviates less than one degree from its northerly course in over 46 km. Masonry road elements such as flanking walls, or curbs, ramps, and raised roadbeds also characterize the system. Several architectural features are associated with road segments. These range from simple cairns and shrines to residential room-blocks and Great House communities with Great Kiva ceremonial structures. Stylistically uniform, these features and structures employ Bonito-style construction of core-veneer masonry and massive walls.

There are no historical data available describing the Chacoan road system. To date, all interpretations have been based on archaeological research and remote sensing techniques. Gordon Vivian pioneered this research in 1948. From 1971 to 1977, the Remote Sensing Project of the Chaco Center – in conjunction with the National Park Service and the University of New Mexico – undertook investigations of the Chacoan road network. Their efforts focused on the use of ground verification studies for the extensive mapping of road alignments appearing in aerial photographs. From 1980 to 1983 the New Mexico Bureau of Land Management undertook a comprehensive effort to document the road network by means of ground verification (Kincaid 1983).

Mesoamerica

Studies pertaining to Mesoamerican road networks are relatively recent, and most such studies have emphasized ground verification and mapping. The sites of Casas Grandes, La Quemada, Xochicalco, Teotihuacan, and the Maya lowlands have been the subject of most surveys to date, while the Tarascan and Sonoran regions have been the subject of the most recent surveys. The road networks of these regions provide a glimpse into both the Late Classic, and the Protohistoric developments of the fourteenth through sixteenth centuries AD (Mendoza 2001).

The area of La Quemada, Zacatecas, lies within a semiarid region of Mesoamerica's Northern Frontier. This area is dominated by a series of hill-fort centers, each of which is characterized by the presence of civic-ceremonial precincts, agricultural terraces, and secondary centers with related defensive features. An extensive intra-regional network of roads connected the primary centers of La Quemada and Los Pilarillos with secondary centers, and in turn, isolated mound groups, isolated platforms, defensive positions or fortifications, and agricultural terraces. This system, by contrast with that of Chaco Canyon, served to integrate communities within a tightly constricted area. Road segments linking the La Quemada road network with regions beyond the valley have yet to be fully mapped or verified.

The specific road-related features identified with La Quemada include (a) formal causeways or other elevated road segments; (b) road segments terminating at elevated platforms; (c) causeways of between 5 and 7 m to 12 and 14 m in width with road-bed elevations of between 30 and 40 cm; (d) causeways that extend to wide, low platforms and stairways with precipitous descents down steep escarpments; (e) parallel road and canal or other irrigation segments; and finally (f) where the larger causeways are concerned, such roads are identified with defensive positions. At La Quemada, the aforementioned features are taken to represent a sociopolitical pattern geared to militarism or related defense activity (Trombold 1991b).

Where the road networks of the Mesoamerican Epiclassic era (ca. AD 650–900) are concerned, the central Mexican city-state of Xochicalco, Morelos, provides a salient example. The site of Xochicalco, like its La Quemada contemporary, is situated in a strategically located acropolis-centered hill-fort locality. Most of the road segments identified with Xochicalco emanate from the hill-fort to other centers within the valley below, and as such, Xochicalco provides a characteristic example of roads as symbols of power, prestige, and levels of regional integration. In other words, this position holds that Mesoamerican road networks function primarily as mechanisms for social integration or as symbols of the power and prestige of social or religious elites (Hirth 1991). The scale and magnitude of construction activity invested in the road systems of Mesoamerica have led some scholars to speculate that such roads were less functional and more ceremonial in character. Monumental construction and related public works are taken as indicators of political power, and thereby elite command of critical resources (such as slaves and construction personnel) in the valley during the pre-Columbian era (Trombold 1991a).

Mesoamerican economic systems, by virtue of the nonexistence of draft animals, and thereby, wheeled vehicles, were limited to human burden bearers. Despite this limitation, such systems were every bit as formal as those of other Old and New World polities. Primitivist interpretations of New World economies have unnecessarily minimized the perceived scale of economic formations in Mesoamerica and the New World despite available ethnohistorical data. The extent and magnitude of investment in road construction, and scale of integration made evident by the contiguity in the system, is again a key indicator of the types of sociopolitical formations that once prevailed in Mesoamerica. The Aztec era provides only a hint at what prior civilizations engaged in the way of road network investment in construction and maintenance, and by any account, the investment was substantial and culturally significant. Robert Santley's recent projection of road networks for the Basin of Mexico presents us with a system that was highly integrated and equally complex (Santley 1991).

The utility of a formalized – organized, linear, weatherproof – road network over which to maintain the movement of goods and services was critical to trade and exchange in Mesoamerica. Like the ancient informal paths that preceded them, formalized roads served to guide and expedite the movement of goods and services on both an intra- and inter-regional scale.

A typology of Aztec era roads was recorded by Fray Bernardino de Sahagun, the sixteenth century Franciscan cleric who documented such aspects of postconquest central Mexican culture (Sahagun 1963). Of the seven types of roads identified by Bernardino de Sahagun the ochpantli and oquetzalli road types have been isolated as representative of the Xochicalco road types. The first term pertains to the "main road" and the second to the "royal road" networks of the Aztec era. The well groomed roads of Xochicalco are interpreted as the royal road type. This interpretation is based on the monumental nature of the associated architecture (primarily defensive in character), the cut-stone pavements, and the relatively large width of the roadbed itself. In addition, archaeologist Kenneth Hirth distinguishes between "road" and "thoroughfare." Roads are "transportation arteries at the regional level which connect two or more spatially separated sites"; thoroughfares are "streets and other communication corridors which organize space and/or direct traffic flow within the community" (Hirth 1991). The fragmentary nature of the data precludes a region-wide economic and social interpretation of the Xochicalco network.

The Xochicalco road network exhibits a number of distinct architectural characteristics, including:

a. Stone-surfaced intra-site rough-cut mosaic pavements or roadbeds of 3–5 m widths
b. Intra-site masonry ramps
c. Parallel platforms flanking key road segments or thoroughfares leading into the site core area
d. Roads which bisect massive rampart walls with narrow gateways in order to access intra-site thoroughfares
e. Intra-site pavements or roadbeds edged with cut-stone masonry blocks
f. Stucco used along flanking masonry edging in the intra-site sectors
g. Intra-site pavements made flush with surfaces traversed and modified with ramps – both smooth and stepped
h. Lateral masonry walls flanking intra-site pavements
i. Access causeways along circuits of defensive ditches or moats
j. Evidence for the use of a probable wooden bridge spanning a defensive moat adjacent to Cerro de la Bodega

Transport architecture extending beyond the site perimeter consists of less formal construction techniques in addition to significantly less evidence of overall integration with the site core of Xochicalco.

Recent studies provide indications of a massive road network that connected the Classic period center of Teotihuacan with an ancient trade corridor linking that site with the Puebla Basin, and by extension, the Mexican Gulf lowlands. Unlike the more defensive character of the La Quemada and Xochicalco road networks, the Teotihuacan corridor linking Teotihuacan with a whole host of ancient mercantile centers in the Mesoamerican highlands and Gulf coastal plain served a key transport function for the movement of goods and services provisioned and sought by Teotihuacan.

The road-associated settlement hierarchy of the Teotihuacan Corridor, as well as the recent identification of specific features of transport network architecture along the Teotihuacan Corridor, is currently under study. Additional features of Mesoamerican transport network architecture include (a) causeways – such as the Street of the Dead – measuring some 40 m in width; (b) the presence of Momoztli structures, or elevated platforms or shrines (often laden with trade offerings) situated at the crux of important crossroads along the corridor; (c) an approximate inter-site road width of 24 m, and 60 cm depth, for sites located on the Teotihuacan Corridor; (d) spur roads that connect road-associated settlements with the principal arteries of the Teotihuacan Corridor and with other key nodal points or market centers; (e) related architectural styles and construction along the course of the transport network; (f) roughly equidistant spacing of road-associated settlements at 8–9 km intervals for specific Teotihuacan related centers; and (g) stepped ramps, road shrines, crossroads, and attendant roadbed linearity. The overall network is dendritic in structure, in that the main road connects with primary centers, which are in turn connected to a constellation of secondary centers sharing affinities with key terminals along the Teotihuacan Corridor.

Peru

The most intensively studied ancient road system of South America is that of the Inca Empire, extending over a vast area from Ecuador to Chile, from the coastal deserts to the Andean highlands, into the Bolivian forests. This network included some 20,000 miles of roadways and encompassed 40,000 miles at the point of European contact. This road system constitutes “South America’s largest contiguous archaeological remain,” and provides valuable insights into the organization and technology that are hallmarks of the Inca state (Hyslop 1984).

In contemplating the vastness of this road network, one is struck by the enormity of the Inca achievement. First, there is the effectiveness of the political infrastructure that organized and mobilized a labor force specialized in the building and maintenance of roadways. Second, the Inca were exceptionally efficient in their use of resources, both natural and human. Pre-existing roadways were frequently incorporated into the Inca network. Inca engineers did not seek to modify natural topography to any great extent unless required to do so in order to achieve safe passage. Where road modifications were concerned, locally available materials were utilized and work was performed by locally organized labor pools under the supervision of a road administrator. Third, the Inca brought to bear a vast body of technical knowledge and expertise, accumulated over the course of centuries among the diverse ethnic groups of the empire. Finally, the efficiency of the road network insured that Inca rulers could maintain communication with – and thereby, the integration of – every corner of the empire.

Four primary state roads divided the empire into cosmologically defined quadrants (Urton 1981). The sacred geography associated with road networks reflected the Inca preoccupation with cosmology defined *vis-á-vis* extant social divisions. Cuzco, the political and administrative center of the Inca state, was linked via these sacred paths to the most ancient shrines and temples. Roadways not only defined the partitioning of sacred space, they also served as linkages in a massive transport and communication network.

Road characteristics varied considerably in terms of construction methods and the extent of labor investment. Construction methods varied with the highly fractured and variable topography of the region, and as such, a single road might include both road segments with very complex architectural features and evidence for intensive labor investment, and simple unpaved or earthen pathways. Ultimately, road construction varied with localized conditions, topographic obstacles, available materials and labor, and the importance of the specific road segment to ceremonial and ritual activities.

Coastal routes varied from simple “pole-roads” to broad thoroughfares with stone or adobe sidewalls. Pole-roads were paths marked by linear arrangements of wooden posts placed at intervals. High-altitude roads on nonagricultural lands were, by contrast, engineered for durability in order to withstand harsh climatic conditions. Such roads incorporated elaborate stone curbs, retaining walls, and paving. These later constructions are among the best-preserved roads in evidence for the Andes. Roads traversing agricultural fields are characterized by very high sidewalls – of 1 or 2 m in height – designed to protect crops from travelers or livestock such as llamas and alpacas. Such walls were likewise built of stone or adobe. Agricultural roads were relatively narrow so as to minimize their impact on the availability and productivity of arable lands.

Where roads crossed wet plains or slopes, stone paving was used to preserve the roadbed. If flooding was unavoidable, the road was constructed on an elevated surface or causeway. Inca causeways were of rubble-core construction, with or without stone retaining walls. In those instances where existing slopes were less than 10° off horizontal, the Inca used a combination of stone or rock-cut ramps, stairways, or switchbacks in order to buffer ascent and descent. Depending on the steepness of the existing slope, structures ranged from a single retaining wall to a series of walls and benches built on the downhill side of the slope, and intended to serve as secondary retaining features.

Bridges are among the most spectacular structures engineered by the Inca. While sixteenth century European construction employed the principle of the arch in bridge construction, the Inca were able to span greater distances through a variety of engineering principles and techniques. Early Spanish explorers marveled at the sight of Inca suspension bridges which were unknown in Europe. Though made of woven and braided fiber coils, these suspended structures supported considerable pedestrian traffic, in addition to European horses and carts of the conquest period. Other types of spans built by the Inca included floating bridges supported by pontoons of reed bundles, wooden bridges manufactured from logs placed over stone abutments (with or without cantilevers), and a variety of stone bridges. Culverts were stone-lined troughs left open, or capped, if necessary for safe passage. Somewhat wider rivers were spanned by stone columns placed adjacent to one another, thereby forming "multicell" culverts which supported the overlying roadbed. Some stone bridges employed cantilevered abutments supporting very large stone pavers. Finally, natural rock formations were utilized as bridged areas where available.

An integral component of Inca era road networks was the *tambo* system. Tambos were multiuse structures or facilities maintained by the Inca state but administered locally. Hyslop estimates that between 1,000 and 2,000 of these facilities were in use throughout the Inca empire. Tambos exhibit considerable variation in size, ranging from sites with a few isolated structures to large administrative centers representing a multitude of activity areas. Storage and lodging constitute the primary uses for which tambos were employed. Storage structures included silos, corrals, and adjoining rooms. Lodging in tambo facilities was temporary, and intended either for travelers or as permanent residence for local administrators. Tambos were also employed in the processing of raw materials, military and ceremonial activities, local administration, and craft production. Tambos were equidistantly spaced on any given route at intervals representing a day's travel time. According to recent Inca road surveys, tambos were spaced at intervals that average between 15 and 25 km. The combined tambo system and vast complex of roadways formed a critical component of the state's infrastructure. This highly efficient transport and communication network supported the state's practical needs for efficient military mobilization, colonization, economic maintenance, and administration. In addition, the complex network of roads supported the ideological needs of the Inca hierarchy, providing a highly visible set of linkages between the people and the state.

Rockets in Ancient Korea

Chae Yeon-Seok

The development of Korean rockets as tactical weapons began in the late fourteenth century. According to *Koryo Sa* (The History of the Koryo Dynasty) and *Cho Son Wang Cho Silok* (The Historical Records of the Choson Dynasty), King Wu (1377–1389) of the Koryo dynasty (918–1392) ordered the establishment of the Hwa-tong-do-gam (General Bureau of

Gunpowder Artillery) in 1377 on the recommendation of Choi, Mu-Son (1325–1395). Commissioned temporarily at the height of Japanese piracy, the Bureau was charged with administering the manufacture of gunpowder and firearms.

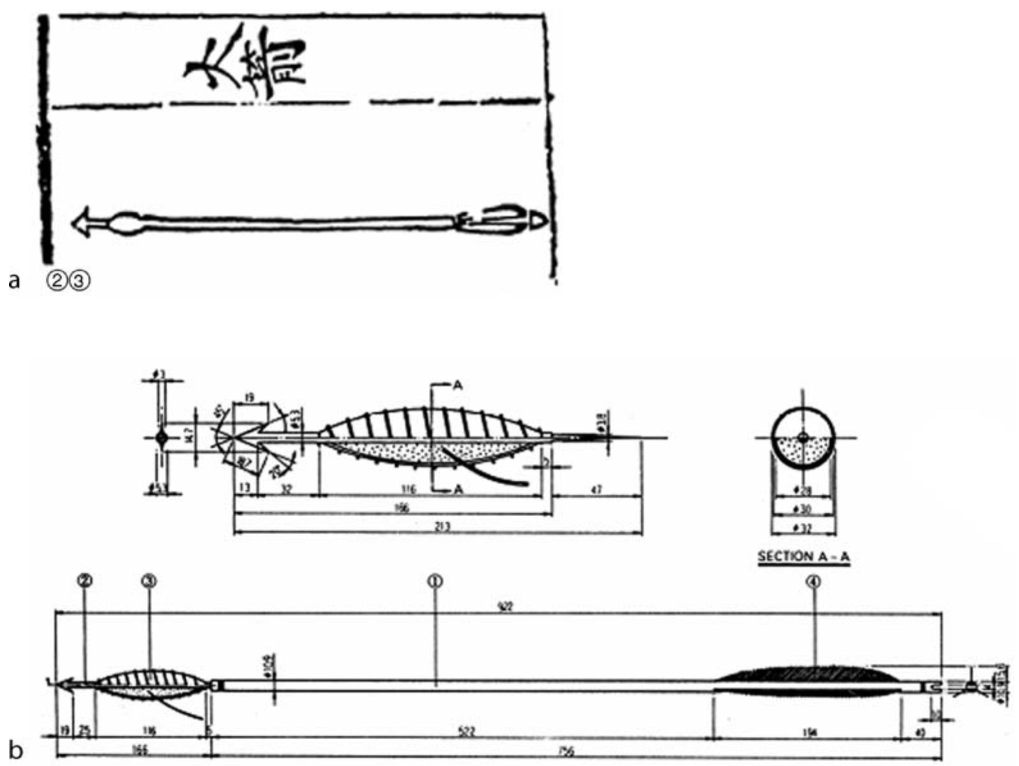
Choi, Mu-Son produced a variety of gunpowder and firearms in the newly commissioned Bureau. Fire arrows, called *Haw-Jon*, manufactured at Hwa-tong-do-gam between 1377 and 1391 near the end of Koryo Dynasty were not, unlike some Chinese counterparts, rocket-propelled arrows but exclusively incendiary arrows. They were shot with a bow. Figure 1a illustrates the fire arrow as described in *Kuk Cho Ore Sorye* (Introductory Remarks on National Rituals/Formalities of National Functions) of the Chosun Dynasty (1392–1910) published in 1474. Figure 1b shows a drawing of fire arrows in metric units converted from the Korean measurement system in which one *chuck* corresponds to 312.4 mm, one *chun* to 31.2 mm, one *pun* to 3.1 mm and one *le* to 0.3 mm.

Unfortunately there is no direct documentary evidence attesting that firearms manufactured at Hwa-tong-do-gam involved rocket-propelled firearms. However, *Kuk Cho Ore Sorye* contains illustrations of rocket-propelled firearms called *Sin-Gi-Jeon*. Moreover, *Hwa Po Sik Un Hae* (Korean Annotation of Gunpowder and Firearms Method, 1635) makes reference to the identity of the propellant cases of *Sin-Gi-Jeon* and *Ju-Hwa* (running fire), a term used for rocket-propelled arrows of the Koryo Dynasty. It is inferred from these historical records that the *Ju-Hwa* manufactured at Hwa-tong-do-gam was the first Korean rocket.

According to *Kuk Cho Ore Sorye*, the arrow shaft of the Ju-Hwa is made of a bamboo stick, and the arrowhead is iron. The tail fins of the arrow are feathers. Although there is neither a direct nor detailed description attesting that *Ju-Hwa* was rocket-propelled, that may be inferred from other historical records. *Choson Wang Cho Silok* records King Sejong speaking to an official PyeongAn, in HamGil province:

> Running-fire is very efficient and incomparable because it can be fired easily using a quiver by a mounted soldier. It is detrimental to the enemy; its loud noise and shape instill fear and incite surrender. Once used at night, its exhaust flame lightens the fields and shakes the enemy's spirits.
> When used where the enemy is lying in ambush, its flame and smoke cause the enemy to disclose themselves for fear. Running-fire does not fly straight and it spends more powder and requires more precaution than cannon.

"Its loud noise and shape," implies a propulsive device which produces thrust by ejecting combustion gases



Rockets in Ancient Korea. Fig. 1 Drawings of *Hwa-Jeon* (a) Fire arrow (*Ju-Hwa*). Drawing from *Kuk Cho Ore Sorye* 1474). (b) Fire arrow (*Hwa-Jeon*). Drawing in metric units (from Chae 1981). ①: arrow shaft, ②: arrowhead, ③: black powder, ④: fins.

Rockets in Ancient Korea. Table 1 Powder charge of rockets and cannons in fifteenth century Korea

Rockets		Cannon and guns	
Name	**Powder weight**	**Name**	**Powder weight**
Large running fire	2,628 g	Chun Ja Chong Tong (General cannon)	870 g
Medium running fire	41.4 g	Dae Wan Gu (Large motor)	870 g

and thus produces the loud noise. "Once used at night, its flame lightens the field," excludes the possibility that *Ju-Hwa* was a cannon or rifle as it produced "flame and smoke" during flight. In addition, the motion of ancient rockets does not generally follow a straight line because it depends on stabilizing sticks made of bamboo with an exhaust hole in the powder charge in the propellant case. Most of the weight of a solid-propellant rocket is due to the propellant. *Ju-Hwa* "spends more powder" than a gun or cannon as it continues to eject combustion gas in flight.

According to *Hwa Po Sick Eon Hae*, the medium running fire was charged with 41.4 g of black powder. Extrapolating the weights of small and large running fires from the weight of the medium-sized running fire and proscribed volumes of propellant cases of the small and large running fire, the weight of small and large running fire is given by 12 and 2,628 g, respectively. The weight of black powder for a large running fire is significantly larger than that of the largest cannon used in fifteenth century Korea with the black powder weight of 870 g (Table 1).

Korean Rockets of the Fifteenth Century

The reign of King Se Jong (1418–1450) of the Choson dynasty marked a turning point in the development of firearms, moving beyond the imitation of Chinese models and creating a distinctive Korean model. In the 30th year (1448) of the reign of King Se Jong the details and manufacturing methods of firearms and ready-to-launch munitions were compiled, illustrated and published in the *Chong Tong Deong Rok* (Reproduced Records of Firearms and Gunpowder). No copy of *Chong Tong Deong Rok* had survived, but part of it is in *Kuk Cho Ore Sorye.*

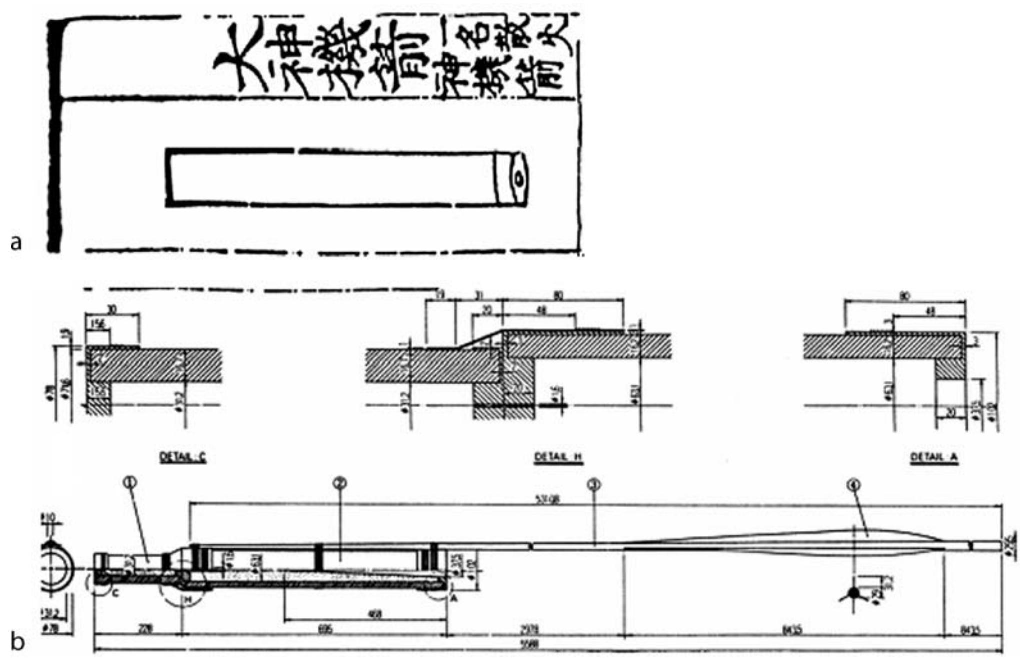
According to *Hwa Po Sik Eon Hae*, three types of rocket-propelled arrows were in wide use in their mature form by the 29th year (1447) of King Se Jong's reign: large, medium, and small running fires. In *Choson Wang Cho Silok*, such firearms are no longer mentioned by those names after 1448 and onward, but instead a new set of names of firearms begins to appear, namely *Sin-Gi-Jeon*, literally meaning "magical machine arrow." However, the specifications and manufacturing methods of the medium-sized *Sin-Gi-Jeon* described in *Hwa Po Sik Eon Hae* are identical to those for the *Ju-Hwa*. Thus, it is inferred that the *Sin-Gi-Jeon* was based on the *Ju-Hwa* and developed further to include versions of various sizes: small (*So*), medium (*Chung*), large (*Dae*), and multiple bomblets magical machine arrows.

Dae-Sin-Gi-Jeon (Large Magical Machine Arrow)

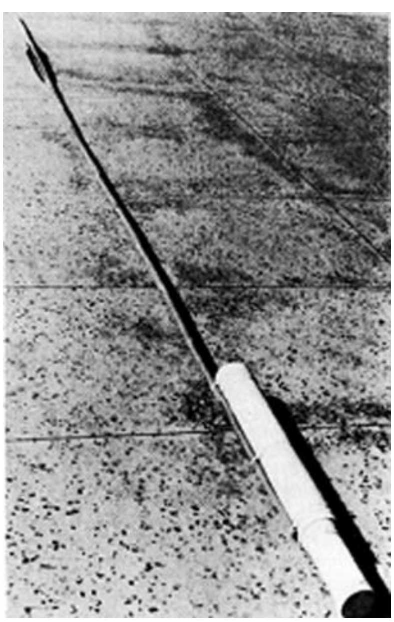
Figure 2 shows a drawing of the *Dae-Sin-Gi-Jeon* (large magical machine arrow) in the *Kuk Cho Ore Sorye,* and a drawing reproduced in metric units. The propellant case filled with black powder is a cylindrical tube made of paper. It is 695 mm long, 17.8 mm thick, and the internal diameter is 63.1 mm. Both ends of the propellant case were sealed with paper several times and attached to the front end of the bamboo shaft by strings. At the bottom end of the propellant case, opposite the warhead, a hole was made to allow exhaust fumes to exit. The bamboo shaft is 5.3 m long with the cross-sectional diameter increasing from 10 mm at the front to 29.5 mm at the rear. At the rear of the bamboo shaft three feathers were evenly distributed in between. The "Firearms Illustration" in *Kuk Cho Ore Sorye* records that they are bird feathers. However, there is no feather of size 30 mm × 840 mm, and it is reasonable to conjecture that they were made of leather, considering that arrows fired from a cannon at that time were equipped with feathers made of leather.

An explosive tube is mounted on the front end of the propellant case. A detonating fuse extends from the explosive tube through a hole made on the surfaces of the explosive tube and the propellant case into the propellant case. Such an arrangement enabled the explosives to detonate during or near the end of the flight to the target. The overall length of the *Dae-Shin-Gi-Jeon*, including the explosive tube, reached 5.6 m. *Dae-Sin-Gi-Jeon* was primarily used to launch an offensive on enemies across the Aprok river at its estuary from Eui-Ju City. Considering the width of the estuary, the *Dae-Sin-Gi-Jeon is* surmised to range from 1.5 to 2 km.

The *San-Hwa-Shin-Gi-Jeon* (Fire scattering magical machine arrow), an application of *Dae-Sin-Gi-Jeon*, was also used. Instead of employing the explosive tube of *Dae-Sin-Gi-Jeon*, the front part of the propellant case was occupied by a bundle of paper explosives called *So-Bal-Hwa* (small fire burner) connected by a detonating fuse. *San-Hwa-Sin-Gi-Jeon* was designed to disperse paper explosives ignited when they were near the target.



Rockets in Ancient Korea. Fig. 2 Large magical machine arrow (a) Propellant case from *Kuk Cho Ore Sorye*, 1474. (b) Drawing in metric units. ①: warhead, ②: propellant case, ③: bamboo, ④: fins.



Rockets in Ancient Korea. Fig. 3 Image of large magical machine arrow.

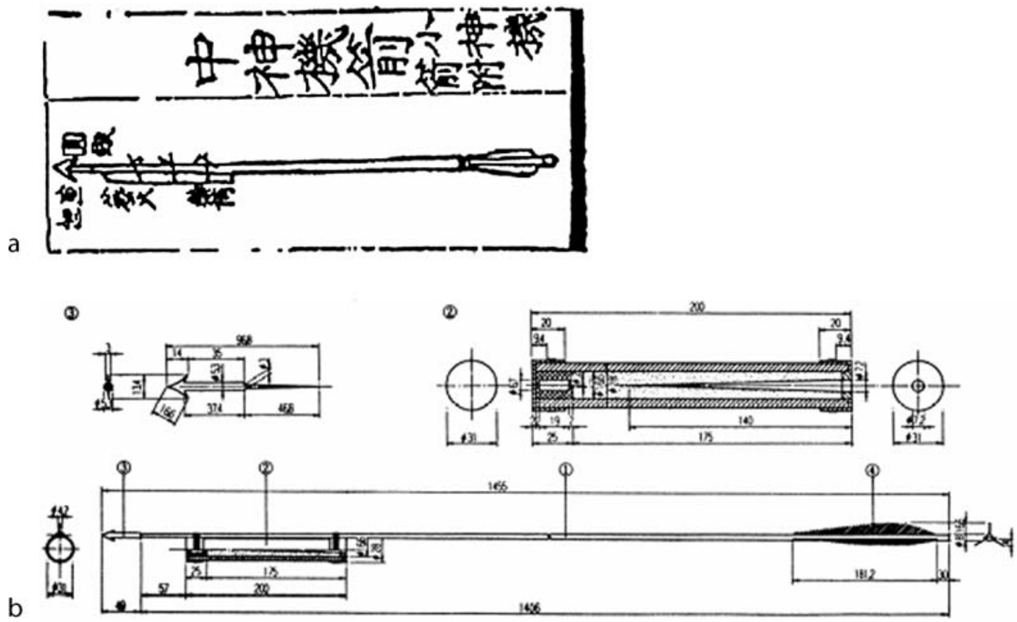
Dae-Sin-Gi-Jeon is the largest rocket ever made employing explosive cases made of paper, and a reproduced version is shown in Fig. 3. It was 350 years later that rockets of comparable size were manufactured elsewhere; in 1805 William Congreve of England produced 6-pound rocket with a propellant case 550 mm long, a diameter of 110 mm and an overall length including stabilizing sticks of 4.3 m.

Medium and Small Magical Machine Arrow (Chung- & So-Sin-Gi-Jeon)

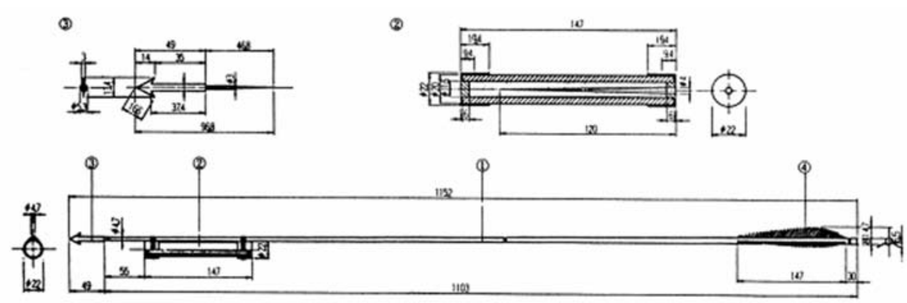
The *Chung-Sin-Gi-Jeon* (medium magical machine arrow) has a 1.4 m long bamboo shaft with a 200 mm long propellant case attached to the front. An arrowhead weighing 5.5 g is fixed at the front end of the *Chung-Sin-Gi-Jeon*, and at the rear end are attached 17.8 cm long bird feathers. There is no mention on the range of *Chung-Sin-Gi-Jeon*, but it is estimated to range from 150 to 200 m.

A detailed drawing showing the internal structure of the medium magical machine arrow is reproduced in Fig. 4. The lower part of the propellant case is bound with twine as in the large magical machine arrow. The propellant case is charged with powder up to the height of 175 mm leaving an empty space with a corresponding height of 25 mm. A small explosive tube (*so-bal-hwa-tong*) 56.2 mm long, 47.8 mm in circumference, 4.4 mm thick and 6.9 mm in internal diameter is inserted into the propellant case. The length from the end of the cylindrical case to the attachment twine is 6.3 mm, and the diameter of the nozzle is 2.2 mm. Finally, the powder in the propellant case of the medium magical machine arrow was connected with fuses.

The *So-Sin-Gi-Jeon* (small magical machine arrow) is the smallest version of the series as shown in Fig. 5.



Rockets in Ancient Korea. Fig. 4 Medium magical machine arrow. (a) Drawing from *Kuk Cho Ore Sorye*, 1474. Drawing in metric units. ①: warhead, ②: propellant case, ③: bamboo, ④: fins.



Rockets in Ancient Korea. Fig. 5 Drawing of small magical machine arrow in metric units.

Its propellant case, 15 cm long with a cross-sectional diameter of 15 cm, is attached to the front of a 100 cm-long bamboo shaft. At the rear end bird feathers are attached. The diameter of the exhaust hole installed in the propellant case is 4 mm, and the range is estimated to be about 200 m. Figure 6 shows pairs of reproduced running fire, and small and medium magical machine arrows reproduced in 1979.

Multiple Bomblets Magical Machine Arrow (San-Hwa-Sin-Gi-Jeon)

The multiple bomblets magical arrow is similar to the large magical machine arrow in size, but it differs in the warhead system. A propellant case serves as a warhead instead of an explosive tube.

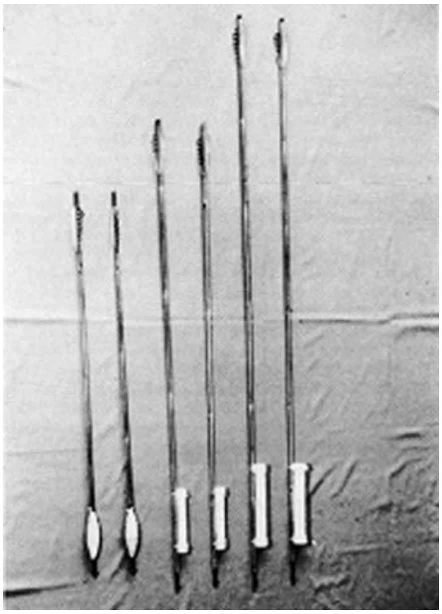
The detailed internal structure of the propellant case and explosive system of the multiple bomblets magical machine arrow is shown in Fig. 7. The lower part of the propellant case was bound with twine as in the large magical machine arrow. The propellant case was charged with powder up to the height of 579.5 mm, leaving an empty space corresponding to the height of 115.6 mm. Several layers of paper were attached to the top surface of the powder. Several land fire tubes (*Ji-Hwa-Tong*) attached to small explosive tubes (*So-Bal-Hwa-Tong*) were placed on the top of the propellant case with their fuses attached to the propellant charge.

The "Firearms illustration" section of the *Kuk Cho Ore Sorye* provides detailed explanations on manufacturing arrows, including charging propellant cases. A long, coned-shaped awl was inserted through the hole in the bottom of the propellant case. Then a small quantity of powder was spread and hardened with an empty cylindrical iron stick with its external diameter equal to the internal diameter of the propellant case.

Rocket Launch Device: Hwa-Cha (Fire Cart) and Launch Pad

The structure of the launch pads for rockets is relatively simple, since it primarily serves the function of providing a direction to the target. Even now, launch pads of rocket cannons retain such simplicity, resembling a piece of a chimney.

During the reign of King Moon Jong (1450–1452), proper launch pads were developed for the *Sin-Gi-Jeon*. King Moon Jong himself was interested in the development of firearms. When he was a crown prince he assumed some responsibility at the Bureau of Weapons. He also played a pivotal role in developing a *Hwa-Cha* (fire cart). *Hwa-Cha* could be loaded either with a launch pad capable of launching 100 *Sin-Gi Jeon* in sequence or with a gun tube pad capable of launching 200 *Se-Jeon* (bullets). Figure 8 shows a drawing of the fire cart in *Kuk Cho Ore Sorye* and a drawing reproduced in metric units.



Rockets in Ancient Korea. Fig. 6 Pairs of running fire and small and medium magical machine arrows.

The most notable feature of the *Hwa-Cha* is that the inclination of the launch pad was variable. The general feature of carts up to the reign of King Se Jong was to load a launch pad on the axle of the wheel. However, the car invented during the reign of King Moon Jong employed a column on and in the middle of the axle of the wheel, which enabled the launch pad to be inclined up to 40°. The first *Hwa-Cha* was dispatched in 1,451, and in the same year 700 additional carts were soon dispatched to strategic coastal regions and fortresses. During peace time *Hwa-Cha* served as wagons.

The diameter of the wheel is 874.7 mm. The hub is made of wood, 225 mm wide and 206.2 mm in diameter. Each wheel has 15 spokes. The spindle on which the wheels revolve is made of wood, 1,312.1 mm long, and consists of three parts: a middle square pillar and two end columns which are inserted into two wheels. Two wide posts are set up at both ends of the top side of the middle square pillar. A small post is set up at the center of the square pillar. Thin wooden boards are attached between each wide post. Two yokes are set up at both ends of the wide posts. An upper center crossbar is placed between the ends of both wide posts. It has a hole in the center for the small post. A rear crossbar is attached at the rear of (four-cornered part) of both yokes. Several thin wooden crossbars are attached between the rear crossbar and the upper center crossbar. This forms a wooden box to hide some arms. Its length and width are 624.8 and 515.5 mm.

Four U-shaped nails are driven into the front and middle of the column part of the yokes to insert rods, which are used to pull the fire cart. Two men could draw the cart on level ground, but it would require another man pushing from behind going uphill, and two more men had to push the cart when it was going up a steep hill.

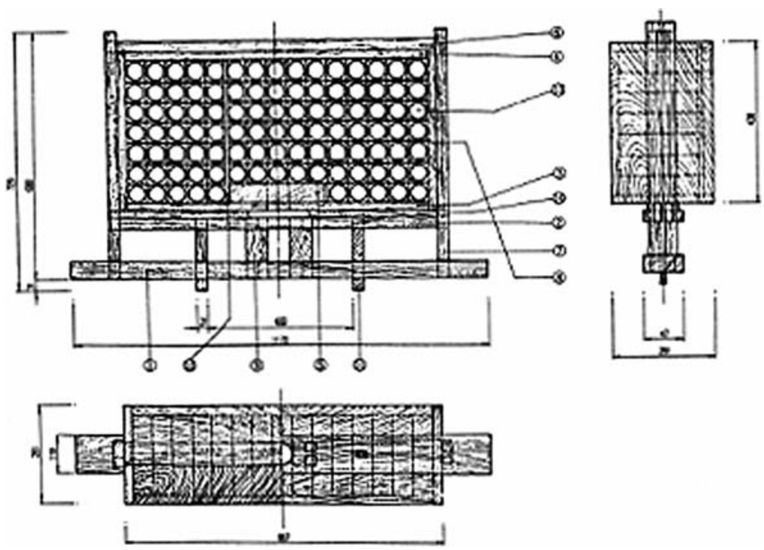
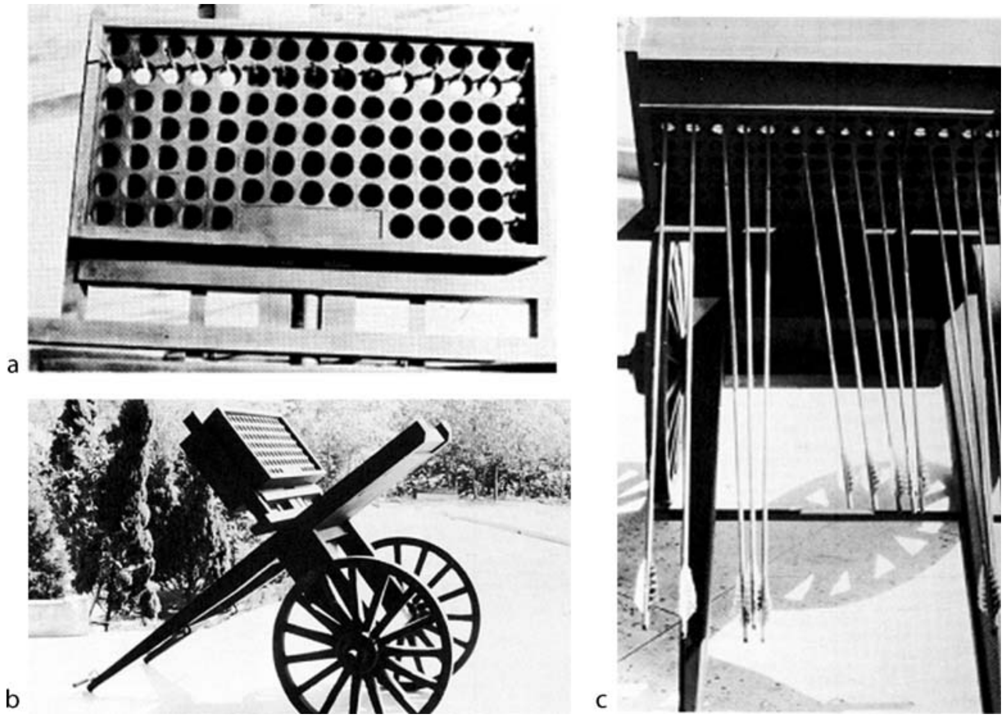
Rockets in Ancient Korea. Fig. 8 *Hwa-Cha* (Fire cart) (a) Drawing from *Kuk Cho Ore Sorye*, 1474. (b) Drawing in metric units. ①: yoke, ②: axletree, ③: small post, ④: wide post, ⑤: upper center crossbar, ⑥: lower center crossbar, ⑦: rear crossbar, ⑧: front crossbar, ⑨: rod, ⑩⑬⑰⑲⑳㉒㉔: thin wooden beam; ⑱: U-shaped nail.



Rockets in Ancient Korea. Fig. 9 Drawing of magical machine arrow launcher in metric units. ①: first crossboard, ②: second crossboard, ③/④: top/bottom wide boards, ⑤: rectangular block of wood, ⑥: third crossboard, ⑦: column, ⑧: side wide board, ⑨: small square column, ⑩: detailed board, ⑪: assistant column; ⑫: thin column; ⑬: cylindrical-hole-wood-block.

Figure 9 shows a drawing of the launch pad for magical machine arrows based on the descriptions in *Kuk Cho Ore Sorye*. It consists of a rectangular box containing blocks with 100 cylindrical holes and a supporting mechanism. They are comprised of seven rows of blocks. The end of each block is pierced with a wire and both ends of the wire are attached to the external surfaces of the side boards of the rectangular box. The supporting mechanism houses the rectangular box and consists of a set of columns and crossboards. The first crossboard is 1,171.6 mm long, 109.3 mm wide, and 47 mm thick. It has a 62.4 mm diameter hole in the center into which the small post of the fire cart is inserted. The main body of the launcher is supported by two columns, small square columns, and assistance columns.

The design of the fire cart and the magical machine arrow launcher enabled the cart body to be raised above the axle by short pillars to regulate the angle from 0° to 43°. The magical machine arrow launcher when fully



Rockets in Ancient Korea. Fig. 10 Fire cart and magical machine arrow launcher (Hangju Fortress Museum, Korea). (a) Magical-machine-arrow-launcher with medium and small magical machine arrows. (b) Fire cart equipped with a launch pad.

loaded could launch 100 medium or small magical machine arrows in groups of 15 at a time. According to the *Moon-Jong-Silok*, 700 fire carts were built in Korea in 1451. Figure 10 shows a version of a fire cart and launch pad loaded with small and medium magical machine arrows reproduced in 1979.

The first Korean rocket manufactured in Hwa-tong-do-gam between 1377 and 1389 provided the technological heritage for forthcoming rockets called *Sin-Gi-Jeon*. *Kuk Cho Ore Sorye* served as a technical manual for manufacture and operation of the rockets. While the large *Sin-Gi-Jeon* is the largest rocket ever made amongst those employing a propellant case made of paper in the fifteenth century, the use of the unit of length "le" corresponding to 0.3 mm demonstrates that *Sin-Gi-Jeons* were manufactured with a considerable level of precision. Historical records attest that 33,000 or so running fires and magical machine arrows were maintained in Korea by 1447, and dispatched for action with the fire cart from 1451. These weapons are believed to have served as powerful weapons for raiding Chinese and Japanese bandits.

Unfortunately, neither the *Sin-Gi-Jeon* nor the fire cart survives, primarily because they were made of wood and paper. In order to verify the technical feasibility of drawings and manufacturing methods in *Kuk Cho Ore Sorye*, small and medium *Sin-Gi-Jeons* were reconstructed together with their fire carts and launch pads for a flight test at the Daejeon Exposition

Rockets in Ancient Korea. Fig. 11 Flight test of small and medium *Sin-Gi-Jeon* at Daejeon Expo 93.

in 1993. Figure 11 depicts the moment of the flight test of 100 small and medium *Sin-Gi-Jeons* in 1993. The *Sin-Gi-Jeons* traveled between 100 and 200 m in distance. The successful test cleared the obscurity surrounding the rockets which had arisen from the fact that there were no remaining models; it demonstrated that they were nearly flawless in terms of design and function.

Rockets in China

Pan Jixing

Traditionally, a rocket is a flying device launched by direct-reaction using a solid black powder of high-nitrate composition. The appearance of rockets signified a revolution in the development of firearms. All modern rockets were gradually developed on the basis of traditional ones. In Ancient China the rocket was generally called *huojian* (fire-arrow) which sometimes meant incendiary arrow and sometimes rocket. Both of them were invented in China. It is necessary to differentiate one from the other. From 968, the classical fire-arrow was sent by low-nitrate gunpowder in paste form from a bow or crossbow. It was thus an incendiary arrow, although it was the earliest gunpowder weapon. Since the beginning of the twelfth century solid gunpowder of high-nitrate composition and fuses were made and used for making fireworks and firecrackers. Some of them were directional devices, such as the *di laoshu* (earth-rat), *qihuo* (flying fire), and others. This provided a necessary premise for making rockets. During 1127–1234 the invention and military use of rockets were perfected in China on the basis of fireworks technology. There were two types of early rockets having different names.

The so-called *pili pao* (thunder-bolt missile) used in the Battle of Caishi between the Song and Jin was actually the earliest rocket-propelled bomb in the world. It was an enlarged *ertijiao* (double-bang firecracker) and was made according to the principle of *qihuo* (flying fire) used by the Song people in an earlier time. The *fei huojiang* (flying fire-lance) used in the Battle of Kaifeng between the Jin and Mongols in 1232 was an ordinary rocket for setting things on fire. Its rocket tube made of paper was fastened to the point of a lance or an arrow. During the thirteenth to fourteenth centuries the Song, Jin, and Mongol troops all used improved rockets to fight with each other. They even used the reaction weapon abroad. For instance, single rockets and multiple rocket-launchers with a common fuse were used by the Mongols in the Battle of Leignitz in Poland in 1241, known as the "Chinese dragon belching fire" in the West. Winged rockets must have been made in about 1300, since it was described in the *Huolong Jing* (Fire-Dragon Manual, ca. 1350).

In the Ming dynasty (1368–1644) rocketry entered a new epoch. Two-stage rockets were designed and made at the beginning of the fourteenth century. There were various kinds of different rockets from single ordinary ones to multiple rocket-launchers and wheelbarrows, as well as winged rockets and rocket-propelled bombs. Their range reached 200–500 paces (330–825 m). There was a special rocket troop in the Ming army and rocket weapons were used as standing weapons by land and naval forces and cavalry troops. It is interesting that a Chinese military officer, Wan Hu (fl. 1440–1495), built a flight device made of 47 big rockets for a flight experiment. He was the first in history to try to use rockets for flight as a means of transportation. All of these ancient achievements in the field of rocket technology can be found in the military work entitled *Wubei Zhi* (Treatise on Armament Technology) written by Mao Yuanyi (ca. 1570–1637) in 1621. After rocket technology was perfected in China it was spread to other parts of the world. It went first to the Arab world in 1240–1260, then to Europe in 1260–1270. The term *rochetta* first appeared in Italian literature in 1330. In the eighteenth century rockets were popular in some major European countries. Rockets arrived in other Asian countries in the same time during the Mongol-Yuan period, first in Vietnam and Korea, then in India and Southeast Asia.

In 1805 the British military officer William Congreve (1772–1825) developed modern rockets made of iron tubes with black powder, which had a range of 2,300 m. But after the mid-nineteenth century rocketry ceased to develop, because modern cannons seemed to be more powerful and effective. Since the beginning of the twentieth century rockets have been given more attention and studied carefully. As a result, various new types of rockets have been developed and used, especially since World War II. Joseph Needham says:

> In this day and age, when man and vehicles have landed on the moon and when the exploration of outer space by means of rocket-propelled craft is opening before mankind, it is hardly necessary to expatiate upon what the Chinese started when they first made rockets fly.

Rockets in India

RODDAM NARASIMHA

Fire arrows (*agni-bāṇa*), shot with the energy of a taut bow-string were used in India and other civilizations for thousands of years. Rockets are different in that they are self-propelled. It is widely agreed that the first recorded use of rockets comes from China in the eleventh century CE. The invention travelled rapidly (presumably through the Mongols) to Europe, where it was first mentioned in 1258 CE and was experimented with and used up to the fifteenth century. The Moghuls in India also used it during the late fifteenth and early sixteenth centuries. However rockets fell into disuse with the increasing accuracy and power of artillery.

The re-emergence of the rocket as a significant military weapon during the eighteenth century in the princely state of Mysore in South India is a fascinating little episode in the history of technology in India, with an interesting sequel in nineteenth century Britain and Europe. Haidar Ali, a bold officer in the army of the Raja of Mysore, and his son Tipu Sultan, used the rocket frequently in various battles in South India, including the four "Anglo-Mysore Wars" fought in the second half of the eighteenth century (Haidar's father had already commanded 50 rocketmen for the Nawab of Arcot, another South Indian prince). The interest in the events of the late eighteenth century arises from two facts: the balance of industrial power began to shift from Asia to Europe in that period, and interesting accounts have been left behind by European observers.

The rockets used by the Mysoreans consisted of a metal cylinder ("casing") containing the combustion powder ("propellant"), which was tied to a long bamboo pole or sword that provided the required stability to the missile. It bears a strong resemblance to the much smaller "rocket" that is a part of the fireworks that are still commonly seen during the Indian festival of lights, Deepavali. Two specimens preserved in the Royal Artillery Museum, Woolwich Arsenal in England have these dimensions:

Casing 58 mm outer diameter – 254 mm long, tied with strips of hide to a straight 1.02 m long sword blade.

Casing 37 mm outer diameter – 198 mm long, tied with strips of hide to a bamboo pole 1.9 m long.

These rockets had a higher thrust and range than anything in use at that time in Europe, as confirmed by later tests in England. The range is often quoted as about 1,000 yards. There are however other accounts that speak of rockets that generally weighed 3.5 kg, tied to 3 m bamboo poles, and with a range of up to 2.4 km; this was by European standards an outstanding performance for the time.

The superior performance of these rockets cannot be attributed to the propellant, which was a standard material like gunpowder. There was nothing unusual about the aerodynamics either; it turns out that their superiority lay in the material employed for the casing. The casing was a metal cylinder made of hammered soft iron. Although it was crude, it represented a considerable advance over earlier technology, as European rockets of the time had combustion chambers made of some kind of pasteboard. For example, Geissler in Germany used wood, covered with sailcloth soaked in hot glue. The use of iron (which at that time was generally of much better quality in India than in Europe), increased bursting pressures, which permitted the propellant to be packed to greater densities; this is what gave the rockets their outstanding performance.

There was at that time a regular Rocket Corps in Tipu's Mysore Army with a strength of about 5,000, with several units of rather more than a hundred men each. There are accounts that mention the skill of the Mysorean operators in giving the rockets an elevation that depended on the varying dimensions of the cylinder and distance to the attack target. Furthermore, the rockets could be launched rapidly using a wheeled cart with three or more rocket ramps.

The first account we have of the use of these rockets is in the Battle of Pollilur, fought on 10 September 1780 during the Second Anglo-Mysore War near a small village about 180 km east of Bangalore. Haidar and Tipu achieved a famous victory in this battle, and it is widely held that a strong contributory cause was that one of the British ammunition tumbrels was set on fire by the Mysore rockets, a scene that is celebrated in a famous mural that can be seen at the summer palace in Tipu's capital Sri-ranga-pattana. Writing about this war, Sir Alfred Lyall, a British historian of the early twentieth century, remarked that, as a consequence of this defeat, "The fortunes of the English in India had fallen to their lowest water-mark."

A celebrated victim of such a rocket attack was Colonel Arthur Wellesley (later Duke of Wellington and the hero of Waterloo), who suffered a traumatic encounter with rockets in a mango grove just outside Sri-ranga-pattana in 1799. From these and other accounts it is clear that the British were caught off guard by the Indians' use of rockets, which at the least caused great fear and confusion. They started developing their own rockets in the early years of the nineteenth century. The programme began when several Indian rocket cases were collected and returned to Britain for analysis. Further development was chiefly the work of Col. (later Sir) William Congreve, who tested the biggest skyrockets then available in London. Their range was found to be about 500–600 yards, less than half that of the Mysore rockets. He then developed his own, using the facilities of the Royal Laboratory at Woolwich Arsenal.

Congreve used these rockets during the Napoleonic wars and in several engagements during the Anglo-American War of 1812, sometimes with little and on other occasions with great effect. They were still rather unreliable and inaccurate, but had greater range than cannons and could even be fired from rowboats. It was a spectacular but unsuccessful attack on Fort McHenry that led to the reference to "the rockets' red glare" in the US national anthem, which began as a patriotic song composed by Francis Scott Key, who was witness to the attack.

One major reason for interest in this episode is that it occurred during a time of global transition in geopolitics, economics, and technology. Clearly, even in the late eighteenth century there were several Indian products technologically superior to Western equivalents, and both sides recognized this. But the British effort that followed had the sophistication of research and development today. Scientific principles were applied, designs made, products developed and tested, and all of this was carefully documented – a process alien to Indians of that time. The Indian rockets were well made but not standardized, being the creation of traditional artisans.

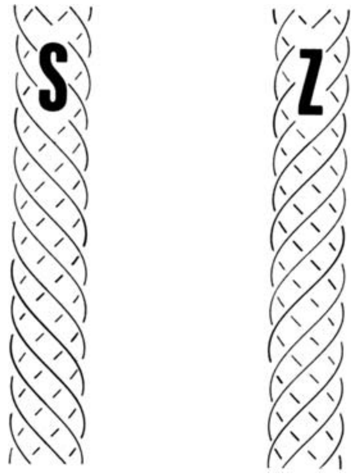
Rope and Knots in Ancient Egypt

Willeke Wendrich

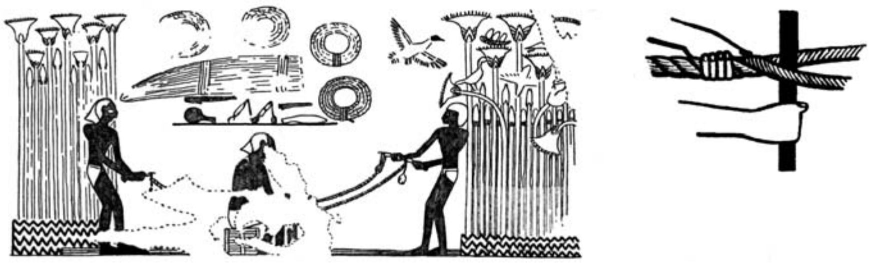
From securing a ship, to tying cattle to a post, building shelters and curing headaches, rope and string were a multipurpose commodity in ancient Egypt. The technology to make rope and string is presumably one of the oldest, predating stone working. Due to the perishable materials used for rope, no extant examples have survived in Egypt until the predynastic period. The material used most widely for the production of rope was papyrus (*Cyperus papyrus*) and other sedges of the *Cyperus* family. For large ropes, the entire stem was used, while smaller string was made of the rind of papyrus stems. The production of papyrus sheets for writing required the thick triangular stems to be peeled and sliced. The peelings made a strong raw material from which extremely fine string could be made. Many examples of such string were found in archaeological contexts, for instance in cordage from the Giza Plateau, in the rubbish tips of the building phases of Khufu's pyramid (ca. 2600 BCE). Its popularity continued into the New Kingdom. At the workmen's village of Amarna (ca. 1350 BCE) remains of a papyrus amphora carrying net were excavated (Wendrich 1989: 182–5).

Cordage was made in a large variety of ways. The fibers were spun or twisted in either S or Z direction (see Fig. 1). Two or three strands were plied to form the string, usually twisted in the opposite direction of the orientation of the strands. Two or three strings might be twisted into a cable. Again the orientation was usually the opposite of the twist direction of the ply.

The production of yarn or fine string followed three steps: (1) spinning and splicing (adding short prespun lengths by twisting the fibers in the same direction as the spin) using a spindle whorl; (2) plying in the opposite direction, and (3) cabling in the same orientation as the spin. This type of string was usually made of flax and had a diameter of approximately 0.5–2 mm for the spun and spliced yarn, 1–3 mm for the plied string, and 2–5 mm for a cable. Flax was typically spun and spliced in S direction, then Z-plied and S-cabled (Kemp and Vogelsang-Eastwood 2002: 75–6).



Rope and Knots in Ancient Egypt. Fig. 1 S and Z orientation of spinning, plying, or cabling.



Rope and Knots in Ancient Egypt. Fig. 2 Representation of rope making, using weights in the tomb of Nefer, Saqqara. To the right: detail of the action of the man seated in the middle.

Producing string of other materials was often done in one phase. Grass string, for instance, was spun and plied in one movement of the hands, the opposite direction of spin (usually z) and ply (usually S) locking the string immediately and preventing it from unraveling (Wendrich 1999: 298–300). Materials for which this technique was used were tall hard grasses (*Desmostachya bipinnata* and *Imperata cylindrica*), leaf and leaf sheath fibre of the date palm (*Phoenix dactylifera*), leaf of the doam palm (*Hyphaene thebaica*) and probably also papyrus peel. The result of this hand-rolling technique was a string consisting of two yarns, usually 'spun' in Z-direction and plied in S-direction (sZ_2 string). A third plying strand (sZ_3 string) was added separately, by doubling the end of one of fiber bundles and working back along the string. For ropes, the entire length of string was folded double and twisted into a cable ($sZ_2[S]_2$ rope).

Papyrus rope, however, was usually not cabled. The enormous ropes used in shipping consisted of multiple strands of complete papyrus culms [stems] twisted together. Such giant plied ropes were built of up to 15 thick strands of papyrus culms, each with a diameter of approximately 30 mm, resulting in a thick rope of 160 mm in diameter. We have few depictions of rope making, for instance in the tomb of Nefer at Saqqara (Fig. 2), dating to the Fifth Kingdom, ca. 2465–2323 BCE. This seems to be a more industrial approach than the hand-rolling method, which could typically be done by anybody at anytime, whenever a piece of string was needed. The use of swinging weights to make long lengths of rope was most probably needed to twist complete papyrus stems. Presumably the stems were first dried, then soaked (to render them pliable again), twisted into rope and left to dry, so that the twist would settle into a strong plied rope. Toward the Greco-Roman period, grass, papyrus, and doam palm leaf string became less ubiquitous and the material that was used most often was the leaf sheath fiber of the date palm. This hard brown fiber did not need much preparation. Soaking in water for half a day would soften the fibrous sheets enough to enable them to be worked into small bundles or tufts, which were then used to make a very hard red-brown string or rope. This material was also worked in the hand-rolling method.

Knots and knotting are part of understanding the use of rope. In all periods of ancient Egyptian history, from at least the predynastic period onward, standard knots such as the overhand knot, the reef knot (also known as square knot), and the netting knot were known and widely used. Studying everyday objects from refuse dumps, clarifies that then, as now, certain people were better versed in the art of knotting than others. The occurrence of a considerable percentage of 'granny knots,' faulty reef knots, testifies to that effect (Wendrich 1999).

Depictions of knots and knotting on Egyptian monuments had a very specific meaning. The hieroglyph for 'protection' (ancient Egyptian *shen*) represented a rope ring, which surrounded what needed to be protected. The *cartouche,* (French for 'bullet') was the protective oval inscribed around the name of the Pharaoh. It represented an elongated rope oval tied at the base.

Knotting had a particularly important protective function in Ancient Egypt. The *tit* amulet, also known as the "Isis knot" represented a looped knot with four ends hanging down. The *tit*, often made of the red semiprecious stone jasper, is thought to be either the girdle of the goddess Isis, or a tampon, with the function of protecting pregnant women from a miscarriage (Wendrich 2006). A more symbolic interpretation should be given to the quite common depiction of two nameless Nile gods, or the gods Horus and Seth, knotting the lotus and the papyrus (or the lily), symbols for Upper and Lower Egypt respectively, around a trachea with lungs. This was the hieroglyph for the verb *semaa* and the knotting of a reef knot around this hieroglyphic sign symbolizes the unification of the Nile Valley and the Delta, the two lands that together formed Egypt. In ancient religious texts, such as the Pyramid Texts, the Coffin Texts, and the Book of the Dead, several references were made to knotting. In all cases this seemed to be a protective action, in keeping with the important protective function of knots in medical and magical texts. This forms a stark contrast with terms used for 'binding,' or 'fettering,' which were used in funerary contexts to describe serious dangers to the deceased. The mummy wrappings were literally considered fetters that prevented the dead from functioning in the afterlife. The action of knotting, however, was related to encircling, the protective embrace, and the guarantee of the integrity of body and *ba*.[1]

[1] The *ba*, a concept often translated as 'soul,' is an integral part of a person. The *ba* is depicted as a bird with a human head and is the free-ranging part of a human being. When a person dies, the body is entombed, but the *ba* can exit the tomb, to return each night to the body.

Ṣāᶜid al-Andalusī

SEMA'AN I. SALEM

Abū al-Qāsim Ṣāᶜid ibn Abū al-Walīd ibn ᶜAbd al-Raḥmān ibn ᶜUthmān al-Taghlibi, better known as Ṣāᶜid al-Andalusī or Qāḍi Ṣāᶜid, was born in Almeria in southern Spain in AD 1029. He was a philologist, natural philosopher, and historian as well as judge. As his name indicates, he was a member of the tribe of Taghlib, one of the largest tribes of Arabia. When the Arabs invaded Spain in AD 711, members of this tribe entered the country and prospered there.

Ṣāᶜid was born into a well-to-do family, whose members spent much of their time and wealth in the quest of knowledge and education. His father occupied a highly respected position in the city of Cordoba, and his grandfather, ᶜAbd al-Raḥmān, was a judge in Sidonia, Spain. After receiving his early education in Cordoba, Ṣāᶜid toured Muslim Spain to further his education. For the same reason, at the age of 17, he moved to the city of Toledo.

Like most young Arab students, Ṣāᶜid studied law, Islamic religion, Arabic language, and Arabic literature. Later in life, he specialized in the study of mathematics and observational astronomy. Among his most famous teachers were al-Fātiḥ Muḥammad ibn Yūsuf (d. AD 1059), Abū Walīd al-Waqshī (d. AD 1059), and Ibn Idris al-Tajibī, who taught him mathematics and astronomy.

Early in the eleventh century, Cordoba ceased to be the principal intellectual center of Spain, and the capital cities of the *Mulūk al-Ṭawā'if* (party-kings) tried to capture its former glory. One such city was Toledo, the capital of the princedom of Banū al-Nūn. When Ṣāᶜid entered Toledo, it was governed by Yaḥyā ibn Dhi al-Nūn (r. AD 1037–1074) and extended his kingdom to include Valencia and most of the eastern parts of Andalusia. During his reign, Toledo became an important literary and intellectual center. In addition to several authorities in Islamic sciences, Yaḥyā's court had several good mathematicians, well-known astronomers and astrologers, several men of medicine, poets, and geometers.

The number of eminent scholars, poets, and philosophers in a ruler's court was one of the status symbols of the time. Probably for that reason, Yaḥyā invited Ṣāᶜid into his court and appointed him a judge (*qāḍi*).

Several of Ṣāᶜid's students later became accomplished scholars. Among them was ᶜAbd al-Bāqi ibn Baryal, who was in part responsible for the style and language of some of Ṣāᶜid's writing. There was also the outstanding astronomer and mathematician Abū Isḥaq al-Zarqali (Arzaquiel) who, with the assistance and the guidance of his mentor, constructed the famed Toledan Tables. These astronomical tables, which were accurate calendars, were translated into Latin by Gerard of Cremona, and became the basis for the Marseilles Tables.

Ṣāᶜid wrote several manuscripts on a variety of subjects. All of his works except for *Ṭabaqāt al-ʾUmam* (Book of the Categories of Nations) are lost. He mentioned in *Ṭabaqāt al-ʾUmam* that he wrote a document on observational astronomy, one on the history of nations, and another on their religions. He may have written a manuscript on the history of Andalusia and one on the history of Islam. *Ṭabaqāt al-ʾUmam* is an authoritative source and a precise reference that identifies the natural philosophers of Muslim Spain.

Ṣāᶜid died in July, AD 1070. Ibn Yaḥyā al-Ḥadidī, the most illustrious dignitary in the court of Ibn Dhi al-Nūn, read his official obituary.

Ṣadr al-Sharīᶜah

AHMAD DALLAL

Ṣadr al-Sharīᶜah al-Thanī, ᶜUbayd Allāh ibn Masᶜūd (fl. Bukhārā, d. 747 AH/AD 1347), was a scholar and astronomer of the fourteenth century.

He belonged to a family of famous religious scholars; his great–great–grandfather, Ṣadr al-Sharīʿah al-Awwal, was referred to as the second Abū Ḥanīfa in recognition of his rank among the legal scholars of his time. Ṣadr al-Sharīʿah, moreover, was himself a traditional religious scholar: he wrote on the subjects of *Ḥanafī* positive law, principles of jurisprudence, Arabic grammar, rhetoric, theology, legal stipulations and contracts, and *Ḥadīth* (the spoken Traditions attributed to the prophet Muḥammed). In addition, he wrote a three-volume encyclopedic treatise, *Taʿdīl al-ʿUlūm* (The Adjustment of Sciences). The first of the three books is on logic, and the second is on theology (*kalām*). The questions discussed in these two books were not unfamiliar to theologians of the time, and it seems quite probable that a jurist would be informed in such areas of research. What is uncommon, however, is Ṣadr al-Sharīʿah's competence in astronomy, which he demonstrates in the third book of the above work.

This last section entitled *Kitāb Taʿdīl Hay'at al-Aflāk* (The Adjustment of the Configuration of the Celestial Spheres) was finished in the year 747 AH (AD 1347) shortly before the death of its author. The motive for writing it, as expressed by the author in the beginning of the book, was to resolve the problems of the longitudinal motion of the moon and the other planets, as well as the latitude motion. The resulting work is indeed a revision of the astronomical tradition from within its own existing framework. In this Ṣadr al-Sharīʿah was obviously driven by the momentum of the revisionist tradition of the thirteenth-century Maragha school, which aimed at reforming Ptolemaic astronomy.

Ṣadr al-Sharīʿah was especially influenced by two sources: the *Tadhkira* of Naṣīr al-Dīn al-Ṭusī (d. AD 1274) and the *Tuhfa* of Quṭb al-Dīn al-Shīrāzī (d. AD 1311). Ṣadr al-Sharīʿah proposed to review critically the planetary models of his two predecessors, and in the course of this revision he proposed his own alternative configurations. The models which he purported to examine and replace were for (1) the longitudinal motion of the moon, (2) the longitudinal motion of the superior planets, (3) the longitudinal motion of Mercury, and (4) the motions in latitude. The mathematical mechanisms utilized by Ṣadr al-Sharīʿah to solve the problems of these models were not new, but his ingenuity lay in bringing some of these different mechanisms together. In three of the above cases he succeeded in producing new models, and in at least two of these the resulting configurations seemed to resolve the theoretical problems of earlier models, while predicting the planetary positions in accordance with the Ptolemaic observations.

Salt

S. A. M. Adshead

Salt, its production, distribution and consumption, was an important element in the economies of all ancient societies and played a significant role in their societies, politics, and culture. This article falls into two parts. First, the principal methods of producing salt before 1800 will be analyzed. Second, the particular methods in use in the four primary civilizations of Western Eurasia (excluding Europe itself), East Asia, sub-Saharan Africa and pre-Columbian America will be outlined, together with their characteristic means of distribution and levels of consumption.

Salt exists in nature in two forms. First, there is actual salt. This takes the form of rock deposits from evaporated seas which can be quarried or mined, spontaneous evaporation at the edge of the sea or saline lakes, and incrustation on the surface of saline soil, both of which may be collected. Second, there is potential salt. This takes the form principally of brine from the sea, lakes, springs or wells, but also of saline earth and the plants growing in it. From potential salt, actual salt can be made by a variety of techniques. In most non-Western cultures these techniques were more important as a source of salt than quarries, mines or collection. Evaporation of brine, whether from the sea, lakes, springs or wells, or artificially prepared from saline rock, earth or plants, accounted for 90% of all salt consumed before 1800. Brine could be made to yield salt in two ways. It could be boiled over an artificial fire and fueled in various ways: what the Chinese called *chien*. Or it could be evaporated naturally by the power of the sun and wind: what the Chinese called *shai*. Artificial boiling and natural evaporation produced different kinds of salt. Quicker, *chien* produced a small-crystal salt, or, if prolonged, cake salt. Slower, *shai* produced a large-crystal salt. Each method had subvarieties whose differences varied the cost, color, consistency, purity, and cleanliness of the salt produced.

Subvarieties of artificial boiling may be classified according to the fuel used. Wood was commonest, but reeds, natural gas, coal, and oil shale were also used. Fuel was the chief item of cost and its availability the principal constraint. The amount required depended on the salinity of the brine. To reduce it, brine salinity was frequently intensified either by preliminary exposure to sun and wind or by filtration through saline sand, earth or ash. Since artificial boiling was everywhere an older method than natural evaporation, it may have been this preliminary exposure which provided the idea of using sun and wind to effect the whole process.

Subvarieties of natural evaporation may be classified according to the number and function of the basins used. First, there was single basin evaporation. Here, brine was run into a single basin, or battery of basins, and allowed to evaporate completely. Salt made in this way, however, was gritty, deliquescent, and possibly injurious to health, because the sodium chloride would be contaminated by the calcium and magnesium compounds contained in most brines and especially in sea water. Next, there was successive basin evaporation. Here, brine was run through a series of basins for catchment, condensation, and crystallization. In this way, sodium chloride could be separated from the calcium and magnesium compounds through the different sedimentation rates of these chemicals. Thus the calcium compounds settled in the condensers, while salt was removed from the crystallizers before it could be contaminated by the magnesium compounds in the mother liquor which was then drawn off. By this triple process, a much purer sodium chloride was obtained. The process could be tuned to give different degrees of cleanliness and size of crystal by varying the frequency of harvest and the ratio of condensers to crystallizers. The more frequent the harvest, the more likely the adherence of the floor of the crystallizer to the salt, so the dirtier the product. The higher the ratio of condensers to crystallizers, the longer the process, so the bigger the crystals. The choice of frequency and ratio depended on cost, especially of land, convenience to the producer, climate, and consumer preference as to the kind of salt. Salt was a sophisticated industry.

Salt has been sought since the first agriculturalists found a vegetable diet bland and insipid compared to meat and fish. It was sought too for its supposed medicinal effects on the internal parasites with which early agriculturalists were endemically affected. Finally, as the "general of foods", it was sought to create flavor, cuisine, and social distance. Salt was an adjunct of civilization. Although the body does require a minimum intake, the quantity is small and satisfied by normal diet, so that salt deficiency is rare in humans.

Most human consumption is in excess of physiological need. Culture, not nature, called for salt. It traveled by whatever form of transport was cheapest for bulk goods, which in premodernity meant by water, where available, rather than by land.

In the Ancient Near East and in its successor the Central Islamic lands, natural salt in the form of rock, spontaneous evaporation and incrustation was widely distributed. Salt never became big business and consumption was high. When Muslims moved beyond their homeland, however, they experienced a shortage of salt. The expansion of Islam to the Mediterranean, North Africa, India, and Indonesia was therefore accompanied by the introduction of new techniques of salt production. In particular, Islam diffused the Chinese technique, invented around AD 500, of successive basin solar cum wind evaporation. That the technique was diffused rather than independently invented in a number of places is indicated by the presence everywhere initially of the original Chinese condensers to crystallizers ratio, itself functionally unnecessary and in some circumstances dysfunctional.

In China itself, before AD 500, salt had been acquired either, in the northwest, by the collection of natural deposit, or, in the southeast, by boiling of marine brine (*chien*). Initially *shai* was regarded as inferior to *chien*. Indeed, in the Mongol period it was temporarily abandoned in its original site. In the long run, however, its absence of fuel costs, plus a number of technical improvements, gave it complete victory over *chien*, save in Szechwan which enjoyed the advantage of natural gas and more saline brine. In India too, though the mines of the Salt Range continued to operate, successive basin solar evaporation became the chief form of production: principally at the Sambhar Lake and on the west coast, but subsidiarily, with technical modifications, in Tamil Nadu. Bengal long remained a center of *chien*, till its industry was overwhelmed by imports from Britain and the Red Sea, the latter being a *shai* center.

In pre-Columbian America and in sub-Saharan Africa, production remained limited and consumption low until the coming of the Europeans to the first and of Islam to the second. Some Matto Grosso Indians neither produced nor consumed salt (the same is true of the Maori in New Zealand). Elsewhere in America, supply was by collection, boiling, or single basin evaporation, though one archaeological site has raised the possibility of an independent Maya invention of the successive basin technique. In Africa, supply was similar, though the Saharan quarries and mines may have been developed before the coming of Islam. The greatest consumers of salt were the Islamic world and China. Despite the development of marine based salines at its extremities, Islam supplied itself mainly by land, using camels for transportation. China supplied itself mainly by water, by junk. There, because sources of supply, chiefly on the coast, were relatively few, salt did become big business. Indeed, until it was supplanted in the eighteenth century by textiles, it was the chief component of the premodern Chinese economy.

Salt in China

Hans Ulrich Vogel

In premodern China, hundreds of terms for different kinds of salt existed which were distinguished according to place of origin, type of deposit, method of production, shape, physical appearance and properties, taste, color, translucence, use, and function within the salt monopoly system. An important and authoritative scientific explanation for the existence of various salt deposits was provided by the *Shujing*. There, in the chapter "Hong fan," saltiness (*xian*) is related to the phase of Water, which by soaking and descending becomes salty. Another important explanation referred to cosmogonical thinking, stating that the clear and light (i.e., underground currents of sweet water and water of rivers and lakes) are to be found above, while the heavy and turbid (i.e., underground brine and sea water) below.

The economically and fiscally most important types of salt were, in descending order, sea salt (*haiyan*), lake salt (*chiyan*), well salt (*jingyan*), earth salt (*jianyan* or *tuyan*), and rock salt (*yayan*). In the late imperial period, sea salt accounted for more than 80% of the empire-wide production. The percentages for lake salt and well salt were about 12 and 6%, respectively. The shares of earth and rock salt are quantitatively negligible.

The Chinese salt production sector reflects typical features of the history of production techniques in China. The far greatest amounts of salt, that is sea, lake, earth, and rock salt, were produced with the help of rather simple and old-established production techniques, which in many cases required a high input of human labor. Manpower also played an important role in well salt production, but, because of the use of deep-drilling methods and exploitation of natural gas resources, this sector contained a revolutionary technological potential. Finally, we can observe that, sometimes, sophisticated production techniques were abandoned, like the method of basin solar evaporation at the salt lake of Xiezhou in Hedong (Shanxi) during the thirteenth to the sixteenth centuries.

Several partly overlapping stages of development may be observed in the production of sea salt. Early sources mention that salt was produced by boiling seawater. It is, however, far from clear whether this statement refers to the rather uneconomic process of boiling seawater directly down or whether prior to boiling a concentrated brine had been prepared. Probably both methods coexisted.

The first written account of the production of concentrated brine comes from the late ninth century. A hollow was dug, covered with wood and bamboo twigs. Sands enriched in salt were heaped up over the hollow and were then leached out by the invading flood. The concentrated brine dripped into the hollow and was tested with grains of cooked rice which floated or descended according to the degree of salinity. Finally, the brine was boiled to salt in iron pans, or pans made out of woven bamboo strips and coated with a layer of clamshell lime. This became the basic method of sea salt production in China. Improvements were added in later ages. For instance, besides sand, ashes were used which were spread out on specially prepared fields, artificially sprinkled from time to time, and exposed to the sun, thus raising their content of salt particles. In this way, the amount of brine and its salinity could be increased. The sophisticated and labor-intensive process of later ages is fully described and illustrated in the *Aobo tu* of 1334 (see Fig. 1).

The production of sea salt by solar evaporation (*shai yan*) began probably in the late Song period. The term *shai yan* is, however, ambiguous. It may either denote the production of salt in successive solar evaporation basins, making use of the fact that common salt would crystallize *after* the precipitation in the condensers of the calcium salts contained in the brine and *before* the precipitation of the magnesium compounds. Or it may be connected with the traditional leaching process, in which the last step in the production process, the boiling of enriched brine, was simply replaced by solar evaporation. The latter technique may be considered a transitional step in the slow shift from the original method of boiling brine to the production of salt in successive solar evaporation basins. This transitional method had probably already begun in the late Song period. A special form developed in parts of eastern Zhejiang where from the late eighteenth century onward the enriched brine was exposed to the sun in portable wooden trays.

While Adshead (1990, 1992) thinks that successive basin solar evaporation of sea salt first appeared in Changlu (Hebei) in 1522 at the latest, and then spread to Huaibei (1550), Shandung (1570), Fujian (1575) and other places, Liu (1988) is of the opinion that it was not adopted at the sea coast before the middle or late sixteenth century. Moreover, there is clear evidence that Fujian was prior to Changlu which took over the method of successive basins from Fujian perhaps in the middle or late sixteenth century (Bai 1988; Lin 1992). From the seventeenth century onward the method of solar evaporation in successive basins gradually replaced the traditional methods of preparing enriched brine for the final crystallization either with the help of fire or solar heat. Generally speaking, either method of solar evaporation resulted in economies of fuel and manpower.

The use of solar evaporation basin methods, however, did not originate at the sea coast, but at the salt lake of Xiezhou in southern Shanxi. In the beginning of Chinese culture, this lake must have been an important and contested source of salt supply. First, salters extracted naturally and spontaneously produced salt, a process which had always been considered an auspicious and divine phenomenon. In the late fifth or early sixth century at the latest artificial solar evaporation basins emerged. For both methods of harvesting (see Fig. 2), the warm southern wind of the summer months was a decisive factor in bringing about crystallization. Salt production in basins was conceived basically as a kind of agricultural process which is suggested by the use of terms like “fields,” “parterres,” “ditches,” “raised paths,” and “sowing salt.” From the late thirteenth to the late sixteenth century, however, solar evaporation basins were given up, and probably only naturally and spontaneously produced salt was extracted. Political reasons were partly responsible

Salt in China. Fig. 1 Sea salt production from the *Aobo tu* of 1334, with the title “Carrying the ashes and pouring them into the leaching basin.”

Salt in China. Fig. 2 The two methods of harvesting salt at the salt lake of Xiezhou, as shown in the *Zhenghe* pharmacopoeia of 1249.

for this, because the method of solar evaporation basins was closely associated with the saline's corvée [a form of unpaid labor required by a lord] system. Solar evaporation basins were reintroduced in the late sixteenth century. A perennial problem was the protection of the salt lake's brine reservoir from intruding fresh water floods caused by inundating rivers. Dikes and spillover areas were constructed for this purpose. One of these inundations silted up the lake's brine reservoir in 1757, so that thereafter wells and pits were constructed for getting brine.

Whether single basin or successive basin solar evaporation was carried out at Xiezhou is debatable. Successive basin solar evaporation was explicitly described for the first time in the early eighteenth century. Educated guesses about the actual date of invention or adoption of successive basin solar evaporation at Lake Xie, however, vary greatly. It is said to have been either the fifth or sixth century (Adshead 1992), the eleventh century (Chai 1993) or the late sixteenth century (Vogel et al., forthcoming).

The production of well salt in Sichuan province can be divided roughly into two periods. From the third century BCE to the eleventh century AD shaft wells were dug for exploiting the underground brine deposits. Recent research has shown that deep drilling was invented in the 1040s, thus inaugurating the era of deep drilled wells from the middle of the eleventh century up to the twentieth century. Salt produced by privately run deep drilled wells was cheaper and of better quality than that offered by the state managed shaft wells. The new type of well was drilled with a heavy iron bit which was fastened to a cable made out of bamboo strips notched together. The cable was attached to the drilling frame's lever beam. By jumping up and down the lever beam the drill was lifted and dropped, thus crushing the rock down in the well and creating a hole with a diameter of only about 13 cm. The upper part of the finished well was tubed with large bamboo stalks. From the late sixteenth century onward it was also provided with a foundation of stone rings, and large tubes made out of wood were used. Slurry and brine were lifted with a bamboo tube which was equipped with a leather valve at its lower end. When entering the brine, the valve opened inward, and it closed under the pressure of the brine when the tube was lifted.

Salt in China. Fig. 3 A Sichuan salt well, as depicted in the Sichuan salt gazetteer of 1882.

A great number of utensils were invented to remove obstructions that occurred during the process of drilling and brine hoisting. Deep drilling, hoisting, and repair operations developed in the course of time. This development was characterized by the use of heavier drill bits, more solid drilling frames, higher hoisting rigs, and larger hoisting tubes and hoisting drums, driven by up to four buffaloes. While in the mid-eleventh century a depth of about 200 m may have been sometimes reached, wells of the mid-eighteenth century may have been more than 500 m deep. And in 1835, the Xinghai well of Furong (*Ziliu jing*) measured more than 1,000 m. The nineteenth-century Furong wells (see Fig. 3) were much more successful than their predecessors in the tapping of subterranean brine and natural gas deposits.

Earth salt was produced in northern Shanxi and eastern Hebei in a way similar to producing sea salt, that is by leaching earth containing salt particles and by boiling down the resulting brine. The exploitation of rock salt was reported from Gansu and Shaanxi, where a kind of red-colored salt was collected in rocky caves.

Salt in India

S. D. Gomkale

As India is one of the oldest civilizations, it is no wonder that salt was produced in ancient India and that one finds its mention in ancient scriptures. The salt industry flourished as a cottage industry for centuries. The word for salt is *Lāvaṇa* in Sanskrit. A passage from *Arthaṣāstra*, a book dealing with the history of the Mauryan period (300 BCE), says that salt manufacture was even at that distant date supervised by a state official named Lavanadhyaksa and the business was carried out under a system of license granted on the payment of fixed fees or part of the output. This tradition, handed down from Hindu kings of old, is even now followed with variations by the Government of India through its Salt Department. The history of many countries shows connections with salt; in India salt was used by Mahatma Gandhi as a tool to win independence, when he completed his famous 400-km march to the sea at Dandi on 6th April 1930. The development of the Indian salt industry will now be briefly examined in two periods, pre- and post-independence.

Salt was prepared in ancient times and until British rule from sources like seawater, subsoil and lake saline water, rock salt deposits, and water extracts of saline soils (particularly in Uttar Pradesh) mainly by solar evaporation. If required, artificial evaporation was resorted to. The salt was produced in the coastal regions of Bengal, Bombay, Madras and the Rann of Kutch and in the inland regions of Rajasthan, Uttar Pradesh, and Central India from saline brines of lakes and as rock salt in Punjab. The salt industry provided a source of revenue to the rulers in the respective regions, and it received protection and encouragement from them. However, the industry faced a sort of setback and discouragement from the British rulers who not only raised the taxes and levies as early as 1768 but also later started importing salt around 1835–1836 from European countries, Aden, and other places. The salt industry in Bengal province first felt the impact of the British policy which then affected the salt industry not only in other parts of their empire but also in Goa, which was under Portugese rule. The quantity of salt imported, mainly in Bengal, in the pre-independence period ranged between 0.4 and 0.6 million tons annually.

However, the British rulers reconsidered their drastic policies around 1930–1931, which helped to revive the Indian salt industry, and salt production picked up. Changes and improvements in salt production methods, particularly from sea water, based on scientific principles were brought about by an Indian chemical engineer, Kapilram Vakil. Before establishing India's first large scale marine salt farm at Mithapur in 1927 with the support of the Maharaja of Baroda, he had earlier (1919–1920) studied in detail the status of the salt industry in the eastern states of Bengal and Orissa. Thus production of salt in large salt works established on the basis of scientific knowledge began in India before independence.

After Independence, the majority of rock salt producing areas went to Pakistan. Salt is now mainly produced from sea water, subsoil brines, and inland lake brines. India exports salt; the imports are around 8,000–15,000 tons per year in recent years and it is mostly as rock salt from Pakistan.

Efforts have to be made to improve the quality of salt produced from both sea water and subsoil brines in the field itself, and this is one of the challenges faced by the Indian salt industry. The industry is highly labor intensive and thus has a low output. It is necessary to upgrade the technologies, adopt mechanization, and improve transportation, loading, and port facilities. This is another challenge to be tackled by the Indian salt industry, an ancient industry that must adapt to changing times.

Salt Production in Mesoamerica

Eduardo Williams

Common salt, or sodium chloride, has always been a strategic resource of primary importance. In pre-Hispanic Mesoamerica salt was used mainly for human consumption, as the native diet (consisting mainly of plants such as maize, beans, chili peppers, and squash) had little chloride and sodium (Williams 2003). Chloride is essential for digestion and respiration, and without sodium our organism would be unable to transport nutrients or oxygen or transmit nerve impulses. Throughout the world, once human beings began cultivating crops, they began looking for salt to add to their diet (Kurlansky 2002: 6–9).

In the preindustrial world, sodium chloride had several important uses apart from its role in the diet, particularly as preservative of animal flesh, as a mordant for fixing textile dyes, as a medium of exchange, and as a principal component in the preparation of soaps and cleansing agents (Parsons 1994: 280).

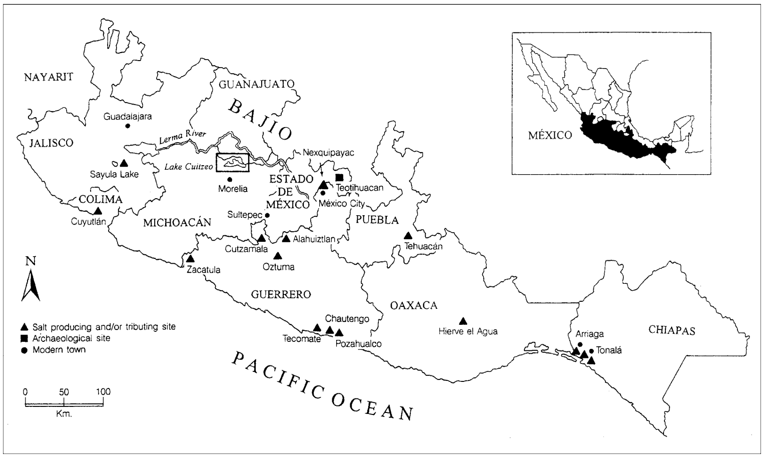
An ancient technology where salt was very important was textile dyeing. There may have been a direct functional link between saltmakers and cloth dyers in Mesoamerica; saline solutions have been commonly used as mordants by traditional cloth dyers in several parts of the world to fix dyed colors in textiles (Parsons 2001: 241). In fact, salt's important role in the Mesoamerican economy can be indirectly gauged by the huge number of dyed textiles that circulated through commerce and tribute. Among the Aztecs, for example, cotton cloth had many uses. Cloth was used for clothing, bedding, bags, awnings, decorative hangings, battle armor, adornment for statues of the gods, and shrouds for the dead (Smith 1998: 91). Cotton textiles served as items of exchange, as well as currency in the markets; they were exchanged as gifts among the nobility, and formed the dominant item of tribute payment at all levels (Smith 1998: 91).

Imperial tribute received by the Aztec state every year included 128,000 mantles or capes, 19,200 garments, and 665 warrior costumes. Most of these items were woven with dyed cotton thread, and the amount of salt used in the dyeing process must have been very high indeed. To this we should add the 4,000 "salt loaves" paid to the Aztecs by several tributary provinces every year (Smith 1998: Table 7.2).

Throughout Mesoamerica, salt was one of the most important items of trade and tribute. Access to major natural sources and control of long-distance salt trade was a fundamental factor in the formation of states. Among the Maya, for instance, many ancient trade routes had one or two key resources, whose exchange was the stimulus for the origin and growth of commerce. One of these resources was salt and to a lesser degree cotton, obsidian, and jade (Andrews 1983: 134).

The Tarascans of west Mexico expanded their empire from their homeland in central Michoacan (Fig. 1) toward the Lake Cuitzeo basin in the east, the Sayula Lake in the west, and the Pacific coast of Michoacán and Colima to secure many strategic resources such as salt, obsidian, copper, gold, and silver, which were lacking in the empire's heartland (Pollard 1993; Williams 2003).

Mesoamerican salt sources can be broken down into three types: saline inland lakes, highland springs, and coastal estuaries (Kepecs 2003: 126). The methods used to extract salt in pre-Hispanic times consisted of boiling brine, leaching brine through salt-laden earths, and solar evaporation. These processes often were combined (Kepecs 2003: 127). Salt itself is usually not preserved in the archaeological record. The archaeological



Salt Production in Mesoamerica. Fig. 1 Map showing salt-producing sites in central-western Mesoamerica (© Eduardo Williams).

markers or material remains linked to saltmaking with native techniques consist of (1) pottery vessels (which were used and discarded in great quantities at salt production sites); (2) shallow solar evaporation ponds made of sand and lime; (3) canals for taking the water from the springs to the production sites; and (4) mounds of leached, discarded earth (Williams 2003).

Salt production and trade played a fundamental role in Mesoamerican culture from the earliest times. By 1200 BCE, Olmec merchants from the Gulf of Mexico penetrated highland and Pacific coastal Guatemala, Oaxaca, and central Mexico in their quest for salt and various other strategic resources such as obsidian, jade, serpentine, iron ores, basalt, cacao, marine shells, animal pelts, and exotic bird feathers. Olmec traders actively engaged in salt extraction and trade along the Gulf coast in the Formative (Diehl 2004: 128). During this same period in Oaxaca saltmaking was restricted to villages near saline springs. As early as 1300 BCE some salt-making areas were visited briefly, but no houses were built. During the Middle Formative (ca. 900–300 BCE), the production of salt by boiling brackish spring water in pottery jars was a common activity. Saltmaking was probably one of Formative Mesoamerica's most widespread regional specializations (Flannery and Winter 1976: 39–40).

What follows is a brief discussion of pre-Hispanic saltmaking in several areas of Mesoamerica. This discussion is based on archaeological, ethnohistorical, and ethnographic data (for a detailed discussion, see Williams 2003).

The Basin of Mexico

Parsons (1994, 2001) studied saltmaking at San Cristóbal Nexquipayac, a small village on the northeastern shore of Lake Texcoco, central Mexico. According to Parsons, saltmaking at Nexquipayac involves six basic sequential steps:

1. collecting the soils whose salts are to be leached
2. mixing the soils in the correct manner
3. filtering the water through the soil mixture in order to leach out the salts and concentrate them in a brine solution. A conical pit excavated in the workshop to a depth of 40–50 cm and 90–100 cm in diameter was used for this
4. boiling the brine to obtain crystalline salt
5. drying the crystalline salt and
6. selling the dried salt (Parsons 1994: 263, 269, 2001).

The Sayula Basin, Jalisco

The initial process used to extract salts in the Sayula basin must have been the leaching of saline sediments. The leaching process consisted of "washing" and filtering saline earth with fresh water; the result was a salt-laden liquid or brine. This stage of production required various types of installations. The producers built a filter sustained by a wooden fork, composed of a rectangular base of sticks on which sedge, fodder, and sand were placed. The resulting brine was collected in a circular pan (Valdez et al. 1996: 179).

Following the extraction process, it was necessary to reduce the collected brine through natural or induced evaporation to achieve the final product – salt. Although salt production carried out until recently in the Sayula basin relied on solar evaporation, the historical texts always refer to fire reduction in ceramic vessels (Valdez et al. 1996: 179; Liot 2000).

Cuyutlán, Colima

In pre-Hispanic times, the most common salt-making technique in coastal Colima was by boiling the brine.

S

When seawater or water from saline wells was not used, it was necessary first to obtain water with a high saline content, or brine, through several processes of leaching and washing of saline soils; later the resulting brine was boiled to evaporate the water. Both processes, filtering and evaporation, were carried out using clay pots. This method was effective, but not too practical when attempting to produce large volumes of salt. As demand increased, new technologies were developed. Toward the end of the sixteenth century filters were first introduced in Colima. These consisted of wooden platforms with woven branches or sticks supporting several layers of filtering substances. A similar device is still used in Cuyutlán, Colima (Reyes 1995: 152, 154).

Lake Cuitzeo basin, Michoacán

There are several thermal springs in the eastern end of Lake Cuitzeo, whose water, which has a high mineral content, is used for the production of salt. Each salt-producing unit (known as *finca*) consists of two or more *estiladeras* (Fig. 2), wooden structures that are used as filters to separate the salt from the earth by leaching. In every *finca* there are several *canoas* (wooden troughs, manufactured like dugout canoes; Fig. 3), where the brine that has been filtered in the *estiladera* is evaporated by the sun. Each *finca* has an area of some 50 m^2 where salt-bearing soils are extracted and mixed. There is also a network of canals that bring water from the springs to the *fincas*, with a depth of ca. 50–80 cm, and several meters in length (Williams 1999).

The tools used by the saltmakers are quite simple: shovels, hoes, and picks to excavate the soil, wheelbarrows to take it to the *estiladera*, buckets to take the water to the *canoas*. The tools used in the past, however, were quite different: a type of sack made of jute fiber was used to carry the earth, and clay vessels were used to carry the water within the *finca*.

Salt Production in Mesoamerica. Fig. 2 This device, known as *estiladera,* is used for filtering the water from the springs through salty soil to obtain brine by leaching (© Eduardo Williams).

The salt-making process can be divided into four stages: (1) soils are extracted, mixed, and prepared; (2) brine is obtained by leaching the earth in the *estiladera*; (3) brine is evaporated by the sun in the *canoas* and salt is collected; (4) the finished product is packed and sold.

Although the tools and permanent fixtures used today for making salt in the study area are not the same that were employed during the early colonial era, much less in pre-Hispanic times, the basic process for saltmaking still used in this area is in many ways similar to the one described in the sixteenth century *Relaciones Geográficas*. Both ancient and modern saltmaking requires extracting the soil, mixing two or more types of earth, adding water, leaching and evaporation (Williams 1999). Saltmaking in coastal Michoacán is similar to what has been described earlier (Williams 2002; see Figs. 4–6).

Coastal Guerrero

The process known as *tapeite* in coastal Guerrero, still used in sites such as Tecomate, Chautengo, and Pozahualco, consists of leaching salt from soils where saltwater marshes dry up during the dry season. The

Salt Production in Mesoamerica. Fig. 3 The *canoas* are shallow troughs made with dugout pine trunks, used in the solar evaporation of brine. Note the crystallized salt on the right, the liquid brine on the left (© Eduardo Williams).

Salt Production in Mesoamerica. Fig. 4 Filtering device known as *tapeixtle*, used on the coast of Michoacán for leaching estuary water to produce brine (© Eduardo Williams).

Salt Production in Mesoamerica. Fig. 5 Shallow pools made of sand and lime, known as *eras.* They are used in the solar evaporation of the brine. The *tapeixtle* is in the background, covered by palm fronds (© Eduardo Williams).

Salt Production in Mesoamerica. Fig. 6 Harvesting the crystallized salt from the *era,* coastal Michoacan (© Eduardo Williams).

saltmakers carefully break up the thin upper crust of earth and carry it to their saltworks, where they deposit it in a large filter known as *tapeite,* which is constructed on a raised base of wooden or cane slats covered with palm or tough grass. Adobe sides create a rectangular basin lined with coarse sand and a second layer of fine, sifted sand. Brackish groundwater is drawn from a shallow well dug next to the *tapeite* and poured over the saline earth. After seeping through the filter, the water is channeled into a plaster-lined holding tank. The concentrated brine is poured into the solar drying pans, where it evaporates to leave white granular salt crystals (Good 1995: 2).

The Maya Area

Salt was a regional necessity everywhere in Mesoamerica, yet the white salt of Yucatán was also a bulk luxury, traded far beyond the regional level. Flowing from international trading centers to regional markets in foreign territories, it augmented regional supplies as a product of superior quality (Kepecs 2003: 129). The pre-Hispanic Maya obtained salt from several sources, the most abundant ones being the coastal saltworks. The primary source of salt in pre-Hispanic Mesoamerica was coastal Yucatán, where salt was obtained through solar evaporation. Archaeological evidence shows that Yucatecan saltworks were active from the Late Formative (ca. 300 BCE–AD 300). In colonial times salt production in Yucatán was approximately 20,000 tons per year, enough to satiate the needs of several thousand people, or the whole of the Maya Lowlands through history (Andrews 1997: 40). Salt was scarce in the southern Maya lowlands of Guatemala and Belize. It was imported in bulk from the north coast of Yucatán, although recent fieldwork has documented closer sources of salt than those of the north coast (McKillop 2002).

A method for making salt which is still found in a few sites near the Chiapas coast is the one known as *tapesco*. It involves leaching marsh soil with estuary water which is then evaporated in small solar pans. The *tapesco* salt-making operation takes place mainly during the dry season (from January to May or June). The soil to be leached is raked up and placed on raised wooden structures known as *tapescos*, the bottom part of which consists of a three-layered filter made of thin sticks covered with grass reeds, which in turn are covered by a thin layer of sand. Salt water is drawn from small shallow wells and poured over the soil in the *tapesco*, thus leaching the soil. After passing through the filter the water collects in a mud-lined pan beneath the *tapesco.* The brine is then placed in a series of small shallow solar evaporation pans, where evaporation takes place anywhere from 4 to 6 days, depending on available sunlight (Andrews 1983: 62–3).

Veracruz

During the Early Formative (ca. 1200–900 BCE) in El Salado, Veracruz, solar evaporation in pottery trays was

S

the primary method of salt production. This method was supplemented by some saltmaking involving boiling brine. During the late Classic (ca. AD 600–900) brine reduction involved a two-step process whereby salt content in the brine was first increased by boiling in pots; this brine was later reduced to loaves by boiling over fire in shallow ceramic basins (Santley 2004).

Samūˤīl ibn ˤAbbās (al-Maghribī)

E. Ruth Harvey

Samūˤīl (or Samau'al) ibn ˤAbbās, also called Abū Nasr Samūˤīl ibn Yahyā ibn ˤAbbās, was a Jew whose father's family origins were in Fez in Morocco. Samūˤīl is often called al-Maghribī, "the westerner," but he spent his life in Iraq, Syria, Kurdistan, and Azerbaijan, and died in Maragha in about 1175 (570 AH). He was famous as a mathematician and physician, and left a number of works on both subjects. In 1163 he underwent a conversion to Islam and subsequently wrote a polemical treatise against the Jews; in an autobiographical appendage to this work he provided a very interesting account of his careful upbringing, extensive education, and the dreams which prompted his conversion. Samūˤīl practiced medicine at Baghdad (where he wrote some of his works) and Maragha (where he served a number of local princes and important personages).

The early Arab biographers ascribe many works to Samūˤīl, but not all of these are extant. Steinschneider and Brockelmann list 17 treatises, some of which are works not mentioned by the biographers but which are ascribed to Samūˤīl in manuscript; some attributions are doubtful.

The only extant medical treatise attributed to Samūˤīl is an elaborate work on sex and gynecology entitled *Nuzhat al ashāh fī muˀāsharat al-ahbāb* (The Entertainment of Friends and the Dealings of Lovers), often referred to in catalogs as *De Coitu*. Works of this kind are not infrequent in the Arabian medical tradition; Samūˤīl's treatise was written for the ruler of Hisn Kayfa, Muḥammad ibn Qara Arslan, and was famous enough to have survived in a number of widely scattered manuscripts; it has never been printed. An account of the work may be found in Leclerc. It contains two books. The first deals with sex, both homosexual and heterosexual, sexual desire, diet, and hygiene; it contains an account of the physical and moral characteristics of women from different countries. The second book deals with such topics as impotence, aphrodisiacs, conception, sterility, and female ailments. There are manuscripts in Paris, Berlin, the Escorial, I eipzig, and Istanbul. The Berlin catalog lists (in Arabic) all the chapter headings of the *Nuzhat*.

Some of the treatises on mathematical subjects ascribed to Samūˤīl by the early biographers are no longer extant, but copies of his *al-Tabsira fīˀ ilm al-ḥisāb* (Introduction to Arithmetic) survive. Both Leiden and Oxford have manuscript copies of a work entitled *Fī kashfˀawar al munajjimin* (On the Errors of Astronomers), in which Samūˤīl defends the idea of scientific progress, citing an arithmetical work of his own, *Al-bahir*, as an example of an advance on ancient mathematics. Brockelmann says that a manuscript of a work entitled *Al-bahir fīʾilm al-ḥisāb* attributed to Samūʿīl exists in Istanbul; perhaps this is the one referred to in *Errors of the Astronomers*. Another work on arithmetic, *Al-mujiz al-mardawi fī al-ḥisāb*, also exists in a single manuscript in Istanbul.

The Arabic text of Samūʿīl's polemic against Judaism, *Ifhām al-Yahūd* (Silencing the Jews), together with his autobiogrphical addition, has been edited and translated into English by Perlmann, who provides in his introduction the best account of Samūʿīl and his works. Perlmann points out that the work *Al-Ajwiba alfakhira raddan ʾan il-milla al-kafira* ascribed to Samūʿīl by Brockelmann derives from Samūʿīl's work but is not by him. Another polemical work against the Jews, the *Contra Judeos* of Samuel Marochitanus which was translated from Arabic into Latin in 1339, has often been ascribed to Samūʿīl ibn Abbas; it contrasts Judaism unfavorably with Christianity, not Islam, and is clearly the work of another author.

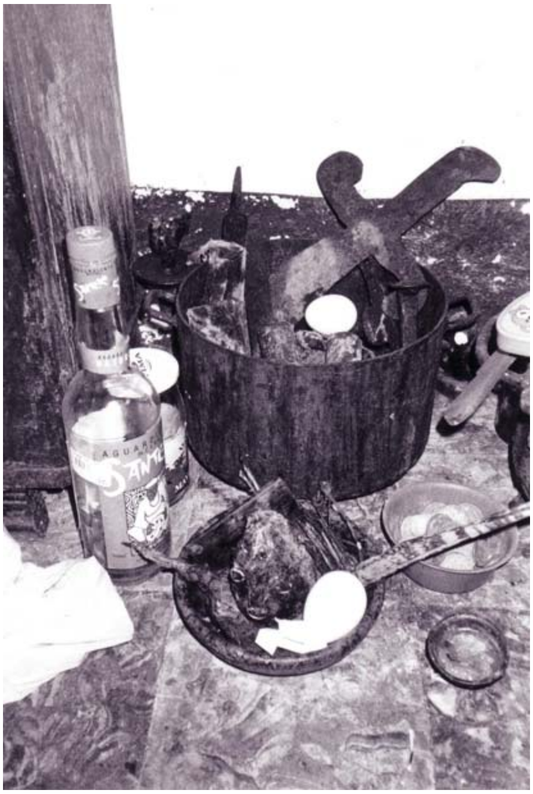
Santería

Johan Wedel

Santería has its roots in the slave trade when a large number of slaves were taken from Africa to Cuba. Many were from the Yoruba people, who now live in southwestern Nigeria. The Yoruba, well known for their artistic traditions, urban lifestyle, and a well-developed division of labor, brought with them a belief in their divinities, *orishas*. In Cuba, the orishas merged with the saints of the Roman Catholic Church, which, in turn, led to the creation of santería, "the way of the saints" (Thompson 1983; Brandon 1993; Lawal 1996; Matibag 1996; Thomas 1997; Wedel 2004).

Only a handful of the more widely recognized orishas survived the Middle Passage. As the divinities acquired their Catholic equivalents, they became to be known as *Santos* –saints. Oshún, for example, the orisha of freshwater, acquired a Catholic equivalent in the form of Virgen de la Caridad del Cobre. Shangó, the manly warrior who represents thunder, lightning, and fire, found a counterpart in the Catholic saint Santa Barbara. Apart from these two popular divinities, some of the most prominent orishas/santos include: Eleggua, messenger and guardian of crossroads; Ogún, lord of war and iron; Obatalá, father and lord of peace and purity; Yemayá, mother and ruler of the seven seas; and Oyá, female warrior, guardian of the cemetery, who is associated with strong winds.

The actions and adventures of the divinities appear in the many santería myths (*patakies*), which, in turn, are related to various kinds of divination systems (Martínez Furé 1979; Valdés Garriz 1997; Pérez Medina 1998). In one myth, the supreme god Olodumare-Olofi first



Santería. Fig. 1 Eleggua, guardian of crossroads, is represented by a "head" of cement with eyes and mouth made of cowrie shells while Ogún, lord of iron, is represented by a cauldron with iron tools. (Photo by Johan Wedel).

Santería. Fig. 2 When sacrifice is performed, ashé, divine force, is released. The santería objects are then covered with feathers from sacrificed fowls in order to "cool" the "hot" blood. (Photo by Johan Wedel).

Santería. Fig. 3 Sacrifice of a goat during an Afro-Cuban quasi-religious ceremony in the street Callejon de Hamell, Central Havana. (Photo by Johan Wedel).

created the universe and then distributed his *ashé*, life force, to the orishas/santos. As humans develop their relationship with the divinities through rituals and sacrifices, they benefit from the ashé that came from the high god Olodumare.

In Cuba today, as well as in other Latin American countries and in the United States, people frequently turn to santería for all kinds of problems. Illness, however, is a particularly common reason for consulting a priest (see also Sandoval 1979, Pasquali 1994; Sandoval 1995; Jones et al. 2001; Wedel 2004). Using divination, the priest will relate the client's problems to the santería mythology and a number of proverbs. The priest (*santero* or *santera*) uses cowrie shells when divining with the dilogún divination system, while the high priest (*babalao*) uses a chain made of coconut shell or tortoise shell when divining with the Ifá system (Bascom 1952, 1980; Mason 1993; Matibag 1997; Valdés Garriz 1997; Wedel 2004). It takes many years of training to become a skilled diviner. A babalao is considered "mature" after working and divining for 16 years (Wedel 2004: 92).

Once the priest has identified the client's condition through divination, spiritual cleansing, offerings, sacrifices, and minor rituals are commonly suggested. Santería priests usually have extensive knowledge of a multitude of herbs and plants, and some of these may also be recommended (Marks 1987; Brandon 1991; Cabrera 1993; Wedel 2004). In the case of an illness, clients are often told to pay a visit to a physician. From the perspective of santería, however, it is not sufficient to try just to cure the affliction; the underlying reasons for the problem must also be identified. The priest will also explain why a person has been struck by ill health and may attribute the problem to a lack of ashé, to afflicting spirits, to disturbed social relations and sorcery, or to the client's lifestyle (Wedel 2004).

In santería, it is recognized that both physical and mental illnesses are frequently related to disturbed social relations and these are expressed in terms of sorcery (cf. Stoller and Olkes 1987; cf. Geschiere 1997). An envious neighbor or family member, for example, might be said to have performed sorcery on the client (although the priest seldom reveals the name of the evildoer). The client may then be advised to break up a relationship, move to another house, change jobs, or avoid certain persons in order to become well. An affliction may also be caused by a spirit or divinity who wants the person to change his way of life and become a practicing priest (Wedel 2004).

When divination discloses a serious illness and it is established that medical treatment will not be adequate, initiation may be recommended. This was expressed by a Cuban babalao who also works as a physician, who said: "We do this when modern medicine can do no more, when you reach the limits of science" (Wedel 2004: 121). A similar opinion was articulated by

Santería. Fig. 4 Osain is the lord of herbs and plants. He is represented by a calabash with powerful, secret herbs, which is hung from the ceiling. If a menstruating woman comes into contact with the calabash, it will lose its power. (Photo by Johan Wedel).

Santería. Fig. 5 Afro-Cuban objects arranged by the artist Salvador Gonzalez at Callejon de Hamell, Central Havana. (Photo by Johan Wedel).

another babalao: "We religious people say that sometimes a person has to attend *el brujo blanco* [the "white sorcerer"] who is the [biomedical] doctor. Sometimes he has to attend *el brujo Yoruba* [the "Yoruba sorcerer"], who is the santero or babalao" (121).

Initiation into santería, which also may take place for reasons other than illness, is a "rebirth", a gradual process designed to change a person's experience and transform the whole lifeworld of the devotee (cf. Turner 1969, 1986; cf. Willis 1999; Wedel 2004). The "newborn" builds a beautiful altar for his/her personal divinities (Flores-Peña and Evanchuk 1994; Brown 1996, 2003), and is kept in isolation for seven days, while a godmother or godfather feeds and cares for them. The initiate is also given *omiero*, a mixture of secret herbs said to contain large quantities of ashé (Brandon 1991).

During the initiation, which is largely secret and closed to the noninitiated, a divinity will be "placed in the head" of the initiate. This orisha/santo, who is said to be the "father" or "mother" of the initiate, will then offer its protection for the rest of the initiate's life. The initiation also involves a complex divination session, including ritual cleansing, animal sacrifices, offerings to the dead ancestors, and dancing to the sacred santería drums. During the drum ceremony, the divinity may "descend" into the body of the novice, who may experience possession trance (cf. Goodman 1988, 1990; cf. Turner 1992; Murphy 1993, 1994; cf. Willis 1999; Wedel 2004).

For one year after the initiation, everyone will address the initiate as iyabó. He/she is close to the divine world of the santos/orishas and must obey certain rules, such as wearing white clothes and not visiting cemeteries. The initiate will also acquire new social relations and become a "sister" or "brother" to others who have been initiated by the same godmother or godfather. Through initiation, an intimate relationship between humans and the world of the orishas/santos is created, and the initiate develops a new understanding of what has caused the affliction and how to avoid problems in the future.

Śatānanda

K. V. Sarma

Śatānanda, son of Śaṅkara and author of the popular astronomical manual *Bhāsvatī*, was a resident of Puruṣottamapurī, the modern city of Puri, in Orissa. The *Bhāsvatī* was written in the Śaka year 1021, AD 1099. The epochal constants are also given for Puri, instead of for Ujjain as is normal in astronomical manuals. In 82 pithy verses distributed in eight chapters, the *Bhāsvatī* sets out the several computations required for preparing the daily almanac. There is a traditional statement that eclipses computed according to the *Bhāsvatī* would be exact. Towards the beginning of the work, the author avers that he was composing the work on the basis of the (Old) *Sūryasiddhānta* condensed by Varāhamihira in his *Pañcasiddhāntikā*. There is also a pun in the word *Bhāsvatī*, based on the above, since *bhāsvān* means *Sūrya* (Sun). There is a pun on the word *Śatānanda* as well; the literal meaning of the word is "one who revels in hundreds," and in this work the author used the centismal system for commencing the epochal position and specified several of the multipliers and divisors in computation in terms of hundreds. There are several recensions of the work and some manuscripts add an *Uttara-Bhāsvatī*.

Śatānanda introduced certain other innovations in his work. For the computation of Mean planets, he took not the *Ahar-gaṇa* (number of elapsed days), but the *Varṣa-gaṇa* (number of elapsed years). As the commencement of the year, he did not take the Mean *Meṣādi* (Aries ingress), but the True *Meṣādi*, which is advantageous in certain aspects. Another specialty of Śatānanda's is that, as mentioned above, he adopted the centismal system for commencing epochal positions and for specifying multipliers and divisors. The positions of the sun and the moon are stated in terms of *nakṣatras* (constellations) and not in *rāśis*, which is normally the case in texts of this type. Then again, Śatānanda took AD 528 as the zero precession year and the rate of precession as 1 min per annum.

The popularity of Śatānanda's work in North and Northeast India is attested to by the presence of a large number of manuscripts of *Bhāsvatī* in these regions and by the fact that most of his commentators hail from there. Some of the principal commentators are Aniruddha (*Śiśubodhinī*, 1495), Mādhava (*Mādhavī*, 1525), Acyuta (*Ratnamālā*, ca. 1530), Kuvera Miśra (*Ṭīkā*, 1685), Rāmakṛṣṇa (*Tattvaprakāśikā*, 1739), and Yogindra (1742).

Science as a Western Phenomenon

Roshdi Rashed

Philosophers, historians, and sociologists of science all accept as a basic postulate that science is essentially Western. This postulate is still conditioning contemporary scientific ideologies. This article analyzes the characteristics, history, and validity of this doctrine by means of a confrontation with one of the non-Western scientific contributions: science written in Arabic.

Classical science is essentially European, and its origins are directly traceable to Greek philosophy and science; this tenet has survived intact through numerous conflicts of interpretation over the last two centuries. Almost without exception, the philosophers accepted it. Kant, as well as Comte, the neo-Kantians as well as the neopositivists, Hegel as well as Husserl, the Hegelians and the phenomenologists as well as the Marxists, all acknowledge this postulate as the basis of their interpretations of Classical Modernity. Even until our time, the names of Bacon, Descartes, and Galileo (sometimes omitting the first, and sometimes adding a number of others) are cited as so many markers on the road to a revolutionary return to Greek science and philosophy. This return was understood by all to be both the search for a model and the rediscovery of an ideal. One might impute this unanimity to the philosophers' zeal to pass beyond the immediate data of history, to their wish for radical insight, or to their effort to seize what Husserl describes as "the original phenomenon (*Urphänomen*) which characterizes Europe from the spiritual point of view." One would expect that the position taken by those who have stuck more closely with the facts of the history of science would be quite different, but such is not the case. This same postulate is adopted by the historians of science as a point of departure for their work, and especially for their interpretations. Whether they interpret the advent of classical science as the product of a break with the Middle Ages, whether they defend the thesis of continuity without breaking or cutting, or whether they adopt an eclectic position, the majority of historians agree in accepting this postulate more or less implicitly.

Today, in spite of the works of many scholars on the history of Arabic and Chinese science, in spite of the wide representation of non-Western scientists in *Dictionary of Scientific Biography*, the works of the historians rest on an identical fundamental concept: in its modernity as well as in its historical context, classical science is a work of European man alone. Furthermore, it is essentially the means by which this branch of humanity is defined. Occasionally the existence of a certain practical science in other cultures might be acknowledged; nevertheless, it rests outside history, or is integrated into it only to the extent of its contributions to the essentially European sciences. These are only technical supplements which do not modify the intellectual configuration or the spirit of the latter in any way. The image given of Arabic science constitutes an excellent illustration of this approach. Essentially it consists of a conservatory of the Greek patrimony, transmitted intact or enriched by technical innovation to the legitimate heirs of ancient science. In all cases, scientific activity outside Europe is badly integrated into the history of the sciences; rather, it is the object of an ethnography of science whose translation into university study is nothing more than Orientalism.

The effects of this doctrine are not limited to the domain of science, its history, and its philosophy. It is at the center of the debate between modernism and tradition. As was the case in eighteenth-century Europe, we find, in certain Mediterranean and Asian countries of today, that science (which is qualified as European) is identified with modernism. Our purpose here is not to redress wrongs, nor to oppose to that science qualified as European an alleged Eastern science. It is simply a matter of understanding the significance of the European determination of the concept of classical science, grasping the reasons for it and measuring its importance.

We shall begin by sketching the history of this view of European science and then estimate its effects. We shall limit ourselves to posing the problem and advancing several hypotheses, and we also add these two restrictions: the only non-European science considered is one which was produced by various cultures, by scholars of different beliefs and religions, all of whom wrote their science principally, if not exclusively, in Arabic. As for the tenets of the history of the sciences, we shall most often cite those of the French historians.

The concept of a European science is already present in the works of the historians and philosophers of the eighteenth century. In the debate of the Ancients and the Moderns, scholars and philosophers referred to science to define modernity where one combines reason and experience. Historical induction intended to give its concrete determinations to this dogmatic debate, so as to render the superiority of the Moderns indisputable. But the West was already being identified as Europe, and "Oriental wisdom" was already counterpoised against the natural philosophy of the post-Newtonian West, such as we find in Montesquieu's *Persian Letters* (1721).

Classical science is European and Western only to the degree that it represents a stage in the continuous and regular development of humanity. The *Discours Préliminaire* of Abbé Bossut in Diderot's *Encyclopédie Méthodique* offers an illustration of this concept. Dividing the history of the progress of the exact sciences into three periods, this tableau allows conjecture, alleged facts, and facts to intermingle. Its initial postulate is that "…all of the eminent peoples of the ancient world liked and cultivated mathematics. The most distinguished among them are the Chaldeans, the Egyptians, the Chinese, the Indians, the Greeks, the Romans, the Arabs, etc… in modern times, the western nations of Europe." Classical science is European and Western because, writes Abbé Bossut, "…the progress made by the western nations of Europe in the sciences from the sixteenth century to our times utterly effaces those of other peoples."

The concept of Western science changed in nature and extent at the turn of the nineteenth century. With what Edgar Quinet called the "Oriental Renaissance", the conceptualization was completed in its anthropological dimension in the last century. This Oriental Renaissance ended by discrediting science in the East.

If it is true that the eighteenth-century concept still survived here and there, from the first years of the nineteenth century the materials and ideas of Oriental studies contributed the most to the makeup of the historical themes of the different philosophies. In Germany as well as in France, the philosophers adopted Oriental studies for diverse reasons in accordance with an identical representation: the East and the West do not oppose each other as geographical, but as historical positivities; this opposition is not limited to a period of history, but goes back to the essence of each term. In this regard, *Lessons on the History of Philosophy* and other works of Hegel can be invoked. Also at this time, as is shown by the French Restoration philosophers, the themes of the "call of the East" and the "return to the Orient" appear, which translate as a reaction against science, and more generally, against Rationalism. But it is with the advent and growth of the German philological school that the notion of science as a Western phenomenon was regarded as having been endowed with the scientific, and no longer purely philosophical, support which had been lacking until then.

This influence also extended into mythological and religious studies. For example, Friedrich von Schlegel distinguishes two classes of language: the flexional Indo-European languages, and others. The former are "noble," the latter less perfect. Sanskrit, and consequently, German, considered the closest to it, is "…a systematic language and perfect from its conception"; it is "…the language of a people not composed of brutes, but of clear intelligence." There is nothing surprising in this; with the advent of the German school we are already in the realm of classifying mentalities. From now on everything is in place for effecting the passage from the history of languages to history through languages.

The comparative study of religions and myths is developed around the middle of the century by A. Kuhn and Max Müller in particular. The classification of mentalities is perfected. It is from the basis of these tenets and dating from this period that one of the most important efforts to establish the notion of science as Western and European in an allegedly scientific manner is elaborated. This project achieves its full extent in France in the work of Ernest Renan.

For Renan, civilization is divided between Aryans and Semites; the historian only has to evaluate their contributions in a differential and comparative manner. The notion of race would constitute the foundation of historiography. By race, one meant the whole of the "…aptitudes and instincts which are recognizable solely through linguistics and the history of religions." In the last analysis, it is for reasons attributable to the Semitic languages rather than the Semites themselves that they did not and could not have either philosophy or science. "The Semitic race," writes Renan, "is distinguished almost exclusively by its negative traits: it has neither mythology, epic poetry, science, philosophy, fiction, plastic arts nor civil life." The Aryans, whatever their origin, define the West and Europe at one and the same time. Arabic science is, "…a reflection of Greece, combined with Persian and Indian influences."

The historians of science borrowed not only their representation of the Western essence of science from this tradition, but also some of their methods for describing and commenting on the evolution of science. Thus, they applied themselves to discovering the concepts and methods of science and to following their genesis and propagation through philological analyses of the terms and on the basis of the texts at their disposal. Like the historian of myths or of religion, the historian of the sciences must be a philologist as well. In France, the situation is such that philosophers borrow Renan's interpretation and, often, even his terminology. Even though this brand of anthropology has already been abandoned by historians, they nevertheless preserve and propagate a series of inferences engendered by it. These can be enumerated as follows:

1. Just as science in the East did not leave any consequential traces in Greek science, Arabic science has not left any traces of consequence in classical science. In both cases, the discontinuity was such that the present could no longer recognize itself in its abandoned past.
2. Science subsequent to that of the Greeks is strictly dependent upon it. According to Duhem, "…Arabic science only reproduced the teachings that it received from Greek science." In a general fashion, Tannery reminds us that the more one examines the Hindu and Arabic scholars, "…the more they appear dependent upon the Greeks…(and)…quite inferior to their predecessors in all respects."
3. Whereas Western science addresses itself to theoretical fundaments, Oriental science, even in its Arabic period, is defined essentially by its practical aims.
4. The distinctive mark of Western science is its conformity to rigorous standards; in contrast, Oriental science in general, and Arabic science in particular, lets itself be carried away by empirical rules and methods of calculation, neglecting to verify the soundness of each step on its path. The case of Diophantus illustrates this idea perfectly: as a mathematician, said Tannery, "…Diophantus is hardly Greek." But when he compares the *Arithmetics* of Diophantus to Arabic algebra, Tannery writes that the latter "…in no way rises above the level achieved by Diophantus."
5. The introduction of experimental norms which, according to historians, totally distinguishes Hellenistic science from classical science, is solely the achievement of Western science.

Thus it is to Western science alone that we owe both the concept and experimentation. We are not going to oppose this ideology to another. We propose simply to confront some of these elements with the facts of the history of science, beginning with algebra and concluding with the crucial problem of the relationships between mathematics and experimentation.

Algebra

As with the other Arabic sciences, algebra had practical aims, a flair for calculation, and an absence of rigorous standards. It is precisely this that allowed Tannery to make his statement. Bourbaki took this as his authorization to exclude the Arabic period when he retraced the evolution of algebra. The historical writings of the modern mathematician Dieudonné are significant; between the Greek prehistory of algebraic geometry and Descartes, he finds only a void, which, far from being frightening, is ideologically reassuring. Some historians cite al-Khwārizmī, his definition of algebra and his solution of the quadratic equation, but it is generally to reduce Arabic algebra to its initiator. This restriction misconstrues the history of algebra, which in actuality does not show a simple extension of the work of al-Khwārizmī in the West, but an attempt at theoretical and technical overtaking of his achievements. Moreover, this overtaking is not the result of a number of individual works, but the outcome of genuine traditions. The first of these traditions had conceived the particular project of arithmetizing the algebra inherited from al-Khwārizmī and his immediate successors. The second one, in order to surmount the obstacle of the solution by radicals of third and fourth degree equations, formulated in its initial stage a geometric theory of equations, subsequently to change viewpoint and study known curves by means of their equations. In other words, this tradition engaged itself explicitly in the first research in algebraic geometry.

As we have said, the first tradition had proposed arithmetizing the inherited algebra. This theoretical program was inaugurated at the end of the tenth century by al-Karajī, and is thus summarized by one of his successors, al-Samaw'al (d. 1176): "to operate on unknowns as the arithmeticians work on known quantities."

The execution is organized into two complementary stages. The first is to apply the operations of elementary arithmetic to algebraic expressions systematically; the second is to consider algebraic expressions independently from that which they can represent so as to be able to apply them to operations which, up to that point, had been restricted to numbers. Nevertheless, a program is defined not only by its theoretical aims, but also by the technical difficulties which it must confront and resolve. One of the most important of these was the extension of abstract algebraic calculation. At this stage, the mathematicians of the eleventh and twelfth centuries obtained some results which unjustly are attributed to the mathematicians of the fifteenth and sixteenth centuries. Among these are the extension of the idea of an algebraic power to its inverse after defining the power of zero in a clear fashion, the rule of signs in all its general aspects, the formula of binomials and the tables of coefficients, the algebra of polynomials, and above all, the algorithm of division, and the approximation of whole fractions by elements of the algebra of polynomials.

In a second period, the algebraists intended to apply this same extension of algebraic calculation to irrational algebraic expressions. Al-Karajī questioned how to operate by means of multiplication, division, addition, subtraction, and extraction of roots on irrational quantities. To answer this question the mathematicians gave, for the first time, an algebraic interpretation of the theory contained in Book X of the *Elements*. This book was regarded by Pappus, as well as by Ibn al-Haytham much later, as a geometry book, because of the traditional fundamental separation between continuous and discontinuous magnitudes. With the school of al-Karajī, a better understanding of the structure of real algebraic numbers is achieved.

In addition, the works of this algebraic tradition opened the route to new research on the theory of numbers and numerical analysis. An examination of numerical analysis, for example, reveals that after renewing algebra through arithmetic, the mathematicians of the eleventh and twelfth centuries also effected a return movement to arithmetic to search for an applied extension of the new algebra. It is true that the arithmeticians who preceded the algebraists of the eleventh and twelfth centuries extracted square and cube roots, and had formulas of approximation for the same powers. But, lacking an abstract algebraic calculation, they could generalize neither their results, their methods, nor their algorithms. With the new algebra, the generalization of algebraic calculation became a constituent of numerical analysis which, until then, had only been a sum of procedures, if not prescriptions. It is in the course of this double movement which is established between algebra and arithmetic that the mathematicians of the eleventh and twelfth centuries achieved results which are still wrongly attributed to the mathematicians of the fifteenth and sixteenth centuries. This is the case with the method attributed to Viète for the resolution of numerical equations, the method ascribed to Ruffini-Horner, the general methods of approximation, in particular that which D. T. Whiteside designates by the name of al-Kāshī-Newton, and finally, the theory of decimal fractions. In addition to methods, which were to be reiterative and capable of leading in a recursive manner to approximations, the mathematicians of the eleventh and twelfth centuries also formulated new procedures of demonstration such as complete induction.

We have just seen that the concept of polynomials is among those elaborated by the algebraist arithmeticians from the end of the tenth century. This tradition of algebra as the "arithmetic of unknowns", to use the expression of the time, opened the road toward another algebraic tradition which was initiated by ʿUmar al-Khayyām (eleventh century), and renewed at the end of the twelfth century by Sharaf al-Dīn al-Ṭūsī. While the former formulated a geometric theory of equations for the first time, the latter left his mark on the beginnings of algebraic geometry.

The immediate predecessors to al-Khayyām, such as al-Bīrūnī, al-Māhānī, and Abū al-Jūd, had already been able, in contrast to the Alexandrian mathematicians and precisely because of the concept of the polynomial, to treat the problems of solids in terms of third degree equations. But al-Khayyām was the first to address these unpondered questions: can one reduce the problems of straight lines, planes, and solids to equations of a corresponding degree, on the one hand, and on the other, reorder the group of third degree equations to seek, in the absence of a solution by factoring, solutions which can be reached through means of the intersection of auxiliary curves? To answer these questions, al-Khayyām is led to formulate the geometric theory of equations of a third or lesser degree. His successor, al-Ṭūsī, did not delay in changing perspective; far from adhering to geometric figures, he thought in terms of functional relations and studied curves by means of equations. Even if al-Ṭūsī still solved equations by means of auxiliary curves, in each case the intersection of the curves is demonstrated algebraicly by means of their equations. This is important, since the systematic use of these proofs introduces into the practice instruments which were already available to the mathematical analysts of the tenth century: affine transformations, the study of the maxima of algebraic expressions, and with the aid of what will later be regarded as derivatives, the study of the upper bounds and lower bounds of roots. It is in the course of these studies and in applying these methods that al-Ṭūsī grasps the importance of the discriminant of the cubic equation and gives the so-called Cardan formula just as it is found in the *Ars Magna*. Finally, without enlarging any further on the results which were obtained, we can say that both on the level of results as well as that of style, we find al-Khayyām and al-Ṭūsī fully in the field allegedly pioneered by Descartes.

If we exclude these traditions and justify this exclusion by invoking the practical and computational aims of the Arab mathematicians and an absence of rigorous standards of proof in their work, we can say that the history of classical algebra is the work of the Renaissance.

Among the mathematical disciplines, algebra is not a unique case. To varying degrees, trigonometry, geometry, and infinitesimal determinations are likewise illustrative of the preceding analysis. In a more general sense, optics, statistics, mathematical geography, and astronomy are also no exception. Recent works in the history of astronomy render Tannery's understanding of the Arab astronomers and the interpretations which he gives of them manifestly outmoded, if not erroneous. But since we assigned ourselves the task of examining the doctrine of the Western nature of classical science, we shall restrict our discussion to an essential component of this doctrine, experimentation.

Experimentation

In fact, is not the cleavage between the two periods of Western science, the Greek period and the Renaissance, often marked by the introduction of experimental norms? Undoubtedly the general agreement of the philosophers, historians, and sociologists of science stops here; the divergences become apparent as soon as they attempt to define the meaning, the implications, and the origins of these experimental norms. The origins are linked in one case to the current of Augustinian-Platonism, in another to the Christian tradition, and particularly to the dogma of Incarnation, in a third case to the engineers of the Renaissance, in a fourth to the *Novum Organum* of Francis Bacon, and finally, in a fifth, to Gilbert, Harvey, Kepler, and Galileo. Some of these attitudes superimpose upon one another, become entangled or contradictory, but they all converge on one point: the occidental nature of the new norms.

Nevertheless, as early as the nineteenth century, historians and philosophers such as Alexander von Humboldt in Germany and Cournot in France diverge from this predominating position to attribute to the Arab period the origins of experimentation. It is difficult to analyze the origins or the beginnings of experimentation correctly, since no study has been made of the interrelations of the different traditions and the different themes to which the concept of experimentation has been applied. Perhaps it would be in writing such a history, especially a history of the term itself, that one could give an accounting of the multiplicity of uses and ambiguities of the concept. For this analysis two histories are needed: the history of the relationship between art and science and that of the links between mathematics and physics.

With the history of the relationship between science and art, we are in a position to understand when, why, and how it became accepted that knowledge can emanate from demonstrations and from the rules of practice at the same time, and that a body of knowledge possesses the stature of a science while, at the same time, it is conceived in its possibilities of practical realization with an external purpose. The traditional opposition between science and art seems likely to be the work of the intellectual currents of the Arabic period. Certainly one fact is striking: whether we are dealing with Muslim traditionalists, rationalist theologians, scholars of different fields, or even philosophers of the Hellenistic tradition such as al-Kindī or al-Fārābī, all contribute to the weakening of the traditional differentiation between science and art. In other respects, this general trait is at the origin of the opinion of some historians regarding the practical spirit and realistic imagination of the Arab scholars. Knowledge is accepted as scientific without its conforming either to the Aristotelian or to the Euclidean scheme. This new concept of the stature of science promoted the dignity of scientific understanding of disciplines which traditionally were confined to the domain of art, such as alchemy, medicine, pharmacology, music, or lexicography. Whatever might be the importance of this concept, it could only lead to an extension of empirical research and to a diffuse notion of experimentation. One does witness the multiplication and systematic use of empirical procedures: the classifications of the botanists and the linguists, the control experiments of the doctors and alchemists, and the clinical observations and comparative diagnostics of the physicians. But it was not until new links were established between mathematics and physics that such a diffuse notion of experimentation acquired the dimension that determines it, a regular and systematic component of the proof. Primarily it is in Ibn al-Haytham's work in the field of optics where the emergence of this new dimension can be perceived.

With Ibn al-Haytham the break is established with optics as the geometry of vision or light. Experimentation had indeed become a category of the proof. The successors of Ibn al-Haytham, such as al-Fārisī, adopted experimental norms in their optical research, such as that performed on the rainbow. What did Ibn al-Haytham understand by experimentation? We will find in his work as many meanings of this word and as many functions served by experimentation as there are links between mathematics and physics. A thorough look at his texts indicates that the term and its derivatives belong to several superimposed systems, and are not likely to be discerned through simple philological analysis. But if attention is fixed on the content rather than the lexical form, one can distinguish several types of relationships between mathematics and physics which allow one to spot the corresponding functions of the idea of experimentation. In fact, the links between mathematics and physics are established in several ways; even if they are not specifically treated by Ibn al-Haytham, they underlie his work and are amenable to analysis.

As for the field of geometric optics, which was reformed by Ibn al-Haytham himself, the only link between mathematics and physics is a similarity of structures. Owing to his definition of a light ray, Ibn al-Haytham was able to formulate his theory on the phenomena of propagation, including the important phenomenon of diffusion, so that they relate perfectly to geometry. Then several experiments were devised to assure technical verification of the propositions. Experiments were designed to prove the laws and rules of geometrical optics. The work of Ibn al-Haytham attests to two important facts which are often insufficiently stressed: first of all, some of his experiments were not simply designed to verify qualitative assertions, but also to obtain quantitative results; in the second place, the apparatus devised by Ibn al-Haytham, which was quite varied and complex, is not limited to that of the astronomers.

In physical optics one encounters another type of relationship between mathematics and physics and therefore a second meaning of experimentation. Without opting for an atomistic theory, Ibn al-Haytham states that light, or as he writes, "the smallest of the lights", is a material thing, external to vision, which moves in time, changes its velocity according to its medium, follows the easiest path, and diminishes in its intensity depending on its distance from its source. Mathematics is introduced into physical optics at this stage by means of analogies established between the systems of movement of a heavy body and those of the reflection and refraction of light. This previous mathematical treatment of the concepts of physics permitted them to be transferred to an experimental plane. Although this situation on the experimental level might be somewhat approximate in nature, it nevertheless furnishes a level of existence to ideas which are syntactically structured, but semantically indeterminate, such as Ibn al-Haytham's scheme of the movements of a projectile.

A third type of experimentation, which was not practiced by Ibn al-Haytham himself but was made possible by his own reform and his discoveries in optics, appears at the beginning of the fourteenth century in the work of his successor al-Fārisī. The links established between mathematics and physics aim to construct a model and to reduce by geometric means the propagation of light in a natural object to its propagation in an artificial object. The problem is to define for propagation, between the natural and the artificial object, some analogical correspondences which were genuinely certain of mathematical status. For example, they built a model of a massive glass sphere filled with water to explain the rainbow. In this case, experimentation serves the function of simulating the physical conditions of a phenomenon that can be studied neither directly nor completely. The three types of experimentation studied all reveal themselves both as a means of verification and as furnishing a plane of material existence to ideas which are syntactically structured. In the three cases, the scientist must realize an object physically in order to handle it conceptually. Thus, in the most elementary example of rectilinear propagation, Ibn al-Haytham does not consider any arbitrarily chosen opening of a black box, but rather specific ones, in accordance with specific geometric relationships, in order to realize as precisely as possible his concept of a ray.

To recapitulate several points:

1. The tenet of the Western nature of classical science which was launched in the eighteenth-century owes to the Orientalism of the nineteenth century the image that we now recognize.
2. On the one hand, the opposition between East and the West underlies the critique of science and rationalism in general; on the other, it excludes the scientific production of the East from the history of science both *de facto* and *de jure*. An absence of rigor is invoked, as well as the computational attributes and the practical aims of science written in Arabic, to justify this effective debarment from the history of science.
3. This tenet reveals a disdain for the data of history as well as a creative capacity for ideological interpretation, which are admitted as evidence for ideas that raise many more problems than they solve. Thus we have the notion of a Scientific Renaissance, when in several disciplines everything indicates that there was merely a reactivation. These pieces of pseudoevidence quickly become conceptual bases for a philosophy or sociology of science, as well as the departure point for theoretical elaborations in the history of science.

We must ask ourselves if the moment has not arrived to abandon this characterization of classical science and its still lively traces in the writing of history, to restore to the profession of the historian of science the objectivity required of it, to ban the clandestine importation and diffusion of uncontrolled ideologies, to refrain from all reductionist tendencies which favor similarities at the expense of differences, and to be wary of miraculous events in history. The neutrality of the historian is not an a priori ethical value; it can only be the product of patient work which will not be duped by the myths which the East and West have engendered. Above all, it is necessary to cast out the periodization everywhere admitted in the history of science. The term used for classical algebra or classical optics, for example, will integrate the works which extended from the tenth to the seventeenth centuries. Consequently, it will realign not only the idea of the classical sciences, but also that of medieval science. The classical sciences will then reveal themselves as the product of the Mediterranean which was the hub of exchanges among all civilizations of the ancient world. Only then will the historian of science be able to enlighten the debate over modernism and tradition.

Science as a Western Phenomenon: Postscript

The 26 years since the publication of the original French edition of the text above has been a very fertile period for the study of the history of Islamic science. Indeed, we have witnessed an unprecedented rebirth of this discipline. Texts have been written and translated, new collections have appeared, and specialized reviews and journals have been published. These have offered historians the possibility of developing and comparing their research findings with facts. The task remains huge, and we are only at the beginning, but at least this new growth of information puts to rest the argument of ignorance.

With all this new information, one would have expected historians and philosophers to rectify the impressions and ideas they had inherited from the nineteenth century. One would have thought that the doctrine of Western science which we have described and analyzed here would have disappeared along with the props on which that doctrine was based. Indeed we were beginning to see a growing tendency to break with this doctrine and its implications. Then, for reasons which are extraneous to science and its history, images of Islamic society – if not of Islam itself – arose, according to which it was seen as irrational and intolerant and thus a society foreign to science. The aging doctrine was naturally given new life because of these images. How is it possible, under these conditions, to reconcile such an image of Islamic society with scientific results obtained from the heart of that same society? It was enough to back up the preceding doctrine with another, the doctrine of double marginality: with regard to the society which saw the development of science, and with regard to the history of the sciences. Thus, one could still write in 1992, "We must remember that at an advanced level the foreign sciences had never found a stable institutional home in Islam," or "Greek learning never found a secure institutional home in Islam, as it was eventually to do in the universities of medieval Christendom" (Lindberg 1992). As for the second marginality, we have already described how it works. Thus, we are back where we started and the doctrine of the Westernness of science is saved. Undoubtedly, these ideological views are beginning to give way, weakened by new research findings. And even if they are still capable of slowing down the acceptance of facts, it is not widespread, and it certainly will not last much longer.

Science East and West

Dhruv Raina

The social shaping of representations of non-western astronomy and mathematics in eighteenth- and nineteenth-century European scholarship has been of recent scholarly interest from the perspective of the politics of knowledge (Charette 1995; Raina 1999). My own concern has been to focus upon Indian astronomy and mathematics in the French Enlightenment and post-Enlightenment historiography. In dialogue with Said's *Orientalism*, this exploration has sought to examine whether the history of mathematics (the least likely case) is also inscribed within the frame of European colonial adventure and enterprise, as happened in the arts, literature, and social sciences (Assayag et al. 1997). In the study of the French Enlightenment I had qualified the Saidian thesis by suggesting that the so-called "European tradition" was fractured along national lines (Raina 1999). The present project is to focus upon British Indology[1] and its relationship with the corpus of French scholarship that preceded it. More specifically, the article attempts to ascertain when the first texts of Indian astronomy were translated into a European language, and by whom, and it elaborates upon how the Indian tradition of mathematics came to be constructed as one that was devoid of the idea of proof. While this characterization acquired stability in the nineteenth century, the construction itself was prefigured in the eighteenth century. In other words, it is suggested that historians of science mobilized the ideas of proofs or demonstrations as a criterion for demarcating different mathematical traditions.

Edward Said's thesis links the production of knowledge about the Orient with the exercise of colonial power (Said 1978). Does this thesis envelope the landscape of European writing on India? The thesis needs qualification from a number of points of view, for the landscape in Said's view is envisioned as monolithic and homogeneous. The eighteenth century has been considered the formative period for the emergence of the discourse on colonialism, but this discourse was not yet "monolithic or univocal." European writing on India comprised a network of "intersecting and contending discourses," and was preoccupied with a wide range of questions on authority (Teltscher 1995: 2). The representations of India in this writing are naturally very "diverse, shifting, historically contingent, complex, and competitive." The texts themselves are shaped often by "national and religious rivalries, domestic concerns," and the cognitive or intellectual cultures of the respective interlocutors (Teltscher 1995: 2; Raina 1999; Jami 1995). Critical studies on oriental scholarship have sought to situate these texts in national and religious contexts and to identify the elements they share (Županov 1993; Inden 1990). It has been argued that until the eighteenth century it was possible to speak of a European tradition of writing about India that differentiated into several national traditions by the middle of the eighteenth century. The birth of a specifically British tradition is put around 1765 when the East India Company was granted rights to collect land revenues and administer civil justice in Bengal (Teltscher 1995: 3). With the founding of the Asiatic Society British writing on India especially from the 1780s onward was marked by the impulse of British writers to "foreground the textual nature of their activity" (Teltscher 1995: 6).

European writing on India following the discovery of the sea route has been categorized into three distinct genres. The first comprises writing relating to travel, trade and the exploits of European powers on Indian soil. This writing was limited to the activities of Europeans in India; wherein an exotic India was presented to the West, and which either projected European superiority or criticized European institutions. But there was little elaboration of the philosophical or religious literature of India or its history (Kejariwal 1988: 14). The missionaries in India in the seventeenth and eighteenth century provided a second set of accounts. This writing itself is internally differentiated. On the one hand, we have letters recording the progress of missionary activity in India. On the other, Jesuit missionaries resident in India were studying Indian philosophy, religion, and culture. It may even be suggested that they were the first Europeans to be acquainted with Indian languages (Kejariwal 1988: 15). And finally, there is the scholarly writing on India. The French missionaries who came to India in the late seventeenth century were the first to have spoken of India's scientific past. French Indology, according to Filliozat, emerged in the early decades of the eighteenth century, when the King's librarian requested Étienne Fourmont, of the Collège Royale, to draw up a list of works of note from India and Indo-China, to be purchased for the King's library. By 1739, a catalogue of Sanskrit works had been prepared, and copies of Vedas, epics, philosophical and linguistic texts, and dictionaries had been procured (Filliozat 1955: 1–3). Curiously enough there were very few, if any, scientific texts that were included in the cargo to the King's library (Raina 1999). The first generation of Indianistes was possibly preoccupied with studying the speculations of the Indians, their philosophy, and the "niveau de connaisances scientifques" (Filliozat 1954). The Jesuit astronomers were the first to study the Indian astronomical systems that Filliozat considers

[1] Indology refers to the study of India. It is the study of cultural aspects such as religions, philosophies, art, and architecture, as well as spiritual and social aspects.

"the first scientific or even cultural achievements of India studied by Europeans" (Filliozat 1957). Kejariwal goes so far to suggest that the "history of French Orientalism is also the history of the rediscovery of ancient Indian astronomy in the modern period" (Kejariwal 1988: 17). The latter point needs some nuancing.

In any case, these accounts were constantly contrasting India with Europe, "through explicit analogy or through implied difference." A fruitful approach into this archive of scientific texts and not just literary or religious texts is to pay attention to moments "which unsettle the confident moments of cultural description," to trace those "competing and fluctuating logics of similarity and difference," that characterize the early discourse of India (Teltscher 1995: 14). In examining these mathematical texts, it is essential to be alert to those moments and descriptions of mathematical results and procedures encountered within Sanskrit texts that were not accompanied by demonstrations or proof or exegesis. Thus the British mathematician and geologist John Playfair in introducing Indian astronomy to an English-speaking audience wrote:

> The astronomy of India is confined to one branch of the science. It gives no theory, nor even any description of the celestial phenomena, but satisfies itself with the calculation of certain changes in the heavens…The Brahmin…obtains his result with wonderful certainty and expedition; but having little knowledge of the principles on which his rules are founded, and no anxiety to be better informed, he is perfectly satisfied, if, as it usually happens, the commencement and duration of the eclipse answer, within a few minutes, to his prediction (Playfair 1790).

There are three core ideas that are evident in this passage, and that run constantly throughout the construction of Indian astronomy and mathematics. Inasmuch as Indian astronomy is a science it differs from modern astronomy in that it (a) lacks a theoretical basis, (b) does not provide a description of celestial phenomena, and (c) is not methodologically reflective ("little knowledge of the principles on which his rules are founded"). On account of the predictive accuracy of the astronomy it merits being a science, and the Indian astronomers are concerned no more with it than in this instrumental context.

The Origins of British Indology and the History of Indian Mathematics

British studies on Indian astronomy and mathematics may be said to lie at the conjuncture of two different historiographies: the French historiography of Indian astronomy and British studies on Indian society and culture. Consequently, British historiography of the sciences of India draws upon these sources and develops not unexpectedly in different directions. Without stretching a point too far it could be added that British Indology on the sciences of India commences with the pioneering work of John Zephaniah Holwell (1711–1798). Holwell came to India as a surgeon's mate in 1732 and was Governor of Bengal for a couple of months in 1760. To historians of science he is best known for his *An Account of the Manner of Inoculating for the Smallpox in the East Indies* (1767). The relevant issue here is not Holwell's article, but the different point of view he adopted for studying the traditions, cultures, and sciences of India. This strayed from the central precepts of Jesuit historiography (Murr 1986). While insisting as the Jesuits did on the antiquity of the Indian people and their literature, he proposed that this antiquity was not reconcilable with the "Christian view of History" (Holwell, quoted in Kejariwal 1988: 19). Misidentifying his account from earlier European scholarship that he considered "defective, fallacious, and unsatisfactory," Holwell proposed instead a philological approach to the "sublime rational source and foundation" of what to the Western eye appeared preposterous superstition founded on irrationality (Kejariwal 1988: 19). It is not germane here to establish whether Holwell could be considered the inaugurator of this approach; but this view was shared by a number of British scholars who founded the Asiatic Society.

One of the earliest British Indologists to speak of the distinctive tradition of Indian algebra was Rueben Burrow. The prior French tradition of the history of science had been preoccupied with the origins of Indian astronomy. Burrow centered the question about the origins of Indian algebra and arithmetic. This will become evident further ahead. That Burrow shared the same viewpoint as Holwell is evident in his "Hints concerning the Observatory at Benaras" (1783):

> Notwithstanding the prejudices of the Europeans of the last century in favour of their own abilities, some of the first members of the royal society were sufficiently enlightened to consider the East Indies and China & c, as new worlds of science that remained undiscovered…had they not too hastily concluded that to be lost, which nothing but the prejudice of ignorance and obstinacy, had prevented being found, we might at this time (be) in possession of the most finished productions of Asia as well as Europe; the sciences might, in consequence, have been carried to a much higher degree of perfection with us than they are at present; and the elegance and superiority of the Asiatic models might have prevented the neglect and depravity of geometry, and that inundation of Algebraic barbarism which has ever since the time of Descartes, both vitiated taste, and overrun the

> publications, of most of the philosophical societies in Europe (Burrow 1783: 94–95).

It is evident from the above that beyond the aesthetic of the search for the marvelous, the encounter with other non-European scientific traditions was encouraged by the ideological impulse to advance the frontiers of knowledge. In that sense Burrow's philosophy of science resonated with that of the Enlightenment thinkers. As far as the history of astronomy is concerned, this project was quite consistent with historical astronomy being pursued in China and India since the late seventeenth century (Han 1995; Raina 1999). The most striking feature of the above passage is that the Indian tradition for Burrow is not characterized as algebraic or geometric. In fact, at this point the characterization is the very reverse of the late nineteenth-century one. Modern European mathematics since Descartes had been overwhelmed by "algebraic barbarism." An exposure to Asiatic models would then have prevented the neglect of geometry that marked contemporary sciences. The relevant concern here is that "until the end of the eighteenth century the British Indologists still entertained the hope that they would discover Indian geometrical texts that would unveil to them the foundations of an Indian geometrical tradition." Thus Playfair would in 1792 pose six questions to the researchers of the Asiatic Society, the first of which was: "Are any books to be found among the Hindus, which treat professedly of Geometry?" (Playfair 1792: 151). For one it could be said that the question that the geometry of the Hindus could have a different basis from the Greek ones is implied by the "professedly" in the question. That this is what Playfair meant might be inferred from his elaboration upon the question he posed:

> I am led to propose this question, by having observed, not only that the whole of the Indian Astronomy is a system constructed with great geometrical skill, but that the trigonometrical rules given in the translation from the *Surya Siddhānta*, with which Mr. Davis has obliged the world, point out some very curious theorems, which must have been know to the author of that ancient book (Playfair 1792: 151).

The rule according to which the "trigonometrical canon" of Indian astronomy is constructed according to Playfair, is based on a theorem:

> If there be three arches of a circle in arithmetical progression, the sum of the sines of the two extreme arches is to twice the sine of the middle arch as the cosine of common difference of the arches to the radius of the circle (Playfair 1979: 152).

Although the theorem was not known to Europe before Viète, the method was employed by the Indian astronomers for constructing trigonometrical tables, and was based on a simpler procedure of calculating sines and arches than through the use of methods that were based on extracting square roots (Playfair 1798: 152). The immediate task for Playfair appears to have been to identify those mathematical works where the theorem on which the trigonometrical rule employed in astronomy is first laid out. This brings us back to Burrow's concern with the origins of Indian mathematics.

Where Are the Geometrical Texts, or Is the Tradition Algebraic?

In the eighteenth century it would be possible to differentiate between the efforts of the British Indologists and that of their French counterparts studying Indian astronomy and mathematics on two counts. Methodologically speaking, while the British Indologists were busy underlining the textual nature of their enterprise, the French astronomers–savants relied a great deal on protoethnographic descriptions of the mathematical and astronomical practices of India. Second, the histories of Indian astronomy of Bailly (1787) and Le Gentil (1781) are preoccupied with astronomical literature and the origins of Indian astronomy.

Even Montucla (1799) relies extensively upon the sources employed by Le Gentil and Bailly and draws inferences concerning Indian mathematics from them. The British Indological tradition on the other hand, engages with specific texts and from the astronomical rules presented there makes a claim that these rules must be based on a mathematical system. They subsequently proceeded to discover mathematical texts. Their focus thus shifts from the origins of astronomy to the origins of Indian mathematics, in particular Indian algebra and arithmetic.

What were the rules encountered and what were the claims made?

Rueben Burrow, a British official in Bengal, was probably amongst the earliest of the British Indologists to engage with the textual tradition of Indian mathematics, although this search was prompted through his exposure to and study of astronomy, including Indian astronomy. This does not mean that these texts did not relate in any way to the histories of Le Gentil and Bailly. Actually, the texts of the former provided an initial viewpoint to interpret the differences between the two traditions. Burrow, like Bailly, entertained a wild hypothesis concerning the origins of the sciences, but this never seemed to have been noticed as much as Bailly's antediluvian hypothesis. Consequently, for Burrow the study of the procedures employed by Indian astronomers in calculating eclipses would advance the progress of modern astronomy as well: "…and the more so as our methods of calculation are excessively tedious and intricate" (Burrow 1783: 101). The sentiment echoes that of Le Gentil and Bailly, and it is certain that he was acquainted with the work of Le Gentil (Burrow 1783: 116), although it is not possible to say the same of Bailly's *Traité*. This fascination with the computational procedures employed in astronomy led Burrow to infer in 1783 the existence of an advanced algebraic tradition:

> It is also generally reported that the Brahmins calculate their eclipses, not by astronomical tables as we do, but by rules…If they (the rules) be as exact as ours, …it is a proof that they must have carried algebraic computation to a very extraordinary pitch, and have well understood the doctrine of "continued fractions", in order to have found those periodical approximations… (Burrow 1783: 101).

The rules for computing eclipses employed by the Brahmins were not only different, but their complexity varied with the requisite degree of exactness:

> …which entirely agrees with the approximation deduced from algebraic formulae and implies an intimate acquaintance with the Newtonian doctrine of series…and therefore it is not impossible for the Brahmins to have understood Algebra better than we do (Burrow 1783: 101).

This was to become the central point from which in subsequent papers Burrow would build his argument for the existence of an advanced algebra among the Indians. One of the first histories of Indian algebra was authored by Burrow and was entitled "On Early History of Algebra" (Burrow 1810), and was possibly published posthumously. The paper emphasized the originality and importance of algebra among the Hindus and contained extracts that were translated from the *Bījagaṇita* and *Līlāvatī*. These extracts were translations into English from Persian translations of the original Sanskrit texts. If we were to go by his own admission in an earlier paper (Burrow 1790), these extracts were translated in 1784, but he deferred publishing them until a full text was obtained. But he prizes the moment "when no European but myself…even suspected that the Hindoos had any algebra" (Burrow 1790: 115). The rationale provided for the existence of treatises on algebra in India in this paper is based on the knowledge of the binomial theorem among the Indians and is the same as that suggested in the earlier paper. Many of the approximations used in astronomy were "deduced from infinite series; or at least have the appearance of it" (Burrow 1790: 115). These included finding the sine from the arc and determining the angles of a right-angled triangle given the hypotenuse and sides without recourse to a table of sines, etc.

The urgency of the moment was then to discover those texts before they perished. Burrow thus emphasized the need for the collection of available astronomical and mathematical texts that until then had not been the focus of attention of the French Académiciens. The idea that the existing tradition was probably algebraic was being insinuated:

> That many of their books are depraved and lost is evident, because there is now not a single book of geometrical elements to be met with; and yet that they had elements not long ago, and apparently more extensive than those of Euclid is obvious from some of their works of no great antiquity (Burrow 1790: 115).

And while Burrow promised to publish translations of *Līlāvatī* and the *Bījagaṇita*, the promise was not fulfilled possibly during his life. Inspired by Burrow's research, Colebrooke embarked on a study of Sanskrit in order to probe some of the issues raised more deeply.

But the just-mentioned paper by Burrow contains a very brief demonstration of the knowledge of the binomial theorem in the Indian tradition, which unlike Newton's understanding was limited to whole numbers alone. Burrow first offers a translation from Persian of the problem:

> A Raja's palace had eight doors, now these doors may either be opened by one at a time, or by two at a time, and by three at a time; and so on through the whole, until at last all are opened together: it is required to tell the number of times that this can be done (Burrow 1790: 118).

Setting out the procedure for resolving it follows the statement of the problem. Write down the number of doors by decreasing from eight to unity. Just under these numbers write down the numbers in the reverse order.

8	7	6	5	4	3	2	1
1	2	3	4	5	6	7	8

Step 1. The number of times the door can be opened one at a time is obtained by dividing the first number 8, by the number under it, the quotient being 8.

Step 2. To obtain the number of times that two different doors may be opened, multiply the quotient 8 by the next number 7, and divide the product by 2 beneath it, the result being 28.

Step 3. To obtain the number of times three different doors may be opened, multiply 28 by the next number 6, and divide the product by 3, and the quotient is 56.

And so on.

"The sum of all the different times is 255" (Burrow 1790: 119). This setting out of the procedure, Burrow calls a "demonstration" and insists that it should be "evident" to mathematicians when inspecting the coefficients of a general equation. So to Burrow goes

S

the credit for providing the first glimpses into the Indian algebraic tradition.

It was left to Samuel Davis to publish the first full-fledged translation and analysis of an Indian scientific work from the Sanskrit into a European language. This was a translation of the *Sūryasiddhānta* (Davis 1789). This translation was based on the reading of an original version of the text procured by Sir Robert Chambers in 1788. Davis encountered a number of obscure technical terms and had to rely upon a *teeka* or commentary procured by Jonathan Duncan (Davis 1789). In fact, if you examine the structure of Davis' paper, it appears as a *teeka* on the *Sūryasiddhānta*, with passages translated from the text and Davis' explanation intercalated between the translated passages. Most British Indologists who worked on Indian astronomy toward the last decades of the eighteenth century were familiar with two canonical European accounts, that of Bailly and Le Gentil.

Without referring to either, Davis begins by contesting the portrait of Indian astronomy and astronomers projected by Le Gentil and Bailly,[2] without naming either of them. The first idea that he rejected was that this astronomical tradition was disfigured over the years by idolatry and that the gems of Indian astronomy had been irretrievably lost over the centuries, in the absence of a textual tradition. The second idea was that the Brahmins had shrouded their astronomy in mystery such that it was impossible to arrive at a cogent account of it. Further, they loathed sharing their ideas with others. Davis set out to show that:

> …numerous treatises in Sanskrit on astronomy are procurable, and that the Brahmins are willing to explain them…I can further venture to declare that, from the experience I have had, that Sanskrit books in the science are more easily translated than almost any others, when once the technical terms are understood: the subject of them *admitting neither of metaphysical reasoning nor of metaphor*, but being delivered in plain terms *and generally illustrated with examples in practice* (Davis 1790: 175) (emphasis added).

The British Indologists were departing from the reading of Académiciens grounded in Jesuit protoethnography, by textually locating their work. This textual grounding would revise the portrait of the French savants (Table 1). A hundred years later in a review of the history of the history of Indian astronomy Burgess was to write: "Mr. Davis' paper, however, was the first analysis of an original Hindu astronomical treatise, and was a model of what such an essay ought to be" (Burgess 1893: 730–731). It appears then, as has been argued elsewhere, that the French savants in India were unable to establish trust with their Indian interlocutors, in total contrast to the first generation of British Indologists such as William Jones (Raj 2001). Two papers of William Jones followed closely on the heels of Davis' papers and a cursory glance at them reveals that they mutually respected and supported each other's enterprise. And yet they both were in agreement with Bailly's thesis of the independent origins of the Indian zodiac, differing very strongly with Montucla on this count:

> I engage to support an opinion (which the learned and industrious M. Montucla seems to treat with extreme contempt) that the Indian division of the zodiac was not borrowed from the Greeks or Arabs, but having been known in this country from time immemorial and being the same in part with other nations of the old Hindu race… (Jones 1790).

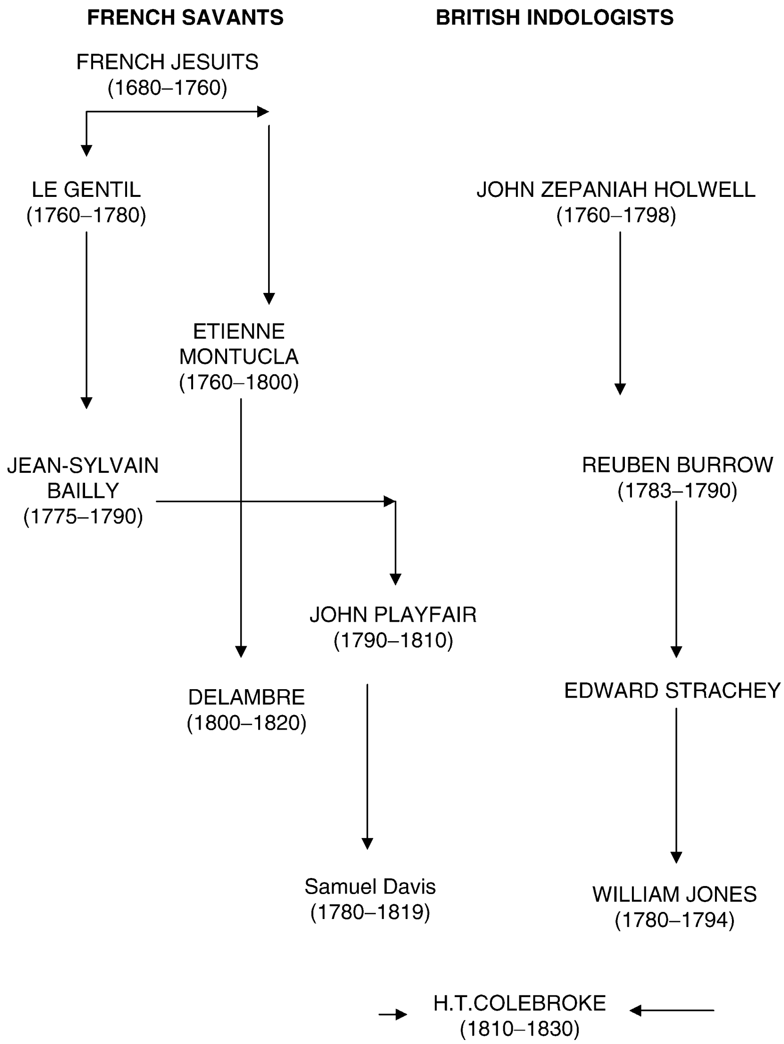
But then they were also gradually transforming and refining the portrait Bailly had left behind. Thus Jones recognized that in Davis' translation resided the hope that it would "convince M. Bailly that it is very possible for an European to translate and explain the Surya Siddhānta" (Jones 1790a).

John Playfair's Program and Colebrooke's Recovery of Indian Algebraic Texts

As far as the history of Indian astronomy and mathematics is concerned I have tried to argue that the French Jesuits of the seventeenth and eighteenth century are the inaugurators of a tradition, which was to inspire the histories of Le Gentil and Jean-Sylvain Bailly (Raina 1999). As has been argued elsewhere, it was Bailly's history that inspired the work of the British mathematician John Playfair and provided a stimulus to subsequent generations of British Indologists writing on Indian mathematics; although they were to disagree with the details of Bailly's *Histoire*, adding some nuance here and digressing from it in another context (Raina 2001). The antediluvian hypothesis proposed by Bailly was the source of both fascination and controversy, and was the outcome of his attempt to juxtapose observations of ancient Indian astronomy with astronomical theory of his day; from which he went on to draw the inference that ancient Indian astronomy was the

[2] More than Bailly and Le Gentil, Davis was refuting Sonnerat's constructions of Indian astronomy: "my present intention, which is to give a general account only of the method by which the Hindus compute eclipses, and thereby to show, that a late French author was too hasty in asserting generally that they determine by set forms, couched in enigmatical verses & C.'. So far are they from deserving the reproach of ignorance, which Mons. Sonnerat has implied, that on inquiry, I believe the Hindu science of astronomy will be found as well known now as it ever was among them, although perhaps, not so generally, by reason of the little encouragement men of science at present meet with…" (Davis 1789: 177). Evidently, Sonnerat, unlike Davis, could not enter the world of the Hindu astronomers on account of his inability to abandon a hermeneutic of suspicion.

Science East and West. Table 1 French savants and British Indologists



source of Greek astronomy (Bailly 1775). However, this reading was located within Jesuit historiography that sought to accommodate Indian history within the Christian conception of history (Raina 2003).

Bailly’s work was introduced to English-speaking readers through an article authored by the mathematician and geologist John Playfair (1748–1819), entitled “Remarks on the Astronomy of the Brahmins” published in the *Transactions of the Royal Society of Edinburgh* in 1789 (Playfair 1790). The article draws extensively upon the *Mémoires* of Le Gentil (Le Gentil 1785) published by the Académie des Sciences, Paris and Bailly’s *Astronomie Indienne* (Bailly 1785). This article of Playfair’s was of prime importance for Indologists working on the history of Indian astronomy for the next four decades, despite the fact that it was inspired by the work of such “un vulgariser.”

Just in and around the time Bailly’s *Traité* appeared, the important tradition of British Indology was beginning to crystallize. Marsden and Bentley were the first to contest Bailly’s assumptions and calculations. This opened the floodgates of criticism in France. Playfair jumped into the controversy attacking Bailly’s critics for their amateurism and for daring to question Bailly’s superior abilities. One of the early papers of the legendary William Jones was dedicated to defending Bailly’s thesis concerning the origins of the Hindu zodiac. Playfair’s central contribution resided in reappropriating Bailly’s *Traité* in the light of the contributions of Davis and Burrow and proposing a set of tasks that could well be considered a research program for the Asiatic Society. These included (a) to search for and publish works on Hindu geometry; (b) to procure any books on arithmetic and going by Burrow's article on the binomial theorem amongst the Indians to ascertain those arithmetical concerns whose trace is not to be found among the Greeks; (c) to complete the translation of the *Sūryasiddhānta* as initiated by Samuel Davis; (d) to compile a catalogue raisonné, with a scholarly account of books on Indian astronomy; (e) to examine the heavens with a Hindu astronomer in order to determine their stars and constellations; and (f) to obtain descriptions and drawings of astronomical buildings and instruments found in India (Playfair 1792: 152–155).

Bailly had stirred a hornet's nest in his time by suggesting that the origins of astronomy were in India, albeit this astronomy was inherited by the Indians from an even more ancient people. Burrow's paper did the same with the origins of algebra. It is at this time difficult to separate the discussion on the history of astronomy from the history of algebra; for both the Académiciens and the Indologists often turn to the history of astronomy to evoke computational procedures that were analyzed mathematically. This program of the recovery of the mathematical literature from the astronomical literature was taken up by Colebrooke, who may be seen as providing translations from the Sanskrit into English of the first texts supposedly dedicated solely to algebra and arithmetic. I say supposedly because portions of some of the texts that Colebrooke's discovers for the English-speaking world were essentially the mathematical sections of larger astronomical canons of the Indian tradition.

A brief recapitulation is required before we proceed to the translations of Colebrooke, for his work certainly marks a departure in the study of the history of Indian mathematics. The objective of this study thus far has been to examine the textual legacy that leads up to the translations of Colebrooke. Stated briefly, two main historiographic currents in the eighteenth century oriented the study of the history of the mathematics and astronomy of India. The first approach was that pursued by the Jesuit savants in India, who were observing the astronomical and computational procedures circulating among Indian astronomers. Their audience did not merely comprise the devout back in France, but the Académiciens and astronomers, two of whom transcribed these proto-ethnographic accounts into a history of Indian astronomy. Administrator-scholars, who studied texts, collated fragments of texts, and published translations with critical editions and commentaries, while indebted to the first, pursued another approach. In the late eighteenth century, Sanskrit commentaries and canonized astronomical or mathematical works were considered the key to obscure technical terms and texts. What needs to be examined is whether by the late nineteenth century, commentaries shared the same destiny as some of the Vedic texts. For it has been pointed out that by the second half of the nineteenth century some Sanskritists belittled, marginalized, and removed "explicit references to the intermediary process of transmission and exegesis of texts without which they would not have had access to them" (Vidal 1997: 25). The status of proofs in the Indian tradition is related to how these commentaries on mathematical texts were read.

The point needs some reaffirmation, since both Colebrooke and Davis who worked with commentaries of canonized astronomical and mathematical texts, respectively, do mention the existence of demonstrations and rules in the texts they discuss. In Colebrooke's introduction to his *Algebra with Arithmetic and Mensuration, from the Sanscrit of Brahmegupta and Bhascara*, there are four terms of concern to us here, namely, demonstration, rule, proof, and analysis that come up often, but it is only the last of these that Colebrooke clarifies. Noted by its absence in the title is the term "geometry," as a systematized science; on the contrary, the translation does allude to mensuration as discussed in the books he translates. The crucial problematic for Colebrooke was, as with Burrow before him, to determine the origins of Indian algebra. Inspired,

	Trope of forgetting	Trope of disfigurement	Historiography
Jesuit savants	The Brahmins had forgotten the original true Noahic religion from which they had descended and fallen into idolatry	The religion of the Brahmins had been disfigured over the centuries as they had tumbled into idolatry and superstition	Jesuit historiography of India
Astronomer savants of the French Enlightenment	The Brahmins had forgotten the intelligence of the astronomical methods that had been their legacy from an ancient people	The Brahmins had disfigured the core of an ancient science that they had inherited from an ancient people	Enlightenment historiography of astronomy

Taken from Raina (2003).

as it were, by the textual exemplars of Davis and Burrow, and guided by the research program John Playfair had drawn up for the researchers of the Asiatic Society, Colebrooke highlighted the pathway to his own work:

> In the history of mathematical science, it has long been a question to whom the invention of algebraic analysis is due, among what people, in what region was it devised, by whom was it cultivated and promoted, or by whose labours was it reduced *to form and system* (Colebrooke 1817: 121) (emphasis added).

The subsequent narrative focuses upon establishing that "the imperfect algebra of the Greeks," that had through the efforts of Diophantus advanced no further than solving equations with one unknown, was transmitted to India. The Indian algebraists, through their ingenuity, advanced this "slender idea" to the state of a "well-arranged science" (Colebrooke 1817: 145–146). In his reading, Colebrooke shares a fundamental historiographic principle, disputed by current scholarship, with Burrow, one that enjoyed currency among historians of mathematics into the twentieth century. In this historiographic frame,

> …the Arabs themselves scarcely pretend to the discovery of Algebra. *They were not in general inventors but scholars*, during the short period of their successful culture of the sciences (Colebrooke 1817: 121) (emphasis added).

The science of "algebraic analysis," a term Colebrooke would later expand upon, existed in India before the Arabs transmitted it to modern Europe (Colebrooke 1817: 121). The evidence for these claims resided in the translations of the *Bījagaṇita* and *Līlāvatī* of Bhāskarācārya,[3] as well as Brahmagupta's (Colebrooke: "Brahmegupta") *Gaṇitadhyāya* and *Kuṭṭakadhyāya* (Colebrooke: "Cuttacadhyaya"), the last two as their name suggests were the mathematical sections of Brahmagupta's *Brāhmasphuṭasiddhānta*. Without focusing too much on the antiquity of these texts, Colebrooke saw his oeuvre as disclosing that the

> …*modes of analysis*, and in particular, *general methods for the solution of indeterminate problems* both of the first and second degrees, are taught in the Vija-Gaṇita, and those for the first degree repeated in the Līlāvatī, which were unknown to the mathematicians of the west until invented anew in the last two centuries by algebraists of France and England (Colebrooke 1817: 124) (emphasis added).

The terrain of historical studies on Indian mathematics was being transformed into a polemical one, with Colebrooke surreptitiously introducing categories that the French Indologists had denied the Indian tradition: typically for the first time he speaks of "modes of analysis," or the "general methods for the solution of indeterminate problems." The historians of astronomy had previously advanced the idea that the Indians had no idea of the generalizability of the methods they employed. In the absence of such generalizability, how could it have been possible to extend the idea of generalized methods dedicated to solving classes of problems in order to extract the different "modes of analysis"? The intention here is not to paint Colebrooke's construction as the diametrical opposite of that of the French historians of science that provided a context to his effort. On the contrary, Colebrooke's project is naturally marked by a deep ambivalence. The ambivalence arises from the fact that he attempted to draw the characterization of Indian mathematics away from the binary typologies of the history of science that were already set in place. The lack of mathematical authority amongst the network of the British Indologists served as major handicap and deterred his ability to create a new vocabulary. This also explains why John Playfair was so important to the Indological enterprise. He was a mathematician of repute who conferred the Indological accounts with authority.

However, Colebrooke begins by pointing out that Āryabhaṭa was the first of the Indian authors known to have treated of algebra. Possibly a contemporary of Diophantus, the issue was important for drawing an arrow of transmission from Alexandria to India or vice versa. Colebrooke leaves the issue of the invention of algebra open by suggesting that it was Āryabhaṭa who developed it to the high level[4] that it attained in India; this science he called an "analysis" (Colebrooke 1817: 130). It is here for the first time that a portion of the Indian mathematical tradition is referred to as analysis, and it is important to get to the sense in which he employs the term. Thus it is noticed that the use of a notation and algorithms is crucial to this algebraic practice. Colebrooke then proceeds to elaborate upon the idea and takes note of the procedures not merely for denoting positive or negative quantities or the unknowns but of manipulating the symbols employed (Colebrooke 1817: 131–132). An important feature of this algebra is that all the terms of an equation do not have to be set up as positive quantities; there is no rule requiring that all the negative quantities be restored to

[3] I have given here the contemporary English spellings of the names of Sanskrit books and scholars. Colebrooke himself spelled the *Bijagaṇita* as *Vija-Gaṇita* and *Bhāskarācārya* as *Bhascara Acharya*.

[4] The high level of attainment was ascribed to the ability of the Indian algebraists to solve equations involving several unknowns and of possessing a general method of solving indeterminate equations of the first degree (Colebrooke 1817: 130).

S

the positive state. The procedure is to operate an equal subtraction "…(*samasodhana*) for the difference of like terms." This operation is compared with the *muqabalah* employed by the Arab algebraists (Colebrooke 1817: 135). The presence of this "analytic art" among the Indians was apparent from the canvas of their mathematics.

This included the arithmetic of surd roots, the cognizance that when a finite quantity was divided by zero the quotient was infinite, an acquaintance with the procedure for solving second-degree equations and "touching upon" higher orders, solving some of these equations by reducing them to the quadratic form, of possessing a general solution of indeterminate equations in the first degree. And finally, Colebrooke finds in the *Brāhmasphuṭasiddhānta* §18:29–49; and *Bījagaṇita*: §75–99; a method for obtaining a "multitude" of solutions to second-degree equations starting from a single solution that is plugged in. It was left to Lagrange to show that problems of this class would have solutions that are whole numbers (Colebrooke 1817: 135–136). The analytic art of the Indians or algebraic analysis is then for Colebrooke: "…calculation attended with the manifestation of its principles." This is manifest in the Indian mathematical texts being discussed since they intimate to the reader a "*method aided by devices*, among which symbols and literal signs are conspicuous" (Colebrooke 1817: 141). In this sense Indian algebra bears an affinity with D'Alembert's conception of analysis as the "method of resolving mathematical problems by reducing them to equations" (Colebrooke 1817: 141). Delambre and Biot would subject these views of Colebrooke to trenchant criticism, but that is another subject (Raina 1999). The issue at stake here is that Colebrooke had insinuated the idea that Indian mathematics was not lacking in methodological reflection or generality, a feature that had hitherto been denied.

Did this algebraic analysis provide for demonstrations or proofs of its rules or procedures? Citing specific sutras from the *Brāhmasphuṭasiddhānta*, the *Bījagaṇita* and the *Līlāvatī*, Colebrooke moves to a characterization of Indian algebra, just as Diophantus is evoked to characterize early Greek algebra. Thus, we are informed that these Indian algebraists applied algebraic methods both in astronomy and geometry, and in turn, geometric methods were applied to "the demonstration of algebraic rules." Obviously, Colebrooke was construing the visual demonstrative procedures employed by Bhāskara as exemplifying geometrical demonstration. Further, he goes on to state that:

> In short, they cultivated Algebra much more, and with greater success than geometry; as is evident in the comparatively low state of their knowledge in the one, and the high pitch of their attainments in the other (Colebrooke 1817: 136).

This passage came to be quoted so often in subsequent histories of science, and in the writings of mathematicians[5] as evidence of the algebraic nature of Indian mathematics. The power of its imagery resides in its ability to draw the boundary between different civilizational styles of mathematics. In this contrast between Western and Indian mathematics it could be suggested that Colebrooke's qualification concerning the "comparatively low" state of one and "high pitch" of the other was lost sight off, and the contrast between the two traditions came to be subsequently accentuated.

This leads me to conjecture that Colebrooke's translation is a watershed in the occidental understanding of the history of Indian mathematics on a second count as well; this is that it inadvertently certified the boundary line drawn between Indian algebra and Greek geometry. This was not Colebrooke's intention at all, but a consequence of the comparative method he had adopted. Colebrooke's particular comparative method consisted in displaying where India's specific contributions to mathematics resided, and he always contrasted these contributions with the Greek and Arab traditions of mathematics.[6] This attempt to accentuate the contrast certainly revealed the differences, but with the loss of the context of the contrast, it was first transformed into a caricature and then stabilized as a characterization. The boundary lines had however been marked out before Colebrooke's time.[7]

Thus there are four specific areas in which "Hindu Algebra appears particularly distinguished from the Greek" (Colebrooke 1817: 137). Some of these have been mentioned above. The additional one that has not been mentioned concerns the application of algebra to "astronomical investigation and geometrical demonstration." In the process the Indian algebraists, Colebrooke suggests developed portions of mathematics that were reinvented recently. This last statement of his prompted a very severe reaction. He then takes up three instances, which he considers "anticipations of modern discoveries" from the texts he discusses and lays out their procedures of demonstration. There is nothing in the subsequent portion of the introduction to suggest that he did not consider these as demonstrations.

[5] The nineteenth-century British mathematician Augustus De Morgan, a self-proclaimed aficionado of Indian mathematics, wrote a preface to the book of an Indian mathematician punctuated with apercus from Colebrooke's introduction. The introduction in fact provides him the ground to legitimate the work of the Indian mathematician for a British readership (Raina and Habib 1992).

[6] Going by his text alone, he appears to have been totally oblivious of Chinese mathematics.

[7] This passage reminds me of the simplistic manner in which Marx's "religion is the opium of the masses" is read out of context.

On reading of the early responses from a French savant to the work of Colebrooke, it is possible to discern that Delambre for one uses a very fine comb in rebutting several of the points taken up by Colebrooke. While Colebrooke himself does not draw a very fine distinction between the use of the term "proof" and "demonstration" in his reading, he does distinguish between algebra and analysis, and as mentioned earlier, he specifies wherein the Indian tradition could be characterized as an algebraic analysis. A study of the reception of Colebrooke's translations of the works on Indian arithmetic and algebra is a matter for a separate study. The curious question to be examined by such a study is that despite its canonical status in Western scholarship on the history of Indian mathematics and algebra, neither Colebrooke nor Davis ever insinuated that it was a tradition devoid of proof or demonstration. And yet, as the historiography of nineteenth-century Oriental mathematics evolved, a theory of the absence of proof would become one of its salient elements. One of the factors responsible for the strong criticism of Colebrooke's work at the time was that it might have been provoked by Colebrooke's method of taking up those demonstrations from Indian mathematics for which equivalents existed in eighteenth-century European mathematics. This would have vitiated both the claims of novelty and originality, both very important features of the new sciences. Second, until the end of the eighteenth century these Indologists still believed that they could discover the origins of an Indian geometry, and the later work of the French Indologist G. Thibaut may be seen to be in continuity with this tradition. But by the end of the nineteenth century the binary typologies of the history of mathematics, that portrayed the West as geometric and the East as algebraic, were well in place in the standard picture.

Science in China

HO PENG YOKE

Scholars in the past found it difficult to focus their attention on Chinese science because in traditional China knowledge did not come under the same groupings as in the West. For example the Chinese pharmacopoeias included knowledge on natural history; the official dynastic histories, some Daoist writings, and the works of some great poets contain information on astronomy and alchemy, and compendia on military science mention meteorology and firearms together with magic and divination. It is true that there are some Chinese monographs on science and technology, such as the *Tiangong kaiwu* (Exploitations of the Work of Nature) and the *Jiuzhang suanshu* (Mathematical Manual of the Nine Sections). Nevertheless knowledge of traditional Chinese science exists mainly in the official dynastic histories, the compendia (*leishu*), the gazetteers, religious works like the *Daozang* (Daoist *Tripitaka*), the numerous book collections (*congshu*), and the general literature.

In sixteenth-century Europe, Francis Bacon (1561–1626), Jean Fernal (1497–1558), and Jerome Cardano (1501–1576) all made reference to three great inventions, namely the compass, the art of printing, and gunpowder. In the minds of many there was only some vague connection between China and these three inventions. Indeed, prior to the middle of the twentieth century the history of Chinese science received little attention both from inside and outside China. It gained recognition in the middle of the twentieth century when Joseph Needham launched his monumental work, *Science and Civilisation in China*. Needham did not pioneer the study of the history of Chinese science. Sinologists and scientists before him had written on acoustics, alchemy, architecture, astronomy, gunpowder, hydraulics, mathematics, and medicine in traditional China. However, Needham demonstrated the originality of many Chinese discoveries and inventions, including the "three great inventions" of Renaissance Europe, and made Chinese science a new discipline of study. Modern scholarship and recent archaeological discoveries have increased our understanding of Chinese science and helped in the reappraisal of some old interpretations.

Excavations carried out first at Anyang between 1928 and 1937 and again after 1950, followed by those done at Zhengzhou in Henan province, substantiated the existence of the Shang dynasty (sixteenth–eleventh centuries BCE) and brought to light many bronze artifacts, foundry sites, and proto-porcelain wares. At the ruins in Anyang the remains of the capital of the last Shang kings were found. This later period of the Shang dynasty is known as Yin (fourteenth–eleventh centuries BCE). Besides bronze artifacts, archaeologists uncovered gold, jade, pottery, and shell objects, wooden artifacts with traces of lacquer, traces of silk fabric, and even a chariot. The most important find, however, was the oracle bones, which were carapaces of a specie of tortoise or shoulder blades of buffaloes that bear inscriptions written by the people of Yin for divination purposes. They contain records of eclipses and novae, as well as names of stars and asterisms. They also show that the Yin people were already using a lunisolar calendar with 12 moons or lunar months in one year. Each month consisted of either 29 or 30 days each, and every 2 or 3 years there was one extra month, known as the intercalary month, added to the year. The numerals in the oracle bones were the earliest known

Chinese numerals until the discovery of the inscriptions on the pottery at the ruins of Banpo, which dated back to about the year 3000 BCE. From the oracle bone numerals we know that the Yin people were already using a decimal system. We also find that the Yin people already had some knowledge of irrigation, agriculture, sericulture, and wine-making. For example, for tooth decay they used a character that included the character for "worms," suggesting that they had made an effort to attribute the problem to a cause. Chinese archaeologists have been quite active in recent years trying to re-establish the Xia dynasty. According to their tradition this dynasty existed for four centuries immediately before Shang, which itself lasted six centuries. Erlitou in Henan province, where bronze vessels dating back to the year 1700 BCE were recovered in 1971, is one of the more promising sites where they hope to discover epigraphical evidence to confirm the existence of that ancient dynasty.

Bronze vessels and pottery are some of the works of art characteristic of the Chinese. Shang bronzes show that the technique of bronze casting had already reached an advanced level. It was also in Shang China that the earliest proto-porcelain ware was discovered. It took the form of a wine container (*cun*), made of kaolin clay, with a yellowish green glaze on the surface about the mouth and a translucent deep green glaze on the inner and outer surfaces. The Western Zhou period (eleventh cenrury – 771 BCE) produced beautiful bronze vessels with inscriptions and proto-porcelain wares, some of which can be seen in many museums today.

In the Spring-and-Autumn period (722–481 BCE) two early texts, which Confucius (551–479 BCE) himself referred to, namely the *Shujing* (Book of Documents) and the *Shijing* (Book of Odes), were written. Both contain astronomical material from about the tenth to the fifth century BCE. The earliest sighting of Halley's comet in the year 613 BCE is recorded in the *Chunqiu* (Spring-and-Autumn Annals), which also contains references to solar and lunar eclipses, meteor streams, and other comets. The *Zhouli* (Records on the Rites of Zhou) informs us that the Zhou kings employed star clerks to observe astronomical and meteorological phenomena and to make astrological prognostications therefrom. The earliest star catalog is said to have been made by a court astronomer Wu Xian, of whom little is known. Two other catalogs were produced by Gan De and Shi Shen between 370 BCE and 270 BCE. The three original catalogs have long been lost. Some fragments claimed to be from the originals are quoted in many old astronomical writings. In the early fourth century Chen Zhuo (fl. ca. 310) constructed a star map supposedly based on such information.

Two weapons with iron plates taken from meteorite sources and dating back to the Western Zhou period were discovered in 1949. In 1976 a steel weapon of the sixth century BCE was excavated in Changsha, Hunan province, showing that by then China had already entered the Iron Age. Subsequently more iron artifacts of the fifth century BCE were found in Jiangsu and Henan provinces. It is interesting that although Europe knew about iron earlier, the Chinese came to know about the making of cast iron not later than the fifth century BCE, soon after iron was known to them. Another interesting technology developed by the Chinese of about that period is the breast-strap harness seen on the horses among the terra cotta warriors guarding the tomb of Qin Shihuangdi in Xian. Showing good understanding of the horse, this method was far superior to the throat-and-girth harness of the Roman chariot adopted in Europe in the early days. Some time between the years 600 and 1,000 the breast-strap technique went to Europe and evolved into the modern harness.

Between the sixth and the fourth centuries BCE the "Hundred Schools of Philosophical Teachings" flourished in China. Some of these schools played an important role in the development of science and technology in China. The philosopher Mozi (b. ca. 479 BCE) is remembered for his techniques of defense and for his knowledge of mechanics and optics embodied in his *Mojing* (The Canon of Mozi). Confucius is said to have edited the *Yijing* (Book of Changes), which contains one of the most subtle and influential methods of Chinese divination. In the past, especially in China, it was difficult to draw a sharp line of demarcation between science and divination. These two subjects were included within the term *shuxue* (mathematics). The writings of the Daoist philosophers and the Naturalists exerted a great influence on early Chinese science, and indeed they provided a set of natural laws that was supposed to be "universal", even more so than what modern scientists believe. Indeed the attempt to be too universal made it difficult for science in traditional China to separate itself from philosophy and to develop into modern science. The greatest name among the Naturalists was Zou Yan (fl. ca. 300 BCE) who lived in the eastern seaboard state of Qi (in modern Hebei province). He was the greatest exponent of the *yin* and *yang* theory and that of the *wuxing* in ancient China.

Traditional Chinese science was based on the philosophy of Harmony of Nature, in which heaven (*tian*), earth (*di*), and human beings (*ren*) were all mutually related. Attempts were made to develop a philosophy to explain everything – from astronomy to astrology, from mathematics to fortune-telling, from alchemy to magic, from philosophy to ethics, from politics to fine arts, and from medicine to music – in a common concept based on *qi*. The word *qi* has a wide range of meanings, which cannot be adequately covered by a single term in translation. Its modern meaning includes "air", "gas", "vapor", "steam", "weather", "trend", "demeanor", "manner", "temper", and a sort of life-giving force, reminding us of the Greek concepts of *pneuma* and *psyche*, the Hindu idea of *prāṇa*, and what modern scientists call "matter-energy".

From *qi* the two opposite and yet complementary cosmological forces *yin* and *yang* and the five *xings* were derived. *Yin* conveys the idea of darkness, the shady part of a mountain, coldness, cloudiness, rain, anything that is feminine, and so on. *Yang*, on the other hand, refers to brightness, the sunny side of a mountain, warmth, clear sky, sunshine, anything that is masculine, etc. The term *wuxing* was generally translated as "Five Elements". This gave rise to some confusion. When the Jesuits rendered the Four Elements of the ancient Greeks into Chinese they used the term *siyuan*, (four *yuans*), but when they translated the Chinese term *wuxing* they called it Five Elements. Unlike the Greek Elements (earth, air, fire, and water), the Chinese *xing*'s were not stationary but were in a state of constant motion rather than rest. They are Fire, Water, Wood, Metal, and Earth. There is an order of production or generation in which Fire produces Earth, Earth produces Metal, Metal produces Water, Water produces Wood, and Wood produces Fire. Then there is an order of conquest or destruction in which Fire conquers Metal, Metal conquers Wood, Wood conquers Earth, Earth conquers Water, and Water conquers Fire. In Chinese medicine for example, the *Huangdi neijing* divides different parts of the body into *yin* and *yang* and associates them with the five *xings*. For example, the heart, the small intestines and the tongue are associated with Fire, the kidneys and the ears with Water, the gall-bladder and the eyes with Wood, the lungs, the large intestines and the nose with Metal, and the stomach, the spleen and the mouth with Earth. The foundation of health, tranquility, and well-being rests on the perfect equilibrium and harmony of the two cosmological forces *yin* and *yang*, which continually ebb and flow. Everything is produced by union and perishes by decomposition. From the two orders of mutual production and mutual conquest the Chinese derived two principles, namely the "principle of control" and the "principle of masking". Any of the five *xings* that conquers another *xing* is controlled by the *xing* that conquers it. For example, Fire conquers Metal, but the process is controlled by Water. Any *xing* that conquers another *xing* is masked by a *xing* that produces the conquered *xing*, i.e., Fire conquers Metal, but Earth masks the effect.

Then comes the system of the *Yijing* (Book of Changes) with its 64 hexagrams said to be derived from the theory of *yin* and *yang* and that of the *wuxing*, although the system was sometimes used to support those two theories instead. Traditionally the origin of the system traced back to the eleventh century BCE when the sage father of the founder of the Zhou dynasty got inspiration from two mystical diagrams, the *Hetu* (River Diagram) and the *Luoshu* (*Luo* Chart). These two diagrams supposedly held the secrets of *yin* and *yang* as well as the *wuxing*. In the *Yijing* heaven and earth, thus *yang* and *yin*, originated from *Dao*. This term probably refers to natural order in this context but is opened to a broad range of diverse interpretations. The system of the *Yijing* was mainly employed for the purpose of divination. Besides divination it also found its use in the "explanation" of scientific phenomena, such as in astronomy and alchemy.

In traditional Chinese thought, divination and mathematics were inseparable. The word *shuxue*, the modern term for mathematics, was only first used in the modern sense in the last century when Li Shanlan (1811–1882) translated Western mathematical works into Chinese. Before then the same term in traditional China referred not only to divination and mathematics but also to astronomy and music. One is reminded of the word mathematics as defined by Boethius (480–524) to include arithmetic, geometry, astronomy, and music, which became the *quadrivium* in medieval Europe. In the eyes of traditional Chinese mathematicians, such as Liu Hui (fl. 263) and Qin Jiushao (1202–1262), divination was the loftiest form of *shuxue* while mathematics (in its modern sense) was only its common form. *Shu* was something that could be predicted by calculations, whether by means recognized by modern scholars as mathematics, such as finding the unknown number in a mathematical equation, or predicting rain in weather forecasts and telling the future using the system of the *Yijing*.

Buddhism and Daoism gradually gained ground over the Confucianists after Han China in the third century. A revival of learning during the time of Song China (960–1279) saw the neo-Confucianists attempting to cover science, particularly cosmology, within their schools of philosophy. The most celebrated among them was Zhu Xi (1130–1200), who sought to explain everything, both natural and human, with *li* (Nature's pattern), *qi*, and *shu*, while Zhang Zai (1020–1077) applied the concept of *qi* to explain natural phenomena and moral issues. Then there was the *xiangshu* (numbers of the symbols of the *Yijing*) school that focused its attention on the elucidation, verification, and application of the system of the *Yijing*. The most famous member of the school was Shao Yong (1011–1077), who used the system to explain natural phenomena and human affairs and to work out past and future events. His new order of the 64 hexagrams was shown by Leibniz (1646–1716) to be similar to the arrangements using the binary notation. Although Zhu Xi's philosophy was adopted as state orthodoxy, it does not imply that it met no opposition. For example, a contemporary, Lu Xiangshan (1139–1192) developed the neo-Confucian school of Idealism or of the Mind, which was later further developed by the Ming philosopher Wang Shouren (1472–1529), who had a large following.

The earliest text on Chinese astronomy and mathematics is the *Zhoubi suanjing* (Mathematical Manual of Zhoubi), which Christopher Cullen showed recently to be a compilation of the first century. In 1973 many important discoveries were made in the excavation of a Western Han (206 BCE–AD 9) tomb in Mawangdui, Hunan province. They included a manuscript recording the ephemerides of Jupiter, Saturn, and Venus between the years 246 BCE and 177 BCE and a silk manuscript illustrating comets in various shapes. Astronomical instruments such as bronze clepsydrae and bronze sundials have also been discovered in other excavations.

The Commentary to the *Jiuzhang suanshu* (Nine Chapters on Mathematical Arts) by Liu Hui (fl. 263) was the most influential text in the history of Chinese mathematics. In 1983 the *Suanshushu* manuscript (Mathematics Book), written on bamboo strips, was discovered in an ancient tomb dating back to the second century BCE at an excavation carried out in Hubei province. A preliminary study shows some similarities between this manuscript and the *Jiuzhang suanshu*. Liu Hui also wrote another, but much shorter text, the *Haidao suanjing* (Sea Island Mathematical Manual), using the right-angled triangle to measure distance and height. Before the time of Liu Hui, around the year AD 190, Xu Yue wrote his *Shushu jiyi* (Recording Omitted Items in Mathematics). Between AD 280 and 473 the *Sunzi suanjing* (Mathematical Manual of Sunzi) appeared. Of all the problems it contains, the one that has aroused most attention among modern scholars is that of the Remainder Theorem. The problem is to find a number, which when divided by three leaves a remainder two, when divided by five leaves a remainder three, and when divided by seven leaves a remainder two. The required answer is 23. Actually this problem involves three indefinite simultaneous linear equations of one unknown, and there is an infinite number of answers of which the required answer is the smallest. Historians of mathematics study this purely as a case of the Remainder Theorem. However, a more important application of this problem was recently revealed. It was found to be the method adopted by Chinese astronomers up to the eighth century to calculate and construct new calendars.

Several other mathematical texts were written in the following three centuries. One must note the evaluation of the ratio of the circumference to the diameter of a circle made by Zu Congzhi (429–500) and his son Zu Keng. They gave three different values, of which the most accurate was $3.1415925 < \pi < 3.1415926$. The method used by Zu Congzhi was described in his book, the *Zuishu*, which unfortunately is already lost. Chinese mathematics reached its golden age of development in the twelfth and the thirteenth centuries. During the twelfth century, mathematicians like Liu Yi and others could solve cubic equations numerically. Their writings are no longer extant, but fortunately we have the works of four great thirteenth-century mathematicians, namely Qin Jiushao, Li Zhi (1192–1279), Yang Hui (fl. 1261–1275), and Zhu Shijie (fl. ca. 1280–1303). The study of numerical solutions of equations of higher degrees is yet another of the characteristics of Chinese mathematics. Li Zhi also had a great influence in the development of mathematics in Japan.

The Chinese emperor regarded calendar-making as one of his duties that came with the mandate bestowed upon him from Heaven. The Chinese calendar took into account the apparent cycle of the sun and the cycle of the moon, both of which cannot be expressed in an exact number of days. The astronomer responsible for constructing a lunisolar calendar had to make accurate observations of the sun, the moon, and the planets, but however accurate his observations, his calendar would eventually, in just a matter of decades, go out of step with observations. In 1972 archeologists working at the site of a Han tomb at Linyi in modern Shandong province, discovered a calendar for the year 134 BCE. Throughout the history of China no less than one hundred calendars had been constructed, not to mention other unofficial calendars sometimes used in certain regions. The most renowned among the Chinese calendars were the *Dayanli* calendar completed by the Tang Tantric monk Yixing (683–727) in 727 and the *Shoushili* calendar prepared under the Mongols by Guo Shoujing(1231–1316) in 1280. They used the method of differences in mathematics to make their calculations. Accurate and new astronomical observations had to be made for the purpose of calendar making. New astronomical instruments were constructed for this purpose. Yixing, for example had to construct his own armillary sphere. The Song dynasty (960–1279) is remembered for the several large armillary spheres made for this purpose. The most famous was that made by Su Song (1020–1101). It was an armillary sphere driven by a water wheel using the principle of escapement.

In the early stages medicine and magic were indistinguishable from each other, as both were practiced by the shamans (*wu*). Shamans and doctors were together referred to as *wuyi* (shamans and doctors). During the Spring-and-Autumn Period (722–480 BCE) there were signs that physicians and shamans had already parted company. There was the celebrated physician Qin Yueren, better known as Bian Que (fl. 501 BCE), who was the counterpart of Hippocrates (465–370 BCE) in China. He was already acquainted with the four important diagnostic procedures used in Chinese medicine: observing external signs (*wang*), listening to sounds (*wen*), asking the patient's history (*wen*), and feeling the pulse (*qie*). These are sometimes referred to as looking, listening, asking, and touching. The earliest Chinese medical writing known to us until recently is the *Huangdi neijing* (The Yellow Emperor's Manual of Corporeal Medicine). Consisting of two parts, the book appears to have been written by several earlier unknown authors but took its final form during the second century BCE. Between the winter of 1973 and the spring of 1974 some valuable medical writings were discovered during the excavations at Mawangdui near the city of Changsha in modem Hunan province. The tomb where these writings were found dated back to the year 168 BCE and hence the medical writings concerned must have belonged to an earlier date. These are the two most ancient Chinese medical writings extant.

The earliest Chinese pharmacopoeia that we have is the *Shennong bencaojing* (Pharmacopoeia of the Heavenly Husbandman). We do not know its exact authorship and neither are we certain about when it was written, although the date could not be later than the second century. It sets a tradition followed by a long series of succeeding pharmacopoeias over a period of more than a thousand years. It mentions the *yin* or *yang* property and the indications of each medicinal substance, noting that some combinations of two or more of them are either beneficial or counterindicative. It divides all the 365 items of medicine that it contains into three categories. Those in the first category have the efficacy of nourishing or prolonging life; those in the second are, as a rule, nontoxic and can be used to restore the constitution of the patient; and those in the third are usually toxic or have side effects. The last category is used for combating diseases. Thus the *Shennong bencaojing* catered to the needs of both the physicians and the aspirants of longevity.

While the physicians had parted company with the shamans, some of the latter devoted their attention to prolonging the human life span. Some of the substances they ingested, such as mercuric sulfide, mica, licorice, and asparagus, are listed in the *Shennong bencaojing* pharmacopoeia. The search for the way to physical immortality probably began in China at least 2,500 years before our time. It is recorded that in the Warring States Period (480–221 BCE) someone presented an elixir to the prince Jingxiang wang in the State of Qu. Some modern writers attribute the first practice of alchemy in China to Zou Yan. Later on the story of the elixir told by the shamans got the fancy of the emperor Qin Shihuangdi, who made several attempts to procure an elixir for himself so that he could live and rule his empire to eternity. Another patron of the shamans was the emperor Han Wudi, who reigned about 133 BCE. It was then that the shamans talked about making gold as the first step toward the elixir. At about the same time, Liu An, the Prince of Huainan, compiled, with the help of a group of shamans and alchemists retained by him, the *Huainan wanbishu* (The Ten Thousand Infallible Arts of the Prince of Huainan). Tradition says that this book dealt mainly with alchemy, especially the making of gold, but unfortunately we no longer have the complete text, and the fragments of the book now left are only concerned with magic. In the following century Liu Xiang, who was said to have inherited this book, was commissioned by the emperor to make gold for the Treasury. His failure landed him in prison.

The earliest Daoist alchemical treatise that is still extant today was written by the alchemist Wei Boyang in the second century AD. Entitled *Cantongqi* (The Kinship of the Three), the text is very obscure, containing a number of alchemical terms with "hidden" meanings. The use of the system of the *Yijing* (Book of Changes) has contributed directly to the obscurity of the text of the *Cantongqi*. Alchemy gained popularity following the work of Wei Boyang. During the fourth century Ge Hong wrote his *Baopuzi neipian* (The Esoteric Chapters of the Solidarity Master), showing the great advancement made in alchemy since the time of Wei Boyang. Ge Hong was at the same time an accomplished physician. Other famous physicians who were also great alchemists after Ge Hong were Tao Hongjing (456–536), Sun Simo (?581–?682), and his disciple Meng Shen (621–718). For the next eight hundred years or so after Ge Hong, alchemy continued to flourish and many alchemical works were written. Most of these works are lost; those that survived are included in the present version of the *Daozang* (Daoist *Tripitaka*), a collection of 1464 Daoist works, only a small fraction of which deal with the subject of alchemy.

In many of their experiments the Chinese alchemists used the process of sublimation and of distillation. They often made use of the reaction-vessel, called *yaofu*. Many of the elixir recipes contained toxic ingredients such as mercury, arsenic, and lead. Hence such elixirs would be quite poisonous. Quite a number of Chinese emperors showed great interest in the elixir and some of them unwittingly perished. For example, the Jin emperor Aidi died in his very prime, aged only 25, as a result of his attempt to avoid growing old. The emperor Wenxuandi of Northern Qi, on the other hand, exercised more caution. When presented with the elixir he decided that the most opportune moment to test it would be on his death bed. At least three Tang emperors died as a result of taking the elixir. Political motives might be behind the early demise of some Chinese emperors, but the alchemists responsible were quickly punished for their failure. With the evidence so efficiently destroyed the full case is difficult to investigate.

There were probably many charlatans among the alchemists, who, when their elixirs brought about the early demise of unfortunate emperors, managed to escape before it became too late. However, there were also alchemists sincerely interested in their work who believed in the elixirs they made. So strong was their faith that many alchemists must themselves have fallen martyr to their own beliefs, or become victims to mistakes in following the obscure and contorted instructions of their predecessors. The most experienced or industrious experimenters were often the most enthusiastic believers, and in the end the surest victims. In this respect the elixir mania must have acted as an inhibiting factor to the progress of chemical knowledge in China.

Many Chinese alchemists were aware of the toxicity of their products. Some tried to neutralize the poison; some recommended only symptomatic treatment; some believed that the ill effects were only side effects associated with the elixir and as such should be completely ignored; some turned to the vegetable kingdom to look for suitable ingredients; and some turned away from the material elixir and practiced "physiological alchemy" (*neidan*) following a regime of meditation and breathing exercise. By the ninth century alchemy in China had already seen its best days. The alchemists gradually relied more and more on the vegetable kingdom for their raw material. Hence there was an alchemical work that included the term *bencao* (pharmacopoeia) in its title, namely the *Waidan bencao* (Pharmacopoeia of Operative Alchemy) by Cui Fang (fl. eleventh century). After the turn of the fourteenth century several books on elixir plants made their appearance. The Chinese alchemists seemed to have gone round one full circle back to the days of the ancient shamans. Alchemy merged again with the tradition of Chinese medicine set by the *Shennong bencaojing* pharmacopoeia.

Hence traditional Chinese medicine and alchemy arose from the same source. At first the shamans practiced both magic and medicine. About the sixth century BCE medicine and magic took different courses. Some shamans developed the art of prolonging human life and reached the conclusion that one had to make gold by artificial means as a first step to physical immortality. That was the beginning of alchemy. Alchemy maintained a close link with medicine, dealing only with different aspects of human life. Quite a number of alchemists were at the same time famous physicians, as in the case of Ge Hong, Tao Hongjing and Sun Simo. A preliminary study shows a close connection between alchemy and Chinese medicine in the similarities between the basic principles used in medical and elixir prescriptions. Medicine and alchemy borrowed from each other. For example, alchemical works are liberally quoted in the more important pharmacopoeias of later time such as in the *Bencao gangmu* (the Great Pharmacopoeia) written in 1596. Although the Chinese alchemists did not succeed in their quest for the elixir of immortality, they played a part as the iatrochemist in Chinese medicine. Another by-product of their experiments was that they stumbled upon gunpowder when some of them caused an accident when they did not exercise sufficient caution in using saltpeter and sulfur, allowing some carbon impurities to get in from the charcoal or wood that they used as fuel.

There was early intercultural transmission of scientific and technological knowledge between China and her neighbors, especially west Asia, before the Christian era. Buddhism first came to China in the second century. Scientific knowledge followed the wakes of missionary and pilgrimage activities. During the eighth century Indian monks and calendar experts, Nestorians, Arab merchants, Korean and Japanese students, and others lived together in the Tang capital Changan (modern Xian) which had a population estimated to be over one million. Mutual exchange of knowledge was inevitable. Muslim astronomers found employment in the astronomical bureau in thirteenth-century China and some Chinese astronomers could have been sent by Hulagu Khan to work in the observatory in Maragha under its director Naṣir al-Dīn al-Ṭūsī (1201–1273). The Renaissance in Europe was influenced in no small measure by Arabic and Indian learning, but Europe also acquired knowledge of Chinese science and technology through the Arabs and the invasion of the Mongols during the thirteenth century. Since the seventeenth century science in Europe has advanced by leaps and bounds while Chinese traditional science remained in a state of stagnation. Toward the end of the sixteenth century the Jesuits arrived in China, using science as a tool to promote their mission. Science from Europe, particularly mathematics and astronomy, demonstrated its superiority to traditional science. In the latter half of the nineteenth century modern science came to China from Europe and North America, and by the twentieth century China had joined the world in the common enterprise of modern science.

Science in Japan

Nakayama Shigeru

The history of Japanese science, technology, and medicine is divided into two distinctly different periods, traditional and modern, the dividing line being the late nineteenth century when Japan started wholesale Westernization. Since the subject matter of modern Japanese development is not much different from Western development, this article deals only with the traditional and transitional periods.

The Traditional Period

The written history of Japan started approximately in the sixth century when Chinese writing, culture, and institutions were brought in by Korean immigrants. Technical professions began in Japan with the immigration of Korean experts in the sixth to eighth centuries. The immigrants slowly settled into Japanese society, and the Chinese view of nature gradually began to take root in Japan. Thus, traditional Japanese science, technology, and medicine are basically a ramification of Chinese paradigms. In the following, we shall elucidate the points of Japanese deviation from the Chinese prototype.

Whereas the Western world of learning had an integral structure of trivium, quadrivium, scientia, or Wissenschaft, the corresponding Chinese world of learning was thoroughly structured with Confucian classics at the center of a structured bureaucracy. Scientific subjects were of peripheral importance, with mathematics and calligraphy being necessary for the civil service examination system, and astronomy, medicine, and architecture being fields with their own branch offices in the bureaucracy. The small replica of the Chinese world of learning and bureaucracy was created during the eighth century in Japan.

In principle, the Japanese Astronomical Bureau was a miniature reproduction of the Chinese bureaucracy, but a closer look reveals significant remodeling to meet local requirements. While in China the astronomical organizations that computed the ephemerides and observed celestial phenomena had important astronomical bureaux, in Japan all of these activities were subsumed under the single *Yinyang* Board, the name of which indicates a clear priority for divination. After that time, the Japanese *Yinyang* art developed into a complex of divination techniques.

Given a Chinese manual of calendrical science from which to determine basic parameters and computational procedures, there was little that local talent or preference could add. On the other hand, when unforeseen and ominous celestial phenomena were observed they had to be interpreted without delay. Thus in astrology the Japanese were thrown upon their own resources, and the practical application of imported knowledge was valued over basic theory.

It was not the regularities of the eternal truths of mathematical astronomy but the unforeseeable omens of the astrologers that attracted attention in Japan. Whereas abstraction and involved theoretical argument were by no means rare in Chinese science, they were vastly less important in Japan.

As the Chinese influence became less noticeable from the tenth century on, the bureaucracy also diminished in strength. Throughout the medieval period, it was in family businesses rather than the government bureaucracy where those with talent enough to pass civil service examinations were employed. Kinship ties returned to their former importance.

Because they were separated from the Asian continent, the Japanese were not totally overwhelmed by Chinese influence. Japanese society was much less bureaucratic than that of China or Korea, and as a result was more able to respond to the incoming intellectual flux. The Japanese received Chinese influence selectively to meet local needs.

Meanwhile, Buddhism reached Japan from India by way of China and Korea. Although enthusiasm for Buddhism waned somewhat in China and Korea, the Japanese have retained it throughout history. In medieval times, Buddhist monks competed with official astronomers in predicting eclipses by use of their *Fu-tian* calendar. In the paradigmatic treatise of Japanese divination art, *Sukuyōkyō*, excerpts from classics of Tantric Buddhism were mixed side by side with Chinese Daoist texts. In Japanese medical classics, certain Buddhist recipes were mixed and preserved. This reflects Japanese intellectual pluralism.

The Platonic conviction that eternal patterns underlie the flux of nature is so central to the Western tradition that it might seem that no science is possible without it. Nevertheless, although Chinese science assumed that regularities were there for the finding they believed that the ultimate texture of reality was too subtle to be fully measured or comprehended by empirical investigation. The Japanese paid even less attention to the general while showing an even keener curiosity about the particular and the evanescent.

This attitude may be seen in the career of Shibukawa Harumi (1639–1715), the first official astronomer to the Japanese Shogun. In the preface to his early treatise *Shunju jutsureki* (Discussions on the Calendar Reflected in the Spring and Autumn Annals, the oldest Chinese chronicle), he stated that astronomers had rigidly maintained that when Confucius dated the events in his *Annals of the Spring and Autumn Era* he made conventional use of the current calendar with little care for its astronomical meaning, so that the dates were not very reliable. "This error is due to the Chinese commitment to mathematical astronomy, so that they do not admit that extraordinary events happened in the heavens. Extraordinary phenomena do in fact take place in the heavens. We should therefore not doubt the authenticity of [Confucius'] sacred writing brush."

Once admitting, as Shibukawa did, that regular motion was too limited an assumption, one could easily conceive such notions as that astronomical parameters could vary from century to century. In the official Chinese calendar in the thirteenth century and earlier, the discrepancy between ancient records and recent observations was explained by a secular variation in tropical year length. Shibukawa revived this variation in the Japanese calendar, and Asada Goryu (1734–1799) extended it to other basic parameters to account for Western as well as Eastern observations then available to him.

The variation terms used in Japanese astronomy were too large to survive empirical testing, and were eventually discarded. It is, however, noteworthy that their cosmological outlook was so flexible that they accepted the notion that all astronomical parameters were subject to change and the whole universe was changeable, while in the West the Aristotelian notion of an unalterable universe was followed rigorously, and irregular motions in the sky were inconceivable.

In early Chinese history, higher mathematics was always associated with calendrical science, in terms of solving indeterminate equations for ascertaining the time of grand conjunction. In Japan, interest in mathematics was also raised in connection with calendrical science in the seventeenth century, and was soon developed as mathematical puzzles to be enjoyed by hobbyists, in the same way as there were enthusiasts of flower arrangement and the tea ceremony. This form of Japanese mathematics called *wasan* was mostly viewed as a popular art. It was not considered a scholarly activity.

I shall not attempt a conceptually rigorous definition of scholarship and hobby here, but merely note that scholarship is usually thought to have some public function while hobbies are regarded as private indulgences which may or may not have significant social value. While art does not require legitimation, scholarship does, and there has to be some basis on which to differentiate one from the other. Some kind of legitimation was found to be necessary for mathematicians and one way of doing so was to invite Confucian scholars to write prefaces to their books, in effect borrowing Confucianism's prestige.

The Japanese mathematicians were generally socially marginal curiosity seekers. During the Tokugawa period, mathematics was not formally recognized by the government. The Tokugawa mathematical tradition existed entirely in the private sector and had no official support. Whenever scholars demand legitimacy from society, they display a sense of mission which reinforces their commitment. This sense of mission is associated with the rise of professions, but the Japanese mathematicians cannot be called professionals.

With the use of mathematical rods, Chinese mathematics developed quite sophisticated algebraic formulae. Building on the Chinese tradition, a significant development was made by Japanese mathematicians to develop numerical algebra into symbolic algebra by writing on paper and making it possible to obtain a more general treatment. Curiously enough, the formulae of *wasan* resemble modern algebraic formulae but they are written vertically. However, due to stylistic differences, there was no intercourse between Japanese and Western developments in mathematics.

Wasan mathematics developed a unique custom in the formative period consisting of the posting of mathematical problems called *idai* (bequeathed questions). A mathematician would post scores of problems of several kinds at the end of a book and then publish it. Another mathematician would post answers to these problems and present his own in the same manner. According to convention, yet a third mathematician would post answers to these problems and issue his own in relay fashion. This mechanism of *idai* caused a chain reaction and greatly stimulated the formation of *wasan* groups. The tradition began with 12 problems from the *Shinpen Jinkoki* published in 1641. A succession of mathematical lineages soon developed and reached their peak during the life of Seki Kowa (Takakazu). Practically all of the important problems in the history of *wasan* date from the period above.

Another feature of *wasan* development was the *sangaku* (mathematical tablet) form that came in the later phase. These tablets included both problems and answers and were dedicated at shrines. The best mathematicians made their accomplishments known through books, but it was largely the custom of *sangaku* which supported the activities of the *wasan* enthusiasts. That *wasan* was a hobby which cost money to pursue is best shown by the elegant diagrams which embellished such work. In fact, the offering of *sangaku* had a strong attraction as it showed a desire to keep their work on more or less permanent view.

Chinese natural philosophy developed certain abstract concepts in ancient times. The *qi* concept, one of the basic ideas which appeared in the *Huangdii Neijing* (The Yellow Emperor's Internal Classic), the earliest Chinese medical compilation, is today interpreted as something akin to energy which is imponderable but permeates and circulates in the macro- as well as the microcosmos. When the *qi* concept was introduced into Japan, medical doctors tended to interpret it as materialistic, unable to comprehend such a highly abstract concept of imponderable energy. Given the difficulty of understanding the subtleties of Chinese philosophical speculation, the Japanese physicians adopted a more simplistic, pragmatic, and empirical approach.

For instance, certain tumors and internal swellings were thought to be stagnated or congealed *qi*. Indeed, the seventeenth-century Japanese physician, Goto Gonzan, attempted to explain the cause of all medical disorders by stagnation of this kind.

Traditional Chinese medicine was concerned primarily with function and only secondarily with tissues and organs. Internal disorders were never local in Chinese medicine. The major physiological and pathological theory was to regulate energy flow internally and externally between the micro- and macrocosmos, so that holistic diagnoses could be applied. They depended heavily on pulse diagnosis as the indication of energy flow. More materialistic Japanese physicians such as Yoshimasu Todo (1701–1773), however, developed stomach and abdomen diagnosis by touching the location of disease, rejecting the traditional pulse diagnosis. Yoshimasu, the foremost figure of the radically critical school, declared that the *qi* of the universe had nothing to do with medicine. This group was prepared to take a position much closer to that of the solidists in the West than had been possible in Japan at an earlier time. Functional analysis lost its importance, and the physical organs could be studied for their own sake. This was nothing less than a gestalt change.

In accordance with the extension of the materialistic inclination of Japanese physicians, they were interested in anatomy and found that Western schema were a great deal more accurate than the Chinese anatomical charts. In mathematical astronomy and calendrical science, Western superiority in accuracy was quickly recognized. In medicine, there is good reason to doubt that there was any difference in therapeutic efficacy before the late nineteenth century. It is above all in the comparison of anatomical charts that the strength of Western medicine would be apparent.

In the second half of the eighteenth century, Sugita Genpaku took up the study of anatomy because it seemed the most tangible, and therefore the most comprehensible, part of Dutch medicine. Following the solidist breakthrough, Sugita's successors in medicine studied physics and chemistry and opened up the world of modern science. The Copernican influence was minor by comparison, because the Japanese cosmos had not been defined by religious authority. The impact of anatomy challenged the energetic and functional commitments not only of medicine but also of natural philosophy. Its effect was bound to be revolutionary.

The learned treatises of the Chinese and Japanese medical traditions lacked terminology not only for brain function but also for mental processes. It was only later scholars with considerable knowledge of Western anatomy, such as Sugita Genpaku, who could abandon the Chinese tradition entirely and display as much anatomical interest in the brain as in the viscera.

Materia medica and natural history books were brought first from China and later from Holland. The first thing for a Japanese natural historian to do was to identify local species with imported Chinese books. This identification work endowed Japanese scholars with new insights into comparative study. While the original Chinese texts were intended for the collection of medicinal herbs for pharmaceutical purposes, the Japanese developed this study into a natural history of visual observations for identification.

In feudal Japan, all occupations were hereditary. The post of official astronomer to the Shogun was created to recognize the personal achievement of Shibukawa Harumi, and was passed down to his descendants. It had no significance beyond the technical, and thus was of no interest to the generalists. Those who held technical posts of this kind, such as medical doctors and Confucian scholars, were from the beginning separate from the general samurai bureaucracy.

When the official astronomer and his subordinates were compiling the ephemerides, Confucian scholars were not consulted. The astronomers had inherited the tradition through their family line since medieval times. At the time of a calendar reform, once every hundred years for a Chinese-type lunisolar calendar, the descendants were usually incapable of innovative work, but able to perform the routine calculations necessary for the distribution of the yearly calendar according to a given formula. In most such cases, talented astronomers in the private sector were appointed to the post of official astronomer. Beginning with Shibukawa Harumi, the number of such hereditary official astronomers amounted to seven families toward the end of Shogunate rule.

Often professionals were encouraged to adopt talented young boys rather than their own sons. Under the rules of samurai society in the Tokugawa period, only the first son was entitled to inherit the family stipend. Later born sons were adopted by other sonless samurai families or left to find ways of obtaining their livelihood themselves. For either, they had to show their ability by studying hard. These younger sons would provide Japan with a pool of talented professionals.

In Japan, there was no social or political reason for a single philosophical orthodoxy. Although nominally based on the centralized Chinese model, Japanese feudal society remained multifocal, consisting of the Shogunate and a hundred fiefs. Thus freedom to choose between several paradigms seems to have been as desirable as the search for a unitary principle was in China.

In China and Korea, the official character of science and learning was rigidly maintained by adherence to the civil service examination system. The Japanese imitated the Chinese bureaucracy for only a short time in the seventh and eighth centuries, and subsequently this failed to take root in Japanese society. It was only in the last quarter of the nineteenth century with the establishment of a modern government system that a centralized bureaucracy complete with civil service examinations emerged. During the Tokugawa period, it was centralized feudalism, in which the Tokugawa government had overwhelming power but in which each fief government was able to maintain a degree of autonomy by having their own independent schools, bureaucracy, and policies, in competition with other fiefs.

The Tokugawa Shogunate wanted to instigate centralized civil and medical service examinations but was unable to impose such a system on the fief governments. As a result, there was no rigidly maintained state orthodoxy of science and learning, although the exclusion of Christian tenets was executed with considerable harshness. In short, the Japanese have enjoyed the merits of multiculturalism. It is not the kind of multiculturalism which involves the peaceful coexistence of different races in one society but rather signifies the acceptance of different cultures by largely one single group.

Science and learning had been substantially privatized and able to respond to imported foreign ideas by the late eighteenth and early nineteenth centuries. Even during the semiseclusion period under the Tokugawa Shogunate, the activity of Dutch learning was practiced by city intellectuals, medical doctors, and merchants in the private sector. Only after the Western threat of invasion became substantially felt in the nineteenth century, particularly after the news of the Opium War and the arrival of Commodore Perry's gunboats in 1853, did the knowledge of Western learning become the business of the public sector. Samurai became interested in Western military technology, finally overthrowing the feudal government and replacing it with a centralized state.

From the seventeenth century onward, when Western knowledge began to exert claims of its own against the backdrop of Chinese learning, Japanese thinkers were critically attentive. As soon as they were convinced that European technical knowledge was superior, the Japanese switched to the new paradigm with remarkable speed. They quickly modified their attitudes and oriented themselves toward achieving certain desirable goals that had been reached in the West. For the Chinese, the encounter with European ideas was traumatic; to accept them was to reject traditional values, and to reject them would leave them with no defense against dismemberment by Western powers. For the Japanese it was merely the appearance of another paradigm to be accepted in their eclectic manner. The Japanese were flexible enough to accept the Western paradigm without strong resistance.

The Transitional Period

Let us now turn to the occupational support groups who successively played a leading role in the introduction of Western science to Japan.

Astronomers and Interpreters

The adoption of Western "barbarian" astronomy in the seventeenth century by the Chinese dismayed conservative elements in Japan. However, it did not promote the desire in others for a similar change in the Japanese calendar, which was modeled on that of the ancient Chinese. As has been mentioned, the eighth Shogun Yoshimune and his court astronomers recognized the superiority of Western over Chinese astronomy, but astronomers were primarily government bureaucrats or technicians whose scope remained limited to their assigned duties of drawing up the official calendar. Their interest in Western science was limited to the precision of astronomical data and methods of calculation, and they made no attempt to jeopardize their hereditary posts by entertaining revolutionary paradigms such as were developing in Europe at that time.

Professional interpreters at Nagasaki were the most well versed in the Dutch language, through which they must have become acquainted with the concepts of Western science. But again, they were also hereditary government officials who remained within the boundaries of their duty of faithful translation and nothing more. Neither official astronomers nor interpreters published their work for general audiences.

Independent Scholars and Physicians

From the late eighteenth century on, a sizeable number of Dutch books containing the term *Natuurkunde* (study of nature) found their way into the country and aroused the interest of various independent scholars in the private sector who set about translating them, although their foreign language skills were much inferior to those of the Nagasaki interpreters. The majority of these "Dutch scholars", as they came to be called, were avant-garde physicians who were primarily freelancers, with no strict subordinative links to the governing elite or subsequent interest in maintaining an existing *status quo*.

Thus they were not inhibited in stepping out of their line of work and were free to extend their interests to anything Western except perhaps the Christian doctrine. Astronomy was the first area in which people sensed that the West was superior, but the notion that the West was superior in other fields of scientific endeavor first spread among these independent physicians.

As they inched their way through Dutch texts, they realized that Western science was more than a variant of the natural history line of their own tradition. As they saw it, its essence could be translated as *kyuri* (literally, investigating the principles of things, a new Confucian term, or "natural philosophy", being a systematic and fundamental investigation and consideration of the nature of things). Thus, although at first there was no clearly established tradition for the term, *kyuri* was later to become the most common, and given the vocabulary of the period, it was an informative translation. In recognizing an enquiry into principles at the bottom of such traditional practical studies as medicine and calendar-making, in becoming aware, i.e., of natural philosophy or physics, they also grasped the hierarchical structure of modern science, from basic to applied. Above and beyond the culturally bound achievements of Western science, they seemed to have sensed that it contained a revolutionary paradigm, since the belief in underlying laws in Nature which could be formulated was weak in Japanese traditional thought. This was in marked contrast to the official astronomers who looked upon science as something that could be handled at the technical level and assigned it only a supplementary role.

The physicians recognized the importance of physics and chemistry as the basis of medical work, and several founded schools for the teaching of Western medicine. Their students, during their apprenticeship and internship days, moved from one school to another in major medical centers like Nagasaki, Osaka, Kyoto, and Edo (Tokyo), and played a role of diffusing knowledge of Western culture as well as medicine. While some physicians remained in the practice of medicine, others turned to the teaching of the Dutch language and even the discussion of international knowledge and politics and also founded schools for such. Thus, the cultural influence of the physicians was more considerable than that of the astronomers who limited their activities to the translation of technical works.

But these support groups were by no means adequate preparation for the reception of contemporary science. The Dutch scholars were still only amateur supporters of uninstitutionalized paradigms, comparable in this respect to gentleman members of the Royal Society. Their schools were few and regarded on the whole as avant-garde. Had they flourished in the seventeenth and eighteenth centuries their work might have had greater consequences. By the mid-nineteenth century, however, modern science in the West had entered the systematically structured world of the university and reached new advanced levels. Reception of learning that was now systematically pursued in Europe within the structures of the university required the creation of an institutional system. It had to be met not by self-taught amateurs but with professional scientists who had received a modern systematic education. These early scholars were not aware of the institutionalized aspect of Western science up until the mid-nineteenth century, remaining bookish translators of the *kyuri*, paradigmatic aspect of Western science.

Samurai

The Opium War between the Chinese and Western colonialists created concern among the samurai cognoscenti, but Commodore Perry's visit to Japan in 1853 and the subsequent threat of war caused all samurai to realize that the Westerners' science was needed for national defense. As a result, young samurai flocked to the schools of Western learning established by physicians. As they were traditionally the ruling class, and in time of war the warriors, it was natural that samurai interest in Western science and technology training was based on more real and pressing needs than reception of and support for particular scholarly paradigms.

First, they tried to learn the Western art of manufacturing firearms, but soon realized that it was impossible to catch up and compete with Western forces by a crash project of manufacturing cannons. They could purchase hardware, but what was really needed was the software of Western military training and tactics. Moreover, the acquisition of Western military discipline was one of the contributing factors in the overthrow of the ruling Tokugawa family by anti-Tokugawa samurai and the subsequent establishment of the Meiji government in 1868. The samurai recognition of Western science was therefore political rather than cultural.

After the revolution, convinced that Western scientific learning was essential, the ruling class set out to disseminate their conviction through the establishment of an educational infrastructure. With Meiji effort and initiative, modern science was fully assimilated in a wholesale introduction through governmental institutions rather than a piecemeal cultural infiltration, as in the previous era, and modern scientific and technological professions became the artificial creation of the new Western-oriented government.

The main practitioners of these new professions were former samurai. In the past they had received hereditary family stipends in exchange for their loyalty to the feudal powers, the Shogunate or local feudatories. But in the 1870s, efforts were made by the Meiji government to curtail the inherited family stipends of the samurai class as a step toward social modernization. While other classes, farmers, artisans, and merchants, could continue to be engaged in their inherited vocations, samurai completely lost their guaranteed source of income. Consequently, they had to find new ways of living independently. Since the samurai could not compete with other classes in the fields of traditional occupations like agriculture and medicine, science and technology was one of these new fields into which jobless samurai were attracted and invited. Almost all of the early graduates of the engineering colleges were samurai. Even as late as 1890, the percentages of Imperial University samurai graduates in engineering and science were 86 and 80, respectively.

Thus, Japanese modern science and technology professions were, in the beginning of their formation, very much "samurai-spirited." The samurai were the class long accustomed by mental habit to think in terms of public affairs and by behavior patterns to play the game of public office. Unlike the European pattern in which science and technology training was one experience of the rising bourgeoisie, the new Japanese scientific and technological professions in the last quarter of the nineteenth century were dominated by the proud old samurai class, comprising the top 5% of the total population.

Table 1 summarizes the sequence of support groups' thrust toward Westernization in Japan.

In the first stage, Western science was confined merely to technical knowledge by technicians in the government sector. In the second, Western knowledge in the form of its revolutionary paradigms was garnered by vanguard physicians but they were alienated from the central power structure. Only in the third stage was Western science fully admitted into the power structure, and after the Meiji Restoration, through institutionalization, it was recognized as a most legitimate study for the youth of the samurai class.

The modernist samurai leadership soon established a policy of Westernization in which the establishment of Western-style educational institutions occupied a central position. During the 1870s and 1880s greater emphasis was placed on science and technology in the Japanese educational curriculum, from elementary school to university level, than in any other nation. For instance, mathematics and science occupied about one-third of the school curriculum at the lower grades (first 4 years) and two-thirds at the upper grades of the 8-year elementary education, though due to the shortage of qualified teachers available, it is somewhat questionable to what extent these ideal plans were put into practice. At the tertiary level too, the emphasis on science and technology was evident in the high percentages of graduates in scientific disciplines of Tokyo University (85% in the 1880s). In Europe in the nineteenth century, the voluntary activities of scientific or professional societies usually preceded their inclusion into the university curriculum. In the case of Meiji Japan, however, and as is generally the case when a foreign discipline is artificially transplanted under state sponsorship, this process was reversed. Tokyo University was established as an indispensable part of the modern technocratic bureaucracy. Graduates in science and technology were mostly samurai descendants who were accustomed to working in the public sector and inspired in technocratic policy-making, rather than by engineering apprenticeship of the traditional artisan class. They were adaptable in "public science" initiated by the government, which was indispensable for the operation of a modern state, in areas such as geographical and geological surveys, weights and measures, meteorological observations, sanitation, printing, telegraph and telephone system, military works, railways, and surveys of national resources.

In addition, the government participated in private entrepreneurial activities, constructed and managed pilot plants, and guided and subsidized new kinds of industries. Their enterprises were, however, from the beginning exposed to financial risk. Many of the projects of the Ministry of Technology eventually proved to be too far ahead of their times, as they intended to introduce the technology of an industrialized society into a preindustrial environment. For instance, their railway construction and textile mill enterprises were economically unsuccessful at the time.

Some of the samurai experiments in the public sector were successfully transferred into the private sector, where they were transformed to the market-oriented "private science" of the traditional artisan,

S

Science in Japan. Table 1 The sequence of support groups' thrust toward Westernization in Japan

Occupation	Astronomers and interpreters	Physicians	Samurai
Leading century period	Eighteenth century	Late eighteenth to early nineteenth century	Mid-nineteenth century
Interest	Technical	Cultural	Political
Status	Technicians	Freelancers	Planners and administrators
Role	Referees of superiority	Diffusion and popularization	Institutionalization

such as Toyota Sakichi, the founder of Toyota Motors. The privatization of science phase was finally completed after World War II.

Science in Korea

Jeon Sang-Woon

Korea is a nation with 5,000 years of history. Located on the periphery of East Asian civilization, it was greatly influenced by China. However, Koreans have developed a culture and tradition independent from that of the Chinese. At the same time, the history of Korean science can be regarded as a branch or an adaptation of Chinese traditional sciences, although, in most cases, Chinese sciences and technology were not adopted in their original form.

Korea had its own unique Paleolithic Age some 500,000 years ago. Some of the tools of the Paleolithic Age found in Korea are not found in any other parts of East Asia. The Korean people of the Neolithic Age differed from the Chinese people in that they belonged to what is often called the northern race. Unlike the lineage from the Paleolithic Age, the lineage from the Neolithic Age has continued to survive down to the formation of the Korean people. Elements of the Neolithic Age combined with each other and then with elements of the Bronze Age in the formation of the Korean people.

The highly developed Bronze Age culture in Korea around the year 1000 BCE was influenced by a northern culture that was different from the Chinese scientific one. Chinese science and technology were adopted on the basis of an indigenous technological tradition. Koreans have always attempted to reshape Chinese technology whenever it was introduced into Korea to make it uniquely Korean and to develop new technology.

Typical examples of this kind of endeavor are found in the bronze sword and mirror. The lute-shaped bronze sword and Korean-style sword and the bronze mirror which has a thick lined design with two knobs, and the thin lined mirror, are uniquely Korean bronze instruments. These instruments reveal unique design and casting skills indicating the highly developed state of bronze-making technology. This technology in Korea has a different lineage from that of the Chinese. This is found in the chemical make-up of the bronze instruments themselves. Even the earliest bronzes found in Korea there are alloys of zinc and bronze.

Koreans demonstrated a special creativity by developing an advanced skill in bronze production and alloy making. Bronze makers in Korea used both mud molds and stone molds to produce bronze items. Stone molds, which are frequently found in Korea, are very seldom discovered in China.

Casting technology utilizing stone molds led to the development of a unique iron ax casting system that developed from the third century BCE in Korea. In this period iron axes were produced in massive quantities by using stone molds. It is a commonly held belief that the Iron Age in Korea started in the fifth to fourth centuries BCE with the introduction of Chinese iron culture. The mass production of iron axes can be explained as the creation of a new technology, which would not have been possible if there had not been an autonomous tradition of iron technology in Korea.

The development in iron-casting technology brought about a dramatic increase in agricultural production on the basis of the mass production of farm instruments. Iron ingots of the late Iron Age found in the southern regions of the Korean peninsula are unique symbols of power and wealth. Iron ingots developed by Koreans spread to Japan, setting in motion the development of an iron culture there.

The widespread use of iron brought about new kinds of earthenware. Kaya culture (or Kimhae culture) of the region produced hardened quality earthenware produced through the combination of the technology of the indigenous people of the area (who were known for their designs which lacked ideogrammatic characters) and Chinese ashen-earthenware skills.

Other regions on the Korean peninsula, such as Koguryo, Paekche, and Silla, were also developing a technological culture. The people of Koguryo, Silla, and Paekche each constructed their tombs in unique ways. The painters of the Koguryo tombs painted their walls with individual and powerful lines and colors. The many kinds of pure gold objects discovered in kings' tombs, with their distinctive designs and refined inscriptions, testify to what seems to have been a highly refined manufacturing technology.

Besides those kinds of technical cultural traditions, several examples of scientific inquiry are known to have been written in the Three Kingdoms period (first century BCE–seventh century AD). Among the most outstanding are the developments in astronomy and medicine. Records indicate that Koguryo had maps of stars in the sky inscribed on stones, and a special astronomic observatory. The paintings of the stars found in a mural of Koguryo support this likelihood. Paekche also had astronomical observatories, and special calendrical specialists were appointed in the sixth century.

The Ch'omsongdae observatory in Kyongju is symbolic of the astronomical enterprise of the Three Kingdom period of Korea. Ch'omsongdae, a stone brick edifice, built in AD 647, is the oldest surviving astronomical observatory. The delicate aesthetic lines that characterize Ch'omsongdae are a symbol of the Korean sense of beauty. Records of astronomic observations dating from the Silla period are indications of very active institutionalized astronomical observation in that period. Astronomers in Silla learned calendrical studies from the Chinese, but were not content with just learning or copying from them. They endeavored to develop their own kind of astronomy. Ch'omsongdae is a valuable part of the heritage of their efforts.

Although actual records of medical prescriptions for long life and for the curing of diseases are scanty, they enable us to picture the systematic herbal medicine practiced in the period.

The period of Unified Silla is best represented by the great quantity of surviving remnants and records. Korea achieved a high level of creative development in science and technology in this period.

The Sokkuram grotto and the Darani scripture, among others, are representative of the achievements of Silla science and technology. The grotto, the most highly regarded edifice left by the craftsmen of Silla in the eighth century, is seen as the highest point in traditional architecture because of its geometric design and daring construction skills. There is no doubt that the Sokkuram grotto was a copy of a rock cave temple in China. However, while the Chinese edifice was built into a natural rock cave, the Sokkuram grotto is an artificial stone cave created on the basis of a harmony of various compositions including circles, spheres, triangles, hexagons, and octagons.

Silla master craftsmen also produced a number of beautiful bells. They successfully combined ancient Chinese bells and tinkle-bells in creating a unique Silla style. A special feature of the Silla bells is found in the dragon shaped hooks for hanging them. Historical records assert that Silla's craftsmen produced an alloy of bronze combined with copper, tin, and lead for a better sound. This was found to be true in a chemical analysis. The Chinese naturalist, Li Shizhen, wrote in his *Bencao Gangmu* that "Persian bronze is good for making mirrors and Silla bronze for making bells." The bell preserved in the Kyongju National Museum was made in 771. It has a height of 3.3 m. Its solemnity and the arrangement of its design patterns are typical of Silla bells.

Master craftsmen of Silla began developing wood print type in the early part of the eighth century. The scroll of Darani scripture found in 1966 was assessed to be a wood type print on white hammered paper produced between 705 and 751. This makes it the oldest surviving printed material in the world. On the basis of surviving evidence, this would prove that printing technology was invented in Korea prior to its development in China. Whatever the merits of this claim are, the fact that Silla technology had developed, in the eighth century, to the level of producing wood type print, is a significant demonstration of its technology. It indicates that the gap between the level of technology in China and Silla was not very wide.

The science and technology of Koryo developed on the basis of the achievements of the sciences and technology in Silla. They were also greatly influenced by the Sung and Yuan dynasties in China, and there are signs of the indirect influence of Islamic scientific and technological culture. The representative achievements of science and technology in Koryo are the development of wood block printing, the invention of bronze type printing technology, and the development of Koryo celadon.

Wood block printing in Koryo developed as a result of the aristocratic interest in print copies of calligraphy in pine wood blocks. It was also stimulated by a religious motivation. Buddhist scripts were made into wood type in order to draw on the power of Buddha in the struggle against the Mongol invasion. Eighty Thousand Scriptures, the world's largest and oldest surviving wood block printing set known, was also produced out of this motivation. The printing of the Eighty Thousand Scriptures is regarded as the highest level of technology in wood block printing.

The invention of a bronze type printing system was created from a totally different motivation. Koryo, having less demand for books than China, could not maintain the enormous amount of wood blocks, time, and labor to produce a variety of kinds of books. Bronze type was invented as a solution to this problem.

Ceramic type printing was invented by Bi Sheng in the China of the eleventh century. However, a metal type printing system was not established even by the fourteenth-century because of the difficulties in casting and the ink and paper needed for metal type printing. However, all these were possible with the science and technology available in Koryo. There, craftsmen knew of the technique of producing sand molds to make bronze print type, and were already producing oil ink suitable for printing with metal type and good quality paper. Because of this, the master craftsmen of Koryo were able to invent bronze type from wood type.

The central element in making bronze type was making sand molds. This was one of the greatest contributions in the development of printing technology. It may have been developed from the accumulated knowledge from production of various bronze vessels and casting of the grand bells.

The craftsmen of Koryo were successful in developing their skills for making celadon. They also adopted the inlaying method, which until that time had only been used in metal ornament making, for celadon making. This illustrates that, while Koryo celadon skills were adopted from Sung China they were never a simple copying of the Sung products.

Astronomy and herbal medicine were also two of the central pillars of science in Koryo as in the previous dynasties. Koryo scientists also developed geography. Major efforts in astronomy in the Koryo period were in observational astronomy and in calendar making. Official records of astronomical observations contain records of observation over 475 years. Among the records, there is a record of 132 occasions of an eclipse of the sun. This is on a par with the astronomic records of Islamic astronomers. There are also notable observations of sunspots.

A systematic foundation of herbal medicine in Korea was established from the sixth to the seventh centuries at the height of the Three Kingdom period. It came as a combination of traditional medicinal prescriptions and the influence of medical theories from China. A system was developed for utilizing herbs found in Korea. *Bencao jingjizhu* (The Shennong Pharmacopoeia with Collected Annotations) written by Dao Hungzhing contains 11 medicinal herbs that originate form Korea. And *Ishimpō* (Tamba no Yasayori's Collected Prescriptions), a famous medicinal book in tenth century Japan, contains various quotations of prescriptions from medical texts from Paekche and Silla. By the ninth century, 22 kinds of medicinal herbs originating in Korea were recorded in the medicinal texts used in China and Japan. A national medical school was established in the tenth century, and national examinations for medical practitioners were introduced. In the twelfth and thirteenth centuries, Sung medical science was introduced into Korea, while native prescriptions of local medicines emerged in Koryo in the form of three volumes entitled *Hyangyak kuguppang* (First-aid Measures with Local Medicines). This represented the first medical text describing herbal medicinal practice in the Koryo period.

In the early period of the Choson dynasty, efforts to create an independent culture brought about a forceful development of science and technology. In 1402, King Taejong proceeded with the development of bronze type print despite strong opposition from high ranking government officials. However, the books printed with the newly developed type (*kemi*) were not of better quality than the books printed with wood type. Furthermore, it resulted in lower efficiency in printing one kind of book, and it did not bring about any improvements in cost and labor productivity. It was a low efficiency technology. However, this project provided the basis for greater improvements when the succeeding king adopted it as a state-funded program. As a result Choson type printing developed to a state of perfection.

Achievements in science and technology reached their highest point during the King Sejong period, which is regarded as the golden age of Korean traditional science. The invention of the rain gauge is one of its achievements. Rain measuring instruments and watermarks were developed between 1441 and 1442, enabling the scientific measurement of rainfall. The invention of a cylindrical rain gauge resulted from efforts to obtain a precise measure. As a result the scientists in the court of King Sejong were able to develop a scientific method for the quantitative measurement of natural phenomena. Government officials maintained the measurement and recording of rainfall throughout the country, utilizing a highly systematic method, for over 400 years.

New astronomical observatories were built during the reign of King Sejong. The great equatorial torquetrum observation platform built in Kyongbok Palace contains a torquetrum, armillary clock, armillary sphere, gnomon, direction markers, an automatic striking clepsydra, a jade clepsydra, and various other kinds of sundials. In order to construct these astronomical observatories, which took 7 years to complete, King Sejong sent mathematicians, astronomers, and technicians to China to study astronomical observational instruments. Scientists designed an astronomical instrument that was modeled on the Guo Shoujing system of the Yuan dynasty in China. However, major aspects of the instrument were modified to reflect Korean characteristics. The astronomical observatory built through such a process was the largest of its kind and among the best equipped in the fifteenth century.

Astronomers of the King Sejong period developed an independent calendar on the basis of their observations and calculations. The publication of the calculation of the motions of the seven governors, the inner and outer parts (*Ch 'ilchongsan Naep 'yon* and *Ch 'ilchongsan Oep 'yon*), is the product of such efforts. The outer part is regarded as one of the most authoritative texts written in Chinese characters on Islamic astronomy and calendar science.

The scientific achievements of the King Sejong period were found in all fields of endeavor. Koryo celadon was developed into Punch'ong ware by early Choson craftsmen to produce unique Choson celadons that differed in style and quality from Koryo celadons. A blue and white porcelain was first imported from China during the King Sejong period and began to be produced in Korea from the middle of the fifteenth century. However the geometric shape and design of the porcelain were entirely different from the Chinese originals.

Military technology also developed unique characteristics in the early period of Choson. The development of

Choson style firearms and turtle ships are representative examples. Firearms began to be used widely from the late Koryo period after introduction of the skill from China. However, by the King Sejong period, firearms production in Choson had abandoned a great many of the Chinese features leading to the development of unique firearms. By totally recasting the firearms, which were improved to strengthen the national system, the Choson court, they were modified and standardized until they had their own style.

There were also notable achievements in geography. The map of the world drawn by Choson geographers in 1402, while based on some of the central maps in China, was a more complete one. Although it did not overcome the Chinese world view, it contained a depiction of Europe and Africa and the Far East which can be said to make a true world map with the most up-to-date geographical knowledge.

In the King Sejong period, actual national measurements were undertaken to produce a complete map of the country.

The map of Choson produced in the fifteenth century, currently preserved in Japan, is a map of the highest quality in comparison with others produced in the same period. Geographical scientists in the King Sejong period endeavored, in addition to making maps from thorough field surveys and study of literature, to do proper geographic work that included national and provincial maps.

The field of medicine experienced a total systematization and concentration of Korean herbal medicine and Oriental medicine. Study of local medicinal herbs was collated into a basic foundation for herbal medicine in Korea. It was developed into a comprehensive system for prescription. The *Hyangyak chipsongbang* (Great Collection of Native Korean Prescriptions), in which a total of 703 Korean native medicines were included, was completed in 1433. Concurrent with these efforts was the editing and publishing of *Uibang yuch 'ui* (Classified Collection of Medicinal Prescriptions). This was a medical encyclopedia, completed in 1445, which incorporated 153 different Korean and Chinese texts, and was regarded as one of the greatest medical texts of the fifteenth century. Also, the *Tongui pogam* (Precious Mirror of Eastern Medicine) was completed from 1556 to 1610 by Hochun.

Agricultural technology also experienced great development in the King Sejong period. Much of the agricultural technology in Korea until this period was based on Chinese agricultural texts. However, they could not provide appropriate guidelines for farming in Korea. To provide these, an agricultural technology text, *Nongsa chiksol* (Theories and Practice of Farming), was edited and published in 1429. This book surveyed the various farming methods in different fields and summarized the most developed and practical methods. This book contributed greatly to the improvement in agriculture in Choson and became the basic farming textbook.

However, Korean traditional sciences suffered a series of ruptures along with their creative development. A number of foreign invasions which decimated the entire territory disrupted the creative tradition in Korean scientific endeavors. The history of Korean sciences and technology is at the same time a history of these efforts. The introduction of Western science and the efforts to systematize the traditional sciences and technologies by "Sirhak" scholars from the seventeenth to the eighteenth centuries is just one example. These scholars advocated practical learning (*sirhak*) under the slogan *silsa kusi* (verification of truth on the basis of factual studies), and accepted some of the little European science that came their way. They thus began what might have become a scientific reformation because they were influenced by modern science and technology in Europe through Qing China, where the same kind of movement had been going on for some time, partly as a reaction to mystical tendencies in late Confucian philosophy. Sirhak scholars pioneered new frontiers in scientific and technological theory and scientific philosophy. However, their efforts were frustrated because of the onset of another round of invasions.

Science of the Native Americans

Ubiratan D'ambrosio

It is commonly accepted practice to refer to the peoples and cultures established in the territory now called the Americas as Native Americans. When the expedition of Christopher Columbus reached the Caribbean Islands in 1492, they called the inhabitants "Indians." This is because of the Spaniards' mistaken view that they had arrived in Asia. Although Columbus himself never realized that he had reached another continent and kept referring to the lands as "Cipango," soon the conquerors realized that they were indeed in a continent as far from Asia as from Europe and dealing with a completely different culture. However, the early chroniclers used the denomination "West Indies" and up to now all the peoples and the cultures native to these newly encountered lands are called Indians.

The denomination "America" also came as the consequence of a fortuitous event. The navigator Amerigo Vespucci, who had visited and described practically the entire coast of the newly found lands, was consulted by German Cartographer Martin Waldseemüller, when he was writing the treatise *Cosmographiae Introductio*, a sort of revised version of Ptolemy's *Geography.* The cartographer, without a name for the new territories added to the original maps, coined the name "Americas" to honor the man who helped them to place these additions to the old maps. This vast amount of land stretched from about the North Pole to the South Pole, between Europe and Asia, roughly in the middle of the waters surrounding the known world. The peoples and cultures of this territory reached by Columbus, strangers to the conception of the world prevailing in the fifteenth century, are mostly referred to as "American Indians." The name Native Americans is not widely used.

The original occupation of the Americas (North, Central, and South) is uncertain. The colonizers have claimed, an obvious political assertion, that the peoples in the Americas were immigrants who arrived from Asia through a glaciation of the Bering Strait no more than 20,000 years ago. Some theories claiming that these peoples are autochthonous were advanced in the early twentieth century, but they were disclaimed on the basis of a lack of scientific support. The best known of these theories is from the Argentinean anthropologist Florentino Ameghino (1854–1911). These claims recur frequently. The theory of a common origin for all of mankind, coming from the heights of Eastern Africa, is the most accepted version for the origin of humans in the Americas. They arrived in migratory fluxes through the Bering Strait, which does not exclude the possibility of ocean access, both through the Atlantic and the Pacific. There is mounting evidence of the presence of humans in these lands since 70000 BCE, but this evidence is very controversial. The most accepted versions place early findings of *Homo sapiens* at about 40000 BCE, without the presence of early hominids.

There is a considerable amount of material relating the impressions of the first Europeans who arrived in the Americas. The first one, the journal of Columbus, is a most important one, but others have also told of the enormous impression made by these peoples and lands on the Europeans. The chroniclers of the conquest reveal their surprise and failure in understanding such different cultures.

Most of the attempts to interpret scientific knowledge in the Americas prior to the arrival of Europeans are limited to a description of what was seen. Buildings, roads, agricultural fields, and artifacts are always listed as evidence of knowledge. Their meaning and cultural context are problematic. An example is the *quipu*, a collection of colored strings with knots, taken as a form of abacus. We now understand these are a very elaborate form of register, both qualitative and quantitative. Also, the wheel appears frequently in pre-Columbian cultures but without the uses so well known in the history of Europe and Asia.

There is a reasonable amount of literature on science and technology in the Americas in the pre-Columbian era written by anthropologists and psychologists. To relate this to the work of historians and philosophers of science and technology is an important step toward a broader understanding of the nature of science and technology and their places in societies. This asks for a clear recognition of the dynamic character of knowledge: from its generation through its organization, both intellectual and social, and through its diffusion. Although these aspects are studied in disciplines such as cognition, epistemology, history, politics, and education, it is practically impossible to understand and explain knowledge in such a fragmented way. This is an important step toward recognizing different modes of thought which lead to different forms of science, which we may call ethnosciences.

Research on the status of knowledge in the Americas in the pre-Columbian period uses methodological instruments and an intellectual posture of classifying it according to accepted, European, views of science. The underlying epistemology is dictated by current scholarship. Thus, research focuses on ethnoastronomy, ethnobotany, ethnochemistry, and so on. The "ethno" prefix stands for "the astronomy of the Aztecs," for example. This reductionist approach does not take into account the meaning of "astronomy" for the Aztecs. This is true for every science. A special situation occurs in the recognition of an ethnomethodology in different cultures. Researchers in this field rely on ethnography, the use of direct observation and extended field research. This produces a naturalistic description of peoples and their culture, uncovering codes, symbols, and categories of analysis which these peoples use to conceptualize, explain, understand, and interpret reality. The generation of these instruments is the essence of studies in cognition and culture. We are thus led to look into the history of science in a broader context, so as to incorporate other possible forms of knowledge, interpretation, and explanation, to deal with nature and natural phenomena.

Generation of knowledge goes on in different environmental settings, according to a multiplicity of stimuli. Practices are created by individuals in response to their immediate needs, motivation, and curiosity, and thus generated, they are intellectually organized as knowledge. A communication system of codes and symbols allows this knowledge to be transmitted informally throughout society and socially organized before it is diffused through education. Its growth into more and deeper knowledge is now a response to further needs and curiosity. These new responses (the *hows* and the *whys*) are incorporated in the pool of common knowledge which keeps a group of individuals together and operational. This is usually called culture.

Cultural forms, such as language, eating and drinking preferences, musical and bodily expression, mathematical practices, religious feelings, familial hierarchy and structure, dressing and behavior patterns, are thus diversified. A larger community is partitioned into several smaller ones, from individuals and their immediate kin to communities and societies, each with distinct cultural variants. The multiplicity of cultural factors is essentially responsible for the dynamic process of the production of new forms of thought and of more sophisticated expressions of the ingenuity of individuals and societies in satisfying their needs of survival and of transcendence. This is the process we call cultural dynamics.

A theory of culture is thus the result of analyzing the intellectual evolution of humankind, focusing on the search for different practices and intellectual tools for explaining, understanding, learning about and managing their natural and sociocultural environment. In "explaining, understanding, learning about and managing," we recognize the Greek root *mathema.* And a natural and sociocultural environment is well expressed by the prefix *ethno.* Thus we have coined the word ethnomathematics to describe the mathematical practices of the day-to-day lives of preliterate cultures. In a broader sense, ethnomathematics is a research program in the history and philosophy of mathematics, with pedagogical implications.

Much has been said about the universality of knowledge, in particular of scientific knowledge. This concept of universality becomes harder to sustain as recent research shows evidence of practices, such as health care and tool use, which are typically scientific, and methodological practices, such as observing, counting, ordering, sorting, measuring, and weighing, all performed in distinctive ways in different cultural environments. This has encouraged further studies on the evolution of scientific concepts and practices within a cultural and anthropological framework. We feel this has been done only to a very limited, and we might say very timid, extent. Indeed, universality of knowledge, more specifically of scientific knowledge, is a fabrication of the colonial ideology.

A new historiography reestablishing authentic universality is needed. There is some agreement about this in several areas of knowledge, but the history of science seems to be immune to this movement. Indeed, the tone of some reviews of recent books and papers in the history of science, in particular mathematics, focusing on this form of redeeming cultural history or proposing a non-Eurocentric view, is discouraging and, sometimes, contemptuous. It is well recognized that the best strategy for hegemony is the suppression of historicity of the subordinates. Here is an example from the history of science: the first nonreligious book published in the New World was Juan Diez Freyle's treatise dealing with the arithmetic of the Aztecs in 1557. Less than a century later, this book had lost its appeal and became completely lost, along with pre-Columbian arithmetic. Freyle's book was ignored and replaced by the arithmetic of the Spaniards.

The suppression of the history of a people involves the removal of all traces of structured knowledge, labeling all forms of knowledge as "popular wisdom," superstition, and folklore.

Early Cultures in the Americas

The early cultures in the Americas are distinct, according to broad ranges of latitude. The peoples in the icy northern regions developed into a culture generally known as Inuit, or Eskimos. Those in the fertile northern prairies and woods of what is the now the United States and Canada, ranging from the Pacific to the Atlantic, were identified under the generic name of "Indians," organized into several distinct nations. Those in the more desert regions neighboring the Rio Grande were distinct nations with a distinguishable urban organization and rather unique architectural forms. South of the Rio Grande, in the highlands of Mexico and Central and South America there are peoples with cultural styles of a rather different nature. These peoples are now called Aztecs in the region around what is now called the Ciudad de Mexico, Mayas in the Central American jungles, mainly southern Mexico and Guatemala, and Incas, spread throughout the mountainous region called the Andes, from the northern part of South America to the northern part of Chile. Aztecs, Mayas, and Incas are called the "high civilizations" of the Americas. In the "lower lands" – coastal areas, the Amazon Basin and subsidiary basins to the South, and much of the territory east of the Andes – other cultures flourished in a very different style. Apart from the high civilizations, and not mentioning those cultures north of the Rio Grande, we have to mention as best organized those located in the Island of Marajo (in the mouth of the Amazon River), with a considerably developed pottery, the agriculturalist Araucanians in the Southern part of South America, and the Guaranis, the latest major group to organize themselves in an agricultural economy, in central South America.

The Aztecs are distinguished by a monumental religious architecture, with abundant pyramids with precise designs to accommodate astronomical data. The Aztec Calendar reveals these achievements. Sculpture was at a level of sophistication comparable to civilizations in the Old World. Commerce was developed and practiced in large fairs. They used numbers and measures, but had no commerce by weight. The Aztecs were skilled workers in ceramics and in metals (gold, silver, copper, tin, and bronze). They had hieroglyphic writing, using colors which endure to the present day, literature, and a school system.

The Mayas had distinctive urbanization styles. Stone pyramids, temples, and palaces, decorated with very elaborate sculptures, were religious centers, and the population was spread in the surrounding jungles. These centers appear to have been temporary. One hypothesis is that they were abandoned as new ones became ready – another possibility is that the mobility was the result of destruction by wars. These peoples had a very advanced astronomy, with data comparable to those available to the Europeans. From the sixth century, they had developed the zero and positional number system, thus producing an advanced arithmetic. They also had a pictorial writing system which was not recognized as such by Europeans. Some early translators relied on reports of books and documents without recognizing this as reading.

Among the classics of their literature we have the elaborated description of the origins of the world and men, the *Popol Vuh*, a book written in the mid sixteenth century, in Central America. The book describes, simultaneously, the myths of origin, the history of kings and the peoples of the region, as well as the catastrophe of the Spanish conquest.

Also very important is the book of natural phenomena, the *Chilam Balam*. It describes a myth of origins, similar to the *Popol Vuh*, when gods of the underworld kept the universe captive. Also of great importance is the war drama *Rabinal Achi*, a piece showing the existence of a form of ritual theatre. It is typical of the post-Classical period of the Maya civilization, from the tenth to the fifteenth centuries. Maya cultures developed a series of artistic expressions which included dancing, theater, music, and literature.

The third high civilization, known as the Incas, took the name after their monarch. The Inca was the highest religious, civilian, and military authority. Although succession was by blood, the successor was not necessarily the eldest son. Like the Aztecs, the religion of the Incas was focused on the divinity of the Sun, and human sacrifices were common. The architecture of the Incas was of a varied nature. Visitors still marvel at what is called cyclopic architecture, buildings and palaces constructed using enormous stones, as in Machu Picchu, Peru.

The early history of these cultures reveals a great dispersion of nomadic groups, with an economy of hunters and collectors. In general, in all of the Americas, animal domestication was modest. In Mexico, turkeys were domesticated; in Peru the llama and the alpaca, as pack animals and for textiles, were also domesticated, as were dogs and some rodents. Some tribes farmed turtles, some bees and birds, mainly parakeets and parrots. Fish from the coasts of Peru were consumed in the high altitudes, transported, and preserved through a sophisticated system of utilization of natural ice.

Agriculture was much more developed. About 6000 BCE we see evidence of the domestication of plants, mainly in the northern region (north of Mexico and southeast United States), among them squash, cotton, and several species of beans. The important development of maize (*Zea mays*) opens up a new era in the development of agriculture and the settlement of people in larger regions, which characterizes the urbanization period. There is much controversy about when this occurred. A recent academic argument about the occurrence of maize in Panama, 5000 versus 3000 BCE, is more important for revealing the search for a new historiography for science and technology in pre-Columbian Americas than for the dating question itself.

Intensive Agriculture and Urbanization

Up to the beginning of the Christian era we see the formation of agricultural cultures. They developed different techniques, using fire, intensive irrigation, fertilization, and terrace agriculture. Agriculture was the main subsistence form and the determinant of the political struggles and the development of economy.

A special and unique type of building, characterized by yards built with stone walls, was recently located in the center of a village in La Puntilla, Peru. There are indications that these buildings, dating about 2,000 years ago, were for centralized work, and not for ceremonies. Other findings, such as finding manufactured products in domestic units, reveal an organized structure for distribution of the production, suggesting the existence of a dominant class controlling production. An intense craftsmanship, which included making andesite and obsidian tools, manufacturing ornaments of marine shells, weaving and spinning, and agricultural processing tasks are present. It is also notable that some of the raw material used in the crafts, as for example spondylus shells, are not local, but brought from distant lands, probably the coastline of Ecuador.

As we advance in time, around the second millennium AD we see the development of a variety of urban styles, the weaving of cotton and wool, pottery and ceramics, statuary, metallurgy, especially work in gold, ritual decoration, and architecture. We notice the development of several forms of pyramids, possibly evolving from the common funerary mounds, and other forms of religious architecture. Ceremonial dressing is varied, with feathers, plants, animals, painting, and bright colors. The period also reveals, probably as a consequence of the permanent struggle for land, the development of a variety of languages, with more than two thousand distinct languages or dialects. In the lower lands there is considerable development of agriculture, mainly manioc or cassava (*Manihoc utilissima*) and sweet potatoes (*Ipomoea batatas*).

There is also evidence of an intense coastal commerce. Indeed, navigation in the Pacific seems to be highly developed among the Andean cultures. There is recent evidence of Japanese arrivals in what is now Ecuador about 3000 BCE. Also, there is a possibility of commercial exchanges between China and South America in the first century AD, and contacts between Mexico and Africa in the first millennium are most probable. There are no doubts about the practice of considerably advanced navigation among the high civilizations.

There is much controversy about the development of a written/pictorial form of language. As mentioned above, recent findings reveal a written language among the Mayas. They also developed calculations, especially for astronomical and commercial purposes, with a sophisticated vigesimal (base 60) system. The register of historical and statistical data was rather sophisticated, as with the surprisingly powerful *quipus* among the Incas. Calculating devices, such as the *yupana*,[1] reveal theoretical approaches as yet not sufficiently studied. We are just beginning to recognize the formal knowledge – logic, mathematics, philosophy – possessed by these cultures.

Colonial discourse was absolutely biased in saying that the American peoples were not highly developed. Agriculture was developed in Asia in the eighth millennium BCE, while there is evidence that it was developed in Mexico only in the fifth millennium BCE. Ceramics and pottery are seen in Asia about 6000 BCE, while they appear in 3000 BCE in the northeast of South America. Proto-literacy is recognized in Mesopotamia about 3300 BCE, but in Mesoamerica only about 800 BCE. Urban cultures are seen in Egypt and Mesopotamia using writing and bronze about 2800 BCE, while limited writing and metallurgy are identified in urban complexes of Mexico and Peru only in the beginning of the Christian era.

What was going on in the centuries preceding the arrival of Columbus was a political process very similar to that which took place in Europe during the Middle Ages, when principalities and other smaller domains were uniting into larger organizations such as kingdoms and nations. The Spanish conquerors were able to take advantage of the local conflicts in destroying the emergent power elites and replacing them with the power of the conqueror, based on a well-balanced State/Church structure controlling the means of production. Although effective production was in the hands of natives, the conqueror assumed the role of the native monarchy in controlling the centralized system. Even now, production is, to a great extent, done by impoverished natives. A 1950 study showed that in Bolivia about four thousand native communities were responsible for about 25% of the agricultural production. The conqueror succeeded in deepening these conflicts. As a result, today different cultures, even different tribes, do not recognize their common history. In the lower lands, East of the Andes and the Amazon Basin and subsidiary basins in the South, and mainly in the Atlantic coast, the strategy was no different.

As we have said before, knowledge is generated as a permanent activity of human beings. It is carried out by individuals and groups of individuals in different environmental settings, according to a multiplicity of stimuli. Among the several stimuli, we have to consider cultural encounters and mutual exposition of different modes of thought. In the evolution of cultural forms subjected to mutual exposition, the possibilities are: first, an absolute domination of one form, either leaving the others in the state of latency or leading them to an eventual total elimination; and second, allowing coevolution, which eventually leads to new cultural forms. This second possibility occurs in systems which are tolerant of the different, of the stranger. Thus, our analysis of the formation of scientific knowledge and the development of technology among the civilizations of Latin America necessarily goes through an analysis of the occupation of territory and the development of means of production.

To conceptualize modes or styles of development is crucial for better understanding the evolution of native knowledge systems, in particular science, in the Americas. The Latin America Economic Commission of the United Nations proposed, in the 1960s, the conceptual basis for development. Development is understood as a strategy resulting from political agreement or group alliances, with the objective of reaching a common goal. Thus a model of development is the result of the power structure and of the social conflicts resulting of the prevalent forms of capital accumulation and distribution of richness. These are based on a complex of historical circumstances that go back to the conquest, colonial period and the early decades of independence. These internal and external conjunctures are in conflict with the values intrinsic to the cultures. To understand the native knowledge systems a new historiography is needed, anchored in the concept of models of development.

Science of the Ottomans

Ekmeleddin Ihsanoglu

The term "Ottoman Science" covers the scientific activities in the Ottoman Empire which was spread over a vast geographical area.

These scientific activities comprise various scientific traditions, including the Islamic tradition inherited by the Ottoman Turks and carried on by the Arabs, who were part of the Empire; then came the traditions of the European people such as the Bosnians and Albanians who had converted to Islam, as well as those of different Christian peoples living in Anatolia and the Balkans, followed by the contributions of native Jewish scholars who emigrated to the Ottoman lands from Andalusia. The Ottoman world had the necessary grounds for the interaction of all these different traditions. The Empire held vast lands in Europe and, as a result of their contact with European science from the very early ages, the new scientific European tradition spread in these lands for the first time outside its own cultural environment where it originated.

The Ottoman Empire that was founded as a small principality at the turn of the fourteenth century gradually expanded into the lands of the Byzantine Empire both in Anatolia and the Balkans, while its sovereignty reached the Arab world after 1517. It became the most powerful state of the Islamic world covering a vast area extending from Central Europe to the Indian Ocean and persevered by keeping the balances of power with Europe. Following its defeat in First World War, the Ottoman Empire came to an end in 1923.

Ottoman science emerged and developed on the foundations of the scientific legacy and institutions of the pre-Ottoman Seljukid period in Anatolian cities and benefited from the activities of scholars who came from Egypt, Syria, Iran, and Turkistan, which were the most important scientific and cultural centers of the time. The Ottomans enriched the cultural and scientific life in the Islamic world by a new dynamism and the Islamic scientific tradition reached its zenith in the sixteenth century. Besides the old centers of Islamic civilization, new centers flourished such as Bursa, Edirne, Istanbul, Skopje, and Sarajevo. The heritage that developed during this period constitutes the cultural identity and scientific legacy of the present-day Turkey as well as several Middle Eastern, North African, and Balkan countries. This article aims to give an overview of the formation and development of Ottoman science in Anatolia and the scientific activities which later expanded from Istanbul, the capital of the Empire, to the Ottoman lands, with the exception of the scientific activities related to non-Muslims due to insufficient studies and researches at hand.

The Ottomans always searched for solutions to the intellectual and practical problems they encountered in Islamic culture and science. Since the early periods, their attitude toward European science and technology was a selective acceptance. After the scientific and industrial revolutions in Europe, there appeared a gap between the Ottomans and the Western world. However, the Ottomans began to make some selective transfers from Western science and gradually the scientific tradition began to change from "Islamic" to "Western." For this reason Ottoman science should be studied under two headings: Classical Islamic Tradition and Modern Western Tradition. Although it is difficult to separate the two traditions in the transition period in a clear cut way, the demarcation between the two traditions became more evident as their contacts became more frequent.

In the classical period, the *medrese* (in Arabic *madrasa* "college") was the source of education and science and the most important institution of learning in the Ottoman Empire. The Ottoman medreses continued their activity from the time of the foundation of the State until approximately the turn of the twentieth century. The basic structure of the medreses remained the same within the framework of the Islamic tradition, but in terms of organization they underwent several changes during the Ottoman period. Starting with the first medrese, established in 1331 in Iznik (Nicaea), all medreses had *waqfs* (charitable foundations) supporting their activities.

Besides the *ulemā* (scholars who were medrese graduates) that provided religious, scientific and educational services, the medreses also trained the personnel for administrative and bureaucratic posts and the courts. Those ulema who were members of the *ilmiye* (Muslim learned, cultural, and religious institution) also played an important role in every aspect of the social and official life. With the reign of Mehmed II (Fatih, known as the Conqueror, 1451–1481), the number of medreses increased considerably and they were graded to differentiate them from each other.

Shortly after Mehmed II conquered Istanbul in 1453, he built the Fatih complex (*Külliye*) (1463–1470) which comprised a mosque at the center with other units located around it, also colleges, one hospital, one *mektep* (primary school), one public kitchen, setting an example for similar institutions that were built by the succeeding sultans and high-ranking members of the ruling class. The structure of an integrated campus was represented by the *Sahn-ı Semān Medreses* (Eight Court Colleges) of the Fatih Complex that comprised sixteen adjacent medreses. Owing to the political stability and economic prosperity of the Conqueror's period, distinguished scholars and artists of the Islamic world assembled in the capital of the Empire. The Ottomans especially protected the Muslim and Jewish scientists fleeing from the persecution that followed the fall of Granada in 1492 and provided them with shelter in the Ottoman lands. Moreover, as the waqfs which were the financial sources of medreses grew rich, scientific and educational life developed further. Following the establishment of the eight court medreses by Mehmed II, the rational sciences comprising mathematics and astronomy, were included in the formal educational system.

The medrese graduates served as teachers, *qādīs*, *kazaskers* (chief judges) and chief *muftis.* Several physicians were trained and many patients were treated in the *daruşşifa* (hospital) of the Fatih Complex which was active until the middle of nineteenth century. It provided services to the society in the fields of religion, education, science, and health, as well as offering food to the needy in its public kitchens. As of the second half of nineteenth century, the Fatih Complex gradually became ineffective, its various units, namely the hospital, *tābhāne* (hospice), *muvakkithāne* (office of the timekeeper), caravanserai and the primary school stopped operating. Finally, after all the medreses were discontinued in the Republican Period in 1924, its colleges, too, were closed down. The mosque, however, continues its principal function from the time of its establishment until the present day.

The establishment of the Süleymaniye complex (*Külliye*) by Süleyman the Magnificent (1520–1566) in the sixteenth century marked the final stage in the development of the medrese system where, besides the conventional medreses, a specialized (Medical College) *Dārüttıb* was founded (1550–1557). Thus, for the first time in Ottoman history, in addition to the *şifahānes* (hospitals), an independent institution was established to provide medical education. The other specialized medreses established by the Ottomans were the *Dārülhadīs* and the *Dārülkurrā. Dārülhadīs* held the highest grade in the medrese hierarchy.

In addition to the medreses, there were institutions where medical sciences and astronomy were practiced and taught by the master–apprentice method. These were the șifahānes, the muvakkithānes and the office of the *müneccimbaşı* (chief astronomer of the sultan).

The institutions which provided health services and medical education were called *dārüşşifa*, *şifahāne*, or *bīmāristan.* The Seljukids had built *dārüşşifas* in the cities of Konya, Sivas, and Kayseri. Similarly, the Ottomans built several dārüşşifas in cities such as Bursa, Edirne, and Istanbul. Some Western sources mention that in Istanbul they were numerous in number in the sixteenth and seventeenth centuries, which is an indication of the importance attributed to them. The Ottoman dārüşşifas were not independent buildings but were constructed as part of the külliyes.

In the Ottoman palace administration, the müneccimbaşı was the head of the astronomers and this position was established sometime between late fifteenth and early sixteenth centuries. They were selected from among the ulemā who were medrese graduates. From sixteenth century onward, they were entrusted with the preparation of calendars, fasting timetables, and horoscopes for the palace and prominent statesmen. Until 1800, the calendars were made according to the *Zīj* (astronomical handbook) of Uluğ Bey (Ulugh Beg); after that, the *Zīj* of Jacques Cassini was used. The chief astronomer and sometimes a senior astronomer fixed the most propitious hour for important events such as imperial accessions, births, wedding ceremonies, the launching of ships, wars, etc., as well as lesser events. Moreover, the chief astronomers followed extraordinary events such as earthquakes and fires as well as astronomical occurrences such as the passage of comets, solar, and lunar eclipses and passed on the information to the palace with related interpretations. The observatory founded in Istanbul was administered by chief astronomer Taqī al-Dīn al-Rāsıd (d. 1585) who was the greatest astronomer of the period. Thirty-seven people held the post of chief astronomer until the end of the Empire in 1923. Muvakkithānes were also under the supervision of the müneccimbaşı.

The timekeepers' offices were public buildings located in the courtyards of mosques or *masjids* in almost every town. They were mostly built after the conquest of Istanbul and administered by the waqfs. *Muvakkits* were the officials that worked at the muvakkithānes and kept the time, specifically the prayer hours. The following major instruments were used in timekeeping: quadrant, astrolabe, sextant, octant, hourglass, sundial, mechanical clock, and chronometer. Depending on the level of the timekeepers' knowledge, the muvakkithānes also functioned as locations where astronomy was taught and simple observations were made.

The Ottoman scientific literature in the classical period was produced mainly within the milieu of the medrese. Scholars compiled several original works and translations in the fields of religious sciences, mathematics, astronomy, and medicine, besides a great number of text-books. These works were written in Arabic, Turkish, and Persian, the three languages called *elsine-i selāse* which were known by the Ottoman scholars. At the beginning, the literature was mostly written in Arabic, but from fifteenth century onward, Turkish was used more often. As of eighteenth century, the majority of scientific works were written in Turkish and upon the establishment of the first printing house in Istanbul in 1727, Ottoman Turkish became the most frequently used language in the transfer of modern sciences.

In recent years, on account of the increasing research and studies on the survey and cataloging of Ottoman scientific literature, our knowledge of Ottoman literature on astronomy, mathematics, and geography has been enriched to a great extent and many new aspects of scientific activities of the Ottoman period were revealed. The results of these studies also illustrate with complete clarity the intensity of scientific activities carried out by the Ottomans. The examination of this literature shows that a total of 582 authors produced 2,438 works on astronomy; 491 authors that we were able to establish produced 1,116 works on mathematics and 458 authors produced 825 works on geography.

Statistics show that the total number of astronomical works is more than the number of mathematical works. This situation stems from the fact that calendars specifically occupied an imported place in astronomy literature. A continuous increase is observed in the number of works in these three disciplines until the eighteenth century. The number of works attained their maximum in the eighteenth century and then started to decrease. As for mathematics, the total number of works continued to increase except for the eighteenth century. Works on mathematics, which recorded a major increase especially in the nineteenth century, attained the maximum in the twentieth century. There is also an increase in the total number of works on geography similar to that of mathematics. The rates of increase of the works in these three subjects are close to each other.

Bursalı Kadızāde-i Rūmī (d. 844 AH/AD 1440, also known as Qādī Zādeh al-Rūmī) made the first important contribution to the development of the Ottoman scientific tradition and literature. He was tutored in Anatolia and settled in Samarkand after he compiled his first work. Qādī Zādeh wrote *Sharh Mulakhkhas fi'l-Hay'a* (Commentary on the "Compendium on Astronomy") and *Sharh Ashkāl al-Ta'sīs* (Commentary on "The Fundamental Theorems" of Geometry) in Arabic and became the chief professor at the Samarkand medrese and the director of the observatory founded by Ulugh Beg (d. 853/1449) in Samarkand. He was also the coauthor of *Zīj-i Jurjāni* (The Astronomical Tables of Ulugh Beg) written in Persian. He simplified the calculation of the "sine of a one degree arc" in his work *Risāla fi Istikhrāj Jaybi Daraja Wāhida* (Treatise on the Calculation of the Sine of a One Degree Arc). Qādī Zādeh's two students from Turkistan, Ali Kuşçu (d. 879/1474) and Fathullāh al-Shirwānī (d. 891/1486), influenced the Ottoman science by disseminating the scientific legacy of the Timurid period in the Ottoman Empire. In the preface of his work *Sharh Ashkāl al-Ta'sīs*, Qādī Zādeh indicated that "the philosophers who ponder about the creation and the secrets of the universe, the jurists (*faqihs*) who give *fetvās* in religious matters, the officials who run the affairs of state, and the *qādis* who deal with judicial matters should know geometry." Thus, he emphasized the necessity of science in philosophical, religious, and worldly matters. This understanding reflects a general characteristic of Ottoman science in the classical period. In the period of modernization, however, the Western concept of man's domination of nature through science and technology was foreign to Ottoman scholars.

Other astronomy books of this period included *Urjuza fī Manāzil al-Qamar wa Tulu'ihā* (Verses on the Mansions of the Moon and their Rising) and *Manzuma fī Silk al-Nujūm* (Verses on the Orbits of the Stars) written in Arabic by 'Abd al-Wahhāb ibn Jamāl al-Dīn ibn Yūsuf al-Maridānī. Two books titled *Risāla fi'l-Taqwīm* (Treatise on the Calendar) and *Sī Fasl fi'l-Taqwīm* (Thirty Sections on the Calendar) by Nasīr al-Dīn al-Tūsī, the founder of the Marāgha school, were translated from Persian into Turkish. Ahmed i Dā'ī (d. ca. 825/1421) was the translator of the second work.

During this period, Egypt was another source for Ottoman science. Hacı Paşa (Celaleddin Hıdır) (d. 1413 or 1417), a well known physician of the time who was educated in Egypt, wrote two books in Arabic titled *Shifa' al-Asqām wa Dawā' al-ālām* (Treatment of Illnesses and the Remedy for Pains) and *Kitāb al-Ta'ālīm fi'l-Tibb* (Book on the Teaching of Medicine) which played an important role in the development of Ottoman medicine. He had many other works in Turkish and Arabic. The works written by Sabuncuoğlu Şerefeddin (d. ca. 1468) on the subject of medicine have an important place in the development of Ottoman medical literature. His first work in Turkish on surgery called *Jarrāhiyāt al-Khāniyya* is composed of the translation of a section on surgery from the general medical book *al-Tasrīf* by Abu'l-Qāsım Zahrāwī, the famous Andalusian physician and surgeon, and three additional sections that he wrote himself. The work, in addition to the classical Islamic medical knowledge, reflects the influence of Turkish–Mongolian and Far Eastern medicine as well as the author's own experiences. The influence of Sabuncuoğlu was observed outside the Ottoman borders, specifically in Safavid Iran. Miniature paintings that depict surgical operations are one of the most significant features of this work that attained great fame in the history of medicine.

Ottoman science developed further owing to the keen interest of Mehmed II and the educational institutions which he established after the conquest of Istanbul. Consequently, some brilliant scholars emerged in the fifteenth century and made original contributions to science in this period. Mehmed II patronized the Muslim scholars, meantime he instructed Georgios Amirutzes, the Greek scholar from Trabzon, and his son to translate Ptolemy's *Geography* into Arabic and to draw a map of the world. Patriarch Gennadious prepared a book on the Christian belief titled *I'tikādnāme* (The Book on Belief) for him; the works *Geographia* and *De re Militari* by Francesco Berlinghieri and Roberto Valtorio, respectively, were presented to him by the authors. The Sultan's interest in European culture had started while he was a *şehzāde* (prince) at the Manisa Palace in 1445 where Italian humanist Ciriaco d'Ancona and other Italians taught him Roman and European history. Mehmed II also encouraged the scholars of his time to produce works in their special fields. For example, Hocazâde and 'Alâ al-Dîn al-Tusî were both asked to compare Ghazali's *Tahâfut al-Falâsifa* (The Inconsistency of the Philosophers) which criticized the views of peripatetic philosophers regarding metaphysical matters and *Tahâfut al-Tahâfut* (The Inconsistency of the Inconsistency) written by Ibn Rushd as a response to Ghazali's work.

The most notable scientist of the Mehmed II period was Ali Kusçu, a representative of the Samarkand tradition. He wrote 12 works on mathematics and astronomy, among them his commentary on the *Zīj-i Uluğ Bey* in Persian. His two works in Persian, namely *Risāla fi'I- Hay'a* (Treatise on Astronomy) and *Risāla fi'l-Hisāb* (Treatise on Arithmetic) were taught in the Ottoman *medrese*s. He rewrote these two works in Arabic with some additions under new titles, *al-Fathiyya* (Commemoration of Conquest) and *al-Muhammadiyya* (The Book Dedicated to Sultan Muhammed), respectively. Another noteworthy scholar of the Sultan Bayezid II period (1481–1512) was Molla Lūtfi. He wrote a treatise about the classification of sciences titled *Mawdu'āt al-'Ulum* (Subjects of the Sciences) in Arabic and compiled a book on geometry titled *Tad'īf al-Madhbah* (Delos Problem) which was partly translated from Greek. Mīrīm Çelebi (d. 1525), a well-known astronomer and mathematician of this period and the grandson of both Ali Kuşçu and Qādī Zādeh, contributed to the establishment of the scientific traditions of mathematics and astronomy and was renowned for the commentary he wrote on the *Zīj* of Ulugh Beg.

Some Jewish scholars who found shelter in the Ottoman Empire after the fall of Granada in Spain, (1492) also contributed to the Ottoman scientific literature. Among them the medical and astronomical works in Arabic written by Ilya ibn Abram al-Yahudī, the Andalusian scholar who settled in Istanbul during the reign of Bayezid II and changed his Jewish name to 'Abd al-Salām al-Muhtadī al-Muhammadī (sixteenth century) after embracing Islam, are examples of such contributions. In a treatise which he wrote in Hebrew and later translated into Arabic in 1503, he introduced the instrument of his own invention called *al-Dābid,* and stated that it was superior to the *Dhāt al-halaq* (armillary sphere) invented by Ptolemy. This treatise illuminates an aspect of Ottoman scientific literature which is not much known. Scientific literature developed considerably in the period of Süleyman the Magnificent. We find two major mathematical books in Turkish titled *Jamāl al-Kuttāb wa Kamāl al-Hussāb* (Beauty of Scribes and Perfection of Accountants) and '*Umdat al-Hisāb* (Treatise on Arithmetic) by Nasuh al-Silāhī al-Matrāqī (d. 971/1564). His book in Turkish titled *Beyān-ı Menāzil-i Sefer-i Irakeyn* (Description of the Stopping Places of the Campaign to the Two Iraqs) related to geography, should also be mentioned. Musā ibn Hāmūn (d. 1554), another famous Jewish physicians of Andalusian descent who was Sultan Süleyman's physician, wrote the first Turkish book on dentistry. It was one of the earliest independent works on dentistry and was based on Greek, Islamic, and Uighur Turkish medical sources and in particular on Sabuncuoğlu Şerefeddin's works.

In the sixteenth century, important works on astronomy were written by the representatives of the Egypt-Damascus tradition of astronomy–mathematics. In 1570 Taqī al-Dīn al-Rāsıd came to Istanbul from Egypt, and in 1571 he was appointed müneccimbaşı by Sultan Selīm II (1566–1574). He combined the Egypt-Damascus and Samarkand traditions and wrote about thirty books in Arabic on mathematics, astronomy, mechanics, and medicine. Shortly after Sultan Murād III's (1574–1595) accession to the throne, he started the construction of the Istanbul observatory. This institution was conceived as one of the largest observatories in Islam and was comparable to Tycho Brahe's Uraienborg observatory built in 1576. There is a striking similarity between the instruments of Tycho Brahe and those of Taqī al-Dīn. In his astronomical tables called *Sidrātü Munteḥā'l Efkār* (The Lotus Tree of the Extremity of Thoughts), Taqī al-Dīn states that he started the observations in Istanbul in 1573 with 15 assistants. The observatory was demolished on 4 Dhu'l-Hijja 987 corresponding to 22 January 1580.

Therefore, it can be estimated that he carried out observations from 1573 until 1580.

Taqī al-Dīn invented new instruments that were added to those already in use for observations in the Islamic world. The instruments that he used were (1) armillary sphere, (2) mural quadrant, (3) azimuthal quadrant, (4) parallel ruler, (5) ruler-quadrant or wooden quadrant, (6) an instrument with two holes for the measurement of apparent diameters and eclipses, (7) *Dhāt al-awtār* an instrument with chords to determine the equinoxes, invented by Taqī al-Dīn to replace the equinoctial armillary, (8) *Mushabbaha bi l-manātiq*, another of his inventions, the nature and function of which is not clearly explained, (9) mechanical clock with a train of cogwheels, and (10) *sunaydi* ruler, apparently a special type of instrument of an auxiliary nature, the function of which was explained by Alaeddin el-Mansur. Taqī al-Dīn used a mechanical clock of his own make, as well as a wooden wall dial that he set up in the observatory. He described the clock with the words: "We built a mechanical clock with a dial showing the hours, minutes, and seconds and we divided every minute into 5 seconds." This was a more precise clock than those previously used and it was considered to be one of the significant inventions in the field of applied astronomy that was developed during the sixteenth century.

Taqī al-Dīn found a different method of calculation to determine the latitudes and longitudes of stars by using Venus and the two stars near the ecliptic, i.e., Aldebaran and Spica Virginis. He determined that the magnitude of the annual motion of the Sun's apogee was 63″. Considering that the value known today is 61″., the method he used appears to be more precise than the methods of Copernicus (24″.) and Tycho Brahe (45″.).

Starting with Ptolemy in the second century AD and continuing until Copernicus in the sixteenth century, the Western world used chords for measuring angles. For this reason, the calculation of the value of the chord of (1°) was an important matter for astronomers. Thus, while Copernicus used the method based on the calculation of the chord of (2°) that yielded an approximate value, Taqī al-Dīn used trigonometric functions such as the sine, cosine, tangent, and cotangent to measure the values of angles, in line with the tradition of Islamic astronomy. Inspired by Ulugh Beg, Taqī al-Dīn developed a different method for the calculation of the sine of (1°). Furthermore, he applied decimal fractions to astronomy and trigonometry which had been previously developed by Islamic mathematicians such as al-Uqlidīsī and al-Kashī; prepared sine and tangent tables accordingly and used them in his work titled *Jarīdat al-Durar wa Kharīdat al-Fikār.*

Ottoman scientific tradition reached its highest level in the sixteenth century, meanwhile the scholars began to follow the innovations that developed in Europe in a selective way. Within this framework, the Islamic world first came into contact with the Copernican astronomy around the middle of seventeenth century. The earliest work that was translated from European languages on this subject is the astronomical table by French astronomer Noel Duret (d. ca. 1650) called *Nouvelle Thèorie des Planétes* which was printed in Paris in 1635. Ottoman astronomer Tezkereci Köse Ibrahim Efendi of Szigetvâr translated this work in 1660 under the name of *Secencelü'l Eflak fî Gayeti'l İdrak* (Mirror of Revolving Spheres of Heaven on the Limits of Perception) which mentioned Copernicus' heliocentric system of the universe. The first reaction to this book came from the chief astronomer Mehmed Efendi who said: "Such presumptuousness is abundant among the Europeans." However, after learning its application from the translator and comparing it with the *Uluğ Bey Zic* (The Astronomical Tables of Uluğ Bey), he appreciated the work and awarded the translator. The initial reaction of the chief astronomer is a typical example of the cautious approach of the Ottomans who were sure of their own scientific tradition and acquisitions and did not immediately accept the scientific superiority of the West.

The basic concept of the perception of the new astronomy of Copernicus with "the sun at the center of the universe and the earth in motion" which created major disputes in Europe was not taken up as a subject for polemics; for the Ottoman astronomers there was no religious dogma against it. Until modern astronomy lessons were started at the new educational institutions established in the last quarter of the eighteenth century and the beginning of the nineteenth century, the majority of the works on astronomy translated from European languages were composed of astronomical tables.

The Ottomans needed the knowledge of geography in order to determine the borders of their continuously expanding territory and to establish control over the military and commercial activities in the Mediterranean, the Black Sea, the Red Sea, and the Indian Ocean. They made use of both the geographical works of classical Islam and works of European origin. By adding their own observations, Ottoman geographers produced original works as well. The first source of the Ottoman knowledge of geography is the Samarkand tradition of astronomy and geography.

From sixteenth century onward, noteworthy geographical works were produced by Pirī Reis. In 1511, Pirī Reis drew his first world map and presented it to Sultan Selim I in 1517. A section of this map is now kept at the Topkupi Museum in Istanbul. It was drawn on the basis of a number of Islamic and European maps including Columbus' map of America. This first Ottoman map which included preliminary information about the New World showed southwestern Europe, northwestern Africa, southeastern and Central America; it was a portolano, without the latitudes and longitudes but with lines delineating coasts and islands. Pirī Reis drew his second map and presented it to Süleyman the Magnificent in 1528. Only the part which showed the North Atlantic Ocean and the newly discovered areas of the time that comprises North and Central America is now extant. Pirī Reis also wrote the book *Kitāb-ı Bahriye* (Book of the Sea) in Turkish in 1521. In this work, he presented drawings and maps of the cities on the Mediterranean and Aegean coasts and gave extensive information about navigation and nautical astronomy. Admiral Seydi Ali Reis (d. 1562) was the author of the work titled *al-Muhīt* (The Ocean) in Turkish; he was a notable figure in maritime geography in his period. This work contains astronomical and geographical information necessary for long sea voyages and his own observations about the Indian Ocean.

Another work of the sixteenth century which contains information about the geographical discoveries and the New World is the book titled *Tārih-i Hind-i Garbi* (History of Western India). This anonymous work based on Spanish and Italian geographical sources was presented to Murād III in 1583. It is important in showing that the geographical discoveries of the West were known to the Ottomans. The work has three parts; the third part, which is the most important one comprising two thirds of the whole book, relates the adventures of Columbus, Balboa, Magellan, Cortes, and Pizarro within the 60 years that started with the voyage to America between 1492 and 1552.

In the seventeenth century, cartography was organized as a profession in the Ottoman Empire; 15 individuals were occupied with the art of surveying in eight locations in Istanbul.

With the sixteenth century, some European physicians arrived in the major Ottoman cities, mainly Istanbul. Meanwhile the spread of many infectious diseases of European origin brought new methods of treatment, preventive steps and ideas. The new medical doctrines of Paracelsus (d. 1541) and his followers, the theories, and applications of treatment with chemical substances which became widespread in Holland in the seventeenth century and the new iatrochemistry appeared in the Ottoman medical literature with the names of "tıbb-ı cedid" (modern medicine) and "tıbb-ı kimyevî" (chemical medicine). Salih b. Nasrullah b. Sellüm (d. 1670), one of the most famous followers of these developments, quoted many European sources in his work called *Nüzhetü'l Ebdan* (Pleasure of Bodies) and noted the compositions of their medicines. Furthermore, he translated Paracelsus' work on iatrochemistry from Latin into Arabic. In the same manner, el-İznikî (d. eighteenth century) also prepared his work called *Kitab-ı Künüz-i Hayat el İnsan Kavanin-i Etibba-ı Feylesofan* (The Book on the Treasury of the Life of Humans and the Laws of the Philosophers–Physicians) where he presented the old and the new medicine together by making use of the works of the European physicians along with Arabic, Persian and Ancient Greek sources. Ömer Sifaî (d. 1742) stated that he translated his work called *el-Cevher el-Ferid* from European languages into Turkish and the medicines in the book were taken from the books in Latin written by European physicians. Thus, in the Ottoman medical literature, the new medical knowledge and methods of European origin were quoted together with the traditional knowledge of medicine and methods until the beginning of the nineteenth century.

Ottoman medical literature carried both the classical Islamic and the European medical information until the beginning of the nineteenth century when Şānīzāde Atāullah (d. 1826) wrote his work titled *Hamse-i Şānīzāde* (Five Works of Şānīzade) composed of the following branches of medicine: anatomy, physiology, pathology, surgery, and pharmacology. These were based totally on modern European sources without any reference to traditional medicine.

The famous Ottoman scholar and bibliographer Kātip Çelebi (d. 1658), also known as Hacı Halife, was one of the first Muslim intellectuals to notice the gap between the levels of scientific development in Europe and the Ottoman world. Kātip Çelebi was able to approach analytically both to classical Islamic culture and modern Western culture. He wrote on a variety of subjects in Arabic and Turkish. In the field of history, he translated the *Chronik* of Johann Carion from Latin under the title of *Tārih-i Firengī Tercümesi* (Translation of European History) and compiled his *Ravnak al-Saltana* (Splendor of the Sultanate) on the basis of works by authors such as Johannes Zouaras, Nicestas Acominate, Nicephorus Gregoras, and the Athenian Laonikas Chalcondyle. In the field of geography, he translated the *Atlas Minor* of Mercator and Hondius under the title *Lawami'al-Nūr fi Zulmāt Atlas Minur* (Flashes of Light on the Darkness of Atlas Minor). Furthermore, in his work titled *Mīzān al-Haqq fī Ikhtiyār al-Ahaqq* (The Balance of Truth and the Choice of the Truest), Kātip Çelebi criticized the intellectual life of his period.

The Ottoman Empire was geographically a European country and had common borders with many states in the West. This had been influential in making it the first country outside the Western world where modern science and technology had spread. This proximity also provided the Ottomans with an awareness of the new explorations and inventions that appeared in Europe. The relationship, which was formed within a selective process of transfer, characterized the nature of the Ottomans' attitude vis a vis Western science and technology and their attitude toward the innovations developed in Europe. The adoption of these innovations by the Ottomans differed from those of the Russians, Chinese, and Japanese. Also, it did not conform to the theories of "central-peripheral" and "exploiter-exploited" interpretation of the spread of Western science outside its cultural environment. The attitudes of the Ottomans toward Western science and technology are better interpreted as "selective attitude adopted by a powerful Empire in response to the developments outside its own sphere and area of influence." The Ottomans started to transfer European technology, especially in the fields of firearms, cartography, and mining as of the fifteenth century. Furthermore, the Ottomans had the opportunity to become acquainted with the Renaissance astronomy and medicine through the Jewish scholars who took refuge in the Ottoman Empire. In spite of this, the Ottomans considered themselves to be superior to the Europeans, both spiritually and culturally, in addition to their military superiority. Furthermore, their feeling of sufficiency from the aspect of both the educational system and economy was the reason for their being selective in the transfer of science. It is obvious that the Ottomans, in their periods of progress, did not feel the need to follow the intellectual and scientific activities such as the "Renaissance" and the "Scientific Revolution" that emerged in the West. The following interpretation made by some modern historians that: "The Ottomans did not understand that such developments would constitute a danger for them in the future" is anachronistic. Since the Ottomans, along with the other societies that had deep-rooted civilizations, became aware of the unsurpassable progress made by the Europeans in science and technology after the effects of the Industrial Revolution. The military striking power of the Europeans that resulted from the "Industrial Revolution" grew to a great extent as compared to the past; their ability to reach swiftly to every corner of the world on land and sea by steam engine and their means to produce an unrivaled amount of goods for the world markets with the new industrial technology, established the crushing superiority of the Europeans.

In these periods the Ottomans required immediate transfers of science and technology to strengthen their military power. Thus, they established the imperial engineering schools at the end of the eighteenth century and the imperial medical school at the beginning of the nineteenth century. Major reforms known as the *Tanzimāt* (1839) led to a shift in the process of selective transfer to include civilian projects and objectives. In the second half of the nineteenth century individuals started to establish professional and learned associations similar to those in the West. These new corporate bodies which did not exist in the classical period, added a new dimension to Ottoman scientific life with their legal statute and work procedures.

The concepts and information related to both the East and the West appeared side by side in the Ottoman scientific literature in the eighteenth and early nineteenth centuries. An example is the presentation of the heliocentric and geocentric systems of the universe in the same work. It is possible to observe the same situation on the subject of medicine. In the eighteenth century, along with the transfer of the practical medical knowledge of Europe, the classical concepts such as the "ahlat-ı erbaa" (four humors) in physiology and traditional anatomy were still dominant.

The teachers at the Imperial School of Engineering that was established toward the end of the eighteenth century to teach modern sciences to the officers, began to prepare their textbooks by translating and adapting the works selected from among the textbooks which were taught at the military technical schools in the West. The first scientific publications that came out at the turn of the nineteenth century were the books prepared by the Chief Instructor of the Imperial School of Engineering, Hüseyin Rıfkı Tamānī (d. 1817). They were composed of compilations and translations on the subjects of astronomy, mathematics, and geography and were printed many times. These works were followed by 13 volumes comprising the compilations and translations based on the Western and especially French sources prepared by Ishak Efendi (d. 1836) who was Tamānī's student and later his successor as the chief instructor at the school of engineering. His most famous work is *Mecmu'a-i 'Ulūm-ı Riyāziye* (The Compendium of Mathematical Sciences). This four volume work occupies a special place, because it is the first wide scope attempt in the Ottoman world in the preparation of a textbook containing many modern scientific disciplines, among which are mathematics, physics, chemistry, astronomy, biology, botany, and mineralogy. Ishak Efendi had a significant role in finding Turkish equivalents for the new scientific terms and disseminating them to the other provinces outside Istanbul.

Obviously the Ottoman's perception of modern European scientific traditions lacked an overall approach although they followed it closely. It is also clear that their scientific activities concerning research and production of new knowledge and technology – despite various relevant examples – did not have priority in their planning. Research activities conducted by Ottoman scientists inside and outside the Empire, particularly in the European countries, did not reach the critical mass as compared to the contemporary Russian and Japanese examples.

During the classical period, the Ottoman scientists and scholars displayed a remarkable success in developing Islamic science and were able to make new contributions to the various branches of science. However, in the modernization period they were not able to show a parallel performance but were successful in developing the modern scientific terminology of universal Islamic character and the Ottoman Turkish language to a level that would enable them to express their modern scientific and scholarly knowledge on various disciplines. The cultural and scientific heritage of the Ottoman period constituted the scientific and cultural infrastructure of many states founded in the Balkans and the Middle East, with the Republic of Turkey in the lead, and formed the foundations of subsequent activities.

Science and Spirit

NITIN TRASI

The word "spirit" is derived from the Latin *spirare*, to breathe, or *spiritus*, breath. The term "spiritual" is sometimes taken to mean matters concerning the supernatural or the occult. However, the true meaning of the word concerns matters pertaining to the spirit, the animating principle in man, as opposed to matters pertaining to the physical and material. Thus "spirituality" in Sanskrit is *adhyātma*; in Pali, it is *ajjhat*.

The true spiritual quest in the most rigorously scientific sense of the term would then mean research into consciousness itself. Although India has had its fair share of occultists and those interested in the paranormal, a significant contribution of India to the world, from ancient times down to the modern age, has been the remarkable research into the nature of consciousness. Right from the Vedic times, the seers of India have been interested in questions about life and its meaning and in consciousness itself. Who are we? Where do we come from? What is the nature of the consciousness that animates us? What is its source? Is there an unchangeable ultimate reality or first principle in life? What is the cause of human suffering, and what is its solution? These and other fundamental questions have engaged their attention. These men have conducted scientific research into consciousness, in which they have explored the mind and the inner world within man himself. They conducted thought experiments and delved deep into their own minds and thinking processes to seek out the basic truths about life, consciousness, and the universe.

S

Vedānta

The four *Vedas* are the most ancient sacred literature of India. They were probably composed over several centuries during the second millennium BCE. The early Vedic hymns contain extremely detailed poetical descriptions of nature, and speculations about the origin and nature of the universe. The *Ṛg-Veda* declares, "Who verily knows and who can here declare it, whence it [the universe] was born and whence comes this creation?" (Nikhilananda 1997). And before this creation? "There was neither existence nor nonexistence then, neither air nor the sky beyond…neither death nor immortality, night nor day…darkness was concealed in darkness there!" (*Ṛg Veda*, III.129.1–3).

Deities symbolized the different forces of nature, but even in these early hymns, there is an awareness of the unity of these deities. "They speak of Indra, Mitra, Varuṇa, Agni, [names of deities]…the One Reality the sages call by many names." (*Ṛg Veda*, I.164.46, *Atharva Veda*, IX.10.28). "In That all this unites, from That all this emerges. The all-pervading One is the warp and woof of all created things." (*Yajur Veda*; *Vājasneya Saṁhitā*, 40.1).

Though the earlier parts of the *Vedas* (the *Karma-kānda*, the ritualistic section) dealt more with means to derive health, wealth, and material prosperity, later on the approach changed, as it was realized that these benefits were all transitory and subject to corruption with time. It is in these latter parts (the *Jñānakānda*, the knowledge section) that the *Vedas* really begin to deal with the question of lasting peace and happiness and the nature of consciousness itself. The concluding portions of the *Vedas* are called the *Vedānta* (*anta*: end, essence) and include the treatises called the *Upaniṣads,* which date back to the last millennium BCE. There are 108 *Upaniṣads*, of which 11 are considered the most important.

The Knower

In the *Upaniṣads*, the approach is highly introspective, and a critically important distinction is made between the "seer" (*dṛk*) and the "seen" (*dṛṣya*). Through a lot of intricate discussion, it is shown that the seer is the unchangeable Consciousness or the knowing principle that cannot be recognized easily, because it is itself attempting to do the seeing or knowing. Just as the eye cannot see the eye, the seer cannot know itself as an object. "How can one know that by which all this is known?" (*Bṛhadāraṇyaka Upaniṣad*, IV.5.15). And yet, itself the knower, who else is there to know it? The seer or the knower is in reality the innermost consciousness within us, the *ātman,* "the light of lights which is my inner being" (*Yajur Veda; Vājasneya Saṁhitā*, 34.1–3). Since whatever it can perceive (the seen or known) cannot be itself (the seer or knower), it therefore has to resort to elimination to recognize itself – a process symbolized by the famous words, *neti, neti* meaning, "It is not this, it is not this" (*Bṛhadāraṇyaka Upaniṣad* II.3.6). The ātman is finally said to be able to recognize itself only through intuitive knowledge and it is therefore said to be *svasākṣi* (self-cognized) (*Vivekacūḍāmaṇi*, 216). This knowing is not an objective but an intuitive knowing, "just as one knows of one's own existence even without the aid of a mirror" (*Amṛtānubhava*, II.76).

The Ultimate Reality

The idea of a single ultimate reality (*Brahman*), the basis of the physical universe appears early in the *Vedas*: "I know the drawn out thread in which all these creatures are strung. I know the thread's thread. I know the great *Brahman*" (*Atharva Veda,* X.8.38). But it is the *Upaniṣads* that elaborate on the details of this monistic idea of a single reality Brahman manifesting as the universe and its diverse objects, including human beings – the doctrine of *advaita*, monism. "Ever unborn, He is born in many forms. In Him alone reside all living things" (*Māhānārāyaṇa Upaniṣad*, 1.2). The relationship of the individual consciousness with this Reality is also stated. The ātman, the individual source of consciousness within a person, is not different from Brahman, the Universal Consciousness, but only appears to be separate because of the limiting adjuncts of the body and mind. The conclusion is finally reached that this (apparent) sundering from that reality is the true cause of insecurity and suffering in life, and reunion (or rather recognition of the essential oneness) with that reality is the only way to lasting, unqualified peace.

The Scientific Approach

Throughout the *Upaniṣads*, the approach is always investigative, and never dogmatic. The Truth is mentioned, but the pupil is expected and encouraged to question it and confirm it for himself, by his own efforts. The criteria of truth are said to be not just *śruti* (scriptural authority), but its conjunction with *yukti* (reasoning) and *anubhava* (experience) (Nikhilananda 1997: 17). "The true nature of things is to be known personally…and not through a sage. What the moon exactly is, is to be known with one's own eyes; can others make him know it?" (*Vivekacūḍāmaṇi*, 54).

Monism was therefore not the only doctrine that was existent, though it was the dominant one. The spirit of enquiry dominated philosophical thought (*darśana*) both in ancient and medieval India, and a wide spectrum of philosophical ideas was explored. At one extreme of this diverse spectrum was the purely materialistic doctrine of the pre-Buddhistic Cārvāka school, which approximated to pure hedonism. There were also the Pūrva Mimānsa of Jaimini, the Uttara Mimānsa ascribed to Vyāsa, the Sāmkhya of Kapila, Patanjali's Pātānjala, Gautama's Nyāya, and the Vaiśeṣika of Kānada. At the other extreme was the *bhakti* (devotional) tradition, with its total emphasis on love of God. But even within this devotional tradition, a variety of philosophical thought was expressed, and (apart from monism) there were several doctrines to explain the relationship of the human with the Divine. The *dvaita* (dualism) school taught that the soul (or self) and God are eternally separate. Its most important proponent was Mādhvācārya, a mediaeval philosopher and religious teacher of South India. The school of Viśiṣta Advaita (qualified monism) of Rāmānuja (eleventh century AD, South India), stated that the individual souls were very close to God and a part of him, but not one and the same ("like seeds in a pomegranate"); while the Śuddha Advaita doctrine ("pure" monism) of Vallabhācārya of mediaeval India made a fine distinction between the individual souls and God, saying that they are related "as sparks to a fire."

Advaita and Science

Science and religion do not always agree with each other. Religion is generally a matter of faith, whereas science depends upon plausible theories and empirical confirmation.

Advaita seems to offer a model of spirituality which agrees with science on these points. In this philosophy, there is no separate individual soul (there is only an illusion or appearance of a separate self or soul). The reality of God according to this theory is that he is the Universal Consciousness, the Source or Ground of all being, and not a personal, anthropomorphic, all-powerful entity. And finally, these things are definitely not asked to be accepted on trust. The individual is encouraged to find out for himself and confirm and corroborate these findings on his own.

Thus advaita presents to the world perhaps the most elegant, the most feasible, and the most scientifically acceptable of all theories of ontology. Advaita has also been shown to be closest to the new physics and quantum mechanics (Capra 1976; Goswami 1993).

Bhagavad Gītā and Karma-Yoga

Probably originally composed in about 1500 BCE, the *Bhagavad Gītā* is considered to be as authoritative as the *Vedas*. The philosophy in the *Bhagavad Gītā* (BG) is generally consistent with the advaitic tradition, though like the *Upaniṣads*, the followers of the non-advaitic traditions interpret it differently. However, its most important scientific contribution to the world is the thoroughly practical philosophy of *karma-yoga* (lit. the art of action, BG: II-50). Consistent with modern management principles as well as modern psychology, karma-yoga teaches an attitude to be adopted toward everyday duties and actions. Excessive concern about results interferes with the efficiency of the activity. Specifically, karma-yoga suggests performing action without worrying unduly about the results – *karma-phala-tyāga* (lit. surrender of the fruits of action) (BG, II.47–48, XII.8–11).

Buddhism

The Buddha

Whereas a large part of Vedāntic philosophy involved intricate discussions on consciousness, the Buddha (sixth century BCE) took a refreshingly different approach. At a young age, the Buddha, then Prince Siddhartha Goutama, was deeply disturbed by what he saw as the terrible inevitabilities of life: suffering, old age, and death. Desperately seeking a solution, and dissatisfied with the answers the scholars offered, he set out to discover the truth on his own. Rejecting all authority, discarding all theoretical speculation, he struggled for many years until one day, illumination dawned upon him. The Buddha spent the rest of his life spreading his message, until he died at the age of 80.

The Buddha proposed that ordinary human existence is an unsatisfactory state in which people make themselves miserable as a result of a basic misunderstanding of their own nature, and that there exists another way of being in this world, *nirvāṇa* (*nibbāna*), which is a release from this misery. Nirvāṇa is not some superhuman state, but rather a natural way of being, accessible to any human being. The way to nirvāṇa does not require acquisition of special powers, nor withdrawal from life or any other extremes. It is therefore called the "middle way."

The Buddha decried appeals to authority or tradition. He proposed a highly scientific, completely empirical approach, without recourse to any pre-existing theoretical concepts. He offered no theory of God and discouraged all speculation on the subject, and restricted himself to purely practical teaching. Based upon a systematic rational analysis of the problems of life, his teachings offered a way to their solution. A psychologist and a philosopher, he formulated his own experiential techniques to study the mind.

The Buddha's teachings include a set of concepts of how the mind works – the oldest psychology of which the world has any record (Anderson 1979: 5). In the Buddhist view, the person is seen not as a solid reincarnating entity, but rather as a flow of mental processes. At any one time, a human being is an aggregation of events, and that aggregation is constantly changing. There is thus no identifying essence at the core of any human being – no eternal soul, no *jivātman*. In other words, the "me" is not a person, but a process, and that process is in a state of constant flux, like a flowing river. This is the principle of *anātman* (no-soul). However, this concept of no-self is most definitely not a dogma. The correct Buddhist position is not to hold any dogmatic views, but rather to see things objectively as they are without mental projections (Anderson 1979: 29–31).

The Buddha is also said to have formulated and taught a detailed step-by-step practical technique to approach the realization of the state of *nibbāna*. This technique is called *Vipaśśanā*.

The Technique

Vipaśśanā means knowledge by seeing, clear perception. It means to observe reality in the right way – as it is, and not as it appears to be, colored by belief and imagination (Goenka 1994). The Vipaśśanā technique is a type of meditation – an observation-based, self-exploratory journey into one's own mind.

Vipaśśanā meditation trains the concentrated attention to follow the mechanics of mental processing with the base of concomitant physical sensations, in a detached fashion (Fleischman 1986). As the sensations arise and pass away, the wisdom of impermanence arises in the mind (everything is impermanent – *anicca* – nothing is eternal) and one attains equanimity amidst life's vicissitudes. The mind is gradually deconditioned (Goleman 1977), and life becomes characterized by increased awareness, reality-orientation and peace (Fleischman 1986). Man is led away from narcissism to mature, social love, and this personal transformation becomes the catalyst for social change and development (Fleischman 1991).

Mindfulness

Vipaśśanā consists ultimately in arriving at a state of mental alertness or attentiveness to the present, both with respect to the outer world, as well as to the inner – the workings of the mind. It is an ongoing process and results in enhanced insight and psychological maturity, as well as equanimity. The spontaneous (not enforced), easy state of mental alertness or awareness which results is known as *sati* (mindfulness), and could be described as a prospective, ongoing awareness of thought and action (as opposed to analysis – which is retrospective deliberation).

Buddhist mindfulness practice has some strong similarities to Gestalt therapy of Western psychology. Both emphasize the *how* of life rather than the *why* (unlike Freudian psychoanalysis). Repression of feelings is not advised, nor is change through inner or outer coercion. Emphasis is on being attentive, perceiving the truth, and being free. As in Gestalt therapy, Vipaśśanā meditation involves focusing on the actual, reduction of conceptual activity, and noninterference in the flow of experience (Anderson 2003: 85).

Vipaśśanā is considered a perfect antistress remedy, an effective cognitive technique for the development of self-awareness (Kutz 1985), and an excellent human potential development method and tool for self-actualization (Chokhani 1995). Vipaśśanā transforms one's approach to life and its vicissitudes including disease, and even death, which one now is able to face with serenity and fortitude. Though Vipaśśanā is not advocated for treatment purposes, it may have therapeutic value, and it has been suggested that combining and integrating it with psychotherapy may offer synergistic advantages (Kutz 1985). Studies carried out on the impact of Vipaśśanā in jails in India have reported its efficacy as a reformatory measure.

Self-Reliance

The Buddha always stressed the importance of self-discovery, and nonreliance on external authority, even his own. Scientific to the end, his dying words were "Be ye lamps unto yourselves. Rely on yourselves, and do not rely on external help. Look not for assistance to anyone besides yourselves – either now or after I am dead" (Burt 1955: 49–50).

The Buddha's teachings have been kept alive in true Eastern tradition by several Buddhist Masters.

Jiddu Krishnamurti

Krishnamurti (1895–1986) was probably the most remarkable spiritual scientist in recent Indian history. Fiercely independent, his approach was in many ways reminiscent of the Buddha's. He was dismissive of authority (including his own) and tradition, and had a completely empirical approach without recourse to theoretical speculation. His "choiceless awareness" sounds similar to Buddhist mindfulness. Like the Buddha, he encouraged people to be their own spiritual guides, and even insisted that he wanted no followers. "To follow another is evil," he said, "it does not matter who it is" (Krishnamurti Information Network).

But whereas the Buddha left a detailed step-by-step methodology, Krishnamurti decried all methods and techniques in the spiritual search. "Truth is a pathless land," he declared, "and you cannot approach it by any path whatsoever" (Krishnamurti Foundation Trust Ltd.). Again, whereas the Buddha created and left behind an organization, the *sangha*, to carry his message, Krishnamurti was against any organization in the spiritual field, and in his own case, allowed only the most perfunctory of organizations for the limited purpose of preserving an authentic record of his message.

"Discovered" as a young boy by members of the Theosophical Society who were convinced that they had found the modern messiah, Krishnamurti was declared the new World Leader and, by the 1920s, was attracting worldwide attention. Then in 1925

Krishnamurti experienced a mysterious spiritual awakening, and in 1929, in an act of renunciation, he abandoned the Theosophical Society, cut himself off from all organizations, and from that time until his death, traveled round the world speaking as a private person – a secular philosopher with no affiliation to any religion, sect or dogma.

The Core of the Teachings

Krishnamurti taught that man, out of his insecurity, has built within himself images as a fence of security – symbols, ideas, beliefs – religious, political, personal. Man's perception of life is shaped by these concepts established in his mind. His thinking, his relationships and his daily life are dominated by these images. They divide man from man, and are the cause of the disorder that pervades the consciousness of mankind, and which prevents human beings from properly working together, ultimately resulting in widespread sorrow, conflict, and misery.

The root cause of this delusion is in the fact that we are ignorant of the general nature of our own processes of thought. To be free from this delusion, we must observe the workings of our own minds. Through observation – close attention to and observation of the activity of thought (Krishnamurti called this "meditation") – one discovers the lack of freedom. One does this observation without choice, without criticism, without acceptance or rejection. The very act of this meditation then, in itself, brings order to the activity of thought without the intervention of will, choice, decision, or any other action of the "thinker." The noise and chaos which are the usual background of our consciousness die out, and the mind becomes generally silent. Our day-to-day work is not affected adversely (to the contrary, it becomes more efficient), because thought arises whenever needed for some genuinely valid purpose, and then stops until needed again.

In this silence, said Krishnamurti, something new and creative happens that is of extraordinary significance for all of life. This something cannot be conveyed in words, so he did not attempt to do so. Rather, he asked those who were interested to explore for themselves, through actual attention to the nature of thought.

Man does not have to go to a hermitage or forest to be free. Freedom is found in the "choiceless awareness" of our daily existence and activity. When man becomes aware of the movement of his own thoughts he will see the division between the thinker and thought, the observer and the observed, the experience and the experiencer. He will discover that this division is an illusion. This will lead to pure observation which is insight without any shadow of the past or of time. This timeless insight brings about a deep radical mutation in the mind – and then there is love, compassion and intelligence.

Truth (spiritual truth) cannot be found through any organization, creed, dogma, priest, or ritual, nor through philosophic knowledge, psychological technique, or intellectual analysis. Man has to find it through the understanding of the contents of his own mind, through observation.

Krishnamurti's teachings are of considerable relevance to mental health. It has been suggested that many of his ideas could be assimilated into modern psychiatric practice and aid toward promotion of mental health (Rao 1995).

These scientists of the spirit from the land of the *Vedas* have much to offer to the world. Their discoveries may well complement modern scientific advances to make for a better future. While modern science has explored outer space, these are the scientists who have explored inner space. While modern science has perfected some kinds of technology, they have perfected the techniques of self-actualization. Whereas science and modern medicine have gone far ahead in studying and treating disorders of the mind, the spiritual psychology of the East has studied and perfected the further development and evolution of the human mind beyond the so-called normal (Wilber 1977, 1989). Perhaps a meaningful synthesis of the wisdom of East and West can lead us to the next phase of human evolution, to a better and more loving human existence, what has been aptly termed the "Next Enlightenment" (Anderson 2003).

Sde Srid Sangs Rgyas Rgya Mtsho

ZHEN YAN

Sde srid sangs rgyas rgya mtsho is a famous Tibetan politician and naturalist. Nicknamed Sde pa, he was born in the water snake year of the eleventh Rab-byung (Tibetan calendar, 1653) in the Northern suburb of Lhasa, Tibet. His father's name was A sug, and his mother, Bu khrid rgyal mo.

Politically, he was a person who inspired controversy, either commendatory or derogatory. But he was a great naturalist. His contributions in Tibetan medicine greatly promoted the development of this branch of science during his time.

Since he was a very talented child, he came to the attention of the fifth Dalai Lama Ngag dbang blo bzang rgya mtsho, who paid special attention to his education. He was summoned to the Dalai Lama's Potala palace to learn the classics of the Buddhism, apparent and esoteric sects. He had many tutors. 'Dar pa was the tutor for languages, Sanskrit and calendar-mathematics; Rong ge ngag dbang for astrology; Lhun sdings rnam rgyal rdo rje for allegorical trees, body measurement, and esoteric recipes. Thus, he became a versatile scholar with a high reputation.

The fifth Dalai Lama assigned him to the post of Sde srid (the Regent or Prime Minister), which was like giving wings to a tiger. During his tenure as Sde srid, he used any leisure time to take advantage of having access to many rare documents and materials available in the palace. He was very erudite in natural sciences, including medical science. His works, for instance *Baidurya dkar po* (White Lapislazuli), and *Baidurya ser po* (Yellow

Lapislazuli), deal with the calendar, mathematical sciences, and religion. However, his achievements in medical science will be emphasized here.

First, he studied *Rgyud bzhi*, the most important ancient Tibetan medical canon. Due to his political position, he had contact with many famous physicians. He admired Dar mo sman rams pa blo bzang chos grags very much, claiming that he was very erudite and had many esoteric effective recipes. He learnt from the different revised and annotated editions produced by the new Gyu thog yon tan mgon po, the greatest ancient Tibetan medical figure. He also made his own annotations and revisions on *Rgyud bzhi*.

Rgyud bzhi, authored by Gyu thog rnying ma yon tan mgon po, or the old Gyu thog, is written in archaic Tibetan language, which is hard to read; moreover, it is written in the form of an ancient Sloka-poet form, which is difficult to comprehend. Based on his experiences and practice, he adopted all the merits from different schools and physicians, discarded the erroneous and extracted the essence. With all these elements as a basis, he wrote a new detailed commentary on *Rgyud bzhi* with the title *Gso ba rig pa'i bstan bcos sman bla'i dgongs rgyan rgyud bzhi'i gsal byed baidurya sngon po'i malli ka zhes bya ba bzhugs so* (The Medicine Buddha's Decorated Four Tantras Annotation, The Blue Lapis Lazuli), or *Baidurya sngon po* for short. The book, twice as long as the original *Rgyud bzhi*, was finished in 1687. Since this is a comprehensive text embodying the merits of all scholars with refined contents, easy to read and understand, many scholars appreciate it. It has become the standard commentary on *Rgyud bzhi* and is treated as a compulsory text for learning it.

Sangs rgyas rgya mtsho also wrote many other medical books. Among them, *Gso rig sman gyi khog 'bugs* (History of Tibetan Medicine) is the most famous and important. Its full title is *Dpal ldan gso ba rig pa'i khog 'bugs legs bshad baidurya'i me long drang srong dgyes pa'i dga' ston bzhugs so* (General Introduction to Medicine, The Happy Feast of Immortals). This is by far the most authoritative text in Tibetan medical history. Furthermore, he was not satisfied with *Baidurya sngon po* only, so he wrote another book, *Man ngag rgyud lhan thabs* (Supplement to Secret Tantra) to make up for the deficiencies of the original classic. His medical works number over 20.

Sangs rgyas rgya mtsho was very enthusiastic about education in Tibetan medicine, paying attention to the training of successors. Right after the enthronement of the fifth Dalai Lama, the spiritual leader ordered that a medical school be established at 'Bras spungs Monastery in the Western suburbs of Lhasa, enrolling young people from the region with *Rgyud bzhi* as its main curriculum. Moreover, the Dalai Lama also instructed the restoration of the class in Xigatze to continue its training of Tibetan medical workers. The title of the class was changed to *Shen xian yun ji si* or *Drang srong 'dus pa'i gling* (Monastery for Aggregation of Immortals). Again, *Rgyud bzhi* was its main curriculum. Unfortunately, the latter was suspended upon the death of the Dalai Lama.

Several years later, Sangs rgyas rgya mtsho selected the site of Lcag po ri (Iron Hill) just opposite the Potala Palace to set up another medical school in line with the will of the late Dalai Lama. The curriculum included, in addition to *Rgyud bzhi*, other books such as *Zeng bu si bu yi dian mi jue ben ji* (Supplements to Collection of Man ngag rgyud) and *Cao yao mi fang* (Secret Herbal Formulary). Practice was also summarized. For instance, herbs were collected each year in the mountains, and students were encouraged to recognize various medicinal herbs and gain a better understanding of nature.

Sangs rgyas rgya mtsho set up an advanced medical class within the Potala Palace, and famous physicians were invited to teach. To improve teaching efficiency, Sangs rgyas rgya mtsho designed and produced a set of intuitive teaching tools, hanging painting scrolls, called *Sman thang* in the Tibetan language.

Under the auspices of Sangs rgyas rgya mtsho, the drawing of a series of *Sman thangs* was initiated. Sangs rgyas rgya mtsho used his *Baidurya sngon po* as a basis for the paintings and, by 1688, a series of 60 paintings had been completed. But, Sangs rgyas rgya mtsho was not satisfied, and he added more detail of pulse feeling, urine analysis and moxibustion, and sketching the actual samples of herbs collected from places throughout the region. Thus, a complete set of 79 paintings was finally produced in 1704.

As an epochal event in the history of Tibetan medicine, Tibetan medical paintings include all aspects of the medical field, such as the origin of medicine, fundamental theory, physiology, anatomy, etiology, pathology, therapeutic methods, surgical instruments, symptoms of all clinical aspects, diagnostics, materia medica and prognosis, and medical ethics as well which is not only the first of its kind but also the only example in the history of world medicine. This popularized medical knowledge with intuitive education, playing a very active role in the spreading and popularization of Tibetan medicine. It is a rare valuable historical relic with very high value that has attracted much attention around the world.

Sangs rgyas rgya mtsho was a great medical man. He made substantial and distinguished contributions to the development of Tibetan medicine. Unfortunately, his political notions clashed with other politicians, and the relationship among them deteriorated after the death of the fifth Dalai Lama. He was assassinated by his enemy and died a premature death at the age of 53.

Seafaring

Robert G. Bednarik

When humans began to cross sea barriers, they demonstrated what they were capable of by harnessing nature. This may have been the most consequential single achievement in human history, because it marked the advent of the domestication of natural systems – the evolution of technologies that harness such energies as wind, wave action, current and buoyancy. The importance of this is not so much in the expanded ability of colonization or the introduction of "assisted locomotion", but in the cybernetic feedback derived from the conscious manipulation of natural systems and its impact on the cognitive and intellectual development of hominins. From an archaeo-technological perspective, early maritime navigational ability provides a more accurate determination of maximal technological capability than any other available evidence – rather in the same way as space travel does today. Hence there are several good reasons to take a special interest in how, when and where seafaring began.

No physical evidence of Pleistocene seafaring has ever been reported, nor have we any credible depictions of watercraft in the rock art or portable art of the Ice Age. Direct archaeological evidence of navigation peters out between 8,000 and possibly 10,500 years ago (Bednarik 1997), consisting of Mesolithic paddles from Holmgaard (Denmark) and Star Carr (England); a worked reindeer antler that may have been a rib of a skin boat in the Ahrensburgian of Husum (Germany); and the somewhat younger canoes and dugouts from Pesse (Holland, 8265 ± 275 carbon years), Noyen-sur-Seine (France, 7960 ± 100 carbon years), and Lystrup 1 (Denmark, 6110 ± 100 carbon years) (Zeist 1957; Arnold 1966; Clark 1971; Ellmers 1980; McGrail 1987 1991; Bednarik and Kuckenburg 1999). Watercraft and paddles of the late first half of the Holocene are also known from two Japanese sites (Aikens and Higuchi 1982: 124; Ikawa-Smith 1986). Bitumen-covered wooden slabs thought to have been part of boats, about 7,000 years old, were found in the Kuwaiti desert, in a stone building at the site As-Subiyah. The subsequent development of watercraft in the Middle East and later elsewhere is not considered here; it does not refer to the beginnings of seafaring.

Indirect evidence of maritime travel occurs in a variety of forms: as human occupation evidence, human remains, rock art or exotic materials found in the archaeology of islands or continents that were never connected to another landmass since humans first appeared. For instance, such evidence can be in the form of insular obsidian on the mainland, as that from Frachthi Cave in Greece, 11,000 years old (Perlés 1979; Renfrew and Aspinall 1990). Much earlier sea crossing and island colonization is indicated by Mousterian tools on Kefallinía, west of Greece (Kavvadias 1984; Warner and Bednarik 1996), and by the presence of Clactonian-like stone tools and human remains in Middle Pleistocene sediments on Sardinia (Martini 1992; Bini et al. 1993; Ginesu et al. 2003). Crete was also occupied during Palaeolithic times, as indicated by human remains of a modern specimen with preserved archaic features (Facchini and Giusberti 1992: 200). In Japan, Palaeolithic seafaring is demonstrated by the remains of four humans at Okinawa (Baba 1998) and by transported obsidian at Kozushima (Anderson 1987), in North America by the two femora fragments and one humerus from Arlington Springs on Santa Rosa Island (reportedly 13,000 years old). However, in comparison to the seafaring evidence in the region of Indonesia and Australia, most such finds from Europe and elsewhere are comparatively recent. The only evidence of a Lower Palaeolithic island occupation outside that region is that from Sardinia, on the order of 300,000 years old. It seems also probable that the first colonizers of Europe crossed the Strait of Gibraltar, even though secure evidence for this is lacking (Bednarik 1999a).

In March 1957, Dutch researcher Theodor Verhoeven found stone implements eroding from a fossiliferous deposit at the site Ola Bula in Flores, a geologically recent island of Indonesia (Verhoeven 1968: 400). A leading archaeologist, Henri Breuil, recognized among these finds a number of typical Lower Palaeolithic stone implements (Verhoeven 1958: 265). In mid-1963, Verhoeven succeeded in demonstrating by excavation the contemporaneity of Flores artefacts with fossil remains of *Stegodonts* (extinct elephants) at a second, nearby site, Boa Leza. Johannes Maringer, an archaeologist of the Anthropos-Institut, Germany, joined him in 1968 and the two excavated together at Boa Leza, Mata Menge and Lembah Menge. The three sites occur within easy walking distance and are all exposures of a geological stratum rich in fossil remains and stone tools (Maringer and

Verhoeven 1970a,b,c, 1972, 1975, 1977; Maringer 1978). This deposit is overlain by a series of rock facies up to 120 m thick, so there can be no question about the great antiquity of this presence of humans on an island that has never been connected to any other landmass. Initially this evidence was estimated to be up to 830,000 years old, based on the geology, palaeontology and the presence of tektites[1] (Koenigswald and Ghosh 1973). Subsequent palaeomagnetic analyses at Mata Menge (Sondaar et al. 1994; Bednarik 1995) suggested that the Matuyama-Brunhes reversal to normal polarity (780,000 BP) occurs just below the fossiliferous stratum. Later applications of fission-track analysis of zircons yielded datings of stone tool-bearing sediments from Boa Leza, Mata Menge, Koba Tuwa and Ngamapa, and all fell between 750,000 and 850,000 years BP (Morwood et al. 1999) (Fig. 1).

It thus seems soundly demonstrated that *Homo erectus*, currently the only available hominin candidate, was sufficiently well established on the island of Flores towards the end of the Early Pleistocene to leave behind numerous major deposits of stone tools. Flores is separated from Bali, the furthest extension of the Asian mainland during the Pleistocene (at times of low sea level), by two other islands, Lombok and Sumbawa (as well as several smaller islands which may have been connected to the larger ones at times of lower sea level), and the lack of any former land-bridge between Bali and Lombok was initially recognized by Wallace (1890). While this is based primarily on biogeographical observations, it is supported by the continuing uplift in the "inner arc" of the Indonesian archipelago, which amounts to at least several hundred metres over the past million years in this tectonically active subduction zone. Despite the rich mainland fauna of both extant and fossil terrestrial eutherians (placental mammals) that can be found as far east as Bali, few of them ever reached the islands of Nusa Tenggara, or southern Wallacea (Bednarik and Kuckenburg 1999: 108–109). Some, such as the dog, pig and macaque, were probably carried by humans, while small mammals, mostly Muridae (mice, rats, voles and relatives), probably crossed on floating vegetation (Diamond 1977). Elephants, however, swam to many of the islands of Wallacea (Hooijer 1957; Verhoeven 1958, 1964; Glover 1969; Bednarik 1999b) and the Philippines (Koenigswald 1949), where they underwent speciation and dwarfism. Elephants are superb long-distance swimmers, able to swim 48 km at sea and at a speed of 2.7 km/h (Johnson 1980). Hominins, however, lacked the trunks and swimming ability of elephants. Even deer, hippos,

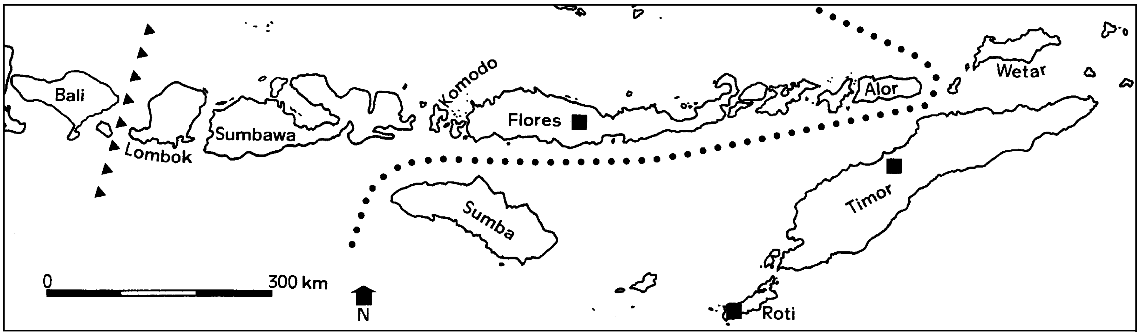
Seafaring. Fig. 1 *Stegodont* remains and stone tools in solid siltstone deposit, ca. 840,000 years old, Boa Leza, Flores. Photo by author.

tapirs and pigs, four of the most capable terrestrial long-distance swimmers, never colonized Wallacea unaided (Fig. 2).

In 1998, Australian Bednarik demonstrated the contemporaneity of human occupation with a *Stegodont*-dominated Middle Pleistocene fauna in West Timor (Bednarik 1999b). His fieldwork in Timor and Roti has involved several Pleistocene sites in the island's western half (East Timor having become politically stable only recently), focusing on the Weaiwe valley near Atambua. There, a sequence of Pleistocene sediments occurs above estuarine clay deposits containing an abundance of marine shells and snails. This demonstrates an uplift of well over 300 m since they were formed. The Weaiwe Formation, a Pleistocene conglomerate, has yielded remains of Stegodontidae from six sites now (Bednarik and Kuckenburg 1999), and evidence of human presence in the fossiliferous stratum occurs at two, Motaoan and To'os (Bednarik 1999b). At the time of its formation, the Pleistocene occupation layer was located close to sea level, which could itself have been much lower at the time.

All of the islands from Bali to Timor and Roti are well visible from the shores of departure, but once the Middle Pleistocene mariners had settled Timor, they could travel no further. The shores of Australia have never been visible from Timor, at any sea level, and it appears that the lack of visual contact prevented the human colonization of Australia for many hundreds of millennia. The initial landfall in Australia is presently thought to have occurred about 40,000–60,000 years ago. By that time, it appears, the Ice Age seafarers had acquired sufficient experience to venture into the unknown, to depart without the certainty of seeing their destination. It would have been known to them since time immemorial that there was a large landmass to the south. They could have predicted this from plumes of smoke occasionally rising from grassfires in

[1] Tektites are glassy objects that are thought by most scientists today to be melt products of terrestrial rocks formed by hypervelocity impacts of large, extraterrestrial objects.



Seafaring. Fig. 2 Map of southern Wallacea (Nusa Tenggara), Indonesia. The presumed dividing line between the Eurasian and Australian continental plates is shown dotted, and Wallace's biogeographical line is between Bali and Lombok. The squares indicate known hominin occupation sites of the Early and Middle Pleistocene.

Australia, from cumulus clouds regularly forming over the land, from the movements of waves, currents, migratory birds and turtles. But there is a great leap from merely predicting the existence of land, to having the courage of embarking on a journey of no return to an unseen shore.

A good deal of evidence from about 33,000 to 27,000 years ago indicates that many islands near northern Australia had been settled by that time. These amazing seafarers, with their still essentially Middle Palaeolithic technology, undertook lengthy journeys to in some cases very small target landmasses (Bednarik 1997). Most of these islands could not have been sighted until a raft reached their proximity; this is the case with the Monte Bello Islands (100 km from Australia), Gebe Island (west of New Guinea), New Ireland (east of New Guinea), and Buka Island (180 km from New Ireland). It thus seems very probable that the maritime competence of the much later Polynesians was the ultimate outcome of a process that began almost a million years ago.

The complete lack of any direct physical evidence of maritime technology from the entire Pleistocene renders it pointless to speculate about the circumstances of these endeavours without additional information. No sustained replicating experimentation of archaeology had been conducted in relation to this subject before 1996. Since then, the First Mariners Project (►http://mc2.vicnet.net.au/home/mariners/web/mariners.html) led by Bednarik has set out to determine the most likely means employed by *Homo erectus* in crossing Lombok Strait >840,000 years ago, and the most likely circumstances of first landfall by *Homo sapiens* in Australia and elsewhere. The project investigates all demonstrated human sea crossings of the Pleistocene and plans to replicate many of them. Archaeologically derived knowledge about the technology of the periods in question, particularly in stone tool knapping, wood and bone working, serves as a reference source for these projects (Bednarik 1997, 1999b, 2001a). Some aspects of relevant material use can be replicated precisely on the basis of form of, and work markings on, archaeological finds, as for instance Middle Palaeolithic bone harpoons or Lower Palaeolithic wooden artefacts. Others must be determined according to systematically derived probability estimates based on experimentation. Expeditions endeavour to create authentic conditions for the construction of a series of primitive vessels and their sailing across the sea barriers in question. This involves, for instance, the use of appropriate stone tool replicas in felling and working bamboo, and in constructing and sailing the rafts. Hundreds of issues of technology need to be addressed, including the means of carrying freshwater, of fishing at sea, of locating sources of stone tool materials for raft construction, issues of maritime design, and the procuring, selection, treatment and utilization of materials for the construction of vessels and equipment (Fig. 3).

Seafaring. Fig. 3 Palaeolithic bamboo raft in heavy seas on Timor Sea, its bow rising several metres above the water. Photo by author.

The first full-size experimental vessel was launched at Oeseli in southern Roti in early 1998 and sailed for sea trials with a crew of eleven (Bednarik and

Kuckenburg 1999). Some aspects of this 23-m-long, ocean-going bamboo raft of about 15 tonnes plus cargo were judged to be unsuitable and the vessel was beached for destructive sampling and material testing. A radically different, simpler design led to an 18-m bamboo raft of only 2.8 tonnes. It travelled with a crew of five men from Kupang to Darwin in December 1998, sailing part of the 1,000-km journey under extreme conditions (Bednarik 1999b; Bednarik et al. 1999). In March 1999, a simple 11-m bamboo platform set out from the eastern-most point of Bali to attempt a crossing of Lombok Strait. It was forced north by strong seas and the attempt was abandoned. But by the end of that year, a similar, 12-m-long simple platform of bamboo, lacking any sail or means of steering, was being built for a second attempt. This vessel was as rudimentary as a raft can possibly be, weighing only 1,080 kg. It crossed Lombok Strait successfully with a crew of 12 men in January 2000. The experiment showed how even a treacherous stretch of sea such as Lombok Strait could be crossed with purely Lower Palaeolithic means (Bednarik 2001b). Similarly, the 12-m *Rangki Papa* ("Father of all Rafts", in the local dialect) succeeded with a crew of twelve in October 2004 in crossing Sape Strait, which separates Sumbawa from Komodo and Flores. In that experiment, filmed by *National Geographic*, the assembly of the 970 kg bamboo vessel took only 4 days. The experiments in the Mediterranean had commenced earlier, in September 1999, on the coast of Morocco, where two prototype rafts were constructed entirely with Lower Palaeolithic stone implement replicas, and then taken for sea trials. One of these vessels, a pontoon-type raft, was made of cane, the other of inflated animal skins (Bednarik 2001a) (Figs. 4 and 5).

The primary purpose of these experiments is to examine each of the many variables involved in Pleistocene seafaring quantitatively, to create the conditions for constructing multiple scenarios within a realistic framework of probability. In this procedure, the confidence that the most probable scenario can convincingly be identified is a function of the variables or determinants accounted for satisfactorily. Therefore numerous experiments are essential, and all need to be conducted under controlled conditions. While the most sensible, economic or logical course of action is not necessarily the one always taken by hominin mariners, there are several arbitrary limiting factors. For instance, these journeys had much to do with survival, and we can reasonably assume that they were on the very limits of the technologically possible at the times in question (Bednarik 1999c). The most probable scenarios can then be tested by reference to known parameters of technological competence at the time in question. These are derived from the archaeological research forming part of the overall project. This would seem to be the only scientific method available to us to generate informed and plausible explanations for the very early maritime feats of hominins.

Seafaring in the Polynesian Outliers

RICHARD FEINBERG, MARIANNE GEORGE

Observers, for many years, viewed indigenous Pacific Islands seafaring as a vanishing art, largely confined to the Central Carolinian atolls of Micronesia. Yet, in a number of small, remote Polynesian communities, traditional vessels and knowledge of how to use them are an active, ongoing concern. Our awareness of these systems of knowledge and practice is preserved in works on Ontong Java and Nukumanu (Sarfert and Damm 1929; Haddon and Hornell 1975 [1936–1938]; Feinberg 1995), Taumako (Davenport 1962, 1964, 1968; Lewis 1972; George 1998, 1999, n.d.; Vaka Taumako Project 1997, 1999), and Anuta (Feinberg 1988, 1991). Important information also is presented on Kapingamarangi by Lieber (1994) and on Tikopia in Firth's voluminous writings.

Generalizations about these "Polynesian outliers" are difficult. They range from communities like Sikaiana (Donner 1995), where sailing canoes have been entirely abandoned, to such isolated specks of land as Taumako and Anuta, where traditional equipment and techniques remain in use or are remembered to a remarkable degree. Even in precontact days, the Polynesian outliers incorporated a good deal of diversity. On Ontong Java, Nukumanu, Takuu, and Nukuria, vessels as well as sailing and wayfinding techniques closely resembled those of Micronesia; on Tikopia and Anuta, maritime technology and practice have been closer to the standards typical of Polynesia. Meanwhile, the impressive seafaring technology of Taumako (Duff Islands) and the Polynesian Reef Islands of the eastern Solomons combines elements known from Eastern Polynesia, the central outlier atolls, and Micronesia (Fig. 1).

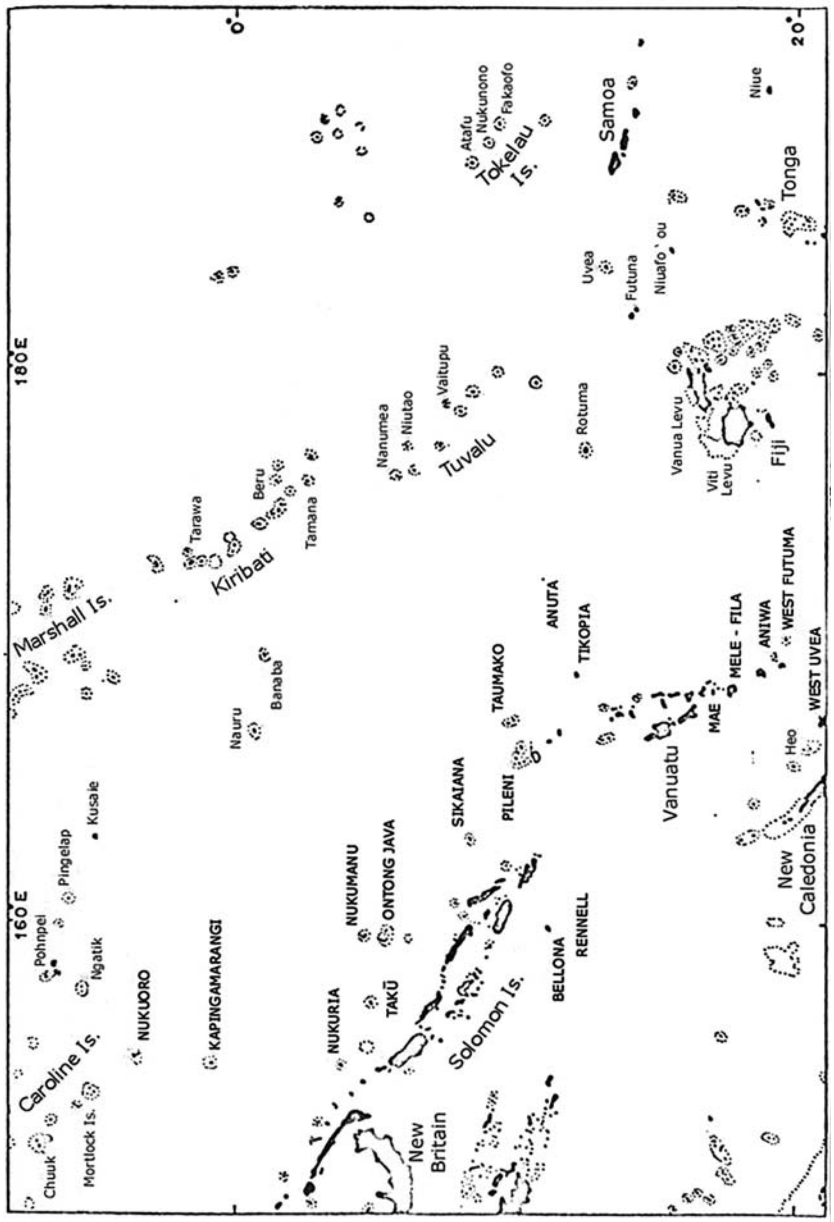
Canoe Construction and Design

Hull design in the central and northern Polynesian outlier atolls resembles that reported for the Micronesian Caroline and Marshall Islands. This is particularly evident in the voyaging canoes that have been described for Takuu (Haddon and Hornell 1975) and Nukumanu (Sarfert and Damm 1929; Haddon and Hornell 1975; Neyret 1977; Feinberg 1995), and in the model voyaging canoes that Takuu craftsmen still produce for sale to art collectors and tourists. These vessels were 40–50 ft long, constructed with deep-V hulls, rigged with triangular pandanus-leaf sails, and were symmetrical from end to end, making bow and stern identical. The outrigger float was significantly shorter than the hull, and small shelters might be built on the outrigger platform, which was always kept to windward when the vessel was underway. These atolls also produced smaller canoes, most of which were round-bottom dugouts, that might be sailed, poled, or paddled. Since the late nineteenth century, large voyaging canoes have no longer been built. On some atolls like Sikaiana (Donner 1995), canoes have been almost totally abandoned except for very small vessels that are intended for fishing on the lagoon, although there is evidence of significant canoe voyaging in times past.[1] Small fishing canoes intended for calm water are also used on Ontong Java, Nukumanu, and Takuu. Somewhat larger canoes may be used to transport cargo to and from visiting ships or for hauling copra and taro from the outer islets. Nukumanu still construct and use large canoes for voyaging to Ontong Java, across 30 miles of open ocean. Contemporary Nukumanu voyaging canoes may be as long as their predecessors, but they are less carefully constructed and resemble the smaller ones in design. They may be rigged for sail, but Nukumanu prefer outboard motors for propulsion, especially on longer journeys. In 2000, Nukumanu islanders told Feinberg that fiberglass motor-driven boats on all of these atolls are gradually replacing canoes (Figs. 2 and 3).

On Taumako (Duff Islands) and the Polynesian Outer Reef Islands of Nifiloli and Pileni, voyaging canoes are called "canoes of Lata." Lata, a widely recognized Polynesian culture hero, is said to be the first person to build and sail a voyaging canoe of the type known as *te puke*. These are built with a roundish hull that is hollowed out from a single log. The top is boarded over and made watertight, except for the area enclosed by a riser box, which provides access for bailing and stowage of nonwater-sensitive cargo and ballast. When under sail the hulls are almost entirely submerged. The crew stays on one of two platforms that straddle the riser box and outrigger beams. Although there is one outrigger float (*ama*) per canoe, it may be fashioned from as many as four float timbers lashed together, depending on how much flotation is needed. The crew situates itself on whichever platform

[1] According to elderly Duff Islanders, the Sikaiana were in regular communication with Taumako prior to the 1917 influenza pandemic, and they ordered and used large voyaging canoes from Taumako.

S



Seafaring in the Polynesian Outliers. Fig. 1 Map of Polynesian outliers and surrounding islands.

is most appropriate for sea conditions and the trim of the cargo. The predominantly submarine hull is subject to less surface tension and wave action than more conventional hulls, making them considerably faster. To the best of our knowledge, this hull design is unique to Taumako vessels.[2] Like the vessels of the central outlier atolls, as well as some from the Polynesian heartland (e.g., the Tongan *kalia*), *te puke* are equipped with shelters on the outrigger platform.

Taumako sails are made from panels of plaited pandanus mats, sewn together vertically to form a graceful, slender foil, or delta wing shape. Unlike many Pacific Islanders who have abandoned pandanus sails in favor of cloth, Taumako sailors prefer pandanus, which they say lasts longer and is easy to maintain and repair. The design resembles "crab-claw" sails of Tahiti and Hawai'i as depicted by artists on early European voyages of exploration, but its symmetrical shape, with long, slender, arcing wingtips, has few parallels in Oceania (Fig. 4).

[2] We must note, however, that few ancient hulls have been recovered from Pacific waters. Perhaps, with further research, we will find evidence of submarine hull shapes from other parts of Polynesia.

Seafaring in the Polynesian Outliers. Fig. 2 Nukumanu outrigger sailing canoe under sail on lagoon.

Seafaring in the Polynesian Outliers. Fig. 3 Small Nukumanu outrigger sailing canoe immediately after launching from beach on lagoon side of the village islet.

Seafaring in the Polynesian Outliers. Fig. 4 *Te puke* type voyaging canoe from Taumako island under sail on open sea.

Most canoes of this description have been constructed on Taumako on order from other communities in the Santa Cruz Islands and elsewhere in the Solomons. In the 1920s, over 200 *te puke* were observed to be sailing in what is now Temotu Province (Davenport 1968). Generally, the Outer Reef Islanders specialized in navigation while the Taumako specialized in canoe building.

For a period of a few decades in the middle to late twentieth century, construction of *te puke* was almost abandoned because of depopulation and suppression of voyaging by colonial authorities. The last working *te puke* broke up off Nifiloli in 1963, although a few local vessels of other designs kept sailing between Santa Cruz (Ndeni) and the Reef Islands until the early 1970s. However, since around 1980 – and particularly since the mid 90s – interest in actively making and using traditional voyaging canoes has revived, in large part thanks to the activities of the Vaka Taumako Project (see below).

Te puke canoes (*nga puke*, pl.) are distinguished from other Taumako vessels by their very large cargo carrying capacity. They are made of heavier and harder woods than other canoe types, have a riser box that lifts the outrigger beams some three feet or so above the top of the hull, have a shelter on the windward platform, and are at least 36 ft in length. Older Taumako state that until Lata made the first *te puke*, they depended on double-hulled *vakalua* for interisland travel. *Nga puke*, being lighter and faster, offered superior performance. One that a group of Duff Islanders sailed from Taumako to Vella Lavella in 1980 was observed by a Solomon Islands government ship to be cruising at a speed of ten knots.[3] With their massive outrig and ingenious lashings, *te puke* are also very strong and seaworthy (Fig. 5).

Te alolili canoes are lighter and faster, designed to carry people and light cargo. They range in length from 18 to 33 ft. The Taumako also make smaller, less elaborate outrigger canoes called *te alotovi*, which may or may not be rigged for sail. And they construct monohulled, nonoutrigger paddling canoes, on which they may either rig lateen sails made of rice bags or add a wooden plank to serve as a motor mount. They use these primarily to transport cargo within the Duff Islands and to visiting government ships. For some purposes they, like other islanders, would like to have fiberglass canoes propelled by outboard motors, and in 2001 there were at least two working outboard engines on Taumako. Scarcity of fuel, however, normally precludes their use. As of January 2002, Taumako still

[3] In 1979 people of Taumako built a *te puke* to represent the Solomon Islands at the 1980 Pacific Arts Festival in Port Moresby. The voyage from Taumako to New Guinea had to be cut short for political reasons. Local officials required them to travel via Honiara, the national capital, which meant taking a risky and nontraditional route. Those officials then held the canoe so long that the seasonal winds ceased before the crew could navigate the vessel from Vella Lavella in the Western Solomons to Papua New Guinea.

Seafaring in the Polynesian Outliers. Fig. 5 "Earth oven" and "fish eye" lashings on cross beams and outrigger struts of *te puke* canoe.

Seafaring in the Polynesian Outliers. Fig. 6 Outrigger canoe of *vaka pai manu* type, rigged with rectangular sail, on beach at Anuta island.

had no fiberglass vessels. However, such canoes from Lata, the Temotu provincial capital, occasionally go to the Duffs on emergency missions.

Canoes on Tikopia and Anuta more closely resemble those documented in the so-called Polynesian Triangle. Anuta is a tiny volcanic island with a small reef flat and no protected water. As a result, Anutan canoes tend to be larger than their Tikopian counterparts. Otherwise, they are similar in design. Hulls are of deep-V construction. They are hewn from a single tree and generally built up with one plank to increase freeboard. Unlike canoes of the Santa Cruz Islands and the Polynesian atolls to the north and west, Anutan craft have a distinct bow and stern, and the outrigger is always kept to port regardless of one's heading in relation to the wind. They range up to about 35 ft in length and average 20–25 ft, with a few that are much smaller. Virtually all Anutan canoes have the same design, with high gunwales and carefully carved bow and stern covers to minimize shipping of water as one passes through the surf and sails on choppy seas. Anutans and Tikopians who live in the central Solomons, either in Honiara or the Russell Islands, have more sheltered water and less time for fishing than their compatriots at home. Their canoes, therefore, are smaller, are usually designed to be paddled rather than sailed, are not augmented by gunwale planks, and typically lack bow and stern covers. Canoes of this type are known as *tovi*; the larger, more elaborate canoes with ornately carved bow and stern pieces are termed *vaka pai manu* "birdlike canoes." The bow and stern pieces (*puke*) are intended to resemble birds (Figs. 6 and 7).

Like the Taumako, Anutans still make their canoe hulls exclusively from local materials – primarily wood and sennit cord. They do not use nails, screws, or other commercial fasteners. They occasionally employ a piece of Styrofoam for caulking, and commercial glue sometimes replaces breadfruit sap to help caulk the joint between the plank and the main hull. However, the only commercial product that they use with any regularity is water-resistant paint, which they apply in an effort to protect the hulls of their larger vessels.

Seafaring in the Polynesian Outliers. Fig. 7 Anutan outrigger canoe of *tovi* type, on beach in Russell Islands. The canoe is rigged with a lantern holder for catching flying fish at night.

The sail and rigging show more Western influence than the hull. Stays may be commercial rope, and rectangular sails usually fashioned from cotton cloth have replaced the old triangular pandanus-leaf sails. Like many other Pacific Islanders, Anutans were happy to abandon pandanus sails, which become heavy and difficult to handle when they get wet. The rectangular sails were introduced in order to provide more surface area in proportion to the mast height. This increases the canoe's speed without decreasing stability; the tradeoff

Seafaring in the Polynesian Outliers. Fig. 8 Anutan child paddling a large bowl (*kumete*) through the surf on the reef flat at high tide.

is that rectangular sails do poorly beating against a headwind.

In addition to *vaka pai manu* and *tovi*, Anutans recognize outriggerless canoes, which they call *puai vaka* "egg canoes." However, they do not make such vessels. Their closest analogues are large wooden bowls (*kumete*) of the type that might be used for preparing puddings or making turmeric dye. These bowls are vaguely canoe-shaped and can be paddled if the sea is not too rough (Fig. 8).

Sailing Techniques

As Lewis (1972) noted, most of the Polynesian outliers use the Micronesian strategy of sailing with the outrigger to windward. In order to accomplish that, they tack by moving the mast, sail, and rigging to the opposite end of the canoe, converting the old bow into the new stern and vice versa. Tikopians and Anutans have adopted the more common Polynesian strategy of having a distinct bow and stern with the outrigger fixed to the port side of the hull. As a consequence, the outrigger is sometimes in the canoe's lee, and many hulls are constructed with a slight bulge on the port side to help keep the outrigger float from being submerged when the wind blows hard from starboard.

Among outrigger canoes, those of Nukumanu and Ontong Java, with their triangular sails, do a relatively good job of beating into a headwind, and Taumako's *te puke* may do better still. George found that one such vessel, *Vaka Taumako*, could point higher and go faster than her 32.5 foot-long gaff cutter rig. It made better than five knots at 75° off the wind in a steep, choppy sea and a twenty-knots breeze. In addition to being extraordinarily efficient, the Taumako sail and rigging may be trimmed to suit a wide variety of conditions.

Anutan vessels, with their rectangular sails, do not sail well unless the wind is either astern or abeam. Therefore, Anutans try to arrange their trips in such a way as to avoid having to beat against the wind. For example, their voyages to Patutaka, 30 miles to the southeast, are usually made during the trade-wind season but at a time when the wind shifts temporarily to the north or west. They assume that it will shift back to the southeast within a few days, and they will be able to journey in both directions with a favorable wind. Should they need to travel at much less than a 90° angle to the wind, they either wait for a change in weather, return to their point of embarkation, or stow their sails and paddle into the wind.

Navigation

Those communities that continue moderate- to long distance voyaging have retained much of their ancestors' knowledge of constellations, movement of astronomical bodies, and star paths. Feinberg (1988, 1995), for example, has documented the continuing astronomical knowledge of Anutan and Nukumanu wayfinders. Conversations with islanders from both communities over a period of several months in 2000 made clear to him that young people have perpetuated this knowledge. At the same time, however, astronomical knowledge in the late twentieth and early twenty-first centuries has apparently declined from what it was a century earlier. Present-day Anutans insist that members of previous generations knew more than they know, and similar views among Nukumanu appear to be confirmed by the reports of Sarfert and Damm, which list many more constellations than islanders recognized in the 1980s.

Both Nukumanu and Anutan navigators maintain their course by swells as much as by the stars, which cease to be helpful during the day or any time the sky is overcast. In this respect, they resemble most other Pacific Island voyagers, many of whom depend on swell patterns even when piloting large ships. Both Nukumanu and Anutans also distinguish between swells and reflected waves, which may be felt at distances of up to 20 miles from land and are useful for making landfall. These are more difficult to discern than ocean swells, and only a few of the most proficient navigators are able to use them effectively. Islanders insist that skill at detecting "land waves" was more widely distributed in their communities in earlier generations. Along with swells, islanders pay attention to wind patterns, which tend to be relatively stable even when stars and the sun cannot be seen.

Like Nukumanu and Anutans, Taumako and Outer Reef Islanders agree that much knowledge of celestial navigation has been lost over the past century.

The most authoritative commentator on this point is Taumako Paramount Chief Koloso Kaveia. Kaveia began his voyaging career as a small boy sailing on canoes based at Pileni in the Outer Reefs prior to 1920. Fellow islanders consider him to be the most experienced and distinguished living navigator and voyager. While Kaveia and other Duff Island navigators are familiar with star paths, however, they consider celestial movements and swell patterns to be secondary to knowledge of the "wind compass" (*nohoanga te matangi*).

Nohoanga te matangi is a comprehensive system that correlates information about wind directions, calendric seasons, and movements of celestial bodies with sea routes. It is not just a wind compass in the unexplained and often partial forms that have been previously reported (e.g., Lewis 1972). It is a tool, rather like a clearing house or slide rule, for bringing into relationship the various fields of information relevant to planning a particular voyage. Its use also presumes facility with weather magic to control wind and sea states, and this requires good command of the protocols for dealing with one's ancestral spirits. *Nohoanga te matangi*'s major elements include ten main celestial bodies that are used in navigation plus the two "wing stars" located to either side of each primary star. The "wing stars" are used in cases when the current, sea state, or wind conditions preclude reliance on the central star paths. Navigation also presupposes a working knowledge of *te lapa* – the luminescent lightning-like appearances that signal the direction and distance of land (see below).

In addition to wind, waves, and stars, islanders rely on a variety of subsidiary techniques to hold a steady course or to home in on a target island. In recent generations, some of these techniques have been abandoned and receded into legend. For example, Anutans say that dolphins, to which they refer as *nga ariki o te moana* (kings of the ocean) might lead a lost voyager to land. Nukumanu speak in similar terms of meteors, which they term *tanaloa* – the name for one of the great pre-Christian gods in much of Polynesia. Other subsidiary techniques are still relied upon and are apparently effective. Most islanders continue to observe the flight patterns of birds as a technique for land finding. Lewis (1972) has reported patterns of phosphorescence (*te lapa*) which Reef and Duff Islanders continue to employ for the same purpose. George has learned that Taumako navigators can make effective use of this phenomenon at impressive distances. In 1980, Kaveia used *te lapa* to find his way between the large islands of the Solomons chain, sometimes at a distance of over 110 nautical miles. It also appears that the appearance of *te lapa* from each island or reef has a distinctive character. The phosphorescent flashes shoot across the ocean surface and are easiest to see in the interstices of intersecting waves.

Social Relations

On Nukumanu and Anuta, navigators are admired and respected for their skill, but they do not hold a formal position. An Anutan navigator is known as *tau tai mau kaavenga* (expert at finding star paths), which is more a description the navigator's skill than a title. In neither community are there rites of passage that mark one's transition to navigator status; most men have some knowledge in this area, but some have considerably more than others. An expert navigator may come from any descent group and any social stratum, from chiefs to commoners. On both Nukumanu and Anuta, education in the skills of boat building, sailing, and navigation also is informal. There are no navigational schools, nor is there any formal apprenticeship. A novice watches the experts and learns primarily through emulation.

On Taumako, the navigator is a highly trained specialist. Kaveia apprenticed for many years with Pileni relatives, then married and returned to Taumako where he studied navigation with his father. In addition, a Taumako navigator must have a canoe and, in earlier times, contacts or partners on distant islands as well as access to red feather money and other valuables. An enterprising person of low rank can acquire the necessary assets, but high-status males have a clear advantage. Today, education in canoe building and navigation has been incorporated into the Vaka Taumako Project in an attempt to ensure the maintenance of older knowledge and practices.

Change

Seafaring practices have changed in all the Polynesian outliers over the past two centuries, but to different degrees and in different ways on different islands. The great voyaging canoes (*vaka hai laa* or *vaka fai laa*) of the central outlier atolls have not been produced since the late nineteenth century, but sailors from Nukumanu and Ontong Java continue to make the 30-mile voyage between the two atolls, and they sometimes still use wooden outrigger canoes powered by sail. Sikaiana, at the opposite extreme, has entirely given up production of ocean-going canoes. Even Anutans, whose seafaring activities depend entirely on outrigger canoes of traditional design, who regularly voyage 60 miles to Patutaka and back, and occasionally still sail to Tikopia, a 150-mile round trip, have replaced pandanus sails with cotton cloth or (occasionally) plastic sheets.

While much has been lost, some of the outliers have nonetheless maintained a good deal of their seafaring knowledge and continue to put it to good use. Anutan reliance on wooden *vaka pai manu*, held together with sennit cord, has continued uninterrupted to the present day. Equally impressive is Taumako's self-conscious effort to reverse a decline in seafaring knowledge through the Vaka Taumako Project – an educational enterprise intended to promote mastery of traditional canoe-building and voyaging skills among younger community members by constructing several *te puke* and *te alo* voyaging canoes and sailing them to remote destinations under the direction of skilled navigators. In 2001 the Vaka Taumako Project launched the first class of over 50 students. The students aim to learn eight necessary skills for building and navigating voyaging canoes using only traditional Polynesian methods. A 65-foot by 40-foot canoe house was erected to shelter and maintain three vessels that have been produced by the project. It is hoped that this canoe house will also serve as a classroom and archive for Taumako voyaging knowledge, and to accommodate visiting students and voyagers.

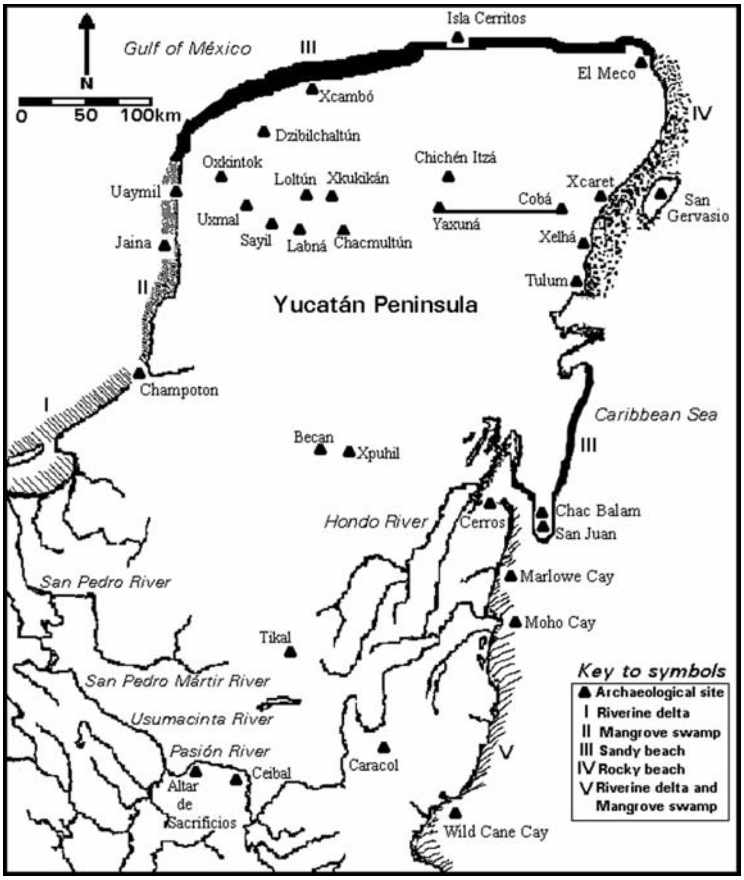
Seaports of the Maya

Rafael Cobos

The marine seacoast of the Maya area extends for more than 1,000 miles and is composed of different environments, which include sandy and rocky beaches, mangrove swamps, and riverine deltas (Fig. 1). These environments were occupied during pre-Hispanic times by individuals who founded numerous communities and built an elaborate infrastructure that caused the rise of seaports during the Preclassic (1200 BCE–AD 200), Classic (AD 200–1050/1100), and Postclassic (AD 1050/1000–1550) periods (Andrews 1990; Nondédéo 1998; Vail 1988).

Ancient Maya seaports are found either directly on the coast or less than 2 to 3 miles inland. As with other seaports in the world, ancient Maya seaports were permanently settled by individuals engaged in different duties that included the maintenance of their community by political, economic, social, and ideological activities. Ancient Maya seaports also provided shelter to sailors, traders, and the merchandise they transported. They facilitated the transportation of goods and gifts that were moved between close and distant regions; they were also used to satisfy basic as well as secondary needs of communities located a few miles inland or hundreds of miles away.

Early explanations about the function of ancient Maya seaports were put forward during the first half of the twentieth century. For instance, it has been suggested that settlements such as Jaina, located in western Yucatán, and Xcaret, located in front of Cozumel Island, functioned as an island necropolis and a port of embarkation to an offshore island respectively. Over the past 50 years, however, the Maya marine seacoast has been the focus of several systematic archaeological investigations, and previously assigned functions of pre-Hispanic coastal communities such as Jaina have been rejected. Regarding Xcaret, archaeological investigations have corroborated its role as a port of embarkation to Cozumel Island as well as a complex seaport that functioned during the Classic and Postclassic periods (Andrews 1990).



Seaports of the Maya. Fig. 1 Maya seaports located in México and Belize.

Systematic research conducted on several pre-Hispanic Maya coastal communities that functioned as seaports indicates that these ancient settlements were arranged in distinctive ways and date to different periods. The unique characteristics of ancient Maya seaports were the result of social, economic, political, and ideological processes that each of them experienced throughout time. For instance, archaeological investigations have revealed three different forms through which these marine seacoast settlements interacted with other marine coastal sites as well as with inland settlements. These three forms of interaction include the coastal port associated with a regional capital, trans-shipment seaports, and the seaport as a social, political, and economically independent unit. A description of each one of these follows.

The Coastal Port Associated with a Regional Capital

Isla Cerritos and Chichén Itzá exemplify the interaction and dependency generated between a top-ranking political unit and a lesser-ranking site. Isla Cerritos is an island off the northern coast of Yucatán whereas Chichén Itzá is located 55 miles directly south and inland (Andrews et al. 1988; see also ►http://www.ncf.edu/andrews/Index.html). The material expression of that dependency suggests that the coastal community of Isla Cerritos was subordinate to the political and economic control of Chichén Itzá to the extent that the main architectural group of the island reproduces on a lesser scale a group of buildings that characterize the regional capital, which include a temple, altar, and colonnaded hall. The contemporaneous nature of the coastal port and the regional capital is demonstrated by the presence of the same types of commercial and utilitarian ceramics. Obsidian found in the coastal port as well as in the regional capital reflects the same supply sources. The remains of shells discovered both in Isla Cerritos and in Chichén Itzá are integrated into the body of archaeological evidence, which demonstrates the interest that the regional capital had in making its presence felt in a very specific sector of the northern Yucatán coast between AD 900 and 1050/1100.

It has been proposed that other settlements located on the seacoast of Belize functioned as ancient

Maya seaports of major inland capitals. The examples include Marlowe Cay associated with Altun Ha, Ramonal-Condemned Point linked to Shipstern, and the Northern River Lagoon associated with Colhá. However, the relationship between Marlowe Cay, Ramonal-Condemned Point, Northern River Lagoon and major inland capitals continues to be speculative, because none of these Maya seaports has been investigated in detail.

Trans-Shipment Seaports

This type of seaport, which served a specialized function, is recognizable by the following characteristics: they are small settlements in comparison to other inland communities, they exhibit a minimum of formal architecture, they are strategic points in the movement of commodities and/or merchandise among regions, and they contain a wide variety of exotic goods by having been part of a complex system of trade or exchange (Inurreta 2004). To date, the best examples of trans-shipment ports analyzed in the Maya area are San Juan, Chac Balam, Moho Cay, Wilde Cane Cay on the coast of Belize, and Uaymil on the northern coast of Campeche (Guderjan and Garber 1995; Inurreta 2004; McKillop 1996, 2005).

For instance, Uaymil emerged as an important coastal port on the northern Campeche coast after AD 800. Uaymil maintained a close relationship with Uxmal and Chichén Itzá, and the archaeological evidence uncovered at Uaymil confirms that this port was founded during the apogee of those two major political units. Uaymil functioned as another link in the chain of coastal sites that facilitated the transport of commodities between Chichén Itzá, located in central Yucatán, and the regions of the western Guatemala highlands, central Veracruz, central México highlands, and western México. When we consider the very strategic location of Uaymil on the northern Campeche coast, along with its internal characteristics and the archaeological materials found at the site, we can interpret that Uaymil functioned as a trans-shipment station. Uaymil's role was to facilitate the movement of merchandise and goods that eventually arrived at Chichén Itzá via Isla Cerritos. Evidently, Uxmal – the great capital of the western portion of the northern Maya lowlands located 55 miles inland – also benefited from the specific role that Uaymil played during the tenth and eleventh centuries (Inurreta 2004; ►http://www.famsi.org/researchreports/bysite/uaymil).

The Independent or Autonomous Seaport

The third type of seaport documented in the Maya area is characterized by its autonomous role. In other words, this type of port was a social, political, and economically independent entity. The autonomous seaport was never under the jurisdiction or hegemony of larger and powerful political units, and this condition allowed such a port to rise and flourish in several environments and during different periods in the Maya area. For instance, Cerros in Belize was an independent seaport located in a region where the riverine delta meets the open sea. By the Late Preclassic period, Cerros functioned as a complex seaport with a site center housing monumental buildings with elaborate architecture and a large residential zone surrounding the site center. The strategic position of Cerros on the coast of northern Belize allowed this site to have access to commodities and merchandise that were transported from inland to the Caribbean Sea or vice versa (Robertson and Freidel 1986).

Xelhá was another autonomous seaport located on the east coast of the Yucatán Peninsula. Xelhá was first settled during the Late Preclassic period or around 100 BC, and was continuously occupied until the sixteenth century (Andrews 1990). The archaeological evidence suggests that Xelhá functioned as an independent seaport during the Early and Late Classic periods and seems to have played a key role in the exchange system of obsidian, jade, and other goods that circulated along the Caribbean Sea and between Central America, Belize, and northern Yucatán (Guderjan and Garber 1995; McKillop 1996; McKillop and Healy 1989). The role played by Xelhá as an important seaport might be attributable to its geographic position along an important marine route that was established by the fifth century.

At Cozumel Island the site of San Gervasio became a seaport by the ninth century. San Gervasio is located in the northern sector of Cozumel and the archaeological evidence suggests two important moments of occupation at the site. The first of this moments dates between the eighth and tenth centuries and corresponds to the Classic period. The second moment of occupation dates from the eleventh to the sixteenth centuries and this period ends around 1518 when the first European conquerors arrived at Cozumel. The role played by San Gervasio as an autonomous seaport during the pre-Hispanic era is attributed to two precious goods produced at the island – cotton for textiles and honey (Sabloff and Rathje 1975). Sixteenth-century historical documents confirm the production of cotton and honey at Cozumel whereas the archaeological data corroborate the important role that these precious goods must have had on the economy of San Gervasio (Roys 1957).

Other Maya seaports that rose as independent political entities include Jaina, Xcambó, and Tulum. The first two seaports flourished during the Classic period whereas Tulum's apogee dates to the Postclassic period (Andrews 1990). The importance of Xcambó as a seaport is attributable to its control of the large salt beds located on the central coast of Yucatán. It seems

Xcambó controlled the production of salt and exported this mineral to other communities located in the Maya area and beyond. The function of Jaina and Tulum as seaports might be explained by their strategic midpoint position along the commercial sea routes that dominated the Gulf of México (Jaina) and the Caribbean Sea (Tulum). In fact, Tulum was spotted by Spanish conquerors early in the sixteenth century and they described it as a town larger than Seville.

This information represents a small part of the tremendous potential that awaits discovery regarding the function of ancient Maya seaports. Future archaeological investigations will continue to contribute to the increase in our knowledge of the features that characterize such complex coastal communities.

Seki Kowa

JOCHI SHIGERU

SEKI Kowa, also called Takakazu, was born about 1642, probably in Fujioka, Gumma, Japan. Seki is his surname, and Kowa is the Chinese reading of characters, so the Japanese reading is Takakazu. His middle name is Shinsuke and pen name is Jiyutei. He was born into a samurai warrior family, the second son of UCHIYAMA Shichibei Nagaakira (unknown–1662[1]), and he became a son-in-law of SEKI Gorozaemon[2] and succeeded to the SEKI family. First he became an auditor of TOKUGAWA Tsunashige (1644–1678) at Kofu (now Kofu, Yamanashi) about 1661, then a chief of the meal service section.[3] He lived at Yamabushi-cho (now Minami Yambushi-cho, Shinjuku, Tokyo) about 1695. In 1704, he became a chief of the Store Room of the Shogun's family, and finally became a landlord of a 300-person village.[4] The Shogun's government normally kept the family records of landlords. But since Seki Kowa's son-in-law, Shinshichiro (1690–unknown) lost his position, owing to his gambling activities, we cannot fix even Seki Kowa's birth year exactly.

Seki studied mathematics under TAKAHARA Yoshitane. Takahara Yoshitane was a disciple of MORI Shigeyoshi, who wrote the *Warizansho* (Books of Division 1622), the second mathematical book in Japanese. But Takahara Yoshitane was little known for his mathematical works. Basically Seki taught himself mathematics, using famous texts of Chinese and Japanese mathematicians, such as the *Yang Hui Suan Fa* (Yang Hui's Method of Computation 1275), which he copied in 1661, and SAWAGUCHI Kazuyuki's *Sampo Ketsugi Sho* (Solving Mathematical Questions 1659). He amended works of other mathematicians, and founded the Seki-ryu school. He is generally considered the founder of Japanese mathematics.

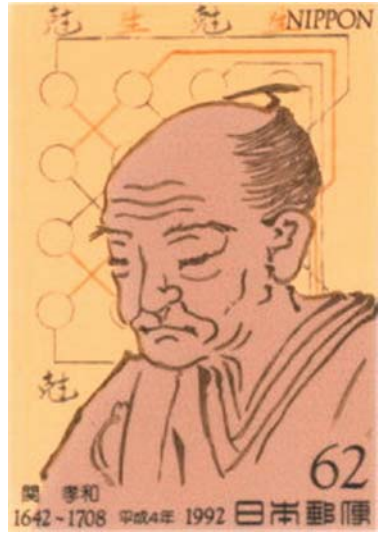
[1] In official documents, Uchiyama Nagaakira died in 1646, but Seki Kowa's youngest brother, Uchiyama Nagaaki (1661–1725) was born in 1661. So Uchiyama Nagaakira was alive in 1661 at least. More, Uchiyama Nagaakira's fathe was died in 1662 in these documents, thus we conclude that Uchiyama Nagaakira was died in 1662. (Jochi, Shigetin (2005): 19).

[2] Gorozaemon is a middle name, and the first name is unknown. Perhaps he is Seki Yoshinao (1591–1673) or part of another Seki family, Seki Toyofusa (about 1632).

[3] His annual salary was 200 *pyo* (150 kg of rice).

[4] His annual salary was 300 *pyo*, which is the same as being a landlord of a 300-person village. The samurai warrior who earned over 200 *pyo* could be received in an audience by the Shogun.

Seki Kowa. Fig. 1 Picture from the Kojukai, Shimminato, Toyama.



Seki Kowa. Fig. 2 Stamp issued in 1992.

The *Tianyuanshu* (lit. Celestial Element Method, Chinese Algebra System) had already been introduced from China by Zhu Shijie's *Suan Xue Qi Meng* (Introduction to Mathematics Studies 1299). This system was for the *Suan Chou* (*Sangi* in Japanese) – counting rods, in the Song and Yuan dynasties in China. In the Ming dynasty, however, new counting tools, *Suanpan* (*Soroban* in Japanese) – abacus – became popular, since no mathematicians understood the *Tianyuanshu* even in China. Japanese mathematicians taught the *Tianyuanshu* by themselves using a Korean edition of the *Suan Xue Qi Meng*. Sawaguchi Kazuyuki was the first Japanese mathematician who mastered it.

Traditional Chinese mathematics used counting tools, *Suan Chou* or *Suanpan*; they had no algebraic symbols. The position of rods (or beads of *Suanpan*) indicates numbers and the power of unknown numbers. This system could only operate with unknown numbers. Seki Kowa created *Tenzan-jutsu* (Japanese algebra system), which could operate with unknown formulae, making it possible to solve complicated problems.

Seki called his method *Endan-jutsu* or *Bosho-ho* (Methods of writing by the side). MATSUNAGA Yoshisuke (1693–1744), a mathematician of the Seki-ryu school, renamed it *Tenzan-jutsu*. Seki indicated one unknown number using one Chinese character and created the symbols of calculations and powers. And he solved the 1458 degree equation in the *Hatsubi Sampo* in 1674.

His works cover the following categories:

1. Japanese algebra system
2. Solution of higher degree equations
3. Properties (e.g., number of solutions) of higher degree equations
4. Infinite series
5. Approximate values of fractions
6. Indeterminate equations
7. The method of interpolation
8. Obtaining Bernoulli numbers using *Ruisai Shosa-ho*
9. Computing the area of polygons
10. Principle of the circle
11. Newton's formula using the *Kyusho* method
12. Computing the area of rings
13. Conic curve lines
14. Magic squares and magic circles
15. Mamakodate (Josephus question) and Metsuke-ji (the game of finding a Chinese character)

These categories had been very problematic before him, and he offered excellent solutions.

In 1712, TAKEBE Katahiro (1664–1739), Seki's student, edited Seki's works and published the *Katsuyo Sampo* 1 year before Bernoulli's *Ars Conjectandi* (1713). Seki obtained Bernoulli numbers using the *Ruisai Shosa-ho* system. It is a typical example of his mathematics. He also worked with what we call Pascal's triangle.

Seki computed to higher powers and obtained the fraction numbers of the last line of Table 1;

$\lambda_0 = 1,\ \lambda_2 = 1/2,\ \lambda_3 = 1/6,\ \lambda_4 = 0,\ \lambda_5 = -1/30,\ \lambda_5 = 0,$ $\lambda_6 = 1/42,\ \lambda_7 = 0,\ \lambda_8 = -1/30,\ \lambda_9 = 0,\ \lambda_{10} = 5/66,\ \lambda_{11} = 0$

$$\sum_{i=1}^{n} i^{\rho-1} = \frac{1}{p}\sum_{i=0}^{p-1} \left(\lambda_i(\rho, i)n^{\rho-i}\right)$$

These are just the same as Bernoulli's numbers.

He was able to compute too much higher numbers than other mathematicians before him, and he obtained the general rule by the inductive method. He, and mathematicians of his school, used this system habitually.

Seki Kowa. Table 1 Shosa-ho's table, Chap. 1 of the *Katsuyo Sampo* (1712)

Settlements in Egypt: Alluvial Settlements in the Nile Valley (and Delta)

David Jeffreys

The River Nile forms a long thin strip of alluvial valley floor, rarely more than 15 km wide, through the hyper-arid desert of north-eastern Africa before fanning out into the Nile Delta north of Cairo. The Nile is fed by two main tributaries, the Blue and White Niles, which merge near Khartum in Sudan, and a minor tributary, the Atbara. The Nile Delta is now reduced to two main distributary channels, the Rosetta (Rashid) and Damietta (Dumyat) branches, with outlying residual canals serving Alexandria in the west and Pelusium in the east; in antiquity up to seven channels are recorded.

Before the construction of the first Aswan Dam in the late nineteenth century, the Egyptian Nile valley and the delta were subject to annual flooding due to monsoonal rains over the Ethiopian plateau which boosted the volume of the Blue Nile. The flood lasted several months, rising in late spring and receding in early autumn, and brought a new deposit of high-nutrient alluvium which provided the basis for Egypt's successful agricultural economy. Despite the popular picture of an idyllic, non-labour–intensive labour cycle, this flood-recession economy was vulnerable, being almost entirely dependent on a successful or "perfect" flood (i.e. neither too high nor too low), and left little resilience to fluctuation (Hassan 1993; 1997): there is for example hardly any evidence for man-made water storage facilities or canals serving marginal or extended catchment areas.

During the Epipalaeolithic period the Nile was building in response to changes in sea level; subsequently there was a down-cutting phase, with the result that the only surviving Palaeolithic sites are now preserved in the high terraces flanking the existing river valley. During the Neolithic (from 10000 BCE) the valley had again been building with alluvial sands and silts accumulating at the rate of about 10 cm per century. The valley floor today presents as a virtually dead flat plain dropping slightly to the eastern and western edges, and forming a slightly convex appearance with the highest, heaviest and newest sediments closest to the river. Throughout Egypt and Sudan the course of the Nile and its subsidiaries is of relatively low sinuosity, although this changes across the delta flood plain.

Upstream of Aswan and the first cataract lies that section of the valley known as Nubia (also Kush, Wawat or Napata); during the 3,000 years of pharaonic culture in Egypt there was a long and complex history of exchange and interaction between the two polities. Culturally Egypt and Nubia seem to follow a similar trajectory up to the foundation of a unified cultural and political Egyptian state in about 3000 BCE, with similar traditions in their lithic and ceramic industries. Thereafter Egyptian material culture develops differently into the highly distinctive pharaonic style in dress and body decoration, pottery production and metal-working, visual representation, and architecture. In Egypt both valley and delta were divided administratively into large land parcels or provinces called *nomes*, each with a local capital. In the Valley these nomes generally straddled the river; in the Delta they were determined by the changes in the distributary system and usually lay between the main channels. In Egyptian texts Nubia is recorded in less detail, and seems to be divided into ethnic/geographical zones: the part north of the second cataract, closest to Egypt's southern frontier at the first cataract, was under Egyptian control through most of the second and first millennia BCE. The desert regions outside the alluvial corridor were only lightly inhabited, except for the Saharan oases, but were exploited for their mineral contents, especially gold, high-grade building and sculptural stones, and pigments, and as an access to the trading routes of the Mediterranean and Red Seas and the African interior.

Settlement archaeology in Egypt is, astonishingly, still in its infancy (O'Connor 1993), and may never achieve its full potential with the onset of modern threats including industrial and residential development, climate change and the rise in the groundwater table brought about by the construction of the Aswan high dam in the 1960s. Traditionally the emphasis in exploratory fieldwork has been on the burial grounds of the valley edges and visible monumental architecture within established archaeological sites such as Thebes (Luxor). A critical factor in the recognition and recovery of information from Nile valley settlements is the mean rise of the valley floor over the past 5,000 years, which has had the effect of obscuring even quite well established settlements or those which have been abandoned by the river as it has shifted course. Stratigraphically shallower and more deeply buried sites, such as the older, shorter-lived towns, and ephemeral rural habitations of all periods, tend therefore not to survive unless they are on the higher ground at the valley edges. We are just beginning to understand just how much settlement archaeology has yet to be recorded from the examples of sites such as Avaris–Piramesse, the sixteenth- to twelfth-century royal capital in the northeastern delta also known by the modern names of Tell el-Daba/Qantir (Bietak 1996), where magnetometer survey has recently revealed huge areas of built environment lying beneath what is now agricultural land which is in private or municipal ownership. In Memphis, a far more extensive settlement area was visible in the eighteenth and nineteenth centuries than can be seen today. How zones such as these are to be treated in the future is yet to be resolved: no effective strategy has yet been proposed for their management, and archaeologists currently proceed largely through private negotiation, returning the land for agricultural or other destructive use after survey and/or excavation.

In Egypt, discussion of settlements has therefore focussed until recently on an impossibly small sample of sites which are almost all atypical of conditions in the Nile valley, leading one leading Egyptologist in the past to suspect that pharaonic Egypt was a "civilization without cities" (Wilson 1960). The handful of sites most often referred to are:

- The Middle-Kingdom (Twelfth Dynasty, eighteenth century BCE) site of Illahun (also known as Lahun or Kahun);
- The New Kingdom (fifteenth–fourteenth centuries) artisan village of Deir el-Medina on the Theban west bank;
- The newly discovered workers' quarters to the southeast of the Giza pyramids; and
- Particularly the large royal Eighteenth Dynasty (fourteenth century) town of Amarna, including its outlying suburbs, flanking necropolis, and another artisans' compound somewhat similar to Deir el-Medina.

None of these towns are strictly speaking "alluvial", however: they are all establishments built (probably deliberately) on the desert edge, whose layout was almost certainly unaffected by the river, and apart from Amarna they are attached to specific monumental building projects, all funerary. Paradoxically there is better data for Nubia, largely due to the intensive series of archaeological surveys in that region, especially the international UNESCO project in the 1960s in advance of the construction of the Aswan High Dam (Säve-Söderbergh 1987). Some of the best-known settlements of all periods are now those in Nubia, as for example the large town and cemetery at the local capital of Kerma, lying in the Nubian heartland above the second cataract (Bonnet 1995, 2000).

In both Egypt and Nubia the tendency was to construct the main settlements in the two main areas not constricted by the floodwaters, that is on the desert margins and the riverside levees (Butzer 1976). It is no accident that many of the earliest known settlements are on the lower desert regions to the east and west of the main alluvial zone, although this itself raises the question whether traces of settlement in other parts of the valley might have been removed by movements in the main and subsidiary channels. In the Delta settlement was more or less confined to natural marine and riverine sand banks (often called "turtlebacks") projecting above the general level of the flood plain. Largely due to the lack of any effective national survey strategy over the years, the impression is given of a gradual migration of settlement from the desert to the flood plain, as seen in the case history of the important pre- and proto-dynastic site of Hierakonpolis (Hoffman et al. 1986). Regional studies at this site and elsewhere (e.g. Memphis) have shown that river movement in both directions was a determining factor in the success and survival of flood plain communities, and the study of post-pharaonic settlements has shown that viability was dependent on the means to provide high ground beyond the reach of the floodwaters. This might be through lateral migration following the levees, or the rapid vertical development of residential building to maintain high, dry living conditions. Over time continued occupation must have been impossible to sustain in certain areas: there are some graphic accounts in more recent times of urban blight due to the rising water level, and examples of structures dating from the Late Antique (Byzantine) period having to be abandoned during the seventeenth to nineteenth centuries as the mean level of the inundation gradually rose. Many towns co-operated in the maintenance of river defences on an annual basis, and the fear of their failure is occasionally alluded to in the pharaonic literature. Paradoxically, religious sites in valley regions were especially vulnerable, because they tended to remain low-lying: they were sacrosanct and did not attract vertical accretion through new construction over the decay of earlier building fabric. There is even some evidence that temples were in fact occasionally flooded: such events were regarded as catastrophic, despite the symbolic inundation-based character of religious architectural ideology. It is worth remembering that while this was an ever-present danger in antiquity and into medieval times, conditions have been quite different for the past century, with perennial irrigation, and increasing urban and suburban sprawl, now possible through the construction of the successive Aswan dams. An appreciation of former living conditions is therefore possible today only through pre-twentieth century documents, notably the excellent series of early landscape photographs dating from the mid-1800s to the early 1900s.

Other considerations aside, it is clear that a seasonal pattern in behaviour and mobility must have applied to the annual rhythm of urban living: during the sowing and harvesting seasons, farmers may well have spent most of their time in temporary accommodation in the countryside, migrating to the desert edges and the main urban areas during the flood. In view of the impermanence of many kinds of rural and at least some kinds of urban habitation, it is perhaps interesting that there should be evidence of a considerable attachment to place. Eulogies of cities survive in the written record, probably the best known being a "hymn" to the city of Memphis (Caminos 1954).

The more typical types of flood plain town share several defining characteristics. Some, but by no means all (and perhaps even a minority) had defensive walls, although the river and municipal earthworks seem to have doubled as military defences; all known large conurbations contain at least one religious centre, with the identity of the cult varying with location; these temples and shrines often had enclosure walls of their own, which have a defensive appearance but are not necessarily built primarily for that purpose (Stevenson Smith 1998). Future work may confirm the suspicion that some major cities, such as Memphis and Thebes, which are often described as capitals, may at times have been long ribbon developments built along the river banks rather than the more familiar model of a highly nucleated, densely occupied urban core (Jeffreys and Tavares 1994).

The only complete town site that survives today in any detail above ground is Amarna, built by the pharaoh Amenophis III and his son Akhenaten (Amenophis IV) in the fourteenth century BCE as a breakaway royal city for the celebration of a new solar cult (Kemp and Garfi 1993). Significantly this is one of only a very few urban regions to be surrounded by boundary markers in the form of rock-cut inscriptions declaring the intention of the ruler, ranged along both sides of the valley but in sight of the town centre. This was probably because the territory for the new foundation was appropriated from the existing nearby provincial capital of Khmunu (Classical Hermopolis Magna, modern Ashmunein), although the major part of the town is on the low desert, not the alluvial plain, probably to maximise the agricultural yield of the requisitioned section of valley floor. Amarna consists of distinct zones representing various discrete functions:

– Residential zones of all social ranks (royal palaces, elite villas interspersed with dependents' quarters, and purpose-built artisanal compounds);
– Religious (temples and solar shrines), economic (food storage and food preparation areas);
– Administrative (police barracks, libraries or storage for diplomatic correspondence) and
– The outlying mortuary districts, including the royal tombs, segregated from the private tombs in a valley due east of the town centre.

Amarna illustrates an interesting tendency in settlement selection, which highlights the importance of landscape symbolism: the "royal valley" is thought to focus sight lines on the central feature of the rising sun, and is embodied in the Egyptian name of the town, Akhetaten ("horizon of the Aten" or sun-disk). In the same way prominent landscape features at other sites acquired symbolic importance, notably at Thebes with its pyramid-shaped mountain on the west bank, and Memphis, at the southern apex of the Delta, with its high-profile layered cliffs to either side (possibly the origin of its earliest name "White Walls").

Even within communities some common features can be identified. Temples conform to a highly distinctive and recognisable pattern, with almost universal features such as the twin-towered pylon featuring flagpoles and monumental statuary, colonnaded courtyards and hypostyle halls with clerestory windows and embrasures; dark and restricted inner sanctuaries; artificially created sacred lakes, and not infrequently causeways, often flanked by ritual statuary such as sphinxes, which linked separate enclosures. There even seems to be a standard plan for houses, the quadripartite ground floor layout incorporating an entrance chamber, communal room and split back section used for different purposes and sometimes featuring a stair to an upper storey or roof terrace (there is evidence for multi-storey structures from both archaeological and representational evidence). Living units of this kind usually occur in terraces along axial or subsidiary streets and alleys, as at Amarna, Deir el-Medina, Karnak and Memphis. Other evidence comes from funerary architecture: it is very likely that tomb plans at different times reflect the general layout of town houses as also illustrated in tomb scenes, with (for example in the New Kingdom) entrance halls, atria that might contain pools or gardens, and back rooms which become sanctuaries and statue rooms in the funerary context. Some tombs at this time have miniature pyramids over or behind the sanctuary, which are certainly an exclusively funerary feature.

For elite residential structures we are more or less dependent on Amarna, where they take the form of villas or compounds freely dispersed through the northern part of the city, and Illahun, where they form a suite of terraces either side of the main street. Relatively few royal palace structures are recorded in any detail (Malqata at Thebes; Piramesse/Qantir in the delta; three separate palace compounds at Amarna; Balat (Ayn Asil) in the Dakhla Oasis (Soukiassian et al. 1990); the short-lived early New Kingdom site of Deir el Ballas just north of Thebes; and a supposedly "ritual" palace at Memphis). There are in addition small "palace" structures incorporated in the large mortuary temples of the Theban west bank, especially those of Ramesses II (the Ramesseum) and Ramesses III (Medinet Habu) (O' Connor 1989).

Sexagesimal System

Marvin A. Powell

The sexagesimal system was an ancient system of counting, calculation, and numerical notation that used powers of 60 much as the decimal system uses powers of 10. Rudiments of the ancient system survive in vestigial form in our division of the hour into 60 minutes and the minute into 60 seconds. Origins of the system of counting are essentially irretrievable because they lie in the period before the invention of writing. They are associated with the ancient Sumerians, whose language incorporated the only known system of sexagesimal counting. The Sumerians were probably also the inventors of the system of calculation, which seems to have its origin in a system of counters (small clay objects also referred to as tokens or calculi) representing the units 1, 10, 60, 60 × 10, 60^2, $60^2 \times 10$, and 60^3. This counter-calculation system may go back as far as ca. 3500 BCE. The method of numerical notation apparently originated from the system of counters by adapting it to a form that could be represented in writing when the first writing system was invented ca. 3000 BCE.

By 2000 BCE this had developed into a system of sexagesimal place notation that functioned like our decimal system but with several important distinctions. Whereas the decimal system uses ten unique symbols, plus a period or comma to separate fractions from integers, the fully developed sexagesimal system of notation used only two unique symbols (those for 1 and 10) and essentially ignored our distinction between fractions and integers. These features, as well as lack of a symbol for zero, reflect its origins in the system of calculating with counters: zero would not have been represented in a system of counters (obviously, one does not count something that does not exist), and unique symbols for the integers 1–60 would have been excluded for practical reasons. Lack of a distinction between fractions and integers goes back to the fact that fractions are essentially alien to prehistoric systems of counting. Names for small quantities that we would call fractions are based on subdivisions of the weight system (*mina* and *shekel*) and were clearly not thought of as fractions in our sense of the word. In keeping with this picture is the symbol for medial zero that appears in Babylonian mathematical texts of the late first millennium BCE. This so-called *zero* is really nothing but a "spacer" symbol and reflects the practice (occasionally observable in surviving texts) of leaving a blank space where we would place a zero.

During the third millennium BCE, this Sumerian sexagesimal system was adopted, along with other features of Sumerian culture, by Semitic-speaking Akkadians, and the Akkadian language, which – like Sumerian – was written in cuneiform script on clay tablets, served as the vehicle for its diffusion and preservation. As an essential part of the education of scribes, it was still very much alive when Greeks conquered the Near East in the time of Alexander the Great. The two centuries of Greek presence in Mesopotamia (330–129 BCE) facilitated the incorporation of Babylonian mathematical astronomy into the Western tradition, and with it also came knowledge of the Babylonian sexagesimal system. This, however, seems never to have been used systematically by Greeks outside of Babylonia. Division of the circle into 360° is a vestige of the Babylonian system that has been transmitted to us by the Greeks.

Modern knowledge of the existence of an ancient sexagesimal system goes back as far as the recovery of Greek mathematics, beginning in the Renaissance. Little, however, was known about its true character until the middle of the nineteenth century when decipherment of cuneiform writing revealed the system in its developed form of the first millennium BCE. Speculations about its origins have tended to postulate conscious creation, as opposed to gradual evolution.

The 360-day year and choice of 60 as base (because 1, 2, 3, and 5 are all prime factors) are among these theories, all equally without evidence. Only in the twentieth century has the Sumerian system of counting become relatively well understood, and the role of clay counters as prototypes of number symbols has only become clear in the last decade.

Shamanism in Pre-Columbian Mesoamerica

Keith Jordan

Shamanism is a term used by anthropologists and historians of religion to describe similar systems of religious thought and practice centered on the role of ritual specialists who enter trance states in order to communicate with the supernatural world for the benefit of their communities. Derived from an indigenous Siberian term for such a practitioner, shamanism is distributed through Asia from Siberia south to Korea and Vietnam. Across the Pacific, it is characteristic of Inuit culture and of many Native American groups throughout North, Central, and South America. It has been used as a model for understanding religious experience and ritual process in New Guinea and other regions of Oceania and to classify the belief systems of peoples from the San Bushmen of southern Africa to the pre-Christian Lapps. It has been posited as the first human religion, the inspiration behind the cave art of Ice Age Europe, and even suggested as prevalent in Bronze and Iron Age Europe.

The shaman is a specialized ritual practitioner who is adept at entering altered states of consciousness understood as journeys to the spirit world. Ritual, asceticism, music, and hallucinogenic plants may be employed to facilitate entry into visionary experiences. The other world entered by the shaman may be conceptualized as the land of the dead, the realm of animal or nature spirits, or the domains of various deities. At least in Asian and American shamanism, the universe is pictured as divided into upper, middle and lower worlds, connected by a central vertical axis, often a World Tree spanning the cosmos from the bottom of the underworld to the farthest regions of the sky. The shaman is able to visit these other worlds by traversing the central axis or similar portals, often via a state experienced as flight, in order to interact with supernatural beings for the good of the community. The purpose of the voyage may be to obtain cures and defeat witches on behalf of an individual client, as is frequent in small hunter-gatherer societies, or to control weather, promote the fertility of game and agriculture, and predict the future. Generally, shamans are “called” to their vocation by unusual hallucinatory experiences, personality traits, dreams, or by a prolonged or severe illness. They train by serving as apprentices to older shamans, and frequently attain full status by initiation rites and/or visionary experiences in which they are symbolically killed and reborn to their new identities. In many varieties of shamanism, the specialist cultivates a relationship with an animal spirit as a familiar and/or alter ego, and is believed to take the form of this animal when traveling the spirit world.

Shamanic practices are still prevalent among some contemporary Native Mesoamerican groups, notably many Maya communities in Chiapas, Yucatan and Guatemala, where shamanism mingles with Christian beliefs, and the Huichol of northern Mexico. Because of these ethnographic observations and because of the shamanic features of pre-Columbian cosmologies, anthropologists and art historians have employed shamanism extensively over the past several decades as a heuristic device for understanding ancient Mesoamerican beliefs. However, some of these interpretations seem to be better founded than others.

The so-called Olmec culture of the Early to Middle Formative Periods (ca. 1500–400 BCE), centered on the Mexican Gulf Coast states of Veracruz and Tabasco, has been conceptualized by many scholars as the “mother culture” of Mesoamerica, the origin of the basic traits shared by all later Middle American civilizations and of an art style diffused from central Mexico to El Salvador and Honduras. More recently, other archaeologists argued that the Olmec were a “sister” culture to their contemporaries and successors. Rather than originating the art style associated with them by champions of the “*cultura madre*” view, they may have produced the finest and most monumental expressions of a pan-Mesoamerican art style which did not originate on the Gulf Coast. Olmec portable stone carvings frequently depict men who appear to be transforming physically into jaguars, the most common animal ally or alter ego for modern Central and South American shamans. In some of these images, human features predominate, while in others varying mixtures of human and feline traits seem to represent shape shifting in varying degrees of progress. One of these figures, now in the Princeton Art Museum, bears an engraving of a toad on its head, and toad bones occur in refuse at the Olmec site of San Lorenzo. This is further evidence for shamanic practice: *Bufo marinus* and other toad species are a source of potent hallucinogens. The shamanic model, as proposed by Peter Furst, F. Kent Reilly and others, fits the evidence well in this instance, though caution is always required in comparing the visual culture of a Mesoamerican group which has left us no written records with ethnographic data collected thousands of years later and from across wide expanses of North, Central, and South America. Equally intriguing but uncertain are interpretations of the body postures of Olmec portable figures as positions facilitating meditative states and the cultivation of trance.

Olmec monumental reliefs at the sites of La Venta and Chalcatzingo, and paintings at Oxtototitlan, showing elaborately costumed figures emerging from the mouths of monsters, have also been given a shamanic interpretation. Reading backwards, from the beliefs of contemporary Maya shamans and the inferred practices of their Classic Maya predecessors, these saurian, ophidian and/or feline mouths represent symbolic portals into the earth and underworld, or perhaps to the celestial realms. The richly garbed figures are Olmec kings performing the functions of the shaman, in these instances journeying to the spirit world to obtain adequate rainfall and agricultural bounty for their polities. They may be the earliest instances of a conception of otherworldly portals in zoomorphic form that has survived to the present Mesoamerica. The difficulty, however, with readings of this sort is that they are inferences based on chains of extrapolations from the historic to the pre-Hispanic Maya and then back to the Olmec. Even assuming the continuity of use of such motifs, disjunctions in their meaning might be expected over time and across geographic and linguistic boundaries.

The late Linda Schele used the shamanic beliefs and practices of contemporary Maya as a fruitful analog for comprehending Classic Maya ritual and iconography, like the images of ancestors conjured through “Vision Serpents” by the bloodletting rites of Classic Maya kings. These represent supernatural portals to the realm of the ancestors and are analogous to the supernatural serpents that swallow and excrete contemporary Maya shamans in their initiatory experiences. Similarly, her work led to the identification of a class of supernatural beings represented in Classic Maya art as the spirit alter-egos of Maya rulers, called *wayob* in the accompanying texts. Her work has received considerable support from the ongoing decipherment of Maya glyphs but is not without its critics. These point out, among other things, that the autosacrifice of blood from their tongues and genitals by Maya rulers may not be physiologically conducive to trance states as claimed in Schele’s original formulation.

The iconography of ceramic sculpture accompanying burials in the Late Formative to Classic shaft tombs of West Mexico has been interpreted by analogy to the shamanism of the Huichol and other contemporary indigenous groups. The most prominent proponent of this approach, anthropologist Peter Furst, identifies horn-like protrusions on the heads of some anthropomorphic figures as a mark of shamanic status akin to the coiffures of historic Sioux medicine men and the horns of shamanic figures in Asian myths. First interprets the emaciated or skeletal state of some of the humans in West Mexican ceramic effigies as representing forces of renewal rather than death, by analogy to the initiation experiences of contemporary shamans who are stripped of their flesh in visions and reconstructed by the spirits in their new identity as ritual practitioners. (Jill Leslie Furst has used the same complex of imagery as a fruitful heuristic device for interpreting the meaning of skeletal deities in Mixtec manuscripts as gods of fertility and rebirth.) The geographic proximity of these West Mexican sites to the current territory of the Huichol and other tribes with strong shamanic traditions supports Furst’s readings, but again caution is required in generalizing meanings across great expanses of time. Contra Furst, Mark Miller Graham interprets the “horns” of West Mexican tomb figures as conch shells symbolic of rulership. While not dismissing the presence of shamanic themes and imagery in this art tradition, he emphasizes the manipulation of such ideas by pre-Hispanic political elites to maintain their status, over what he criticizes as the ahistorical generalizations about visionary experiences in Furst’s writings.

In other instances, the attempt to read ancient Mesoamerican images through a shamanic lens seems strained and stretched. Some scholars seem to interpret every form, material, and function of any given pre-Columbian art object as related to shamanism, as though the culture consisted of little other but such religious practices. A recent catalog of pre-Columbian art from Mesoamerica, lower Central America, and the Andes in the Michael Carlos Museum at Emory University seeks to interpret almost every formal and iconographic feature of portable objects like ceramic vessels in terms of ethnographic observations of shamanism often removed in time by centuries and often by geographical distances of hundreds of miles. Designs on Central American ceramics, for instance, related to the altered perceptions of the shamanic trance; the rattles attached to effigy vessels attempt to evoke the sound of animal allies. All of these interpretations are brilliant and creative. Some may be quite accurate, while others may be stretching the concept of shamanism as a hermeneutic tool for interpreting pre-Columbian art to its limits and beyond. In the present state of knowledge and absence of written records for most of this material, these interpretations are largely unverifiable. There is always the risk of projecting the ethnographic present onto the archaeological past, when, because of the lapse of intervening centuries and the major cultural changes wrought by Christianity and European conquest, ancient beliefs may have been quite distinct from their latter-day descendants in the same region. When analogies to pre-Columbian material are sought in modern shamanistic complexes as far away from Mesoamerica as the North American Plains and the Amazon, their explanatory value becomes more questionable.

Recently, some Mesoamerican scholars, notably the American art historians Cecelia Klein and Esther Pasztory, have sharply criticized the characterization of pre-Columbian art and religion as shamanic. They point out that most societies described as having shamanistic religions in the ethnographic literature operate on a far less complex level of social organization than the civilizations of Mesoamerica. They question the validity of using a construct developed to explain religious behavior among hunter-gatherers or small villages for understanding Mesoamerican state-level societies, like the Aztec and Maya. In the case of the Aztec at least, it is clear that religious life was dominated not by shamans but by a vast bureaucratic hierarchy of priests, most of who were probably not natural born visionaries. Although the mercurial Aztec deity Tezcatlipoca may have had shamanic origins, he was the patron deity of the Aztec monarchy. For the Classic Maya, hereditary sacred monarchs performed the rites characterized as shamanic—clearly a different social context than most of the behaviors classified as shamanism in other parts of the world. On the other hand, Furst contests these critics' categorization of shamanism as limited to relatively egalitarian hunter-gatherer groups, pointing out the dominance of shamanism in several northern South American agricultural town societies.

Some critics equate the use of shamanism to explain pre-Columbian cosmology and symbolism with the romantic primitivism of the New Age movement and its fetishization of Native American religions. Yet, much of Schele's and others' work on Classic Maya shamanism has been confirmed by—and has stimulated—recent epigraphic work. It appears that the beliefs of modern Native Mesoamericans can serve as springboards for framing hypotheses about the ways of their ancestors, but caution is needed to avoid overspeculation and casting the past in the mold of the present.

Shanghan Lun

RICHARD BERTSCHINGER

The *Shanghan Lun* (Treatise on Cold-Induced Fevers) by Zhang Zhongjing was written about AD 210. It is the first important practical work in Chinese medicine that has come down to us. The legend is that within a period of 10 years nearly two-thirds of Zhang's village died of illness, mostly from infectious diseases. Zhang, seeing so much suffering, forced himself to find a way to save them, and looked up the ancient prescriptions and read the ancient books. At the end of the third century, after the political turmoil accompanying the breakup of the Han dynasty, the book was reorganized and edited. In the eleventh century, the Song scholar Lin Yi further recompiled and divided it into two sections: the *Shanghan Lun* as we know it today and the *Jingui Yaolue Fang Lun* (Treatise on the Golden Casket Collection of Prescriptions).

Most admirable in Zhang was his scientific approach to medicine. He berated doctors who used secret remedies to dupe people, saying "what looks magnificent on the surface may be rotten underneath." He attached great importance to close observation and early treatment of conditions, adjusting the remedies to suit the disease and changing the medicine as the cure progressed. He deplored the frequent use of purgatives. As a mild laxative he prescribed pig's bile mixed with vinegar poured into the rectum through a bamboo tube. He observed the fluctuation in temperature during fevers, and devised a model for the progression of disease based upon the separation of *Yin* and *Yang* into *Shaoyang*, *Taiyang*, *Yangming*, *Shaoyin*, *Taiyin*, and *Jueyin*. This has been a most influential categorization in Chinese medical literature.

Earlier works had recorded the reaction of the pulse to pathological conditions, but Zhang extended his theory to included the pulse's reaction to the effects of drugs.

About 200 simple herbal medicines were then known, of which the most common were emetics, purgatives, and antipyretics. For instance rhubarb, sodium sulfate, and croton plant were used as purgatives. For reducing fever there was scutellaria, cinnamon bark, ephedra, and bupleurum. As emetics the stalks of various gourds or melons, and parts of the gardenia were recommended. Such remedies are now in use throughout the world. Rhubarb, for instance, was introduced into Europe in the fifteenth century, and imported up to the ninetieth century. The action of ephedra has been mimicked by modern drugs and is invaluable in asthma.

As analgesics and sedatives, various parts of the aconite plant and almond were used. Almond extracts are still used to relieve coughing. Aconite was toxic, but with extreme care it could be useful as a cardiac tonic and nervine. Ginger, licorice, dates, onion roots, and orange peel were used as digestives.

Artificial respiration is mentioned and the use of it in suicides by hanging. In cases of poisoning, water was forced down the victim's throat to wash out the stomach – much as in modern hospitals. In diet, Zhang also forbade the use of food derived from animals which had died from disease, and stressed the importance of proper storage and hygiene.

His whole work is a clear example of early scientific method. His manner, most obviously suited to herbal medicine, has been largely adopted by the modern Chinese in their presentation of Chinese traditional medicine. With its differentiation of disease by signs and symptoms, it guides the student into a clear etiology, differentiation of condition, treatment plan, and prescription – whether treatment by acupuncture, herbal medicine, massage, diet, or therapeutic exercise is intended.

Sharaf al-Dīn al-Ṭūsī

JAN P. HOGENDIJK

Little is known about the life of Sharaf al-Dīn al-Muẓaffar ibn Muḥammad ibn al-Muẓaffar al-Ṭūsī. He was born in Ṭūs (Iran), probably around 1135. He spent part of his life in Syria and Iraq, and died in Iran around 1213. He had a number of pupils, including the famous polymath Kamāl al-Dīn ibn Yūnus.

Sharaf al-Dīn al-Ṭūsī was one of the best mathematicians of the Arabic tradition. His most important work is a treatise on cubic equations, in which he develops the theory quite beyond the limits reached by al-Khayyām. The Arabic mathematicians only considered positive coefficients, and they therefore distinguished various types of cubic equations, such as $x^3 + bx = c$, $x^3 + c = bx$, $x^3 = bx + c$, $x^3 + ax^2 = bx + c$, $x^3 + bx = ax^2 + c$, and so on. For all these types, ʿUmar al-Khayyām indicated a geometrical solution of a positive root x (negative and zero roots were not taken into account). For al-Khayyām, the coefficients a, b, c were not in the first place numbers: a was a line segment, b was a rectangle, and c was a parallelepiped. Using these data, al-Khayyām constructed two conic sections, and he supposed that these conics intersected in a point P. He then constructed x by means of P. It is obvious that this procedure only works if point P exists. For some types of cubic equations (for example $x^3 + bx = c$ and $x^3 = bx + c$) it is easily proven that a point P always exists, so the equation always has a root x. For other types of cubic equations (such as $x^3 + c = bx$) P may or may not exist, depending on the coefficients of the equation. The only way in which al-Khayyām could find out whether point P existed was by actually drawing the conic sections, which could be done with limited accuracy (it is unclear whether al-Khayyām ever constructed a root x this way, because the subject seems to have been of theoretical interest only). Thus it was not precisely clear when a cubic equation like $x^3 + c = bx$ had a root.

For the particular case of $x^3 + c = ax^2$, some predecessors of al-Khayyām had shown that a root x exists if and only if $c \leq (4/27)a^3$. Thus these mathematicians knew in advance whether a root existed, and they only needed the conic sections to construct x. Sharaf al-Dīn showed that similar (but much more complicated) conditions exist for all types of cubic equations which do not always have positive roots. He meticulously proved the correctness of these conditions by means of the methods of "geometrical algebra" used by Euclid in Book II of the *Elements*. He then gave a geometrical construction of the roots x, and (unlike al-Khayyām) a numerical procedure, which could be used to approximate the roots with any desired accuracy. In the theory of cubic equations, no further progress was made until the discovery of the algebraical solution in Italy after 1500.

In addition to his treatise on equations, Sharaf al-Dīn wrote two short works on elementary geometry. He also invented the "linear astrolabe," consisting of a staff with a plumb line and two cords. The staff contained the markings of the North–South line of an ordinary astrolabe. Although this instrument is easier to construct than an ordinary astrolabe, it does not look nice and it is not user-friendly. Thus it is not surprising that no examples have survived.

Shen Guo

Fabrizio Pregadio

The Chinese scholar, statesman, and scientist Shen Guo was born in 1031 in present-day Hangzhou (Zhejiang). Born into a family of gentry, he entered civil service in 1054, holding minor posts in different provinces where he distinguished himself in a series of projects involving water control. After passing the national doctoral examinations in 1063 he moved to the capital, Kaifeng, and in 1072 was named Director of the Astronomy Bureau. In that position he reorganised the Bureau, planned a program of astronomical observations, and devised a calendar that was effective from 1075 to 1092. His work as astronomer alternated with missions to the provinces, where he was again able to display his skills in hydraulic engineering. The relief maps he made in 1074 (using wooden plates, sawdust impregnated with glue, and melted wax) are among the most celebrated specimens of Chinese cartography.

The whole of Shen's career was influenced by his partnership with Wang Anshi (1021–1086), the leader of the "New Policies" (*xinfa*) group which advocated a reform program aimed at strengthening the central government, regulating finances by law, and exploiting nature for the state's benefit. Shen's memorials to Emperor Shenzong (r. 1067–1084) on a variety of subjects – including military strategy and tax levies – won approbation in a dozen instances. In a related development, Shen was sent as an envoy to the Khitan court in 1075, and, in a feat of diplomacy, was able to put at least a temporary end to the borderland skirmishes and the repeated Khitan claims of Chinese land.

Following his diplomatic victory, Shen Guo was appointed Finance Commissioner in 1077, but that very year also marked the turning point of his political fortune. The opponents of the "New Policies" had succeeded in pressing Wang Anshi into retirement. Shen was in turn charged with duplicity in his fiscal policies, and demoted. Three years later, partially rehabilitated, he was sent to the Shenxi province as

Commissioner for Prefectural and Military Affairs. In 1081 he obtained an important military victory against the Tanguts. One year later, however, he was held responsible for the disastrous defeat that the Chinese troops suffered in the same area, and put on probation.

Shen spent the following years completing a map of the territories under Chinese control, for which he was commissioned by the Emperor in 1076. When he submitted it to the throne in 1088, his rewards included the right of choosing his residence. He thus moved to the "Dream Brook," a garden estate that he had bought some years earlier near present-day Zhenjiang (Jiangsu), and devoted most of his time to writing, until his death in 1095.

Shen Guo's writings include treatises on administration, military strategy, astronomy, medicine, poetry, ritual, and several other subjects. His best known work, entitled after the name of his retreat, is the *Mengqi bitan* (Brush Talks from Dream Brook). Written in the final years of his life, and supplemented by two shorter works probably published posthumously, it consists of about 500 jottings on disparate matters, usually short and organized into topics. The original edition was in 30 chapters, of which 26 are extant. Of special importance from the point of view of the history of science are the sections pertaining to mathematics, astronomy, meteorology, optics, physics, geology, and medicine.

To give only a few examples, chosen among the more important parts of his work but clearly inadequate to reflect the richness of its contents, in the field of astronomy Shen Guo described solar and lunar eclipses, studied the moon phases, and provided reasons for the apparent planetary motions. During his appointment as Director of the Astronomy Bureau, moreover, he modified the design of the sighting tube pointing to the Pole Star in the armillary sphere. In the field of geology he recognized the origin of fossils, and gave an account of the role of erosion. Other jottings are concerned with magnetism, the production of inverted images on concave mirrors, the formation of rainbows, the fall of a meteorite, and the process of printing. All this adds to his skills in cartography and hydraulic engineering.

As several scholars have remarked, Shen Guo never attempted to organize his observations into a general theory. His work is, in many ways, the product of an exceptionally bright mind, motivated by a sharp curiosity in observing, understanding, and describing whatever phenomenon aroused his interest. This was by no means limited to natural processes or to man-made techniques. One chapter of the *Mengqi bitan* deals with supernatural matters, which the author treats with the same sympathy he accords to the other fields that attracted his attention. For a proper assessment of Shen Guo's personality and production, the "scientific" features of his works should be evaluated without neglecting their own context or disregarding other features which we might label as "unscientific."

From another point of view, Shen Guo reveals the short-comings inherent in the equation between Daoism and scientific progress on one hand, and Confucianism and scientific conservatism on the other, which has influenced some recent work in the history of Chinese science. While Daoists were not interested in nature per se (nature was before all an "image," *xiang*, of the absolute principle, the *Dao*), Shen Guo shows that interest in natural facts could be, and indeed was, actively pursued by a "Confucian" scholar and state administrator.

Shibukawa Harumi

Nakayama Shigeru

Shibukawa Harumi (1639–1715) was a Japanese astronomer and calendar reformer whose distinguished service in calendar reform led to his appointment in 1685 as official astronomer.

The Chinese lunisolar Xuan-ming calendar, adopted in Japan in 862, had not been reformed for more than 800 years. Over the centuries the discrepancy in the length of a solar year had increased so that by Harumi's time there was a 2-day delay in the winter solstice.

With able diplomatic skill, Harumi urged that the Shogunate government undertake calendar reform. In 1669 he began conducting astronomical observations, probably the first systematic observations made in Japan. Following the procedures of traditional Chinese astronomy, he set up a gnomon and measured the lengths of shadows at various points before and after the winter solstice, in order to calculate the time of occurrence. He was especially interested in the Shoushi calendar of the Yuan dynasty (1279–1368), a crowning achievement of calendrical astronomy adopted in China in 1282, and his observations were based upon its methods.

In his reference to Western theories, Harumi based his information on scanty sources and came to regard Western astronomers as "barbarians who may have theories but cannot prove methods." It is regrettable that sufficient material for evaluating Western theories was not available to him.

During the eighteenth century Japanese astronomy altered its orientation from China to the West. Harumi belonged to the first generation of astronomers who, with only limited knowledge of Western astronomy, began evaluating the merits of both systems.

Shipbuilding in India: Wadia Shipbuilders

RAJESH KOCHHAR

The British created a vast overseas empire through their supremacy over the high seas. In their colonial enterprise they were ably assisted by the Wadia shipbuilders of Bombay (old spellings are advisedly used) who, drawing on their own skills, local tradition and the raw material available, provided the British navy and merchants with excellent ships.

In the year 1498, Portuguese arrival in India by an all-sea route introduced the navy as a factor in the geopolitics of India, placing the landed rulers at a disadvantage for all times to come. The Portuguese and the Dutch success brought the British to the Indian west coast in 1608, after four years, they inflicted a crushing defeat to the Portuguese at sea. The Portuguese were fanatically anti-Muslim and particularly severe on the Haj pilgrims. The victory of the religiously neutral British was viewed with relief by the Mughal emperors who in turn granted them attractive trade concessions. It was the desire to get such concessions enforced at lower levels that fuelled the (British) East India Company's territorial ambitions. Ironically, the British task was made easier by the Portuguese themselves.

The island of Bombay, which the Portuguese had taken over in 1534, was ceded and granted to the crown of England in full sovereignty under a marriage treaty signed in 1662. Never before had the dowry of a princess been so detrimental to the interests of a kingdom. Bombay was an excellent natural harbour. More importantly, unlike Surat where the British had been permitted to set up their headquarters, it laid outside the territorial reach of the Mughals. The Portuguese viceroy of Goa, Antonio de Mellow de Castro, had boldly declared: 'I foresee that India will be lost the same day on which the English Nation is settled in Bombay' (Da Cunha 1900, cited in Wadia 1957: 9). These words turned out to be prophetic indeed.

The instructions from London were 'to keep Bombay always the seat of our power and the centre of our trade in India'. It gradually became an attractive destination for the native settlers especially the Indian Zoroastrians, the Parsis, who particularly valued the religious freedom and the business opportunities the new city offered.

Until this time, the British had been getting their ships repaired and built mostly in Surat. Like many coastal places, Bombay already had facilities for building small vessels, 'but no proper establishment with a dockyard, attendant builder and ancillary factories for rope-making, coopering, etc, existed' (Wadia 1957: 119). What lent urgency to the establishment of a proper shipbuilding facility at Bombay was the harassment from 1707 of foreign ships by a fleet led by Kanhoji Angre (anglicized to Connajee Angria and variously spelt) and his successors till their defeat by the British in 1751.

The first priority for Bombay was to build coastal boats. The man of the hour was Lowjee Nusserwanjee (ca. 1700–1774) who had been working for a Parsi shipbuilder in Surat since his boyhood and was known to the Bombay officials as the foreman responsible for actually building the ship 'Queen'. In March 1736 he, along with ten other carpenters, came to Bombay expressly to build a grab [a usually two-masted, square-rigged coastal vessel]. When the Master Builder, Mr. Robert Baldry, died in 1740, no replacement was sought from Britain. Instead Lowjee was given the charge. From 1740 till 1764 he was generally designated Master Carpenter and subsequently Master Builder.

It was under his guidance that the first dry dock was built in 1750, and others were added later. A subsidiary dock, the Mazagon, was built in 1774. There was also a small private dock, Old Mughal dock, built around 1835, which was rented out to the Peninsular & Oriental Company in 1854 for their new mail service between Bombay and Suez. Remarkably the government post of Master Builder remained in the family for six generations till 1884, when the dockyard was transferred from the Bombay government to the Indian. There were other Wadias working in junior dockyard positions where they continued until 1913. The Wadia skills were made use of by foreign governments, companies and merchants. The family name Wadia, meaning boat builder in Gujarati was not used in official records, even though later Master Builders sometimes signed their names as Lowjee. All official correspondence was however addressed to the formal name consisting of the given name followed by the father's.

In the first phase of shipbuilding in Bombay, the emphasis had been on repairs and construction of coastal boats for protection. Things soon changed. Increased merchant activity and marine rivalry in Europe resulted in large-scale felling of oak trees in Britain. In 1772 the Company was prohibited from building any large ships. It therefore shifted the shipbuilding activity to India. In any case, teak was a better material than oak.

The dockyard was at its zenith during Jamsetjee's tenure (1792–1821) while his son and successor Nowrojee (1821–1844) 'was the last person to enjoy all the rights and privileges attached to the office. After his retirement there was an all round decline in ship building in Bombay' (Wadia 1957: 296). The golden age of shipbuilding in Bombay however spelt disaster for the teak forests in India. The forests in Gujarat and Konkan were soon exhausted and the Malabar forests severely depleted. It is only when iron and steel ships came into increased use that in 1847 a conservator of forests, Dr. Alexander Gibson, was appointed in Bombay.

Racism

Although the Wadias were well regarded in official circles, they did come across racism. In a particularly unsavoury incident, in 1781, a dockyard carpenter was flogged in a visiting British navy ship on suspicion of petty theft. When the Master Builder Bomanjee Lowjee himself went to the ship to remonstrate, he was also struck. He immediately wrote to the government stating, 'unless they could be supported in their station with reputation they must with reluctance request permission to quit the place and the employment they held under the Company'. When the ship commander stood his ground, it was left to the admiral to write 'a healing letter' (Wadia1957: 164).

The next Master Builder's revenge against racism was subtler. The frigate Marquis Cornwallis built by him in 1800 for the Company was found to be so beautifully constructed and of such great strength that the Admiralty purchased it four years later. On the kelson [the timber immediately above the keel] he secretly carved the words: 'this ship was built by a d…d Black Fellow AD 1800'. Jamsetjee himself drew attention to this when the ship, since renamed Ackbar, returned to the Bombay docks many years later (Wadia 1957: 191).

In 1810, the Wadias built a 74 gun vessel 'Minden' for the British navy, their first ship-of-the-line built outside the U.K. At the same time in competition to Bombay, a similar vessel was built at Kidderpore on subscription by Calcutta inhabitants and presented to the British navy, which however was not impressed. The Minden saw service during the British-American War of 1812. Francis Scott Key wrote the lyrics of the US national anthem in 1814 aboard the 'Minden' where he was detained.

Steam Navigation

Once James Watt's steam engine became available it was used for propelling ships. The lead came from the United States, which had no roads or canals, but had large tree-lined rivers that would not mind inefficient engines. The first practically successful steam vessel on a river was launched in 1807 and on the sea the next year. Britain soon caught up, with the British navy acquiring its first steamer in 1819. Incidentally, the first steam-propelled vessel in India was fitted with an engine and built to the plan brought from England in 1819. It was built for Nawab Ghazi-ud-din of Oudh at Lucknow for use as a toy.

The Calcutta merchants were keen to introduce steam navigation on three routes: on the placid north Indian rivers; in the opium and tea trade with China; and between Calcutta and England via the old Cape of Good Hope route. Early steam machinery was rather daunting. It used coal voraciously and was extremely complex for easy maintenance. The merchants neither had the capital nor the patience to experiment. The Company, divested of its trade monopoly in 1813, had no intention of sinking its money into steam for trade, but it had wars to win. The initiative by private individuals looks significant in retrospect but was economically unviable in its time. What gave steam navigation the initial boost was the amphibian Burmese war of 1824–1826. An 8 HP engine privately brought to Calcutta in 1817 or 1818 was used to power a paddleboat that carried troops over creeks and estuaries of the Arakan coast. Similarly, in 1825, the Company bought a private river steamer 'Diana' built two years previously to operate against the monsoon winds. It was dubbed 'fire devil' by the hapless Burmese (Bernstein 1960: 30).

Bombay's interest in steam was even more pronounced than that of Calcutta and Madras. Monsoon winds made it easier for a sailing ship to reach Calcutta than Bombay. Steam would give Bombay the benefit of its shorter distance to Europe. After waiting for six years for the court of directors to respond to 'a distinct official proposition' first made in 1823, the Bombay government decided to go ahead on its own, and got the Wadias to build a steamer, cleverly named 'Hugh Lindsay' after the sceptical Company chairman. It was a small ship of 411 tons with two 80 HP engines, launched in 1829. In the next four years, it made a total of five voyages to Suez, all heavily subsidized. Average receipts from passengers and letters stood at Rs.14,225 as against the expenditure of Rs.46,250. The acclaimed success of 'Hugh Lindsay' in contrast to the declared failure of 'Enterprise' in its voyage to Calcutta via the Cape established the viability of the over-land route (Khan 1971). This had far-reaching and widespread consequences. Bombay became a gateway to India. The Red Sea and the Persian Gulf were scientifically surveyed and the Suez Canal was dug. More importantly all the countries en route lost their independence.

Introduction of steam navigation did not mean the immediate end of sailing ships. The commercial viability of steam came only when engines were greatly improved and ships were made of iron and then of steel. This effectively brought teak ship building at Bombay to a close, bringing to an end a fascinating chapter in colonial history.

From 1736 to 1884, the Wadias built a total of 334 vessels for a wide variety of owners: the East India Company, private merchants, the Nizam of Hyderabad, the Imam of Muscat and the British navy. Out of these 334, thirty-nine were either specifically built for or subsequently acquired by the British navy during 1777–1849. (For completeness, it may be added that from 1885–1936, another 46 vessels were built at the Bombay dockyards.) If we were looking for a single ship to sum up the career of the Wadia shipbuilders, it would have to be the frigate 'Trincomalee' built in 1817 and probably the oldest ship still afloat. It served the British Navy for 76 years and was then sold off. It was renamed 'Foudroyant' about 1902 and used for the training of boys in seamanship. The original name was restored in 1993 and after that the ship itself. It is now open to visitors at the Hartlepool Historical Quay.

The Wadias received three land grants in Bombay, in 1783, 1821 and 1849 (in two installments) and in 1884 on the retirement of the last Master Builder. In addition, there were a number of presents of medals, rulers and shawls. The prestige carried by the shipbuilding Wadias helped other members of the clan in establishing themselves in various lines of business.

From Ships to Industry

The introduction of steam necessitated the upgrade of Wadia skills. Master Builder Nowrojee Jamsetjee (1774–1860) sent his son Jehangeer Nowrojee and nephew, Hirjibhoy Merwanjee, for an extended stay during 1838–1841 in England, where they studied naval architecture at the Royal Dockyard at Chatham under the Master shipwright. Jehangeer rose to become the Master Builder himself.

Historically, far more significant was the fifteen-month England sojourn during 1839–1841 of Ardaseer Cursetjee (1808–1877) then an Assistant Builder at the dockyard and son of Cursetjee Rustomjee who later (1844–1857) became the Master Builder. 'The prompt repair of the engines of the numerous steamers' arriving in Bombay posed a problem. 'Few of the European engineers and drivers could withstand the climate, and those who were enabled to do so proved so troublesome that a remedy for the inconvenience appeared of paramount importance' Cursetjee 1840: v). The remedy was Ardaseer's officially sanctioned and partly financed visit. While in England, he spent his time getting practical experience in construction and maintenance of steam engines and moving in influential circles. He successfully applied for the post of Chief Engineer and Inspector of Machinery at the Company's factory and foundry in Bombay. The Bombay newspapers variously commented that there would be a 'body of English workmen' under his charge.

This appointment in turn helped him to become the first Indian to be elected as a Fellow of the Royal Society of London in 1841. The distinction seems to have had no impact whatsoever in India. Bombay was perhaps too practical to make sense of an honour bestowed in London, while it was too early for Calcutta to be interested. In any case the Royal Society then was more of a gentleman's club than the learned body it became later. Ardaseer was in effect introduced to India 100 years later, in 1944, by the visiting Secretary of the Royal Society. Belatedly, in 1969, an Indian stamp was issued commemorating Ardaseer Cursetjee (Kochhar 1993).

The Wadia's familiarity with the steam engine had far-reaching consequences. It led to the mechanization of the textile industry. Ardaseer Cursetjee's son Nusserwanjee, who had joined the dockyard in 1844 at the age of twelve, quit his job six years later as he was directed to Manchester by the well-known Parsi textile magnate and philanthropist Sir Dinshaw Petit to select machinery and engines for Petit's textile mill. Nusserwanjee in turn sent his son Nowrosjee 'to school in Liverpool and for factory training'. In 1879 Nowrosjee Wadia set up the Bombay Dyeing and Manufacturing Company, which has maintained an uninterrupted record of dividend payment since 1885. Nowrosjee established another successful mill, the 'Century Mills', which however was sold by his other heir (Koffend 1979: 37–41). The Bombay Dyeing's former Chairman Mr. Neville Ness Wadia, in 1994, did not seem to know much about his FRS ancestor, certainly not that he had published a diary from England. He was greatly helpful in providing source material on the Wadias to this writer.

Shizuki Tadao

Nakayama Shigeru

Shizuki Tadao was a Japanese natural philosopher, born in 1760. He was adopted by the Shizuki family, whose head was a government interpreter from the Dutch. In 1776 he became an assistant interpreter, succeeding his adoptive father, but he retired from that post the following year because of ill health. After leaving public service, he spent the rest of his life in the private study of Dutch books and in contemplation. He died in 1806.

He wrote books about the Dutch language and partially translated the Dutch translation of Engelbert Kaempher's *Geschichte und Beschreibung von Japan* (History and Description of Japan). But Tadao's major work was *Rekisho shinsho* (Introduction to True Physics), a compilation of his own theories on natural philosophy, inspired by his translation of the Dutch version of John Keill's *Introductio ad veram physicam* and the *Introductio ad veram astronomiam*.

In advocating Newtonianism, Keill's work had a polemical tone, and more importantly and quite unlike the readjusted interpretations of later authors, it dealt in abstractions and included a great many elements of natural philosophy. The book especially suited Tadao's inclination toward natural philosophy and Tadao thus became the first Newtonian in the East. He established unitary *qi* (energy) and its dual function (rarefaction and condensation) as the basis for his natural philosophy. He was not successful, however, in relating the natural philosophy that he derived from the theory of monistic *qi* to Newtonian dynamics.

Tadao also raised the question of why the planets rotate and revolve in the same direction in planes not greatly inclined to the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course). He proposed a hypothesis concerning the formation of the planetary system, which resembles the celebrated hypothesis of Kant and Laplace.

Shushu Jiuzhang

Ulrich Libbrecht

The *Shushu Jiuzhang* (A Mathematical Book in Nine Chapters) is a Chinese mathematical work, written by Qin Jiushao and published in 1247. This book is one of the highlights of Chinese mathematics of the Song-Yuan period, 960–1368.

The work is not organized according to mathematical methods, but topically arranged according to domains of administrative practice, with the exception of Chapter 1. The nine chapters are as follows:

1. Indeterminate analysis (*Dayan*);
2. Heavenly phenomena, which dealt with chronological and meteorological questions;
3. "Boundaries of fields," which covered surveying;

4. "Telemetry" or measuring at a distance, a kind of prototrigonometry;
5. Taxes and levies of service;
6. "Money and grain," i.e., taxes;
7. Fortifications and buildings;
8. Military affairs; and
9. Commercial affairs.

An investigation of the socioeconomic information contained in the work proved that all the information was indeed related to the Southern Sung society, especially regarding money and currency (including paper money), credit systems, commercial life, harmonious purchase (*heti*), transportation problems, construction of dikes, taxes and levies of service (*fuyi*), architecture, military affairs, and astronomy. This could mean that the work was written for practical purposes, although it was, partly because of the Mongol invasion of China, never used as a handbook for practical training.

The basis for the common arithmetical procedures was the ancient mathematical classic, the *Jiuzhang Suanshu*. There was one method, the *dayan* rule, which Qin Jiushao learned when he worked in the Board of Astronomy. This method is preserved only in Qin's work.

As for notation and terminology, it is important to note that the zero was printed for the first time in this book, so that we have a complete decimal place-value system. The arithmetical algorithms are the traditional ones, as are the geometrical methods and trigonometrical procedures. The most important part of the work is the "algebra." This dealt with simultaneous linear equations, determinants, and series and progressions. Also covered were numerical equations of higher degree, an extension of the method for square and cube root extraction used in the *Jiuzhang Suanshu* and the *Ten Books of Mathematical Classics*. This method is the same as the Horner–Ruffini procedure. The most important part is undoubtedly the Chinese Remainder Theorem, solved by means of the *dayan* rule. It is the solution of the problem:

$$N = r_1(\mathrm{mod}_1) = r_2(\mathrm{mod}_2) = \cdots = r_n(\mathrm{mod}\, m_n).$$

It is remarkable that Qin Jiushao was able to solve problems where the moduli are not relatively prime – a method not known to Euler and Gauss, and only solved definitively by Stieltjes in 1890.

Silk and the Loom

Dieter Kuhn

In China the raw material silk dominated textile technology as a whole, and dictated the development of looms and their technology in particular. Thus the weaving methods and the patterns depended to some extent on the loom technology available.

The biological prerequisites for silk production on a commercially significant scale are domesticated silkworms *Bombyx mori* L. (sericaria) [*jiacan*] which belong to the family Bombycidae in the order of the Lepidoptera nocturno and various mulberry trees of the family of the Moraceae, such as the *Morus alba* Linn. (*baisang*), *Morus bombycis* Koidz. (*jingsang*), and *Morus alba* var. *multicaulis* (*lusang*), commonly called the domestic mulberry (*jiasang*). Silkworms are generally fed with the fresh leaves of the mulberry tree.

Not only were these two prerequisites present from an early stage in China, as can be seen from pictographs on bone inscriptions of the Shang era, but their biological connection was also recognized. Various archeological discoveries, fragments of textile, and imprints show that in many areas of Neolithic China a form of silk technology already existed which clearly belonged to a long and practically, perhaps even experimentally, oriented agricultural tradition. The production and treatment of silk had begun many years before and by then had already reached a high technical level. So far the earliest find of silk in China is dated between 2850 and 2650 BCE. The earliest cocoons of the domesticated spinner are from the Tang dynasty (618–907).

To understand the importance of silk as far as weaving and the development of weaving patterns are concerned, it is essential to look at the genuine properties of a single silk thread. Unlike other textile fibers silk is not spun but reeled. Silk-reeling (*sao si*) involves taking up the ends of fibers from several cocoons and combining them into a thread. It takes place just before the moth tries to break through the cocoon. This timing is crucial if endless silk threads are required. The length of the cocoon-filaments which can be obtained varies between 700 and 900 m, but without a silk-winding instrument, a reel, and a water basin in which to float the cocoons, silk-reeling cannot be performed. Through the centuries hand-driven silk-reeling was practiced as a seasonal business in small-scale family production. From the terminology used it is certain that prototypes of silk reels and silk-reeling frames (*saochechuang*) were known in the Zhou period. The earliest detailed description of the treadle-operated, highly mechanized silk-reeling frame is from ca. 1090.

Loom weaving, the production of even-textured fabric, requires that the warp threads be kept at a consistently high level of tension. The warp threads (*jing*) are those which, in parallel, run lengthwise across the loom; the weft threads (*wei*) are introduced laterally at right angles to them. A high weaving tension necessitates the use of comparatively elastic warp threads of a kind not naturally found in raw silk. This elasticity is obtained through winding or throwing or else doubling and twisting the thread. Various spinning techniques could spin the thread in the requisite manner. In China the spindle wheel (*fangche*) had been in use since the middle of the first millennium BCE. The spindle wheel was not only very efficient in the spooling of threads, which means transferring a thread from a reel to a spindle, but also most useful in the processes of doubling and quilling, when an empty spindle is filled with a twisted thread which now combines two or three threads in one. Much has been published about the origin of the spindle wheel in the East and in India, but all the pictorial and textual evidence available points to China as the geographical area where the spindle wheel originated in the context of silk technology, especially the spooling and doubling process, as pictured on some Han stone reliefs. It took a long time before the spindle wheel made its appearance in Europe in the thirteenth century. All these inventions and innovations in the processing of silk threads have to be seen in the context of the treadle-operated loom (*jiaotaji*) which was equipped with two treadles in order to mechanize the opening (*kaikou*) of the shed. Thus a clear shed for the shuttle (*suokou*) was formed through which the weft thread could be passed. Such a loom was employed to weave simple tabby fabrics to standards on a large scale. From its structure it may be described as a combined horizontal–vertical or oblique warp sheet loom (*xiezhiji*). Depictions of the loom on stone reliefs from Han times which were found in Shandong, Jiangsu, and Sichuan provide ample evidence of this type of loom. A more complicated loom with a treadle mechanism for the forming of the shed and a system of draw cords (*tihuaxian*) or pattern rods (*wen 'gan*) which looped the warp threads required for the pattern already existed in Zhou times.

If maximum benefit was to be got from the exceptional length of the silk threads, then it was only logical to dress the loom with a silk warp. For this one needed a warp beam (*jingzhou*). The width of the fabric was determined by the length of the warp beam, and by the ideal working width for the weaver, who not only inserted the shuttle containing the weft, but also operated the treadles with her feet so as to form the sheds. In addition, she would have to perform other operations in order to create the particular pattern. On account of these factors, most fabrics of the Han era as well as later generally had a width of about 50 cm (two *chi* and two *cun*). The length varied between 9 and 12 m. The qualities of silk as an ideal warp thread and hence too the dominance of the warp in the weave resulted in the weave pattern being created by accentuating the warp threads. From the Zhou era (1045–221 BCE) until the early Tang era (618–907), therefore, Chinese silk possesses a warp pattern unlike that of other cultures, which, due to differences in the raw material, was produced on wholly different looms and which is weft patterned. Only in Tang times did the patterning technique change to the weft, which resulted in more colorful fabrics. Although it is known from a few silk fragments that the weft pattern was practiced in early China, the change in weaving technique in Tang times was certainly due to influence from the region of Samarkand or Persia.

Several types of looms were already in use and operated as early as Han times (206 BCE–AD 220). They are documented in historical works from Han and Jin times, and especially in the agricultural and encyclopedic works from the Song, Yuan, Ming, and Qing dynasties (960–1911).

The loom which combined 70 or even more movable shafts (healds) with the function of many treadles (*duozong duonie*) was widespread. Although this type of loom was difficult to set up, it was operated until recently in Sichuan province. The big advantage of this type of loom was that one weaver could operate it easily and quickly. Furthermore its advanced and highly efficient patterning equipment qualified it for the production of so-called brocades and other complicated weaves.

Another type of loom which is not clearly distinguished in the Chinese publications from the abovementioned loom made use of figuring healds or pattern rods (*tihuazong*, *wen 'gan*), which were manually lifted. Textual sources mention up to 120 patterning devices. This ingenious hand-operated patterning device was already used on the backstrap loom (*yaoji*) in very early times. The simple backstrap loom originally had no wooden frame but consisted exclusively of functional parts. The weaver sat on the ground. In many old publications it is depicted with a wooden framework. It was used until recently. The earliest weaving implements which may be ascribed to such a loom were excavated from the site of Hemudu, datable to ca. 4300 BCE. It may be justified to assume that the patterning technique with pattern rods which can be created in a sitting position on the ground is older than the use of looms with shafts and treadles which require a wooden frame. Although the simple type of backstrap loom was an excellent device for weaving on a comparatively small scale, it had its obvious limitations which were set by the length and width of the circular warp. In the view of Chinese textile historians this loom with pattern rods belongs to a loom category either of an early primitive type or of ethnic minorities. Only after the horizontal backstrap loom had been equipped with a real warp beam, supported by a wooden framework, which helped to facilitate its operation, can it be regarded as a loom which worked economically and which was suitable for silk weaving with patterning on a large scale. In all probability and in the opinion of a few eminent Western weaving specialists, such a loom with two shafts producing a tabby ground and a system of pattern rods of the heddle rod type that were lifted by the weaver as required by the pattern was the type of loom used and preferred to all others for the production of complex-patterned weaves before Tang times in China.

The third type of loom before Han times was a forerunner of the Chinese drawloom. It employed a string heddle patterning device (*shuzong tihua zhuangzhi*) and a simple treadle-operated shedding device. During Eastern Han times its equipment was improved in such a way that the whole "machine" (*ji*) gained the structural and functional features of a real drawloom (*hualou tihuaji*). This drawloom was equipped with a figure or harness tower and all the lifting devices for the warp threads required. Furthermore there were lifting and depressing shafts. It was operated by a weaver and a drawgirl. This type of loom, which was fashioned in a large variety, dominated the production of high-quality polychrome-patterned silk fabrics until the late nineteenth century when Western looms were introduced into China. Some Western historians of weaving technology have ruled out the use of a drawloom in Han times in China and suggested that it was invented somewhere in the region of Samarkand, Persia, or even the Near East. To support their notion they practically demonstrated that even difficult polychrome weaves could have been produced on pattern rod looms. However the "Rhapsody on Women Weavers" bears witness to the fact that the drawloom with all its characteristic features was already in use in the big workshops of China as early as the first half of the second century AD. The earliest technical description and illustrations on the subject were published in the *Ziren yizhi* (Traditions of the Joiners' Craft) of 1264.

Sinān ibn Thābit

Yvonne Dold-Samplonius

Abū Saᶜīd Sinān ibn Thābit ibn Qurra was born in Baghdad ca. 880. He was the son of the translator and scientist Thābit ibn Qurra (ca. 830–901), who dedicated his *al-Dhakhīra fī ᶜilm al-tibb* (Treasury of Medicine) to him, and the father of the mathematician and astronomer Ibrāhīm ibn Sinān ibn Thābit (908–946). His family came from Ḥarrān, crossroads of caravan routes and cultures on the Upper Euphrates, and the religious center of the Sabian sect. One of the most famous physicians of his time, he directed the hospitals and medical administration of Baghdad under the reign of the Abbassid Caliph al-Muqtadir (908–932). He also served as physician to him and to his successors al-Qāhir (932–934) and al-Rāḍī (934–940). Under the former's persecution of the Sabians Sinān had to convert to Islam. He later fled to Khurāsān, and returned when al-Rāḍī came into power.

Sinān's work, as catalogued by Ibn al-Qifṭī, can be divided into three categories: historical–political, mathematical, and astronomical; no medical texts are mentioned. None of it is extant. In the first category he wrote a description of the life at the court of Caliph al-Muᶜtaḍid (892–902), his father's protector, and a sketch for a government along the lines of Plato's *Republic*. Both treatises are mentioned by al-Maᶜsūdī, who criticizes the latter, adding that Sinān should rather have occupied himself with topics within his competence.

Four mathematical treatises are listed, of which two cannot be by Sinān, since the dates given were in the second half of the tenth century. Of the remaining two, one is connected with Archimedes' *On Triangles*, whereas the other consists of an improvement, with additions, of the book by Aqāṭun (Yāqūt = Euclid), *On Elements of Geometry.*

S

As to the third category, only the content of the *Kitāb al-Anwāʾ*, dedicated to al-Muʿtaḍid, is somewhat known through excerpts given by al-Bīrūnī in the *al-Āthār al-bāqiya min al-Qurūn al khāliya* (Chronology of Ancient Nations). A *Kitāb al-Anwāʾ* is a kind of almanac describing the astrometeorological properties (*anwāʾ*) of the individual days. Sinān's almanac is fundamentally based on an anonymous Arabic translation of Ptolemy's *Phaseis*, in which he provides the times of the rising and setting of prominent fixed stars. Other sources are Ibn Māsawayh (d. 857) and Hippocrates, as well as personal contributions by Sinān. According to al-Bīrūnī, Sinān also relates an Egyptian theory and one by Hipparchus, on where to fix the beginnings of the seasons. Another treatise, seemingly also of astrometeorological content, is on the assignment of the planets to the days of the week, composed for the Sabian Abū Isḥāq Ibrāhīm ibn Hilāl (ca. 924–994). The seven planets were important in Sabian religion; each one had its own temple. Ibn al-Qifṭī lists several works on Sabian rites and religion. Sinān died, probably in Baghdad, in 943.

Siyuan Yujian 四元玉鑒

Karine Chemla

This book (*The Jade Mirror of the Four Unknowns*, also translated as *Precious Mirror of the Four Elements*) by Zhu Shijie 朱世傑, dating from 1303, appears to represent the most advanced achievement of the mathematical tradition of polynomial algebra or the "procedure of the celestial unknown (lit.: origin) 天元術" which developed in North China in the second half of the thirteenth century. Jock Hoe (1977) describes the history of its reception among mathematicians and historians in both East and West. The *Siyuan yujian* shares the same basic features with the first book that has come down to us on this topic, Li Ye 李治's (or Li Zhi 李治's, according to the name chosen for this scholar) *Ceyuan haijing* 測圓海鏡 (Sea Mirror of the Circle Measurements, 1248). The mathematical knowledge it contains is presented in the form of problems, the first four of which lay the foundations for the whole book by gradually presenting, though extremely concisely, how to use polynomials with up to four indeterminates to solve given problems. Mirroring the intimate relationship that the right-angled triangle had with the topic of algebraic equations, and later of polynomials, from the very first appearance of these matters in China, these problems all concern the right-angled triangle, as do 101 of the 284 problems that follow in the *Siyuan yujian*. Once a problem is set, Zhu suggests the choice of one or several unknowns to form polynomials on the basis of the conditions given in the terms of the problem. In the case when one unknown suffices, like Li Ye, Zhu forms two *polynomial expressions*, representing the same quantity, and thus by elimination between them establishes an algebraic equation, a root of which is the unknown sought. Since Zhu does not explain the algorithms, similar to the so-called Ruffini–Horner ones, that can be used to determine this root, he seems to have assumed the reader's knowledge of this procedure. They are found in Qin Jiushao 秦九韶's *Shushu jiuzhang* 數書九章 (Writings on Mathematics in Nine Chapters, 1247) and seem to be common knowledge in the milieu developing the "procedure of the celestial unknown." Yet Zhu elaborates them further, especially in cases where the result is a rational number; he then systematically introduces techniques to expand the root sought.

***Siyuan Yujian* 四元玉鑒. Fig. 1**
$729x^2 - 81x^3 - 9x^4 + x^5$.

These polynomials he uses are written in the form of an array of numbers, as in Fig. 1, where the indeterminate and its successive positive or negative powers receive a positional expression. Note that the writing of a polynomial differs from the writing of an equation, as in Fig. 2, in that

the constant term of the polynomial is indicated, being accompanied by a character, thus allowing the polynomial to contain any power of the indeterminate.

When more than one unknown is needed, Zhu designs several equations involving them, which he represents by tables of numbers, where again position is used to express the various powers of the unknowns. For two unknowns, the vertical direction refers to one unknown whereas the horizontal one refers to the other; the surface of the plane suffices for any monom to be represented by its coefficient written in an appropriate place on the counting board, as in Fig. 3. Yet for three or four unknowns, limitations occur in the representation of all possible monoms and new positions on the counting board are brought into play, but in a less systematic way, as in Fig. 4.

In contrast to equations with one unknown, such equations need the constant term to be indicated by a character. Once these equations are determined, elimination is performed between them until an equation with only one unknown is obtained, which is then solved. Several techniques are used for this purpose, the most basic one resembling the elimination between linear equations put into play by the algorithm to solve systems of simultaneous linear equations presented in the Han book *Jiuzhang suanshu* 九章算術 (The Nine Chapters on Mathematical Procedures). The difference lies in the fact that now the terms involved in the procedure of elimination are polynomials, and no longer numbers. Stress must be placed on a conceptual gap. In contrast to the case for one unknown, the only one Li Ye dealt with, the elimination no longer bears on polynomials representing a given *quantity*, but rather on equations with several unknowns representing a *relationship* between the unknowns.

In the rest of the book, this apparatus is applied to all kinds of mathematical situations, such as geometry and summation of series, involving various applications to economic or social life.

Śaṅkara Vāriyar

K. V. Sarma

Śaṅkara Vāriyar (ca. 1500–1560) was a brilliant expositor of astronomy and mathematics who hailed from Kerala in the south of India. He belonged to the *vāriyar* community which was professionally assigned to certain peripheral duties in temples. Śaṅkara was a direct disciple of the well-known Kerala astronomer Nīlakaṇṭha Somyāji (b. 1444). Among other teachers whom he mentions in his works are Dāmodara (ca. 1450–1550), Jyeṣṭhadeva (ca. 1500–1610), and Citrabhānu (ca. 1475–1550). Śaṅkara mentions that his commentary on the work *Pañcabodha* was completed on the day 1,692,972 of the Kali era, which occurs in AD 1534, from which his date is definitely ascertained.

Śaṅkara Vāriyar wrote an advanced astronomical manual entitled *Karaṇasāra*, to which he added a gloss of his own. But he is better known for his elaborate commentaries on such standard works as the *Līlāvatī* of Bhāskarācārya, the *Tantra-saṅgraha* of Nīlakaṇṭha Somayāji, and the anonymous *Pañcabodha*. The two commentaries, the one on the *Līlāvatī*, called *Kriyākramakarī* (Sequential Evolution of Mathematical Procedures) and that on *Tantrasaṅgraha* called *Yuktidīpikā* (Light on Astronomical Rationale), are highly significant writings in Indian mathematical literature. After giving the meaning of each textual verse or group of verses from these two texts, Śaṅkara sets out the background and evolution of the enunciation commented on, the different aspects thereof, and the step by step derivation of the relevant formula or procedure. This exposition of rationale, couched in simple verses and often running to several pages, serves to give an exposure to Indian mathematical thinking and open up the normally unexpressed mental working of the Indian mathematician, which has led most modern historians of mathematics to presume that much of Indian mathematics and astronomy was borrowed and not original. The rationale elaborated here relates, among other things, to the summations of series, the circle and the irrationality of π and pulverization in the field of mathematics; and the theory of epicycles, ascensional differences, rising of the signs, and problems based on the gnomic shadow, in astronomy. These commentaries are valuable also for the information on earlier authors like Mādhava and Saṅgamagrāma and their theories.

Song Ci

Hong Wuli

Song Ci was born in Jianyang in 1186 of the Southern Song Dynasty and died in 1249 in Guangzhou. He was a forensic scientist, an expert in legal medicine.

A native of Jianyang (now Jianyang County, Fujian Province), Song Ci was born to a family of middle-class bureaucrats. His father was Song Huifu. He was well educated and passed the feudal examination at the highest (imperial) level. He held several posts, including the confidential secretary of the local government, county magistrate, and provincial officials until he was promoted to the provincial official responsible for law suits and jail affairs. At that time, most feudal officials did not take their responsibilities seriously, especially those involving the law, resulting in the pile up of unsolved law suits. Many were legal offenders themselves. Song ordered deadlines to sort out all these cases. Eventually, he cleared a backlog of over 200 cases (Gao 1978).

During his tenure, he set up a whole series of rules for examiners of the wounded or the dead. He stressed that legal medical experts or officials must, under the accompaniment of an examiner, arrive at the spot as soon as possible, and that no fumigation or incense was to be used. The officer or expert should examine the case in person, instead of hearing the examiner's report. He also claimed that "the most important issue in criminality is the death sentence, which should be carefully understood at the very beginning of the case by serious investigation". He also pointed out that the malfeasance of prison officials always begins with a tiny error during the investigation. Lack of experience and cursory investigation are the direct causes of wrong cases and unjust verdicts. He criticized or even punished those fraudulent examiners whenever cases were in question, and he pondered carefully and conscientiously so that few wrong conclusions were drawn (Song 1981). Based on his long-term practical experience, he compiled, in 1247, the famous *Xi yuan ji lu* (*Collected Records of Washing Away the Wrong Cases*, also translated as *The Washing Away of Wrongs*) which is the earliest work in medico-jurisprudence both in China and abroad. This book has been translated into several Western languages (Jia 1984).

Song Yingxing and *Tiangong Kaiwu*

PAN JIXING

Son Yingxing (alias Changgeng, 1587–ca. 1666) was a great scientist and thinker of the seventeenth century. He was born in Fengxin county in Jiangxi province in 1587. After graduating from the county school he became *jüren* or a successful candidate in the imperial examination at the provincial level in 1615. He took part in the highest imperial examinations in Beijing six times, but failed to become a *jinshi*. After that he decided to give up Confucianism and turned to the practical knowledge of natural science. From 1635 to 1638 he taught at Fenyi county school; then he was appointed the prison officer of Tingzhou prefecture in Fujian province from 1638 to 1640. In 1643 he worked as the magistrate of Bozhou prefecture in Anhui province. After the Ming dynasty (1368–1644) was overthrown by Manchu-Qing rulers, Song lived at home as a hermit until his death in about 1666. He had extensive knowledge in both humanistic and natural sciences. He traveled from the south to the north to obtain practical knowledge of agricultural and industrial techniques as well as political and economical information on Chinese society. This made it possible for him to write more than ten books, most of which were completed at Fenyi from 1636 to 1637.

The *Tiangong Kaiwu* (Exploitation of Products from Nature by Means of a Combination of Artificial Skills and Natural Power, also translated as The Creations of Nature and Man, 1637) is his most important work. It consists of 18 chapters on 33 departments of agricultural and industrial production including grain planting, sericulture, spinning and weaving, dyeing, salt and sugar making, vegetable oils, distiller's yeasts, ceramics and porcelain, metallurgy and casting, paper and ink making, coal, alum and copper producing, carriages and shipbuilding, cold weapons and firearms, and pearl and jade exploiting. Apart from detailed descriptions of the above-mentioned techniques, there are 123 useful illustrations in this book. It recorded many advanced technical achievements from the distant past until the Ming dynasty and made a comprehensive generalization them. Some had been rarely talked about in previous works, such as improving paddy and silkworm varieties through artificial hybridization, smelting zinc from calamine, smelting wrought iron from pig iron, producing alloys of copper and zinc, etc. This work also developed many advanced technical ideas, especially the *Tiangong Kaiwu* thought which emphasized the coordination between mankind and nature as well as artificial skills and natural power in order to exploit various products from nature for people's use.

Not only was the *Tiangong Kaiwu* welcomed in China, but it also spread to Japan and Korea from the seventeenth to the eighteenth centuries and became a popular reference work for Japanese and Korean scholars during the Edo period (1608–1868) and the Yi dynasty (1392–1910). It was reprinted in Osaka in 1771. During 1830–1840 five chapters of it were translated into French, then into English and German. The part on sericulture was cited by Charles Darwin and highly valued. In 1869 many chapters on industrial techniques were collected in the *Industries anciennes et modernes de l'Empire Chinois* published in Paris. The first four chapters on agriculture were translated into German in 1964; 2 years later the whole book was published in English in the United States. It was regarded as an "encyclopédie technique" by French sinologist Stanislas Julien of the nineteenth century, and Joseph Needham, the British scholar, called Song a "Chinese Agricola" or "Chinese Diderot." It has now become a world-famous classical scientific work.

Among Song's existing works there are also the *Ye Yi* (Proposals to the Court from Common People, 1636), *Si Lian Shi* (Poems on Praising the Good and Pitying the Foolish, 1637), *Lun Qi* (On the *Qi*, 1637), and *Tan Tian* (On Celestial Bodies, 1637). The *Ye Yi* reflected the author's political and economic thought. He put forward a plan of political reform for the Ming court for averting the political and economical crisis in society. He considered that social wealth was created by labor and that currency should not be the definition of wealth. He believed that increasing social wealth meant producing more consumable goods. Therefore, his ideas are similar to those of Adam Smith.

The *Lun Qi* is a work on natural philosophy. It explains the formation and composition of all things by means of a combination of the theory on the *qi* and the new theory of *yinyang* and five elements. He introduced a new conception of *xing* (form or shape) between the *qi* and five elements, and he explained the material unity in the composition between organic and inorganic substances. He also discussed the idea of conservation of matter in this work. It also dealt with acoustical problems, and pointed out that the formation of sound is the result of the vibration of substances, and the medium of the spread of sound is the air. Song considered that the spread of sound in the air should be in the form of a water wave; he thus put forward a preliminary conception of a sound wave.

In his astronomical work, the *Tan Tian*, he criticized a traditional theory that the solar eclipse was connected with human affairs. He thought that all things including the sun are always changing. He said: "Therefore, the sun today is no longer the same one as yesterday." Most of Song's advanced philosophical thought was further developed by another great philosopher, Wang Fuzhi (alias Chuanshan, 1619–1692). Those in academic circles are familiar with his scientific achievements, but much less familiar with his political, economic, and philosophical thoughts, because those works were only found in the mid-twentieth century and have not been carefully studied yet.

Sphujidhvaja

K. V. Sarma

Sphujidhvaja was apparently of Greek descent, and flourished in Western India under the patronage of the Kṣatrapa ruler Rudradāman II. He wrote the extensive genethlialogical manual entitled *Yavanajātaka* (Horoscopy of the Greeks) in AD 270, which shows the position and influence of the stars at one's birth. Towards the close of his work, Sphujidhvaja says that, before him, in AD 150, the great Greek genethlialogist Yavaneśvara redacted into Sanskrit prose a Greek astrological work, so that it could be studied by those who did not know Greek, and that he, Sphujidhvaja is composing a versified redaction of the work of Yavaneśvara. The work reveals Sphujidhvaja as a competent scholar, a master of Sanskrit versification, and an expert genethlialogist.

Sphujidhvaja states that he composed the work in 4,000 verses. But the only manuscript of the work available today contains only 2,300 verses. In this imperfect manuscript, the first few sections are numbered, but not so the subsequent ones, which number, in all, 79. Possibly several sections are lost. In these 79 sections, the work covers a large number of aspects of horoscopy and natural astrology, including:

- Zodiacal signs and planets, their icons, nature, and relationships
- Iconography of *horās* and decons
- Astrology of conception, birth, and nature
- Horoscopes
- Planetary placements and combinations affecting human beings
- Prediction on the basis of questions
- Reconstruction of lost horoscopes
- Omens and dreams
- Military astrology

The several aspects of each of these topics are looked at from different points of view, and intimations, indications and predictions based thereon are stated categorically.

It is interesting that, although based ultimately on a Greek text, there was substantial Indianization effected in the *Yavanajātaka*. This was accomplished by using Indian equivalents to Greek terms, adopting Hindu deities in place of Greek ones, incorporating the names of Hindu castes and professional orders, mentioning local manners and customs, and the like. *Yavanajātaka* was looked upon as authority by all later Indian genethlialogists and used as such even in the foremost of Indian texts like *Bṛhajjātaka* and *Bṛhatsaṃhitā* of Varāhamihira, *Sārāvalī* of Kalyāṇavarman, *Praśnavidyā* of Bādarāyaṇa, and many others.

The significance of *Yavanajātaka* stems from another point as well. The work refers to contemporary social orders, professions, religious classes and groups, items of ordinary use, manners and customs, dress, and a host of other things related to the life and society of the times. The information provided by the work on these subjects makes it a good source for the study of the culture and civilization of India during the early centuries of the Christian era.

Śrīdhara

R. C. Gupta

The mathematical works of Śrīdhara were very popular and made him quite famous. In spite of his great popularity, some controversies have been raised about his life, work, and time, such as whether he was a Hindu or a Jaina, and whether he wrote before or after Mahāvīra (ninth century AD). Some uncertainties exist because Śrīdhara's works are not fully extant. Often he is confused with other authors of the same name. Here we shall give views which are now generally accepted.

Like so many ancient Indian authors, Śrīdhara did not provide any information about himself in his works. Other sources have not been helpful in finding any glimpse of his personal life. So we do not know his parents or teachers, or even where he was born, educated, or worked. But some evidence shows that he was a Saivite Hindu. An example in his *Pāṭīgaṇita* is about the payment for the worship of the five-faced Hindu god Śiva. He starts his *Triśatikā* with a homage to the same god. However, in a manuscript which has a possible commentary and additional examples written by an apparently Jaina writer, the word "Jinam" is found in place of "Śivam". This led to the claim that Śrīdhara was a Jaina, but other evidence does not support this view.

More serious is the controversy about Śrīdhara's time. That he lived after Brahmagupta is evident from the fact that he literally quoted (and criticized) a rule from Brahmagupta's *Brāhmasphuṭasiddhānta* (AD 628). The most significant question in this connection is whether Śrīdhara wrote before or after Mahāvīra, whose date of ca. AD 850 is certain. There are similarities in the works of these two mathematicians. Most scholars believe that indications generally place Śrīdhara before Mahāvīra. A new fact has come to light recently; David Pingree found that a rule of Śrīdhara's had been quoted by Govindasvāmin (about AD 800–850) in his commentary on the *Horāśāstra* of Parāśara (under 14.97). This latest and direct evidence once again supports the generally accepted view of placing Śrīdhara in the eighth century or ca. AD 750.

Śrīdhara is known to be the author of the following three works on mathematics:

1. *Pāṭīgaṇita* (on arithmetic and mensuration)
2. *Pāṭīgaṇita-sāra* (an epitome of the above)
3. *Bījagaṇita* (on algebra)

The *Pāṭīgaṇita* is a standard Indian treatise on practical mathematics meant "for the use of the people". It is also called *Bṛhat-Pāṭī* (Bigger Pāṭī) and *Navaśatī* (Having Nine Hundred) because it is believed to have 900 stanzas. Unfortunately, it is not extant in full; the available text contains only 251 stanzas. In terms of topics, treatment of definitions, logistics, mixtures of things, and series are available in full, but that of the plane figures is incomplete. Many other treated topics are mentioned in the list of contents, but they are totally missing from the manuscript. These were excavations, piles of bricks, sawn pieces of timber, heaps of grain, shadows, and the mathematics of zero (whose loss is quite sad).

The *Pāṭīgaṇita-sāra* is also called *Triśatī* or *Triśatikā* because it was a "Collection of 300 verses". It was the author's own summary of the larger work on the subject.

Śrīdhara's *Bījagaṇita* (Algebra) seems to be lost completely. We know about it from a statement of Bhāskara II (AD 1150) who also quoted a rule from it. The rule gives a method for solving any quadratic equation and has also been quoted by others. Many other rules from different works of Śrīdhara have also been quoted by various writers. This shows the popularity of his works.

A recently discovered work called *Gaṇita-Pañcaviṁśī* is also stated to be from the pen of Śrīdhara, but it may not be his genuine work. Similarly, a number of astronomical, astrological, and other works authored by different persons of the same name have been ascribed wrongly. Confusions were created both by the similarity of names and also by the proximity of their dates.

In India, ten has been the base of counting since very early times. But the number and names of decuple terms used in the decimal numeration were at variation throughout the ancient period. Later on, the decuple terms were used to denote the notational places when the positional system was developed, and their number was standardized to 18 (which was a traditionally sacred number). Śrīdhara gave a definite list of 18 terms which became standard in Indian mathematics. It runs thus: *eka, daśa, śata, saharsa, ayuta, lakṣa, prayuta, koṭi* ($=10^7$), *arbuda, abja* (or *abda*), *kharva, nikharva, mahāsaroja, śaṇku* (or *śankha*), *saritāṁpati, antya, madhya*, and *parārdha* ($=10^{17}$).

Among the arithmetical rules discussed in the *Pāṭīgaṇita, Sūtra* 49–50 gives a formula for finding the time in which a sum lent out at simple interest will be paid back by equal monthly installments. Under the *Sūtra* 63–64 he presents the famous problem of a Hundred Fowls, in which we have to solve the indeterminate equations in integers. [The hundred fowls problem goes like this: Roosters cost 3 coins each chicks are 3 for 1 coin. If 100 fowls are purchased for exactly 100 coins. Then how many of each are bought?]

S

For mensurations related to a circle, Śrīdhara used the approximation $\pi = \sqrt{10}$, a very ancient Indian value. But there is some evidence to show that he used $\pi = 22/7$ in the lost part of *Pāṭīgaṇita*.

Another of Śrīdhara's great achievements was his mensuration of the volume of a sphere.

Śrīpati

Kripanath Sinha

Śrīpati was the most prominent Indian mathematician of the eleventh century. He was the son of Nāgadeva and lived in Mahārāṣṭra. He flourished during the period from AD 1039 to 1056.

General appreciation for Śrīpati's fame as a mathematician is based on his arithmetic, *Gaṇitatilaka*, and the two mathematical chapters of his astronomical work entitled *Siddhāntaśekhara*. The 13th chapter, the *Vyktagaṇitādhyāya*, contains arithmetical rules, series, mensuration, and shadow reckoning. The 14th chapter, the *Avyaktagaṇitādhyāya*, is one of the few extant Hindu works on algebra. The only edition (by Kapadia) of the *Gaṇitatilaka* contains a valuable commentary by Sihatilaka (ca. AD 1275).

Besides including in his works selected rules of his predecessors, Śrīpati enriched Indian mathematics by giving some improved and some original rules. The *Gaṇitatilaka* contains the earliest known treatment of simple addition and subtraction in any Indian work. Also included is the earliest version of our angular method of addition used to check the accuracy of a sum and simplify addition. The *Vyktagaṇitādhyāya* gives an improved rule for the volume of an excavation.

The *Avyaktagaṇitādhyāya* contains most of Śrīpati's original ideas and rules. In it, he presents the idea of an extensive system of symbolism in algebra, the only Hindu treatment of the cubing of signed numbers, and explicit recognition of the nature of imaginary quantities that is second only to Mahāvīra's. He also provides the earliest versions of our ordinary method of solving simple linear equations by using inverse operations and an early formal treatment of factorization. The rules not only give the ordinary method of factoring based on successive division, but also provide an additional method for factoring a non-square number by expressing it as the difference of two squares.

Śrīpati also displayed his mastery of indeterminate equations by giving an improved rule for solving the factum and original rules for solving the pulverizer. He also described an original method to obtain rational solutions of the square-nature.

All Śrīpati's works are in verses. The *Siddhāntaśekhara* contains only rules, but the *Gaṇitatilaka* is written in an autocratic style of teaching strategy, in which a rule is followed by plentiful exercises. The book is quite secular in nature. According to the author's testimony, it was written for public use. It contains arithmetical and commercial rules, and some problems solvable by simple linear, quadratic, and radical equations. A garland problem and numerous other fanciful problems included in the book make it pleasurable and interesting. The practical and aesthetic values of the *Gaṇitatilaka* cannot be underestimated.

Śrīpati, however, also had some weaknesses. His mathematics of division by zero is all wrong. In the *Vyktagaṇitādhyāya*, he uses the term *caturbhuja* to mean a square, a quadrilateral in general, a cyclic quadrilateral, a quadrilateral with equal altitudes, and an isosceles trapezoid. Because of this inconsistency, his rules on mensuration of quadrilaterals are hard to interpret.

Stars in Arabic–Islamic Science

Paul Kunitzsch

The Arabs in pre-Islamic times – mostly Bedouins, in the Arabian peninsula – already had a good knowledge of the stars. They used certain stars or asterisms for orientation in their desert travels, to fix seasons, and to predict weather, especially rain. For the last two purposes they developed a system of so-called *anwāʾ* (sing. *nawʾ*), in which a star or asterism was observed setting shortly before sunrise and another simultaneously rising, just opposite (the latter one was called *raqīb*, with respect to the first one). At an unknown time and through unknown channels they received – most probably from India – the system of the 28 lunar mansions (*manāzil al-qamar*), stars or asterisms along the path of the moon, near the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course). The indigenous *anwāʾ* were then merged with the lunar mansions, and the 28 mansions were given names from among the former *anwāʾ*. All the five planets visible to the naked eye seem to have been known, since the Arabic language has old indigenous names for them: Mercury – *ʿuṭārid*, Venus – *al-zuhara*, Mars – *al-mirrīkh*, Jupiter – *al-mushtarī*, and Saturn – *zuḥal*. Also, fragments of the Babylonian zodiac seem to have reached the Arabs in pre-Islamic times, though their location in the sky was different from that in Babylonian and Greek (and modern) astronomy; the figure corresponding to Gemini (*al-jawzāʾ*), for example, was located in the stars of Orion, or the figure corresponding to Aquarius (*al-dalw*) in the Pegasus square. Such star lore was also much used in classical Arabic poetry, in pre-Islamic times and afterward. From the ninth century on, Arabic lexicographers and philologists collected the dispersed elements of old Arabic folk astronomy and put them together in special monographs (called *Kutub al-anwāʾ*, Books of the *anwāʾ*). From these, more than 300 old Arabic names for stars and asterisms could be recovered.

A new development began after the Muslim conquest of the lands of the Middle East. Now the Arabs came into contact with Greek science as transmitted and practiced in learned circles, mostly by Christian monks and scholars, in the area. After a period of undocumented first contacts, from the eighth century on, Greek scientific texts were translated into Arabic in great numbers. Scientific astronomy in the Islamic world therefore was largely built on Greek knowledge, with additional elements received from India and Persia. Greek cosmology and Greek theories of the planets, the fixed stars, and other celestial phenomena formed the basis of Arabic–Islamic astronomy. Later Muslim astronomers continued to work with this material, developed it, and introduced many corrections and improvements. But the "Copernican revolution" did not reach the Islamic world; Arabic–Islamic astronomy continued to be Ptolemaic into the nineteenth century.

On the (fixed) stars, the main source for the Arabs was Ptolemy's *Almagest*, which contains in Books VII and VIII a catalog of 1,025 stars arranged in 48 constellations and listed with their ecliptical coordinates, longitude and latitude, and magnitude. These 48 constellations (which also live on, in modified form, in modern astronomy) and the derived nomenclature of the 1,025 known stars were used by Muslim astronomers through all times, in books as well as on instruments (astrolabes, celestial globes, quadrants). To make the catalog valid for all times, Ptolemy proposed to add to the longitudes of the stars a constant of one degree in 100 years, to correct for precession. The Muslim astronomers very soon (in the ninth century) found a better value, one degree in 66 years; later also one degree in 70 years and other values were used. The pictorial figures of the constellations were also basically taken from Greek models; only details of the physiognomy of human figures and clothing were more or less adapted to contemporary local styles.

The main Arabic work on the fixed stars and the constellations was the *Book on the Constellations* by the Persian astronomer Abu'l-Ḥusayn al-Ṣūfī (903–986); al-Ṣūfī anxiously followed the Arabic versions of the *Almagest*, added criticisms based on his own observations, but established his star catalog exactly according to the data given in the *Almagest* (adding a constant of 12°42′ to the longitudes, for precession, for his epoch AD 964). For each constellation al-Ṣūfī added two drawings, one showing the figure as seen in the sky, and the other showing it as seen on the celestial globe (where the figures appear as seen from outside the globe, with the right and left sides reversed against the sky view). Most Islamic globe makers, through all centuries, followed al-Ṣūfī's models in depicting the constellation figures.

Several Islamic astronomers established star catalogs in the manner of the *Almagest*: al-Battānī (epoch 880, precession constant added 11°10′), al-Ṣūfī, al-Bīrūnī (epoch 1031, precession constant 13°0′), and Ulugh Beg (epoch 1437, own observations, but some stars taken over from al-Ṣūfī). Besides these big catalogs, smaller star lists were drawn up by very many astronomers, for use on astrolabes or other instruments. Most of the catalogs and star lists, however, were not obtained through observation; they were adapted from the *Almagest* or derived catalogs by adding the precession constant to the longitudes. A small list of 24 stars obtained through independent observation was established by the astronomers of the caliph al-Maʾmūn for the epoch 214 Hijra = AD 829–830; also other star tables were afterward derived from it by adding the precession constant.

Other celestial phenomena, such as comets or meteor showers, were not considered by the Arabic–Islamic astronomers. Following Greek cosmological theory, they supposed these to belong to the sublunar sphere, i.e., the space between the Earth's surface and the moon, and not to the sphere of the stars. The fixed stars in their opinion were all situated on the farthest, eighth sphere, beyond the seven spheres of the planets and the sun and moon. It was mostly in chronicles and in astrological works that such phenomena were registered, and they were usually regarded as bad omens indicating evil events.

Through Latin translations in late tenth and mainly in the twelfth century in Spain, many star names of Arabic origin entered the West and continue to be used in Western astronomy, mostly in heavily distorted spellings, today.

Stars in Chinese Astronomy

Sun Xiaochun

In Chinese astronomy, stars were called *Hengxing* (fixed stars) or *Jingxing* (warp stars), while planets were called *Xingxing* (movable stars) or *Weixing* (web stars). The traditional Chinese sky was composed of 283 constellations which included 1,464 individual stars. This unique system was first established by Chen Zhuo, an astronomer of the Three Kingdom period (AD 220–280), who collected knowledge about stars from the Han time and summarized it in a new catalog of stars. According to Chen Zhuo, these constellations belonged to three separate astronomical schools: 93 constellations belonged to Shi Shi (Master Shi), 118 to Gan Shi (Master Gan), and 44 to Wuxian Shi (Master of Wuxian). There were also 28 lunar mansions (*Xiu*), which were very important in the Chinese sky. Stars of the three astronomical schools were preserved in the *Kaiyuan Zhanjing* (Treatise on Astrology) of the Kaiyuan period (AD 729) from the Tang Dynasty (AD 618–907). After Chen Zhuo little was changed of the Chinese system of constellations.

The observation of stars started as early as civilization began. Among the oracle bone inscriptions from the Shang Dynasty (ca. sixteenth–eleventh centuries BCE) some stars were mentioned. In the *Shangshu* (Historical Classic), the paragraph concerning four cardinal asterisms has generally been agreed to be the record of the observation of stars from before the twenty-first century BCE. But before the Han Dynasties (106 BCE–AD 220), no description of the total sky existed; only 38 star names were mentioned in pre-Han literature. These stars were either of the 28 *Xiu* or were very popular stars such as *Beidou* (Ursa Major), *Niulang* (α Aql), and *Zhinü* (Vega, α Lyr). They appeared in folklore and poems. During the Warring States period (480–222 BCE) there lived two famous astronomers, Shi Shen and Gan De, who were founders of two of the abovementioned astronomical schools. But what were called Shi Shi's and Gan Shi's constellations did not seem to exist in their own time; they were later developments of the nomenclature of stars during the Han. The earliest descriptions of the total sky was in the *Tianguan Shu* (Monograph on Heavenly Officers) by Sima Qian (145–86 BCE) in which 91 constellations including about 500 stars were mentioned. The earliest star catalog, giving coordinates of 92 leading stars of Shi Shi's constellations and of 28 determinative stars of the 28 *Xiu*, were observed a few decades after Sima Qian. That is, the evidence shows that Shi Shi's constellations were scientifically established during the Former Han (206 BCE–AD 25). Shi Shi's constellations consisted of the brightest stars in the sky. They served as the referential system to constellations of other schools. Most constellations of Gan Shi and Wuxian Shi were just fill-ins among Shi Shi's constellations. It is quite certain that the constellations of the three schools obtained their complete forms during the Han times. Chen Zhuo's work was to summarize them.

Constellations in the Chinese sky are much smaller than the Greek ones. A constellation usually includes several stars linked together with imaginary lines. Some constellations are even composed of single stars. Constellations were called inner ones or outer ones according to their location to the North or South of the equator.

The 28 *Xiu* were the basis of the Chinese sky. They spread near the equator and served as one of the dimensions of the Chinese polar-equatorial coordinate system. One coordinate corresponding to the Right Ascension was given as the hour distance to the determinative star of a certain *Xiu*, which was almost always the most western star in the *Xiu*. With great circles linking the determinative stars and the North Pole, the celestial sphere was divided as segments of an orange. Constellations were described in the sequence of the *Xiu* as they were located.

Historical research shows that the 28 *Xiu* are much earlier than the whole constellations of the three astronomical schools. Some star names seemed to be direct derivations from the mythological, legendary, or astrological meaning of the *Xiu*. A complete set of the names of the 28 *Xiu* was discovered on a lacquered box cover excavated from a tomb dated from 433 BCE. The *Xiu* were formed into four groups of seven which were called Four Images. The Four Images corresponded to the four cardinal points in the sky and the four seasons of the year.

Ancient India and the Islamic world also had similar lunar lodge systems. It is certain that these three systems were originally related. But when and where they were first constructed and how they diffused is still an unsolved problem.

Another feature of the Chinese sky is the existence of the three-wall system. There were three enclosed areas in the sky: *Ziwei Yuan*. *Taiwei Yuan*, and *Tianshi Yuan*. The meaning of *Yuan* is a wall, which was formed by stars surrounding the enclosed area. *Ziwei Yuan* indicated that polar area which included 15 constellations, and the wall was formed with 15 stars. *Tianshi Yuan* and *Taiwei Yuan* indicated two other groups of constellations between *Ziwei Yuan* and the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course). The former had 13 constellations, and the wall was formed with 22 stars; the latter also had 13 constellations, but the wall was formed with ten stars. The names of the three-wall system might have existed early, but their use to indicate groups of constellations was rather late, probably after Chen Zhuo.

Since the Tang Dynasty, the three *Yuan* and the 28 *Xiu* became the main structure by which the stars were organized. The famous astronomer Li Chunfeng (AD 602–670) used this system to describe the sky in *Jinshu Tianwenzhi* (The Astronomical Chapter of the History of the Jin Dynasty, AD 265–420).

The names of the Chinese constellations provide a unique document to be studied. The way stars were named was completely different from the Greek. Stars were organized into a heavenly human society. In the sky you can see:

- Emperor, queen, and princes
- Royal court and clan
- Imperial bureaucracy and administration
- All kinds of buildings and facilities, even a toilet in the sky
- Military installation, armies, and weapons
- Traffic and transportation
- Rituals, ceremonies, and pictures of social life
- Philosophical and religious concepts
- Mythological and legendary figures
- Local states and geographical features

It is a total cultural complexity projected in the sky. In the polar area, for example, the *Ziwei Yuan* was furnished with an emperor, queen, princes, royal high-ranking officials, and facilities in a court. There was one constellation called the North Pole, *Beiji*, the brightest star of which was called *Di* the Emperor. The *Ziwei Yuan* was just like a royal palace; it took the polar area and all the stars turned round it. It reflected the social order of the imperial society of ancient China, as Confucius analogized: "He who is a governor because of his Virtue may be compared to the North Pole Star, sticking to its place and all stars turning about it." In other parts of the sky, social life pictures were reflected.

The *Tianshi Yuan* was a heavenly market, in which all kinds of shops were marked. The Autumn harvest of peasants, the imperial hunt ceremony, and cavalry troops could also be found in the Chinese sky.

Because the appearance of a certain part of the sky is related to seasons, and because it also changes with the precession of the sky, seasonal considerations may help to estimate the time when these earthly happenings were projected in the sky. By and large this practice happened during the Han and was carried on with the impetus given by the philosophy of *Tian Ren Gan Ying* (The Interaction between Heaven and Human Beings) which came to a climax during the Han and which urged a new type of astrology by means of division of the sky. The sky was constructed as a heavenly imperial society so that astrologers could interpret imperial society straightforwardly in correlation with the terrestrial society. Stars in the Chinese sky provided a basis for ancient Chinese astrology.

Throughout the history of China, there has been continuous observation of stars. Although the constellations have been kept basically unchanged, new measurements of the position of the stars were made in almost every dynasty. Star maps were made to study the sky. The earliest existent star map is from the *Dunhuang* collection of manuscripts of the Tang Dynasty. More accurate and scientific star maps are from the Song Dynasty (AD 960–1279). The Suzhou Astronomical Chart on a stone plate made in AD 1274 is well known. Almost all stars in the Chinese sky were carved quite precisely on the planisphere. The star map was based on the observations made during the Song. Even the supernova of the year of 1054 in Taurus was marked on the star map.

Since the late Ming Dynasty (AD 1368–1644), European astronomy began to influence China. Star catalogs and star maps were made in the way Westerners did. Traditional stars were identified with the sky and more stars were observed. But the framework of the traditional constellations was not abandoned. Newly measured stars were counted as supplementary stars in old constellations. New constellations were added only in the southern sky, where stars had not been registered by ancient Chinese astronomers. The pioneer work of this kind was done by Xu Guangqi (AD 1562–1633) and the German Jesuit Adam Schall von Bell (AD 1592–1666) in *Chongzhen Lishu* (Calendrical Treatise of Chongzhen Period, AD 1628) at the end of the Ming Dynasty. In this book, 23 new constellations including 126 stars were constructed in the southern hemisphere of the sky. Their work paved the way for the Chinese sky to be absorbed into world astronomy.

Stone in Ancient Egypt

JAMES A. HARRELL

Rock Varieties and Sources

Much of what remains of ancient Egypt consists of stone (De Putter and Karlshausen 1992; Klemm and Klemm 1993, 2001; Aston et al. 2000; Baines 2000). There are building stones for temples, pyramids, and tombs; ornamental stones for vessels, sarcophagi, shrines, stelae, statues, and other sculptures; gemstones for jewelry; and utilitarian stones for tools, weapons, pigments, and other applications. Still other stones were processed to extract their precious metals. These remains range in age from the Late Predynastic period (beginning about 3200 BCE) to the Roman period (ending about 400 AD; Table 1). In common parlance, the term "stone" includes "rocks" as well as the "minerals" they contain. There are three general categories of rocks – sedimentary, igneous, and metamorphic, and these are further subdivided according to their textures and constituent minerals.

Sediments (mud, sand, and gravel) deposited on ocean floors and land surfaces are hardened into sedimentary rocks through a variety of lithification processes, including compaction, cementation, and recrystallization. Continental sediments are derived from weathered and eroded pre-existing rocks, and are deposited mainly by rivers but also occasionally by wind, glaciers, and other processes. Marine sediments,

Stone in Ancient Egypt. Table 1 Ancient Egyptian chronology

Late Predynastic Period (3200–3000 BCE): Dynasty 0
Dynastic or pharaonic Period (3000–332 BCE): Dynasties 1 to 30
Early Dynastic Period (3000–2686 BCE): Dynasties 1 and 2
Old Kingdom (2686–2160 BCE): Dynasties 3 to 8
First Intermediate Period (2160–2055 BCE): Dynasties 9 to early 11
Middle Kingdom (2055–1650 BCE): Dynasties late 11 to 14
Second Intermediate Period (1650–1550 BCE): Dynasties 15 to 17
New Kingdom (1550–1069 BCE): Dynasties 18 to 20
Third Intermediate Period (1069–664 BCE): Dynasties 21 to 25
Late Period (664–332 BCE): Dynasties 26 to 30
Greco-Roman Period (332 BCE–395 AD)
Ptolemaic Period (332–30 BCE)
Roman Period (30 BCE–395 AD)

in contrast, are composed mainly of biogenic material (hard skeletal parts of algae, protozoa, and especially invertebrate animals) or inorganic precipitates produced by evaporation of seawater, but also sometimes include continental sediments carried by rivers to the seas. Other sedimentary rocks are the result of secondary mineralization of pre-existing sedimentary rocks.

Sedimentary rocks used by the ancient Egyptians include: limestone (from biogenic marine sediments); rock gypsum and rock anhydrite (both from evaporative marine sediments); sandstone, including siliceous (quartz-cemented) sandstone or quartzite (from continental sediments and, in part, shallow nearshore marine sediments); and travertine and chert (both from secondary mineralization of limestone). Nearly all the ancient quarries for limestone, travertine and chert were located in the hills and cliffs bordering the Nile River valley between Cairo in the north and Isna in the south. Some limestone was also quarried along the Nile Delta's Mediterranean coast near Alexandria. Quarries in the Nile valley from Isna southward into northern Sudan supplied the sandstone. Rock gypsum and rock anhydrite were obtained from Egypt's Red Sea coast, and rock gypsum also came from the Faiyum in the Western Desert. A beautiful blue rock anhydrite comes from an unknown source and may have been imported into Egypt.

Igneous rocks form through the crystallization of magma (molten rock). They are referred to as "plutonic intrusives" when they form deep below the Earth's surface, "volcanic intrusives" when emplaced in the shallow subsurface (dikes and related rock bodies), and "volcanic extrusives" when coming from a volcano and deposited on the surface (lava flows, and airborne pyroclastic falls and flows).

Igneous rocks used by the ancient Egyptians include: granite, granodiorite, quartz diorite, diorite, and pyroxenite (plutonic intrusives); andesite and dolerite porphyries as well as other porphyritic rocks (volcanic dikes and lava flows); basalt and obsidian (volcanic lava flows); and tuff and related rocks (volcanic pyroclastics). Apart from the famous granite and granodiorite quarried at Aswan on the Nile River, the igneous rocks came from the Faiyum in the Western Desert (basalt) and especially the mountains of the Eastern Desert (all other rocks, excluding obsidian). Obsidian (volcanic glass) does not occur in Egypt, and was imported from the eastern Mediterranean and southern Red Sea regions.

Metamorphic rocks are derived from pre-existing sedimentary, igneous or other metamorphic rocks through the application of high pressures, high temperatures, or chemically active hydrothermal fluids deep below the Earth's surface. The metamorphosis occurs in the solid state (without melting) through secondary mineralization and recrystallization. The resulting rocks are either foliated, with a parallel alignment or planar segregation of their constituent minerals, or non-foliated.

Metamorphic rocks used by the ancient Egyptians include anorthosite gneiss and tonalite gneiss (foliated); and marble, metaconglomerate, metagabbro, metagraywacke, serpentinite, and steatite (non-foliated). The anorthosite gneiss comes from the Nubian Desert west of Lake Nasser, and the other rocks were quarried in the mountains of the Eastern Desert.

The other stones employed by the ancient Egyptians are minerals found mostly within the plutonic and metamorphic rocks. These are the gemstones used for jewelry and include: amazonite, a variety of microcline feldspar; emerald, a variety of beryl; garnet; peridot, a variety of olivine; numerous varieties of quartz (agate, amethyst, carnelian, and other colored chalcedonies, jasper, milky quartz, and rock crystal); and turquoise. These minerals were quarried in the Sinai (turquoise), St John's Island in the Red Sea (peridot), the Nubian Desert west of Lake Nasser (agate, carnelian, and other chalcedonies); and the mountains of the Eastern Desert (all the rest). Lapis lazuli, a gemstone rock rather than a mineral, was also widely used in Egypt but was apparently imported from Afghanistan. The plutonic igneous and metamorphic rocks are also the source of much of ancient Egypt's gold, copper, silver, tin, and some iron and lead, with sedimentary rocks supplying additional copper, iron, and lead. All of these were obtained from the Eastern Desert with much of the copper (derived from malachite) also coming from the Sinai.

Plate tectonics and other earth movements in combination with erosion processes have brought the originally deeply buried sedimentary, igneous and metamorphic rocks to the surface in Egypt. The geologic map in Fig. 1 shows the generalized distribution of these rocks. The exposed plutonic igneous and metamorphic rocks, which form mountains in the Eastern Desert, are commonly referred to as the Precambrian “crystalline basement” and in Egypt are over 550 million years old, whereas the sedimentary and volcanic igneous rocks are mostly less than 100 million years in age. For images of many of the stones used by the Egyptians (especially the ornamental varieties) as well as information on the ancient quarries, see the author’s website at ►http://www.eeescience.utoledo.edu/egypt/.

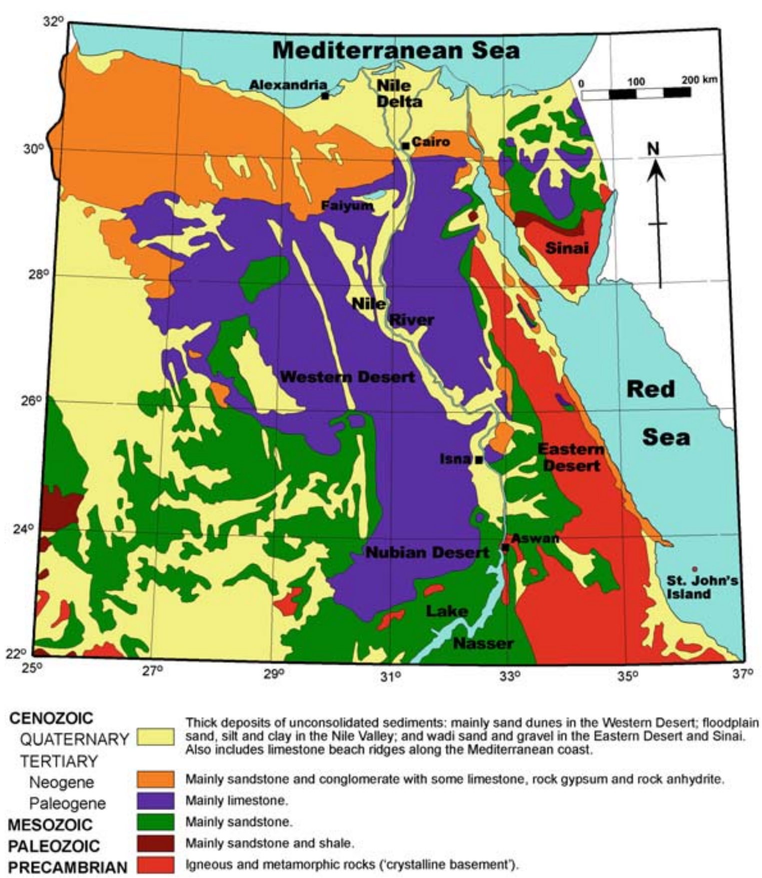
Building Stones

Limestone and sandstone were the main building stones of ancient Egypt. From Early Dynastic times onward, limestone was the material of choice for pyramids, mastaba (bench-like, rectangular) tombs, and temples within the limestone region. From the late Middle Kingdom onward, sandstone was used for all temples within the sandstone region as well as many of those in the southern part of the limestone region. Both limestone and sandstone were also employed for statuary and other non-architectural applications, when harder and more attractive ornamental stones were not available. Along the Red Sea coast, the temples and other important buildings of the Ptolemaic and Roman periods were built with the locally available rock gypsum and rock anhydrite.

Ornamental Stones

In contrast to the drab, unpolished building stones, those employed for ornamental applications, have attractive colors and patterns, and also take a good polish due to their greater hardness. The principal applications of the various stones and their periods of use are as follows:

1. Exterior veneer on pyramids: Old Kingdom – granite and granodiorite



Stone in Ancient Egypt. Fig. 1 Generalized geologic map of Egypt (adapted from an unpublished geologic map by the Egyptian Geological Survey and Mining Authority).

2. Pyramid capstones: Old and Middle Kingdoms – granodiorite and possibly basalt
3. Linings of burial chambers and passages in pyramids and mastaba tombs: Early Dynastic period through Middle Kingdom – granite, granodiorite, and siliceous sandstone
4. Door lintels, jambs, and thresholds of temples: Early Dynastic through Roman periods – granite, granodiorite, and siliceous sandstone
5. Temple pavements: Old Kingdom – basalt and travertine
6. Temple columns: Old and Middle Kingdoms – granite
7. Interior wall veneer, pavement, and columns for temples and other buildings: Roman period – andesite-dacite porphyry, granite, granodiorite, metaconglomerate, metagabbro, metagraywacke, pegmatitic diorite, quartz diorite, rhyolite porphyry, tonalite gneiss, and trachyandesite porphyry
8. Basins: Roman period – granite, andesite-dacite porphyry, and tonalite gneiss
9. Barque shrines: Middle and New Kingdoms – granite, siliceous sandstone, and travertine
10. Small statue shrines (naoi): Old Kingdom through Roman period – granite, granodiorite, metagraywacke, and siliceous sandstone
11. Obelisks: New Kingdom and Roman period – granite; and New Kingdom only – metagraywacke and siliceous sandstone
12. Offering tables: Old Kingdom through Roman period – granite, granodiorite, metagraywacke, siliceous sandstone, and travertine
13. Small vessels and figurines: Late Predynastic period through Old Kingdom – andesite porphyry, anorthosite gneiss, basalt, granite, metagraywacke, obsidian, pegmatitic diorite, quartz rock crystal, red-and-white limestone breccia, rock gypsum, serpentinite, silicified (petrified) wood, travertine (the most commonly used stone), tuff, and tuffaceous limestone; and Middle Kingdom and Second Intermediate period only – blue rock anhydrite
14. Canopic jars[1]: Old Kingdom through Roman period – travertine
15. Sarcophagi: Old Kingdom through Roman period – granite, granodiorite, metagraywacke, and siliceous sandstone; Old through New Kingdoms only – travertine; New Kingdom through Late Period only – metaconglomerate; and Late Period only – basalt
16. Small to colossal statues and other sculptures: Early Dynastic through Roman periods – granite, granodiorite, metagraywacke, red-and-white limestone breccia, siliceous sandstone, and travertine; Old and Middle Kingdoms only – anorthosite gneiss; early New Kingdom only – marble and pyroxenite; Late Period only – dolerite porphyry; Late through Roman periods only – basalt and metaconglomerate; and Roman period only – andesite-dacite porphyry
17. Scarab and shabti[2] figures: New Kingdom through Roman period – metagraywacke, serpentinite, steatite (usually glazed), and travertine
18. Stelae: Old Kingdom through Roman period – granite, granodiorite, metagraywacke, and siliceous sandstone; and Late Period only – metaconglomerate
19. Cosmetic and ceremonial palettes: Late Predynastic and Early Dynastic periods: metagraywacke. Note that many of the above objects were also carved from non-ornamental limestone and sandstone.

Gemstones

The many precious and semi-precious gemstones available to the ancient Egyptians were employed primarily for beads, pendants, amulets, inlays, and seals. Agate, amazonite, carnelian (including sard) and other colored chalcedonies, garnet, jasper, lapis lazuli, obsidian, rock crystal and milky quartz, steatite (usually glazed), and turquoise were used from the Late Predynastic through Roman periods. Amethyst was employed mainly during the Middle Kingdom and again during the Ptolemaic and Roman periods. The Romans were the first to use emerald and peridot for jewelry, and also imported into Egypt other gemstones from India, including aquamarine (beryl); carnelian, onyx, sard, and sardonyx (all varieties of chalcedony); and sapphire and ruby (corundum).

Utilitarian Stones

Perhaps the heaviest used and least glamorous stone employed by the ancient Egyptians is chert, which is also commonly referred to as flint. From Predynastic times onward it was used for tools (awadze, adzes, knife, and sickle blades; axe and pick heads; choppers; drill bits; and scrapers) and weapons (dagger blades, and spear and arrow points). Even when metals (copper, bronze, and later iron) became commonplace

S

[1] Canopic jars were containers (usually four) found in ancient tombs which stored organs and viscera which were believed to be essential for the dead person's existence in the afterlife.

[2] A shabti was a model servant figure which was supposed to do the hard work for the deceased in the afterlife.

for these applications, chert was still a popular low-cost alternative. For tools and weapons requiring the sharpest edges, imported obsidian was employed. A wide variety of stones, especially hard ornamental ones, were used for the heads of maces, a club-like weapon.

From Late Predynastic times into the Late Period, the quarrying and much of the carving of ornamental stones was done with hard, fracture-resistant stone tools known as pounders and mauls. These were primarily of dolerite, but siliceous sandstone, anorthosite gneiss, and fine-grained granite were also occasionally used. These same rocks were also employed as grinding stones for smoothing rough, carved stone surfaces. The actual polishing of these surfaces was probably done with ordinary, quartz-rich sand of which Egypt abounds. For the softer sandstone and limestone, picks of chert (as well as metal tools) were employed.

Eye shadow made from finely ground galena (dark gray) and malachite (green) was used by both Egyptian men and women. The grinding was done on cosmetic palettes carved mainly from metagraywacke. Egyptian temples and tombs were richly painted with bright primary colors made largely from ground stones: azurite (blue), gypsum and limestone (white), hematite ochre (red and orange), limonite ochre (yellow and brown), and malachite (green).

Grinding stones for grain have been used throughout Egyptian history, and generally were carved from the harder and less valuable ornamental stones, such as granite, granodiorite, and siliceous sandstone. During the Ptolemaic and Roman periods, large numbers of grinding stones made from vesicular basalt were imported.

Extra 1: What is in a name?

A persistent problem in Egyptian archaeology is the misidentification of ornamental stones. The primary sources of these errors are archaeologists, museum curators, and art historians who are unfamiliar with correct petrological nomenclature as applied by geologists. Geologists themselves have also contributed to the problem by applying different, competing rock classifications to the stones. It is not uncommon to see objects carved from the same stone referred to by multiple, contradictory rock names in museum exhibits and catalogues as well as in reference works. This is not only a great source of confusion to the general public, but it has also misled some scholars into thinking the different rock names refer to different materials. A classic example of this problem is the stone known by the technically correct name "metagraywacke" (a slightly metamorphosed greywacke sandstone to siltstone), which is commonly referred to incorrectly as "schist," "slate," "basalt," and "siltstone." "Travertine" is another notorious example. This stone, which consists of the mineral calcite, is frequently called "alabaster," which in geological nomenclature is a rock consisting of the mineral gypsum. In an effort to avoid this misidentification, travertine is increasingly being referred to as "calcite-alabaster" or simply "calcite."

Another commonly misidentified stone is the "granodiorite" from Aswan, which is often referred to as "black granite," "diorite," or "basalt." For example, the famous Rosetta Stone, which provided the key to translating Egyptian hieroglyphic writing, is widely described as basalt when it is actually Aswan granodiorite. A final example is the anorthosite gneiss from the Nubian Desert, which is frequently misidentified as diorite.

Extra 2: Bekhen-Stone to Basalt

Basalt is the fine-grained, black volcanic rock seen in lava flows all over the world. What few realize is that the word *basalt* is of ancient Egyptian origin. It began in the third millennium BCE as *bekhen*, which was the ancient name for a dark grayish green metagreywacke, a slightly metamorphosed greywacke sandstone to siltstone, quarried in Egypt's Wadi Hammamat. During the Greco-Roman period *bekhen* was transliterated into *basanites*, and during the Middle Ages a transcription error in a copy of Pliny the Elder's "Natural History" changed *basanites* to *basaltes*. This error went undetected in subsequent centuries when Pliny's description of the misnamed *basaltes* as having a "dark color and hardness of iron" was mistakenly thought to refer to the volcanic rock that today we call *basalt*.

Extra 3: Limestone or Concrete Pyramids?

The Old Kingdom pyramids at Giza, Saqqara, and other nearby necropoli on the Nile River's west bank have long been recognized by Egyptologists and geologists as having been constructed with blocks of limestone. The limestone for the bulk of the pyramids, the "core blocks," came from quarries excavated in the limestone bedrock surrounding the pyramids. A better-quality limestone, with a uniform light gray color and finer texture, was applied over the core blocks to form the pyramids' exterior surfaces. These "casing blocks" came from the Tura–Masara quarries across the Nile River, on its east bank.

In the early 1990s, these long-held beliefs about the building materials for the pyramids were challenged by David Davidovits, a French materials scientist, who claimed the pyramids were made from poured concrete rather than quarried limestone. Although the "concrete pyramids" hypothesis has received a lot of attention in the international media, Davidovits has so far failed to convince any Egyptologists or geologists of his views. The reasons for this are twofold. First, Davidovits' arguments ignore and run counter to nearly all archaeological and geological evidence bearing on the pyramids. And second, Davidovits has been unable to experimentally produce a concrete resembling the pyramid stones using the techniques he thinks the ancient Egyptians employed.

Stonemasonry of the Incas

Jean-Pierre Protzen

> And what one admires most is that, although these [stones] in the wall I am talking about are not cut straight but are very uneven in size and shape among themselves, they fit together with incredible precision without mortar (Acosta, lib. 6, cap. 14; 1962:297).

Like Father Acosta in the seventeenth century, the modern traveler stands in awe before the Inca walls of huge stones, some weighing over a hundred metric tons, tightly fitted together. They wonder about how people who did not know the wheel and had no iron tools transported and dressed stones of that size, and mated them one to another in such a way that, as the saying goes, not even the blade of a knife could be inserted into the joints. Answers to these questions have been replete with speculations ranging from the intervention of extraterrestrial beings, to the application of an herb, the juice of which softened the stone, to the more prosaic investment of an immense labor force. Recent studies of Inca construction, however, demonstrate that the awe-inspiring, tightly fit megalithic masonry was well within the technological reach of the Incas (Protzen 1985, 1986, 1993). It is to be hoped that the fantastic tales of extraterrestrial intervention will be put to rest once and for all.

Quarrying

The Incas did not practice quarrying in the proper sense. The stone is neither cut off a rock face nor is it detached from bedrock by undercutting. The Incas gained their building stone either by picking suitable blocks out of a rockfall or by prying it loose from fragmented rock faces. Large blocks of five or more tons were only minimally shaped in the quarries; all the fine work was done at the construction site. Smaller building blocks were dressed on most sides in the quarries, and only the finishing and the fitting to other stones was reserved for the site.

The Incas chose the stones to be quarried with great care. Proper workability, texture and color of the stone mattered a great deal and they often went far out of the way, up to 30 km from a construction site, to quarry the appropriate stone. To access the quarries and transport the stones, the Incas built well-engineered roads, 4 to 5 m wide. For example, to get a specific rose rhyolite for the so-called Sun Temple at Ollantaytambo and reach the quarries of Kachiqhata, the Incas built enormous ramps, the total construction volume of which exceeded the volume of quarried stones by a factor of 40. This is the price the Incas were willing to pay for a select stone.

Cutting and Dressing

To cut and dress stones the Incas used simple river cobbles of various sizes as hammers. These tools and their fragments are found in abundance in the ancient quarries scattered among roughed out building blocks and in the quarrying waste. The hammerstones are easily distinguished from other stones by both their shape and their petrological characteristics; they are water-worn rounded stones of materials different from the quarried stone and the surrounding bedrock. The hammers come in different sizes; some are as small as an egg, others are the size of a football, and others still are two to three times the size of an American football. The largest of these hammerstones were used to break up and roughly shape the raw stones, the medium sized to dress the faces of the building blocks, and the smallest to draft and cut their edges and corners. The technique involved is exactly as Garcilaso de la Vega "El Inca" described it: "The quarryfolks,..., who had no other instruments to work the stones, but some black cobbles they called hihuana (sic. for hihuaya), with which they dress the stones by bruising rather than cutting." (lib II, cap. XXVIII; 1976:119, tomo I).

Indeed, when hitting the workpiece straight on with a hammer stone one crushes the rock producing little more than dust. However, if one increases the angle of impact to about 15 to 20°, little chips can be torn off. By further increasing the angle to some 45° by imparting a twist to the hammer just before impact, larger chips can be removed, thus accelerating the process considerably. The impact of the hammer leaves a small pitmark on the workpiece. Such pitmarks can be observed on every face of every building block in every Inca wall of cut stones, regardless of the building blocks' material. Smaller, finer pitmarks found along the edges of the building blocks indicate that smaller stones were used to cut the edges. The particular technique in cutting edges requires that the edge be shaped by hitting the workpiece with grazing blows directed away from the workpiece, which results in corners with dihedral angles larger than 90°. It is these obtuse angles that account for the characteristic beveled joints of Inca cut stonemasonry and that brings about the chiaroscuro effect.

Extensive experiments have demonstrated that the process is relatively easy, effective and precise, and not as time consuming as one might assume. Twenty quarry people working side by side could rough out a block 4.5 m long, 3.2 m wide, and 1.7 m high – the dimensions of one of the largest building blocks in an ancient Inca quarry near Ollantaytambo – in less than 15 days.

Fitting

The most intriguing question about Inca cut stonemasonry concerns the precision fitting of the blocks. It has been repeatedly argued that the Inca stonemasons ground the blocks into place using a mixture of sand and water. The evidence, however, does not support this hypothesis. Where walls have been dismantled or fallen apart one finds the exact imprint of the stones which have been removed or fallen off. Very often the shape of the imprints determines a unique position for the stone it once accommodated. To grind in a stone, however, requires that the stone can move freely along a path in at least one direction. Thus, the ground stone would fit in any, and not just one, position along that path. Furthermore, if the stones had been ground into place the joints should show signs of abrasion, but they do not. Instead one finds the typical pitmarks which result from pounding.

The imprints seen on dismantled walls indicate that when laying a wall, the Inca stonemasons left the top face of every new course uncut until it was to receive a new course. The bottom face of the block of the new course was cut first, and a suitable bed was carved out of the course already in place. A similar approach was used for the rising joints; it is the side of the block already in situ that was carved to match the precut shape of its new neighbor. The technique used appears to have been one of trial and error. The masons started by outlining the shape of the new stone atop the course it was to be fitted to and proceeded to carve out a bed. By trying the fit time and again the masons obtained a perfect match. Granted, the trial and error technique is a tedious one, and perhaps not very convincing if one considers megalithic building blocks of several dozens of tons. However, it works and does not postulate the use of tools and machinery of which no traces have been found. The Incas had plenty of time and manpower at hand. Since they moved huge blocks over many kilometers, it is not inconceivable that they were capable of setting up a stone several times to achieve the desired fit. It is of course also conceivable that the Inca stonemasons knew of another technique to transfer the shape of one stone to another without actually trying it in successive steps. Vincent Lee has in fact proposed such a technique. Inspired by log cabin builders, Lee suggests that the shape of one stone was scribed onto the other with an ingenious but simple device consisting of a stick and a plumb bob. Although very plausible, Lee's hypothesis does not bear out in the field, as will be shown below.

Assemblage

When assembling a wall, the Incas often had several construction crews working simultaneously and side-by-side. Where two crews met in a course the final gap in the wall was closed with a "wedge" stone introduced into the masonry bond from the front of the wall. Because in the last gap there is not enough room to maneuver the stones for the usual one-on-one fitting, the Inca stonemasons hit on the ingenious idea of the wedge stone that fits to its neighbors only along a very narrow band near the face of the wall. Once one knows what to look for, it is relatively easy to spot wedge stones in an Inca cut-stone wall and to determine its construction sequences. If scribing had been the predominant fitting technique, there would have been no need for wedge stones: even the last stone could have been scribed for a perfect match and lowered into place. But many wedge stones clearly were not lowered into the gap they were intended to fill, since they are wider at the bottom than at the top.

Transporting

Another vexing problem is how the Incas transported and heaved enormous building stones. Rough abrasion marks found on building blocks at Ollantaytambo suggest that the stones were simply dragged along the ground. From these marks it is even possible to determine the direction in which the blocks traveled. The dragging of big stones is consistent with chroniclers' reports: "These Indians used to move very large stones with muscle power, pulling them with many long ropes of lianas and leaf fibers,..., and they [the stones] are so big that fifteen yokes of oxen could not pull them." (Gutierrez de Santa Clara lib. 3, cap. 63; 1904–1929:550). And dragging big blocks involves large transportation crews: "Four thousand of them were breaking stones and extracting stones; six thoudand were hauling them with big ropes of hide and leaf fibers;..." (Cieza de León cap. LI; 1967:170)

Six thousand people dragging a stone is not unreasonable; many Old World transportation problems were solved with very large work forces. Engelbach, for example, calculated that it would have taken 6,000 men to haul the unfinished obelisk at Aswan from the quarries to the Nile. The questions raised by a transportation crew as numerous as this, which remain largely unanswered, are how the crew was harnessed to the stones and how it negotiated turns on the narrow roads on the steep slopes of the Andes.

An experiment carried out in 1994 in the town of Ollantaytambo involved the dragging of a 14 t heavy Inca building block a distance of about 150 m. One hundred and eighty four people from the town, men and women, volunteered for the task. They were given no instruction of how the task had to be performed. They brought ropes, which they wrapped around the block like a net in such a way as to have six leading ropes extending from the stone in the direction it was to be pulled. The 184 people were distributed over the six leading ropes, which they grabbed and leaned into to drag the block the requisite distance with relative ease over a surface roughly equivalent to the roads from the quarries.

Antecedents

John Hemming argued emphatically that the high skills of the Inca stonemasons "cannot have been developed in the century or less of Inca ascendance. Architecture anywhere in the world evolves from precursors". Here, the precedent is Tiahuanaco at the south end of Lake Titicaca. Tiahuanaco has some of the world's finest stonemasonry: carefully fitted rectangular ashlars, and exquisitely worked monolithic gates and statues. It is said that Pachakuti, the 9th Inca, was so impressed by this stone work when he first saw Tiahuanaco that he advised his architects to take careful note of how this masonry was made because he wanted Cuzco to be built in the same manner. It is also said that he imported Qolla laborers from the Lake Titicaca area to work on construction projects (Sarmiento de Gamboa cap. 40; 1943:111–112). But because Tiahuanaco culture developed at least a millennium before the Incas, and may have reached its peak some five to six centuries before Pachakuti's rise to power and nothing similar has been built in the interim, one may question why the Qolla laborer should remember any of the ancient techniques.

Stone Tools in Mesoamerica: Flaked Stone Tools

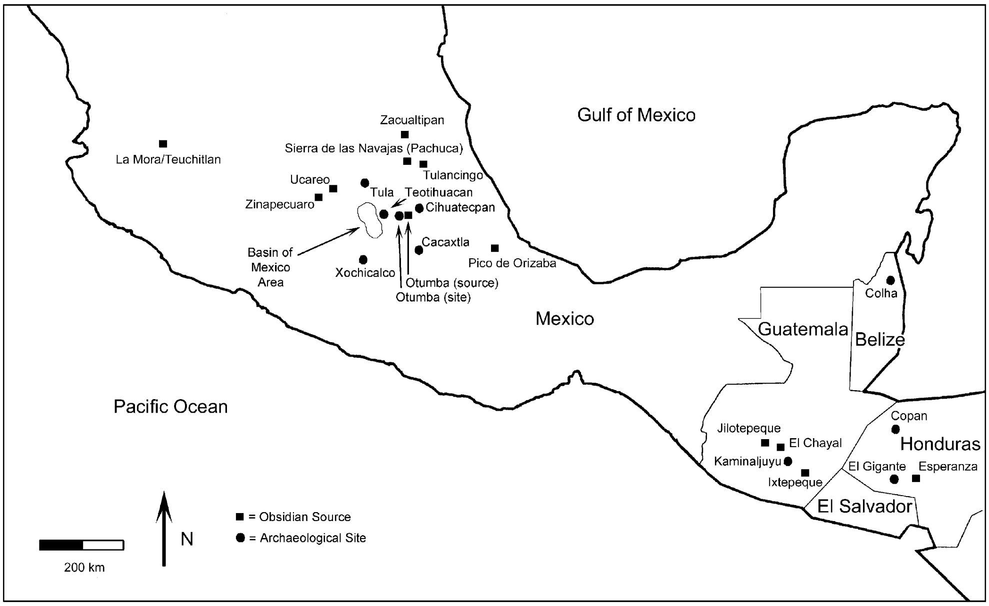
Bradford W. Andrews

Flaked stone tools in pre-Hispanic Mesoamerica were used for a wide range of domestic, *militaristic, and ritualistic activities*. Geographically, Mesoamerica refers to present-day Mexico, Guatemala, Belize, and parts of Honduras and El Salvador. Undoubtedly, the most popular tool was the prismatic blade that was usually made of obsidian, the most important toolstone in the region (see obsidian Note). Simpler flake tools and biface implements, such as projectile points and knives, were also present throughout Mesoamerica. These implements, however, were not as important as blade tools except during early Mesoamerican prehistory, or at sites like Colha in the Chert Bearing Zone of Belize where obsidian was scarce (Fig. 1) (Hester and Shafer 1994; Shafer and Hester 1983). This discussion focuses on the Mesoamerican blade technology, but flake and biface technologies are also briefly reviewed. Reference is made to chronological trends and how blades and other items were produced and used.

Early Prehistory-Flakes and Projectile Points

Research indicates that as early as 15000 BCE small foraging groups who made impressive projectile points inhabited much of Mesoamerica (MacNeish 1976; Weaver 1981). These groups are referred to as Paleo-Indian (prior to 7200 BCE) "big-game" hunters. They employed a biface technology requiring the use of percussion and pressure techniques to shape biface (e.g., projectile points) and uniface (scrapers) tools. The manufacture of biface tools like projectile points require the removal of flakes from both sides, or "faces" of *a relatively flat piece of stone*. Uniface tools like many scrapers, in contrast, are made by removing flakes from only one side of *a piece of stone*. The flaking techniques used to make both types of implements are similar, so they are referred to here as products of biface technology.

S



Stone Tools in Mesoamerica: Flaked Stone Tools. Fig. 1 Map of Greater Mesoamerica. Illustration by the author.

Stone Tools in Mesoamerica: Flaked Stone Tools. Fig. 2 The direct freehand percussion technique. Illustration by Karen Andrews. Used with her permission.

Paleo-Indian bifaces were initially made from large flakes using direct percussion, which were then "thinned" with pressure. Direct percussion involved directly striking a piece of raw material (i.e., nodule, flake, or blade) with a stone, bone, antler, or wood hammer (Fig. 2) (Hester 1972: 99). In contrast, the pressure technique involves placing a tool of bone, antler, or wood against the edge of a piece of raw material and pushing on it to "press" off flakes.

Many Paleo-Indian points in Mesoamerica were the fluted varieties associated with the Clovis and Folsom Traditions (Weaver 1981). Clovis points have been found in Northern and Western Mexico, and as far south as El Salvador (Weaver 1981). In Central Mexico, a similar development referred to as the Cordilleran Tradition emerged around 13000 BCE; it was associated with the appearance of pressure flaked, willow-shaped projectile points, crude blades, and scrapers (MacNeish 1976: 322, Fig. 2). Early Paleo-Indian points were hafted on spears and used as thrusting weapons. By about 9000 BCE, however, the *atlatl*, or spear thrower appeared, providing hunters with greater thrusting force and accuracy (MacNeish 1976: 324). In the Aztec language of Nahua, the word atlatl refers to what is known in English as the spear thrower. This device consists of a stick that supports a dart-tipped shaft. During the throwing action, the stick acts as an extension of the arm and a lever that propels the "butt" end of the dart shaft generating greater thrusting power and accuracy than a shaft thrown by hand (Adams 1977: 339). Point size is usually used to differentiate larger spear points from smaller atlatl points, with atlatl points measuring generally less than 6 or 7 cm in length. This criteria is subjective, however, and many finely flaked points dating to this period could have been either spear or atlatl points (Fig. 3).

The appearance of the spear thrower occurred in tandem with the gradual replacement of big-game hunters by groups who foraged for a wider range of plant and animal resources. This shift is associated with the Mesoamerican Archaic period (7200–2500 BCE). Generally, Archaic flaked stone tools are characterized as expedient (Clark 1987), consisting of simple flakes made with direct percussion or bipolar percussion. Bipolar percussion involved striking the top of a cobble resting on an anvil stone, enabling the transmission of force from both "poles" of the cobble; this technique is effective for reducing small pieces of raw material that

are otherwise difficult to flake (Fig. 4). Unmodified tools, or those flaked into slightly refined forms, were "amorphous" in form and their production resulted in a miscellany of chunks and shards. This expedient technology is found in Mesoamerica from the Basin of Mexico (Boksenbaum 1980; Tolstoy et al. 1977) to the Pacific coast of Guatemala (Fig. 1) (Coe 1961). Expedient techniques for making flake tools continued well into the Preclassic (2500 BCE–AD 300) period (Aoyama 1994: 136; Clark 1987).

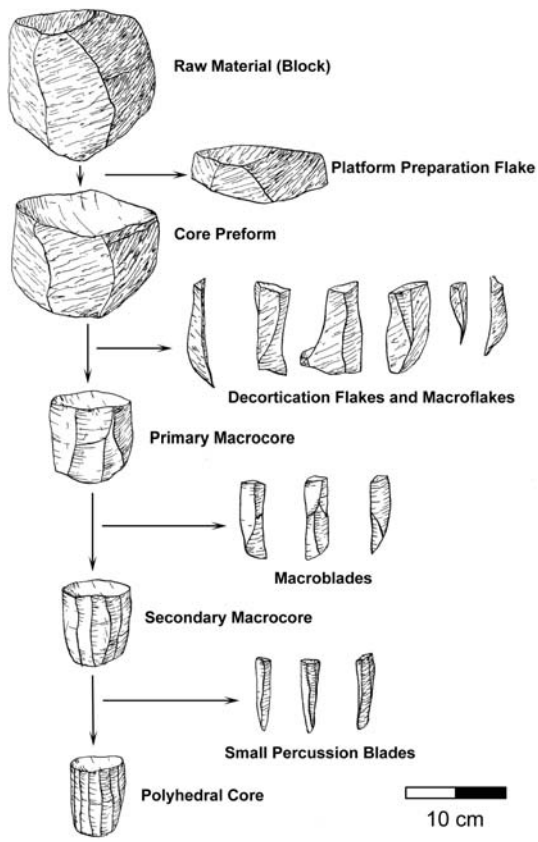
Mesoamerican Blade Technology

Even though a few pressure blades may have been made in Central Mexico after 3400 BCE (MacNeish 1964), blade production did not become prominent until the Middle Preclassic (900 to 300 BCE) period (Hirth and Flenniken 2002: 123). The factors responsible for the emergence of the Mesoamerican blade technology remain a topic of debate (See Origins of blade technology Note). By the time socially complex societies like Teotihuacan (AD 100–650) and Xochicalco (AD 650–900) (see Fig. 1 for site locations) had emerged, blade production had become a specialized occupation carried out by skilled craftsmen. Teotihuacan, located near the Basin of Mexico (Fig. 1), had an impressive population of 125,000 people by AD 500, most of whom performed their domestic cutting *and piercing* activities with blade tools. As such, evidence for specialized blade production has been used to study the complexity of this society's economy (Andrews 2002; Millon 1973; Spence 1981, 1987). Recent research has examined the skill of blade makers to determine *how* often they worked (See Measuring skill Extra).

The Mesoamerican blade technology resulted in the production of similar types of tools (Clark 1989a, b; Sheets 1978a, 1983), although some spatial variation did exist (Flenniken and Hirth 2003). This variation can be attributed to numerous factors including distance to obsidian sources, the quality of different types of obsidian, how it was acquired (e.g., directly from the source, in the marketplace, etc.), different production techniques, and localized demand for specific types of products (Hirth and Andrews 2002).

In general, blades were detached from cylindrical cores using percussion and pressure techniques. Obsidian was acquired from quarries in the form of blocks and nodules (Darras 1994; Healan 1997; Pastrana 1998) and as cobbles in stream deposits (Spence 1981). The initial step involved making a core platform. A platform is the surface where force was applied to remove blades. Large platform preparation flakes were detached from the upper end of the pending core (Fig. 5). This procedure created a smooth concave surface on a core preform (Clark and Bryant 1997). Sometimes platforms were further modified with pecking and grinding (See Pecking and grinding Note).

Next, relatively large decortication flakes and macroflakes were detached from the lateral sides of the core preform (Fig. 5). Decortication is the removal of the cortex or weathered surface of the stone. Additional macroflake detachments gave the preform more symmetry, resulting in a primary macrocore with irregular ridges on its lateral facets. Then, macroblades were removed from the primary macrocore to make a secondary macrocore (Fig. 5). Macroblades were



Stone Tools in Mesoamerica: Flaked Stone Tools. Fig. 5 Schematic diagram of the initial steps in core production. Illustration by author.

Stone Tools in Mesoamerica: Flaked Stone Tools. Fig. 6 Broken macroblade biface tools discarded at a blade-making workshop at Teotihuacan. Photos by Alejandro Serabia. Property of the author.

relatively long, parallel-sided items with one or more dorsal ridges (Kerley 1989: 165). These blades were roughly 2.5 cm wide and more than 1 cm thick (Hirth and Andrews 2002: 4). By themselves, macroblades were sturdy cutting implements, but they were also further shaped into more specialized biface tools (Fig. 6) (Andrews 2002; Hester 1972). Macroblade removal created a series of parallel, irregular ridges running the length of the core. Next, small percussion blades were detached to make the polyhedral core (Fig. 5). These blades are thinner than macroblades, with widths of less than 2.5 cm, and their removal created more regularized parallel ridges running the length of the core.

Most initial core shaping and blade-making activities were accomplished with direct percussion. Indirect percussion, however, was also probably used. This technique involved placing one end of an antler, bone, or wood punch on a platform and then striking the opposite end with a hammer stone (Bordes and Crabtree 1969; Crabtree 1968, 1972; Hester 1972); it permits more precise control over the transmission of force than direct percussion (Fig. 7). As a consequence,

Stone Tools in Mesoamerica: Flaked Stone Tools. Fig. 7 The indirect percussion technique. Illustration by Karen Andrews. Used with her permission.

relatively standardized percussion blades can be made with indirect percussion. Although still a subject of debate (Pelegrin 2003), the recovery of extremely symmetrical macroblades at sites like Kaminaljuyu in the Maya region (Fig. 1) suggests that indirect percussion was used in ancient Mesoamerica (Hirth 2003).

The polyhedral core was reduced to make the delicate pressure blades that were common place in ancient Mesoamerica. The Aztec technique for making these blades has been reconstructed according to historic information and replication experiments (Clark 1989c; Crabtree 1968; Sahagun 1963: plate 778; Titmus and Clark 2003; Torquemada 1975; Tudela and Corona Nuñez 1977). The reconstruction proposes that seated craftsmen secured cores against an immovable object with their feet, and then used their stomach muscles and torso to "press," or push blades off with a long-handled wooden stick called an *itzcolotli* (Fig. 8) (Clark 1989c: 153; Titmus and Clark 2003). In some areas of Mesoamerica, however, pressure blades were also removed with a hand-held technique (Flenniken and Hirth 2003).

First-series blades were the initial pressure blades removed from a polyhedral core (Fig. 9). These blades eliminated irregular ridges left by the blades previously removed with percussion. Sometimes second-series blades were taken off after first-series blades depending on the shape of the polyhedral core (Clark and Bryant 1997: 115). If the core was cone-shaped, first-series blades often extended only part way down the sloping core face, resulting in a secondary polyhedral core. In turn, second-series blades were removed to extend the parallel ridges the entire length of the core.

The product of first- and second-series blade detachments was the pressure core (Fig. 9). Pressure cores yielded third-series blades that are generally regular and consistent in shape (width and thickness) and have two dorsal ridges, *thereby making them prismatic in* cross section. The dorsal ridges were mechanically important because they helped "guide" the transmission of force from the platform resulting in successful pressure blade removal.

Many pressure blades were further modified in a variety of ways. Most of them were snapped into

S

sections and used for cutting activities. One parallel edge could be hafted in a piece of wood or bone, making the section easier to handle. A piece of wood or bone was incised deep enough to insert the blade section, which was then secured with a sticky adhesive composed of pine pitch and ashes.

Pressure blades were also made into specialized forms such as projectile points, lancets, and notched eccentrics. Small pressure blade projectile points were used for hunting and warfare. Many of these items were too small to be propelled effectively with a spear thrower (Fig. 10a, b). Consequently, their size and minimal weight indicates that they were used to tip arrows propelled with a bow. This conclusion is interesting because small blade points occur in archaeological deposits that supposedly predate the Postclassic (AD 900) introduction of the bow in Mesoamerica (See Introduction of the bow in Mesoamerica Note).

The slender needle-like, lancet blades (Fig. 10c–e) may have been used in textile production, but they were most important for bloodletting (Clark 1980; Flannery 1976; Parry 1983; Sugiyama 1995). Historic sources and ritual archaeological contexts where lancets have been found indicate that they were used to draw blood (Clark 1989d: 314; Durán 1971: 263; López de Cogolludo 1957; Motolinía 1950; Nuttall 1903; see Landa in Tozzer 1941: 113–114). Lancets are often portrayed in bloodletting rituals depicted on Mexican and Maya codices, Maya monuments, and polychrome vessels (Clark 1989d: 314). As an act of auto-sacrifice, this practice was essential for appeasing the gods by providing them with blood nourishment (Berdan 1982; Hassig 1988; Hirth 2000).

Eccentrics made from pressure blades occur in a variety of strange shapes including crescents and trilobal sections (Fig. 10f–h). Pressure blade eccentrics may have functioned as ornamental elements sewn on articles of clothing (Spence 1996). They also probably had symbolic significance because many of them have been found in burials and ritual cache deposits (Gamio 1966; Moholy-Nagy 1989; Parry 2002; Stocker and Spence 1973; Winter 1989).

The end byproduct of the core-blade sequence was the exhausted pressure core, often measuring no more than 1.5 cm in diameter (Fig. 9). At some sites like the Aztec city of Otumba (Otis Charlton 1993) and the pre-Aztec city of Xochicalco (Fig. 1), lapidary craftsmen used exhausted cores to make beads (Fig. 11). The slender cores were fractured into sections using bipolar percussion and then ground and polished to perfection.

Mesoamerican Biface Technology

Biface flaking techniques were used to make impressive biface and uniface items for domestic, military, and ideological purposes. One important utilitarian uniface artifact in Central Mexico was the maguey scraper (Fig. 12). The maguey plant (*Agave atrovirens*) was a valuable source of water, food, fiber, and fuel, among other things (Evans 1990; Sauer 1963; Sheehy 2001). Near Teotihuacan, large maguey scrapers at the Aztec (AD 1350–1520) period site of Cihuatecpan were made of relatively coarse obsidian from the source of Otumba (Fig. 1). Maguey scrapers were used to process maguey fibers and to initiate the flow of a sticky liquid that was converted into a fermented drink called *pulque*. Evidence suggests that pulque was a valuable source of nutrition and potable liquid in large cities like Teotihuacan where sanitation was a serious problem (Sheehy 2001: 265).

Large, impressive bifaces were used for combat and may have had symbolic significance given the central importance of warfare, conquest, and human sacrifice that emerged during the Classic period (AD 300–900) (Fig. 13). These items occurred in many forms. At Teotihuacan (AD 100–650), evidence has indicated that the large atlatl points for the city's army were made by craftsmen under the direction of state officials (Carballo 2004).

Like the small eccentrics made from pressure blades, the contexts in which large eccentrics have been found indicate that they had symbolic significance (Gamio 1966; Moholy-Nagy 1989; Parry 2002; Stocker and Spence 1973; Winter 1989). At Teotihuacan some of the most impressive eccentrics are anthropomorphic figurines (Fig. 14). Other impressive pieces appear to combine multiple symbols into one implement, such as a projectile point, a serpent, and a trilobal motif signifying blood droplets (Fig. 15). Many of these items were undoubtedly associated with warfare and sacrifice because they are often recovered in offerings with human sacrificial victims decorated as warriors (David Carballo Personal communication 2005).

At Xochicalco, ten impressive eccentrics were found together atop the site's major public pyramid. They occur in several forms including circular uniface elements (Fig. 16). These artifacts were probably components of public rituals that were conducted for the benefit of the masses (Andrews and Hirth 2005).

The stone tool technologies prevalent in pre-Hispanic Mesoamerica varied over both time and space. This discussion has provided a brief overview of the early flake and biface technologies, and a description of the blade and biface technologies prevalent from the time of Christ until the Spanish conquest in the early sixteenth century. The Mesoamerican blade technology was the most important, enabling the production of prismatic blades that were further shaped into different types of tools. Overall, flaked stone tool production in Mesoamerica provided a remarkable variety of highly functional implements used *for a variety of activities*.

Acknowledgements

This article would not have been possible without the assistance of various organizations and individuals. The artifacts from Xochicalco were recovered and analyzed with generous support from the Foundation for Mesoamerican Studies, Inc. (FAMSI grant 01029), the Proyecto Especial Xochicalco (directed by Norberto González Crespo) funded by the Instituto Nacional de Antropología e Historia (Instituto Nacional de Antropología e Historia), and the Xochicalco Lithic Project (directed by Kenneth Hirth) funded by National Science Foundation research grants 9429292, 9496188, and 9121949. Karen Andrews, Constantino Armendariz, David Carballo, Susan Evans, Luis Gonzalo Gaviño, Timothy Scheffler, Alejandro Serabia, Saburo Sugiyama, Gene Titmus, and James Woods provided invaluable assistance with many of the figures. Finally, I appreciate the editorial feedback from David Carballo, Susan Evans, and Haley Harms.

Extra: Obsidian in Mesoamerica

Obsidian is an igneous stone that is often described as “volcanic glass” (Whittaker 1994: 69). This siliceous material is created by the extremely rapid cooling of volcanic ejecta, a process that prevents the formation of any crystalline structure (Cobean 2002: 23). Obsidian is very smooth and glassy to rough or grainy in texture, and is usually black to gray in color, but it also can be red, brown, green, silver, and aquamarine. This variation in color is the result of chemical impurities. Obsidian occurs in block or tabular form in large veins, or as isolated chunks and cobbles in flows of volcanic material. It can also be found on talus slopes or alluvial streambeds in a “weathered” cobble form. Having eroded out of primary geologic context, the weathered cobble surface exhibits tiny cones or fracture planes that are produced by rolling action. Obsidian is easy to work with because of its noncrystalline structure and it produces an extremely sharp cutting edge. One disadvantage of obsidian is that it is brittle, so that tools and tool edges can break more easily than other flakeable stone like cherts and flints.

Throughout most of Mesoamerica obsidian was the primary raw material used to make flaked stone tools. In the region, obsidian flows are found in two major zones of geologically recent volcanism (Glascock et al. 1988). One major zone is an east–west trending band of sources scattered from the state of Veracruz on the Gulf of Mexico to the western state of Michoacán bordering the Pacific Ocean; well-known sources in this zone include Pico de Orizaba, Sierra de las Navajas (Pachuca), Otumba, Zacualtipan, Ucareo, Zinapecuaro, and La Mora/Teuchitlan (Fig. 1). The southern zone is located in Guatemala, El Salvador, and western Honduras; well-known sources in this zone include Jilotepeque, El Chayel, Ixtapeque, and Esperanza (Fig. 1).

Studies of obsidian artifacts from archaeological sites using techniques such as instrumental neutron activation analysis (INAA), X-ray fluorescence (XRF), and more recently, laser ablation-inductively coupled plasma-mass spectrometry (LA-ICP-MS) have revealed that large quantities of these materials were transported across the landscape. By tracing the distribution of different sources archaeologists have been able to reconstruct routes of obsidian trade and transport and how they changed over time (Asaro et al. 1978; Boksenbaum et al. 1987; Braswell and Glascock 1998; Cobean et al. 1991; Glascock et al. 1991, 1994; Moholy-Nagy 2003; Nelson 1985).

Extra: Origins of the Mesoamerican Blade Technology

Hirth and Flenniken (2002: 123) have rightly pointed out that research on the origins of the Mesoamerican blade technology has been limited. Emerging *en force* during the Middle Preclassic (900–300 BCE), by 700 BCE prismatic blades had become the primary flaked stone tool from the Central Highlands to the Chalchuapa area of El Salvador (Aoyama 1994: 174; Clark and Lee Jr. 1984; Coe and Diehl 1980: 247–249; Grove 1974: 33, 48; Hirth and Flenniken 2002: 123; Marcus and Flannery 1996; Pires-Ferreira 1975: Table 5; Sheets 1978b: Tables 3 and 5; Sweeney 1983: 619).

Two researchers that have addressed the emergence of the Mesoamerican blade technology are Parry (1994) and Clark (1987). Their views are somewhat complementary, but they emphasize different factors. Parry (1994) suggests that the principal motivating factor may have been a demand for the production and exchange of many uniform, standardized implements. A blade technology enables such outputs, but a relatively high level of skill is required to make large batches of standardized blades efficiently. Hence, an increasing demand for blades during the Middle Preclassic created a need for blade-making craftsmen. These specialists supported themselves, at least in part, by exchanging blades at the regional and perhaps interregional level. Parry (1994: 94) further notes that many blade workshops are found in large settlements with monumental architecture, sometimes quite distant from obsidian sources. He tentatively states that this evidence may indicate that early craftsmen were attached, or sponsored by the ruling elites in these settlements.

Clark (1987) suggests that the widespread adoption of the Mesoamerican blade technology was related to the competitive elite behavior associated with ranked or chiefdom societies. These societies differed from the Archaic foraging groups (7200–2500 BCE) in that people lived in larger sedentary communities that were socially hierarchical (Webster et al. 1993). Clark (1987) maintains that there was no real technological advantage to a blade technology because the expedient flake tools made during the Archaic period were functionally adequate. Moreover, the Mesoamerican blade technology required specialized training because it was difficult to learn. It also required the organization of core production at the source and the transport of cores to the settlements where they were reduced. Consequently, Clark (1987) suggests that the adoption of this technology was complex enough to necessitate the sponsorship of the elites who ruled the early Mesoamerican chiefdom societies (Clark 1987: 274). Accordingly, these elites financed and organized the acquisition and production of cores and their distribution to blade-making craftsmen in large settlements.

Many researchers have debated various reasons why blade technologies arose at different times and places throughout the world. The Parry (1994) and Clark (1987) models for the emergence of Mesoamerican blade technology cannot be used to explain the adoption of blade technologies in societies that were less complex than chiefdoms (Hirth and Flenniken 2002). Worldwide examples include the Paleolithic and Neolithic blade technologies of Europe, Asia, and North Africa (Inizan and Lechevallier 1990; Pelegrin 1997; Tixier 1976), the Paleolithic microblade technologies of Siberia and Japan (Flenniken 1988; Kobayashi 1970), and the microblade technologies of North America (Andrefsky 1987; Arnold 1985; Bradley and Yevgeny 1996; Magne 2004; Morrow 1988; Parry 1994; Rasic and Andrefsky 2001; Reid 1976; Yesner and Pearson 2002). These societies ranged from highly mobile to relatively settled groups who probably never attained the level of social complexity typically associated with chiefdoms.

The adoption of blade tools in northwestern North America may relate to functional aspects of the technology (Yesner and Pearson 2002). This argument recently summarized by Magne (2004: 94) states that microblades were a "response to any of several possible causes, such as lithic raw material shortage alleviated by efficient blade production, preference for composite slotted armaments, or resource uses for which microblade design is most efficient, such as slicing, peeling, piercing..." It has also been suggested that blade technologies may be best suited to societies where the tasks involved in food acquisition or production (subsistence tasks) were predictable (Rasic and Andrefsky 2001: 77). Here the manufacture of standardized blade "replacement" parts for tools repeatedly used for the same tasks would be technologically efficient.

The development of craft specialization and exchange (Parry 1994), and the competitive elite behavior associated with emerging chiefdom societies (Clark 1987) indeed may have played a role in the emergence of the Mesoamerican blade technology. The functional argument that blades are better for economies with predictable subsistence tasks also deserves consideration. The Mesoamerican Preclassic period (2500 BCE–AD 300) was associated with a profound shift from small-scale foraging societies to larger settled chiefdom societies. Hence, compared to the nomadic foraging lifestyle of the Archaic period, the daily tasks associated with settled agricultural economies during the Preclassic were certainly more predictable because they were tied to the strict seasonal cultivation of specific crops. Moreover, the patchy distribution of obsidian across the landscape would have made a blade technology more effective for supplying the needs of large settlements with tools from distant sources. Craft specialists producing highly standardized blades for specific tasks would have been able to efficiently supply the needs of people in very large settlements.

Extra: Measuring the Skill of Ancient Blade-Making Craftsmen

In ancient Mesoamerica obsidian blades were made by specialized craftsmen. Some researchers have recently begun to focus on measuring the skill of these craftsmen as a means for identifying how much time they devoted to blade-making activities (Andrews 2003; Clark 2003; Clark and Bryant 1997; Hirth and Andrews 2005). Defining the time spent making blades is important because it helps archaeologists infer how many blades were in demand and how much economic exchange there was between members of an ancient society. This kind of information reflects the complexity of a society's economy. Unlike the modern world where everyone specializes in a particular job, most prehistoric societies were primarily composed of people who provisioned themselves with all their daily needs. As societies became larger people began to specialize in different occupations and exchanged their products for things they did not produce. Hence, the level of specialization in a society is a measure of economic inter-dependency.

Measuring craftsman skill is founded on the assumption that aptitude should vary according to the amount of time invested in blade production (Clark 2003); in other words, highly skilled craftsmen should be those who made the most blades. Essentially, this assumption is based on the premise of "practice makes perfect" (Clark 2003).

So, how does one go about measuring the skill of ancient blade-making craftsmen in Mesoamerica? The one advantage to studying flaked stone artifacts is that they are made with a reductive technology. That is, flaked stone tools are shaped by reducing, or removing pieces of stone from a larger stone until the desired form is achieved. The pieces that are removed are called byproducts. Careful study of the byproducts of Mesoamerican blade production has made it possible to identify those artifacts that are mistakes, items that represent one means for measuring craftsman skill.

Mesoamerican blade craftsmen usually made blades in household workshops (Clark 1997; Healan 1986; Hirth 1995, 2002; Spence 1981, 1986, 1987). Several artifacts found at these workshops have been identified as mistakes; these items include the hinge-fractured blade and the plunging blade. A hinge-fractured blade is a blade that failed to extend all the way to the bottom of a core (Andrews 2003). The distal end of a hinged blade has a fracture plane that curves outward from its ventral to dorsal surface (Note No. 3, Fig. 17a) . These artifacts are mistakes because the craftsman's intent was to remove a blade that extended the entire length of the core. Also, hinged blades leave behind a deep scar that inhibits the removal of subsequent blades from that part of the core (Note No. 3, Fig. 17b).

A plunging blade removes the distal tip of core (Andrews 2003). In contrast to the hinge fracture, a plunging blade's ventral surface curves inward at the bottom of the core thereby removing more core length than intended (Note No. 3, Fig. 17c) (Clark and Bryant 1997: 123; Crabtree 1972). This mishap reduces the length of subsequent blades, thereby reducing the overall amount of cutting edge that can be produced from a core. The forces resulting in the production of these mistakes are described in detail elsewhere (Andrews 1999, 2003; Clark and Bryant 1997; Santley et al. 1986; Sheets 1978b).

It has been suggested that the frequency of mistakes in a collection of byproducts should be useful for measuring the skill of flaked stone tool craftsmen (Clark 1986, 2003; Sheets 1975, 1978b; Torrence 1986: 147). Consequently, comparisons of hinged and plunging blade frequencies from Mesoamerican blade workshops have been used to make comparative assessments of skill (Andrews 1999; Clark 1997; Hirth and Andrews 2005). Workshops with the highest level of skill have the fewest errors.

Preliminary assessments of craftsman skill at the immense Classic period (AD 100–650) city of Teotihuacan and the smaller Epiclassic (AD 650–900) city of Xochicalco indicate that Teotihuacan's craftsmen made fewer mistakes (Andrews 1999). Hence, based on the assumption that skill varied in relation to time spent in production, it appears that Teotihuacan's craftsmen made and exchanged more blades than the craftsmen at Xochicalco. This finding fits previous characterizations of Teotihuacan's economy as being highly complex (Millon 1973; Spence 1981), with many specialists throughout the city dependent to a significant degree on nonagricultural production for their livelihoods. In contrast, Xochicalco's economy appears to have been less complex, with more limited evidence of craft production and economic interdependence (Hirth 2000). In this way, measuring the skill of flaked stone tool producers has contributed to supporting earlier inferences about economic complexity.

Extra: The Pecked and Ground Core Platform

Another source of variation in the Mesoamerican blade technology was core platform treatment. Sometimes single facet platforms were pecked and ground, creating a flatter, slightly rough surface. This type of platform became widespread during the Postclassic (AD 900–1519) period (Garcia Cook 1967; Healan 1986: 141; MacNeish 1967; Tolstoy 1971), but it emerged in the preceding Epiclassic (AD 650–900) period (Hirth et al. 2003), and perhaps was present even earlier in some areas of Mesoamerica (Santley et al. 1995: 46; Sheets 1983: 216). The pecking and grinding of platforms took place during different phases of the reduction sequence throughout the region. For example, at Tula (Fig. 1), the capital of the Toltec empire, platforms were pecked and ground at the macrocore stage (Healan 1986: 141), whereas at Xochicalco, an Epiclassic (AD 650–900) city, they were pecked and ground on small, already partially reduced prismatic cores (Flenniken and Hirth 2003).

Experimental research suggests that this process involved initially flaking a platform as flat as possible with percussion and pressure techniques (Flenniken and Hirth 2003). Flattening the platform surface was important to minimize subsequent grinding expenditures. After flattening the platform, it was probably pecked with a flake of siliceous material such as chert or quartzite. Evidence suggests that this process could be efficiently accomplished by inverting the core in one hand and then striking it against a flake resting on an anvil stone (Flenniken and Hirth 2003: 104). Pecking produces hundreds of tiny fracture cones across the platform surface. When a platform was pecked sufficiently flat, it was then ground in a circular motion on a large, slightly concave grinding stone. The chert shatter produced during pecking efforts would have provided an efficient grinding substrate; experiments indicate that adding water to the substrate produced a very effective grinding paste (Flenniken and Hirth 2003). Other materials such as volcanic ash or quartz sand also may have been used as grinding substrate.

The pecked and ground platform modification made blade removal easier for two reasons. First, the tiny fracture cones produced during the pecking stage made blade removals easier (Flenniken and Hirth 2003). Experiments indicate that less pressure force is needed because the tiny microfractures help to facilitate a macrofracture, permitting successful blade removal. This outcome of the process was extremely important, especially at sites like Epiclassic (AD 650–900) Xochicalco where blades were detached by hand from very small (>8 cm in length) prismatic cores (Flenniken and Hirth 2003). Experiments have demonstrated that it is difficult to generate enough force with the hand-held technique to produce successful blades using cores longer than 8 cm in length. Second, the pecked and ground surface reduced the risk that the pressure tool used to remove blades would slip off the platform. This outcome aided the craftsman in the precise application of force.

Extra: The Bow and Arrow in Prehistoric Mesoamerica

The date when the bow and arrow became prevalent in prehistoric Mesoamerica is still a subject of debate. The established date for the introduction of the bow in North America is sometime around AD 200 (Holmer 1986), much earlier than what is generally accepted for Mesoamerica. Citing a lack of archaeological and iconographic evidence for the bow, Hassig (1992) has suggested that it did not become common in Mesoamerica until the Postclassic (AD 900–1519) period. Other researchers, however, have suggested that the bow was present during the Classic (AD 300–900) period (Linné 1934) or perhaps even earlier during the Preclassic (2500 BCE–AD 300) period (Tolstoy 1971).

One reason for believing the bow was common in Mesoamerica prior to the Postclassic period is the presence of small projectile points (>3 cm in length, Fig. 10b) at many sites predating AD 900. Many of them were fashioned out of prismatic blade sections that were made with pressure. The use of these implements as effective tips for spears or *atlatls* (spear throwers) is hard to imagine because they are so small. Indeed, research indicates that many *atlatl* points average over 4.5 cm in length (Thomas 1978: 469). As a result, it has been suggested that small points found in mortuary offerings at Classic period Teotihuacan may have had a ceremonial or ideological significance (Parry 2002).

Although small points predating the Postclassic period may have had a ceremonial function, recent research at the Epiclassic (AD 650–900) city of Xochicalco suggests that such items were used to tip arrows (Andrews and Hirth 2005). This conclusion supports earlier claims that the bow was present at Epiclassic Xochicalco (Sáenz 1961: 40–43, 1967: 10, 14) and at the contemporary site of Cacaxtla (Fig. 1) in the modern state of Tlaxcala (Baus de Czitrom 1986: 529). Most of the small points at Xochicalco have been found throughout the city in nonceremonial contexts. In addition, they comprise the entire collection of projectile points ($N = 83$) recovered in the city's public armory (Andrews and Hirth 2005). Hence, there is little doubt that these points were used to tip arrows, and given the central importance of militarism and conquest at Xochicalco (Garza Tarazona and González Crespo 1995; Hirth 1989, 2000), they were probably used for combat.

String and Stories

David Turnbull

Elizabeth Barber in her classic *Women's Work: The First 20,000 Years* made the revolutionary observation:

> We don't know how early to date this great discovery – of making string as long and as strong as needed by twisting short filaments together… Soft flexible thread of this sort is a necessary prerequisite to making woven cloth. On a far more basic level, string can be used simply to tie things up – to catch, to hold, to carry. From these notions come snares and fishlines, tethers and leashes, carrying nets, handles, and packages, not to mention a way of binding objects together to form more complex tools… So powerful, in fact, is simple string in taming the world to human will and ingenuity that I suspect it to be the unseen weapon that allowed the human race to conquer the earth, that enabled us to move out into every econiche on the globe during the Upper Palaeolithic. We could call it the String Revolution (1994: 45).

Barber's insight – that the capacity to join things together through lashing, binding and knotting, with string or cordage is what enabled people to move – is of profound importance. It cannot, however, have occurred in isolation from two other essential capacities: movement and communication. How and why human movement is accomplished is central to our understandings of the growth and transmission of culture and civilisation and is thoroughly social and embodied. Movements are always performed by groups of people through the actions of their own bodies and are coordinated and motivated through ritual, music, dance and stories. Movements through the landscape also create trails both cognitive and material. 'We know *as* we go' (Ingold 2000: 230). Historically stories, string and trails were very likely co-produced with one another; they certainly inform each other mythopoetically through the fundamental commonality of narrative, journeying and weaving. Weaving and story telling reflect a common origin in the derivation of text and textile from the Latin verb *texere* to weave. Knowledge and stories are complexly intertwined with traveling, movement and journeys, as is reflected in the original Greek etymology of such terms as

- Symbol (to move or throw things together);
- Metaphor (to transport across space);
- Theory (from *theoros*, someone who travels to see things);
- Travel (from travail, to work);
- Episteme (putting oneself in a good position); and
- Method (from *hodos*, a traveling way).

What weaving, stories, and string share is the complex duality of tension and connection, difference and similarity. Stories join ideas, string joins things together and both are dependent on tension. String and cordage derive their connective capacity from tension in knots, binding, or twining. Weaving depends on the tension between the warp and the weft.

Stories and narrative have an essential tension or irony that comes from the listener's implicit double recognition that the coherence, the order we impose on the world, lies in linking things together, whilst also recognising that entirely contradictory orderings and associations are equally possible, and that in relating one narrative in terms of another stories are told and understood against the background tradition of other stories. Stories are a way of dealing with the ontological multiplicity or 'bothness' of life, the tensions and incommensurabilities between the contingent and the ordered, between the anomalous and the classified, between differing subjectivities, spatialities and temporalities, between the personal and the theoretical, the concrete and the abstract, the essential contradictions and the inexpressibility of human existence (Pelton 1980: 258). The trickster myth, that is common to so many cultures, reveals the multiplicities and tensions in the way the human world is storied and performed through language. In Norse mythology, for example, the links are apparent in the role of Loki the trickster god of mischief and destruction who also taught mankind the art of netting (Turner and van de Griend 1996). In Greek myth it was Athena the goddess of many things but especially love, procreation, wisdom, civilisation, strategy and weaving (Barber 1994: 241).

Barber's insight that string, an almost invisible and seemingly trivial soft technology, gave us the capacity to move, requires a radical rethinking of the stories we tell ourselves about the origins and nature of human civilisation and existence. Archaeology has, until now, celebrated early cultural development as basically lithic (related to stone) and technological, a process based in utilitarian stone tools and weapons, giving us a rather androcentric (centred or focused on males) picture of early man conquering the world with stone axes. Focusing on string brings into prominence the catching of small birds, animals and fish through netting. It emphasises the capacity for movement of humans by land and by sea. Most importantly it brings into visibility the early development of non-utilitarian ornamentation and symbolisation. These capacities for enabling symbolic expression, mobility, and relatively low key methods of hunting and tracking give a very different perspective on the early development of technology and culture. But, there are profoundly differing views about whether all this constituted a 'revolution' occurring in the Palaeolithic period around 26,000 BP as Barber believed, or whether they occurred considerably earlier and more incrementally. If so string was not a human innovation but a hominid one.

Two key areas in which the early uses of string are evident is in very ancient shell beads and in new datings of the earliest movements by sea. Recent discoveries of clusters of beads and pendants with drilled holes reveal the necessity of the almost invisible technology of the string, thread, cord or fibre to suspend them. At the same time they suggest the development of a capacity for reflection and symbolisation, for abstraction and communication. Such capacities are normally taken to be prototypically human, but there are some archaeologists who date ostrich shell beads in Africa as far back as 200,000 years ago (Bednarik 1997a–c). Recent finds, at Blombos in South Africa, of pierced shell beads showing signs of wear by threads or clothing are dated at around 75,000 years ago, and maybe as old as 280,000 (Douglas 2004: 26). Dating disputes will always permeate archaeology, but it is clear that Neanderthals made necklaces implying symbolisation and least proto-language (Arsuaga 2002). The other and most important development was travelling by boat across open sea passages. Australian Aborigines were perhaps the world's first sailors, arriving in Australia across an ocean gap of around 50 km at least 60,000 years ago. Water transport over this breadth of deep water would require string of some sort in the form of lashing and knots to tie together what was most probably a bamboo raft (Jones 1989; Thorne and Raymond 1989: 39ff).

The earliest direct evidence we have currently for string as twisted plant or animal fibre and hence as the basic component of clothing or textiles is 26,000 BP and there are figurines wearing string skirts which are dated around 20,000 BP. The use of twisted cords for weaving on looms has developed from the earliest times in cultures around the world from the Andes to China (Adovasio and Hyland 2000), as has the use of knots for mnemonics and decoration and the celebration of string in games and stories. Perhaps the most highly elaborated use of string was in the *quipu* of the Inca. Gary Urton's research suggests that these knotted strings were examples of how something as simple as string is capable of generating a hugely complex system of signification, codification and narrative (Urton 2003; Quilter and Urton 2002; Salomon 2004). Similarly Weiner (2001: 236) suggests that the *kirugu*, the sacred knotted cord of the Iatmul of the Sepik in Papua New Guinea maps out the stories of their migrations.

String, stories and trails, in their complex interactions and their multiple embodied skills and practices, may be the earliest of technologies and may well have been developed by our hominid ancestors, all of which should give us pause in our contemporary story tellings that locate our cultural origins in developments of stone technologies around 35,000–40,000 BP. Our cultural origins now look much less gendered, much less based in the technology of killing large animals, much less Eurocentric, and much less special to humans. We and our ancestors created trails, travelled by water, joined ideas and things together making ourselves and our world.

Suanxue Qimeng

Karine Chemla

The *Suanxue qimeng* (*Introduction to Mathematical Studies*), the first book composed by Zhu Shijie, a Chinese mathematician of the Yuan dynasty, was published in 1299 (Du 1966; Ho 1970–80). It differs from his second one, the *Siyuan yujian* (1303), in that its mathematical content presents a stronger continuity with the Chinese mathematical tradition. Most of the topics treated in it can be traced back to the Han classic which founded this tradition, the *Jiuzhang suanshu* (*The Nine Chapters on Mathematical Procedures*, hereafter called The Nine Chapters), probably completed between the first century BCE and the first century AD. Indeed, Zhu Shijie deals there with the rule of three, the distribution into unequal parts, and their composition or reiteration along the lines opened by the sixth of *The Nine Chapters*. He also describes how to perform the same computations with fractions and presents algorithms to obtain areas and volumes, even though he considers some forms not found in *The Nine Chapters*. The rule of excess and deficit, which was transmitted to the West where it became known as the rule of false double position, receives in his *Suanxue qimeng* a presentation as complete as in *The Nine Chapters*, even though it had been partially forgotten and sometimes transmitted in an imperfect state during the time elapsed since the composition of the latter (Chemla 1997). Moreover, Zhu Shijie devotes a chapter to an improved presentation of the algorithm for the solution of systems of simultaneous equations given by *The Nine Chapters* and comparable to the so-called *Gaussian pivot method* (Chemla 1992, 1996).

In addition to this, the *Suanxue qimeng* includes the treatment of topics that had emerged in the previous decades in Northern China, Zhu Shijie's homeland, such as the "procedure of the celestial unknown", a technique that puts into play polynomial algebra to obtain an equation to solve a given problem (Du 1966).

Yet, in contrast to *The Nine Chapters*, Zhu Shijie, in a first part of the book, makes clear which algorithms can be used to perform the basic arithmetical computations on the counting surface and includes new procedures for such computations when particular numbers are involved. It is interesting that some of the procedures he described could be used later without change when the abacus replaced the counting surface. In this respect as in others, such as the treatment of topics like the summation of all kinds of series, the inclusion of tables of unit conversion, a style of practicing mathematics in close contact with the problems of socio-economic life, or the use of certain new technical terms, the *Suanxue qimeng* repeatedly evokes the writings of Yang Hui, a mathematician who had lived slightly earlier in Southern China (Lam 1979). Indeed, in contrast to the period before the unification of China under Mongol rule, when mathematics seems to have developed independently in the north and the south of China, the time of unification when Zhu Shijie worked might have allowed the partial merging of these two traditions; his book may be our first reflection of this (Du 1966).

Sugar in Latin America

JUDITH VIDAL

The sucrose from sugar cane is identical to that in beet sugar and other sugars such as glucose, dextrose, fructose, levulose, and lactose. The chemical formula for sucrose is the oligosaccharide $C_{12}H_{22}O_{11}$. After refining, sugar is 99.9% pure.

Sugar cane was first cultivated and processed in India thousands of years ago. Gradually, medieval trade routes brought the product and its cultivation to the Mediterranean basin and Madeira where it languished on a small scale until its introduction to the Caribbean and Brazil. Columbus took it to Hispaniola on his second voyage in 1493. Cortés took it to New Spain, Balboa to Central America, and Pizarro to Peru. It was in Brazil, however, that the efforts of Duarte Coelho Pereira converted his captaincy of Pernambuco into a prosperous sugar-producing center fashioned after the *engenhos* (sugar works) of Madeira from whence the first cuttings and processing technology came. This became the model for an industry so vital to Portugal they courted Dutch capital to finance the African slave trade to supply the necessary labor. In exchange, the Lowlands received the crude sugar for refining and distribution. So profitable was this arrangement that the Portuguese eventually abandoned their enterprises in the Far East for the Brazilian milk cow, as Emperor João III fondly referred to the flourishing colonial sugar industry.

Aside from the introduction of large-scale cultivation and processing, the techniques of sugar production changed little since the early days of Venetian and Dutch refining and trading monopolies. Cultivation was usually from small cuttings or rattoons planted in evenly spaced furrows and allowed to mature for periods from 6 to 18 months – depending on the type of cane, the time and amount of rainfall or irrigation, temperature, storms, quality of soil, disease, and pests.

Plantation owners and managers were constantly alert for crop dangers and began to employ technicians to advise them. They experimented with irrigation systems, tested new strains of cane from both seed and rattoon, and tried crop rotation. Harvest had to follow immediately upon maturation. Normally this was by hand-held machetes wielded by slave laborers. Sometimes they used slash-and-burn techniques.

Harvesting was simultaneously accompanied by manually loading the syrup-filled stalks into mule-drawn carts for transport to the sugar houses. The cane was then handfed through the vertical or horizontal cylindrical presses which were originally adapted from wooden olive presses. These were two- or three-roller, metai-clad, devices with gears powered by humans or animals (*trapiches*) or water (*engenhos*). The extracted syrup flowed through wooden troughs or, in some cases where capital and topography permitted, through Roman-style aqueducts to the boiling sheds. Large *engenhos* comprised thousands of acres with thousands of residents in self-sufficient hacienda communities. More modest enterprises relied on hand-carrying the crude syrup to nearby pots for boiling.

Early production systems were ecologically complete, for the crushed stalks (or bagasse) were dried and used as fuel to fire the boiling vats. The ashes and extraneous leaves and stalks were tilled back into the soil as fertilizer and also served as animal fodder. Slaves found that unprocessed molasses from pieces of stalk that were not disposed of quickly underwent inversion and began fermentation; this primitive rum was used as currency to reward slaves and keep them cooperative but was not recognized as a commercial product for export.

Until the nineteenth century, the juice from the raw cane went through a series of open-pot boilings at extremely high temperatures. This process was watched very carefully to avoid fire and to avert burning the sugar. Slaves ladled off the scum of debris which flocculated with animal grease at the top; other impurities settled to the bottom in sedimentation. Lime was then added to help clarify the syrup. This purification, also known as defecation, removed the maximum number of impurities. The clear syrup was then placed in evaporating pans. The sludge of megasse sugar was next scooped into hanging clay cones with open bottoms to allow the heavy brown molasses to drip out. The resulting crude sugar was about 96% pure and fit for transport in casks or in loaves.

Shipped to European ports, crude sugar was sometimes sold directly, but most was transshipped and refined by a process of reheating in huge vats to which water and bone carbon filters were added. After a series of washings, the clear liquid was evaporated in copper pans and allowed to crystallize or granulate – the finer the quality, the whiter the crystal. As with the processing of raw sugar, refining would remain unmodified until the nineteenth century introduced steam vacuums and centrifuges to the finishing processes.

Throughout the colonial period, every finishing process was done by the mother country or its agents, usually in the Lowlands. Therefore, refining always occurred in Europe. The most efficient refineries were scattered around Antwerp which remained the capital for finishing sugar until war razed the production centers and blockaded trade. Britain, France, and Germany then built their own refineries. Long before Britain took possession of sugar-producing lands, England monopolized refining and distribution industries. This availability of mass production coupled with a growing popular taste for sweetened coffee and bread with treacle (molasses) provided an amenable consumer base for the confection in England and on the continent which demanded the colonial product.

Having pirated the rattoons and seeds of Brazilian and Spanish haciendas, European powers sought to monopolize refining and trade. In 1662 Catherine of Braganza married Charles II of England; her dowry included former East Indian territories such as Bombay and Tangiers and also a taste for tea which swept the court with exceeding popularity and would eventually displace both coffee and cocoa as England's hot, sweetened beverage of choice.

The Caribbean was an entrepôt of plantation islands. England, Spain, Portugal, France, and Holland all engaged in slave trade with Africa, and all quickly learned the commercial value not only of sugar but also of its intermediary byproducts, molasses and rum. After the molasses dripped off the crude muscovado sugar, the syrup was fermented and distilled into rum on the islands as early as 1530 and used as currency to purchase African slaves. Molasses was shipped directly to North American ports where New England distilleries enjoyed a burgeoning business. From the time of the capture of Jamaica in 1655, rum was regularly issued to British sailors, for it lasted longer than the traditional ale on high seas at certain temperatures. In 1754 it was watered down to grog and freely rationed until the 1960s. The sugar interest monopolized parliament and led to colonial uprisings which reshaped the empire.

Britain and its competitors consolidated their territories and introduced technological advances. As early as 1794, steam was used to power a three-roller press in Jamaica. A similar steam-driven mill operated in Cuba in 1797 – 10 years before the first successful steamboat. These machines were neither uniformly nor extensively adopted and operated imperfectly. Early fixed iron rollers often clogged or broke when the woody stalks of older cane were fed through the press. Shutdowns were costly, for the syrup in cane spoiled if not processed within 3 days of harvest. Mechanical repairs and waiting for replacement parts also impeded production.

The vacuum pan was invented by Edward Charles Howard in England in 1813, but it was not introduced to the colonies until 1835. This pan admitted steam through holes in the pan's bottom which was lined by a filtering cloth and capped by a dome connected to an air pump with a condenser. Interior heating coils were added by Daniel Wilson, and in 1828 Louisiana planter Valcour Aime implemented these improvements in his sugar houses and also introduced the use of the polarimeter to value raw sugars in cane. Despite patent disputes a system of multiple evaporation in six to ten successive pans was widely adopted and diversely adapted throughout the world. Penzoldt's centrifugal machine invented in Germany in 1837 for drying wool was modified for sugar by Sir Henry Bessemer. Cane-processing technology was adapted for beet sugar. In London the Fairrie family experimented with decolorizing agents for their refinery and discovered animal charcoal.

With the mechanization of sugar in the latter nineteenth century came the professionalization of technical advisors and managers. Technical assistants had to know how to assemble equipment correctly, keep it in good repair, and operate it. Agricultural experts were consulted to identify the best strains of cane for a particular climate or soil. Hawaiian planters of the 1850s maintained an experimental station which offered soil analyses, pathology reports, and pest controls. Entomological research at the British Museum identified natural predators and prescribed counter parasites.

The first mechanized harvests were successful in Australia. In the 1960s, Cuba contracted with Soviet engineers to develop a combine harvester. The self-propelled model ruined the rattoons and the ground for several seasons. Eventually the Cubans developed a harvester but technical problems diverted its production to Australia in 1984.

The sucrochemical industry experimented with research and development. Cane sucrose sales were eroded by beet sugar, high fructose corn sweeteners (HFCS) in processed foods, and synthetic sweeteners. New applications included gasohol, furniture, paper, and plastics. Brazil was the only successful producer of commercial gasohol although Australia and the US successfully converted their sugar industries to gasohol production during World War II.

The original sugar-producing countries of Latin America and the Caribbean still produce their crops of precious cane, but unstable governments, lack of capital, natural disaster, and inefficient management hinder technological growth.

Śulbasūtras

K. V. Sarma

The *Śulbasūtras* are manuals in India which prescribe the construction of different types of fire altars. Every householder was instructed, by the Vedic religion, to maintain a sacred fire, primarily for daily worship and offerings. These fires, called *gārhapatya* (domestic), *dakṣiṇa* (southern), and *āhavanīya* (oblatory), were to be maintained, without their ever going out, in altars of different designs, such as circular, semicircular, square, rectangular, and triangular. Seasonal and special worships required altars with elaborate designs like that of an eagle with outstretched wings. The size, shape, direction, position, and the number and measure of the bricks used, and also the increase in the measure, for extraneous reasons, were all specified in the *Śulbasūtras*. These traditional practices are referred to in the *Ṛgveda*, the earliest of the Vedas, and elaborated in the *Yajurveda*. Later they came to be written down as manuals, supplementing the regular texts depicting sacrifices, and also in independent texts called *Śulbasūtras*. Adherents of different Vedas and Vedic schools had different *śulba* texts, named after the authors of these texts and pertaining to the Veda which they advocated. This is how the *śulba* texts named after Āpastamba, Bodhāyana, Kātyāyana, Mānava, Maitrāyaṇa, Varāha, Hiraṇyakeśin, Satyāṣaḍha, Vādhūla, and Laugākṣi, pertaining to one or the other of the schools of the *Yajurveda*, and *Maśaka Śulbasūtra* pertaining to the *Sāmaveda* came into being.

The *Śulbasūtras*, meaning pithy aphoristic statements (*sūtra*) for work with string (*śulba*), prescribes, by means of addition, subtraction, multiplication, division, and squaring, simple rules not only for the construction of circles, squares, rectangles, triangles, wheel-shapes, trapezia, and rhombi, but also for extending these figures by specific proportions as required in different sacrifices. It also specifies methods to reduce a circle to a square of equal area, and vice versa. A fine approximation of the value of the $\sqrt{2}$ is contained in the rule given in the *Baudhāyana-Śulbasūtra*: "Increase the measure of the side (of a square) by its third part, and the third part by its fourth part. The fourth part is decreased by its own thirty-fourth part. (The approximate diagonal will result.)" The rule gives the approximation:

$$\sqrt{2} = 1 + \frac{1}{3} + \frac{1}{3 \times 4} - \frac{1}{3 \times 34},$$

i.e., 577/408, i.e., 1.4142157, which is very approximate to the correct value of the $\sqrt{2}$.

The *Śulbasūtras* specify or give geometrical constructions for the following (1) to draw a straight line at a right angle to a given line, (2) to construct a square on a given side, (3) to construct a rectangle of given sides, (4) to construct an isosceles trapezium of given base, top, and altitude, (5) to construct a square equal to the sum of two squares, (6) to construct a square equal to the difference of two squares, (7) to construct a square equal to a given rectangle, (8) to construct a rectangle with a given side and equal in area to a given square, (9) to construct a square equal in area to a given isosceles triangle, (10) to construct a square equal in area to a rhombus, (11) to construct a square equal in area to a given circle, and (12) to construct a circle equal in area to a given square.

It would seem that the sacrificial hall of the Vedic Indians formed, as it were, the workshop and laboratory to formulate and develop their geometry.

Sun Simo

Fabrizio Pregadio

The Chinese physician and medical author Sun Simo (alternative spelling: Sun Simiao) was a native of Huayan, in modern Shensi. His biography is so much a composite of fact and legend that it is even impossible either to substantiate or invalidate his traditional dates (581–682). From official, autobiographical, and hagiographic sources it emerges that he retired at an early age on Mount Taibai, not far from his birthplace. He repeatedly declined imperial summonses and official titles, but was almost certainly in Emperor Gaozong's retinue from 659 to 674, when he retired on account of illness. He seems to have spent an extended period in Sichuan, which may explain why many legends that concern him are located in that area. After his death he was venerated as *Yaowang* or "King of Medicine" (by which he is still known) in temples dedicated to him.

Sun Simo is the author of two of the most important Chinese medical compilations, the *Qianjin fang* (Prescriptions Worth a Thousand or, Remedies Worth their Weight in Gold), also known as *Beiji qianjing yaofang* (Important Prescriptions Worth a Thousand, for Urgent Need), and the *Qianjin yifang* (Revised Prescriptions Worth a Thousand). The former, in 30 chapters, was completed soon after the middle of the seventh century (apparently in 652). The latter, also in 30 chapters, dates from the late seventh century. Both works are preserved in editions derived from versions published in the eleventh century, when they were edited to be used as textbooks in the Imperial Academy of Medicine. In these texts, Sun provides an extended compendium of contemporary medical knowledge, arranged in sections dealing with such subjects as pharmacology, etiology, gynecology, pediatrics, dietetics, acupuncture, moxibustion, and specific diseases. Both texts include a wide selection of prescriptions (about 5300 in the *Yaofang*, about 2000 in the *Yifang*).

Among the many points of interest in these compilations, three deserve special mention. The first is the priority that Sun Simo accords to gynecology and pediatrics, the two branches of medicine with which he deals first in both works. The second is the importance given to medical ethics, reflected in this well known passage from the first chapter of the *Qianjin yaofang*: "When someone comes to look for help, a doctor should not question rank or wealth, age or beauty, nor should he have personal feelings toward that person, his race, or his mental capacities. He should treat all his patients as equal, as though they were his own closest relatives." The influence of Sun's medical ethics spread beyond China, reaching Korea and Japan through quotations of relevant passages in texts of these two countries.

A third aspect is Sun's relationship with Daoism (Taoism) and Buddhism. The nature of his involvement with the Way of the Celestial Masters (*Tianshi Dao*, one of the main traditions of liturgical Daoism) is debated. In the two chapters entitled *Jinjing* (Book of Interdictions) of the *Qianjin yifang*, Sun quotes formulas used in exorcist rituals by the Celestial Masters. This raises the issue of how he gained access to them. His interest in Daoism is also reflected in the chapter on "Nourishing the Vital Principle" (*Yangxing*), and in another extant text on physiological disciplines which is attributed to him, the *Sheyang zhenzhong fang* (Pillowbook of Methods for Nourishing [the vital principle]).

Another source which points to Sun's relationship with Daoism is the *Taiqing danjing yaojue* (Essential Instructions from the Books on the Elixirs of the Great Purity). This text –available in an excellent English translation – consists of a collection of alchemical methods, probably derived from the Six Dynasties compilations centered around the now lost *Taiqing jing* or Book of the Great Purity, one of the main early alchemical canons. Although Sun's authorship cannot be definitively proved, we know from his own witness that he was involved in the compounding of elixirs around AD 610. Among the medical disorders which he experienced, of which he left a first-hand account in his medical works, is intoxication due to elixir ingestion.

In addition to Daoism, recent research has pointed out Sun Simo's close connection with Buddhism. For example, he refers to Indian massage techniques, and mentions methods for the treatment of beriberi from works edited by Buddhist monks. Perhaps under the influence of Tiantai disciplines, he also introduced meditation in his medical practice. Moreover, the above mentioned "Jinjing" section of the *Qianjing yifang* includes incantatory formulas in Sanskrit. The main factor behind these Buddhist elements may have been Sun's interest in the doctrines of the Huayan school. Some passages of his texts, especially those on medical ethics, acquire new meaning if read in this light.

Sun Zi

Ang Tian Se

Of all the mathematicians in ancient China, we know the least about the life of Sun Zi. The fact that he was given the honorific designation of *Zi* (Master) after his surname led some people like Zhu Zunyi (AD 1629–1709) to identify him with Sun Wu, a celebrated tactician in the sixth century BCE. Then Ruan Yuan (AD 1764–1849) assigned him to the late Zhou period of the third century BCE. With regard to the text written by Sun Zi, Dai Zhen, the eighteenth century scholar and mathematician, citing from internal evidence, argued that the text could not have been written earlier than the Han dynasty at the turn of the Christian era. Though this text by Sun Zi was listed in all the bibliographical chapters of the *Sui Shu* (Standard History of the Sui dynasty), the *Jiu Tang Shu* (Old Standard History of the Tang Dynasty), and the *Xin Tang Shu* (New Standard History of the Tang Dynasty), there was no mention of its author. This shows that as early as the middle of the seventh century AD, no one seemed to know who Sun Zi was.

Sun Zi had neither high political position nor influential social standing to merit a place in official history. He appeared to be merely a scholar with some Buddhist inclinations as is evidenced in a problem mentioning the length of a *sutra*. The mention of *wei qi* (encirclement chess), and the taxation in terms of silk floss in other problems indicates the text of Sun Zi could not have been written earlier than the third century AD and later than the fifth century. Thus we assume he lived around AD 400.

Sun Zi Suan Jing is the earliest existing text to provide a description of the rod numerals and their operations. It also gives the names of large and small numbers, tables of measures for length, weight, and capacity, as well as densities for metals. The most famous problem is the oldest example of the remainder problem which reads as follows:

> "Now there are an unknown number of things. If we count by threes, there is a remainder 2; if we count by

fives, there is a remainder 3; if we count by sevens, there is a remainder 2. Find the number of things."

The problem has since evolved into what is now known as the Chinese Remainder Problem. Written in modern form, the problem can be expressed thus:

$$N \equiv 2(\mathrm{mod}3) \equiv 3(\mathrm{mod}5) \equiv 2(\mathrm{mod}7).$$

It appeared that Sun Zi's solution of the remainder problem had been extensively employed by the ancient astronomers to perform complicated computations of the calendar. By the thirteenth century, the problem was fully developed by Qin Jiushao with a sophisticated method of solution which also tackled the difficult case where the moduli were not relatively prime.

Sundials in China

Edoardo Proverbio

The measurement of time has a long history in China. Besides clepsydrae and water clocks, sundials and incense clocks were the only timekeepers employed in the epoch preceding the introduction of mechanical timepieces.

The earliest form of timekeeper used in China appears to be the sundial. Although the use of a simple vertical pole, employed to determine the epoch of solstices by measuring the length of the sun's shadow, appears to go back to Shang times (ca. 1500–1000 BCE), it is more difficult to establish the epoch in which the shadow of a simple style was used in China to measure time. Perhaps the most ancient reference is the one made by Joseph Needham et al., contained in the *Shi Ji* (Historical Record), which goes back to the beginning of the fifth century BCE. This reference, as well as those in subsequent epochs, makes no mention of the typology of these ancient sundials. Among later apparent references to the building of sundials of the equatorial type, there is the one contained in the *Sui Shu* (History of the Sui Dynasty), which refers to a "graduated sundial" the shadow of which reproduced the motion of the heavens. It was built by Ge Heng, a master of astronomical learning and instrument maker active in about the middle of the third century AD. One of the first descriptions of a Chinese equatorial sundial that has come down to us is contained in the *Duxing Zazhi* (Miscellaneous Records of the Lone Watcher) by Zeng Minxing (ca. AD 1176) in which, among other references, it is stated that Zen Nanzhong, master of astronomy and a highly skilled instrument maker, who was active in Chiangsi province, invented and built many water clocks and sundials: "he also made two wooden dials with diagrams on them. One was set upon a wooden support for reading (the hours by) the sun's shadow" (cited in Needham 1986).

But the only extant ancient objects that appear to have been built and used as accurate timekeepers are the two so-called Han sundials, dated as former Han, perhaps going back to the second century BCE. These two objects have been interpreted in different ways. The most probable interpretation is, however, the one proposed by White and Milman in 1938. According to them the base-plate of these sundials was inclined in the equatorial plane, and the central gnomon was not a style but a rectangular plate connected with a perimetral T-shaped gnomon by a bronze bridge. Time would thus be shown by the position of the shadow of the peripheral gnomon in line with the bridge according to the graduation engraved on the face of the sundial. The season would be shown by the height of the shadow of the T-shaped gnomon on the central rectangular plate. Upon these ancient, supposedly equatorial solar timekeepers the graduations appear on one face only.

The most remote mention of the existence of Chinese equatorial sundials with surfaces graduated and a gnomon extending both above and below the equatorial plane plate appears to go back to the twelfth century. The *Duxing Zazhi*, mentioned above, reports the following passage: "So at Yunchang (Chiangsi province) he (Zeng Nanzhong) made a *Gui Yingtu* (diagram of the sun shadow) and constructed a sundial (*gui*). The dial was supported on posts so that it was high toward the south and low toward the north (i.e., in the plane of the equator). The gnomon pierced the dial at the center, one end pointing to the north pole and the other to the south pole. After the spring equinox, one had to look for the shadow on the side facing the north pole, and after the autumn equinox one found it on the other (the under) side" (Needham 1986). Numerous examples of late (Ming and Ching dynasties) Chinese equatorial sundials graduated on both sides have come down to us. The dials existing in the imperial palace at Beijing are of this kind.

Besides fixed equatorial sundials, two portable equatorial sundials made of lacquered wood, with inscriptions in red and black, or black only, were constructed in China, at least as far back as the Sung period (tenth–twelfth centuries). The largest production of these portable sundials appears to have been concentrated somewhere around the nineteenth century. Their construction is quite simple. They are generally composed of a rectangular piece of wood as a base plate with a compass needle having an azimuth graduation for meridian orientation set in it. A second, mobile lunette (the plate dial) is connected to the board at the middle.

The lunette is thus half the size of the base plate. The plate dial is graduated and may be raised or lowered to any desired angle so that the gnomon, fixed at right angles at the center of the graduation, may point at the pole whatever the latitude of the observer may be. The dial is then fixed in position by means of a ratchet prop. It is interesting to note that the latitude scale materialized by the position of the ratchet is given not in degrees or by the names of cities, but by the 24 fortnightly periods (*chi*) into which the ecliptic (the band of the zodiac through which the sun apparently moves in its yearly course) was subdivided in traditional Chinese astronomy. The hour lines of the equinoctial dial plate are also expressed in the so-called Chinese "double-hours" associated with the 12 ideograms of the duodenary cycle. In fact, despite their everyday, popular origin, these timekeepers seem to embody elements of the long tradition of Chinese geomancy or topomancy, divination by means of configurations of earth.

So we must believe that Chinese equinoctial sundials belong to the pure Chinese chronometric tradition, an interpretation that takes us back to the origin of the Chinese science known as *Feng shui* (geomancy, wind and water), based on the use of the geomantic compass, and of the ancient divinatory system based on the *Yijing* (I Ching, Book of Changes).

The first portable (and fixed?) horizontal solar time pieces were introduced into China starting from the end of the sixteenth century by Matteo Ricci and other Jesuit missionaries. Indeed, Father Ricci himself, in the preface to his memoirs, wrote: "As for their clocks, there are some which use water, and others the fire of certain perfumed fibers made all of the same size; besides this they make others with wheels which are moved by sand, but all of them are very imperfect. Of sundials they have only the equinoctial type, but do not know well how to adjust it for the position (i.e., the latitude) in which it is placed" (cited in Needham). The structure of these Chinese horizontal sundials which have come down to us is perfectly similar to that of the European "diptych" sundials, whose center of diffusion in Europe appears to have been Nuremberg in the late sixteenth century. Chinese horizontal sundials were not constructed before the end of the Ming dynasty (second half of the seventeenth century), and we have significant evidence showing that this kind of sundial was also employed more for geomantic purposes than as simple timekeepers.

Besides the two types of portable sundials so far mentioned, few specimens of a third kind of sundial, probably horizontal, consisting of a rectangular ivory plate, each one ruled for a different latitude, with hour and declination lines engraved, exist in China. The time of day and the period of the year were presumably indicated by the shadow of a style fitted into a central hole.

Unfortunately, given our still insufficient knowledge on the latter, as on other Chinese sundials previously discussed, it is often difficult to know exactly on what working principle they were based and the precise uses for which they were constructed and put to use. Even more uncertain is the epoch in which many portable Chinese sundials, still extant in museums and on exhibition, were built, where they were built, and by whom.

S

Sundials in Islam

Boris A. Rosenfeld

The first sundials were formed by nomads who made holes in the tops of their tents. The sunbeam entered the tent through the hole and reached the floor or walls at different places at different hours. The time could be determined by the positions of these spots. From these developed the mural sextant described by the Islamic scientist and traveler al-Bīrūnī (973–1048) in his *Ḥikāya al-āla al-musammā al-suds al-Fakhrī* (Information on the Instrument Called the Fakhri Sextant) and instruments in the observatories of Ulugh Beg (1394–1449) in Samarqand and of Jai Singh (1686–1743) in Jaipur, Delhi and, other cities of India. In these instruments the sunbeams entered the instrument through the hole in its top and reach a special scale in its lower part.

The ancient Greeks invented sundials with gnomons, so that the time could be determined by the position of the shadow of the end of the gnomon on the plane or curved surface. The theory of sundials with gnomons obtained the name *Gnomonic*. Analogous sundials were used by ancient Arabs, Indians, and Chinese. Al-Bīrūnī in *Kitāb fī ifrād al-maqāl fī amr al-aẓlāl* (The Exhaustive Treatise on Shadows) wrote about all of these. All three nations measured the lengths of the shadows of a gnomon in parts: the Greeks in sixtieth parts, Islamic scientists in 12th parts called feet, Indians in seventh or 6.5th parts called fingers. The Greek division of the gnomon into 60 parts came from the tradition of Babylonian astronomers. The Arabic division is explained by their travels in deserts where they used their own bodies as gnomons and measured their lengths with their own feet. The Indians used the horizontal palms of their hands and erect fingers, and they measured the lengths of the shadows of their fingers on their palms with other fingers.

The most detailed descriptions of different kinds of sundials and of their theory appeared in the medieval Islamic countries. The first known to us, although nonextant, was written in Baghdad by Ibrāhim al-Fāzārī (d. ca. 777). It was called *Kitāb al-miqyās li ʻl-zawāl* (Book of the Gnomon for the Noon). The first extant Arabic treatise on sundials was also written in Baghdad by Muḥammad al-Khwārizmī (ca. 780–ca. 950) with the title *ʿAmal al-saʿāt fī basīṭ al-rukhāma* (Construction of Hour [lines] on the Plane of a Sundial). The sundial described in this treatise consisted of a horizontal marble board (the literal meaning of the word *rukhāma* is "marble board") and a gnomon (*miqyās*). When the sun accomplishes a visible diurnal circle on the celestial sphere, the shadow of the end of the gnomon describes an arc of a conic or (in the equinoctial days) a segment of a straight line on the plane of the sundial. On this plane the arcs of conics for the days of the entry of the sun in different zodiacal signs (beginnings of months of the zodiacal calendar) and a segment of the straight line for the equinoctial days are drawn. (For Baghdad these conics are hyperbolas). The hour lines are lines joining the points of these arcs and segments corresponding to the same hours of a day (in this treatise hour lines are straight lines). In the treatise the construction of this sundial is described and the tables for the functions necessary for this construction for different latitudes are given (the most detailed tables for 33° (Baghdad) and 34° (Samarra) are given). In al-Khwārizmī's treatises *ʿAmal al-miknasa* (Construction of al-miknasa) and *ʿAmal al-mukḥula li'l-saʿāt* (Construction of al-mukḥula for [determination of] Hours) different kinds of sundials are described. These include a horizontal plane sundial with a vertical gnomon used in *kanīsas* – churches or heathen temples – and a sundial with a conical surface whose name literally means "vessel for storing antimony (*kuḥl*)" because of its likeness to this vessel.

In the treatise by Thābit ibn Qurra (836–901) *Maqāla fī ṣifa al-ashkāl allatī taḥduthu bi mamarr ṭaraf ẓill al-miqyās fī saṭḥ al-ʿufq fī kull yawm wa fī kull balad* (Article on the Description of Figures Obtained at the Passing of the End of the Shadow of a Gnomon on a Horizontal Plane on any Day and in any Town), the horizontal sundial can be used at any latitude when the trajectories of the end of the shadow of the gnomon are arcs not only of hyperbolas but also of parabolas, ellipses, and circles. In his *Kitāb fī ālāt al-saʿāt allatī tusammā rukhāmāt* (Book on Horary Instruments Called Sundials) all kinds of plane sundials – horizontal, vertical, and oblique – are described.

Different kinds of sundials which secured the timely calls of Muslims for prayers are described in Arabic *zījes* (astronomical handbooks with tables) and in special treatises written by *muwaqqits* (timekeepers). Many kinds of sundials are described in al-Bīrūnī's book, *The Exhaustive Treatise on Shadows*, mentioned above. This is also true in the book by al-Ḥasan al-Marrākishī (d. 1262) *Kitāb jāmiʿ al-mabādī wa ʻl-ghāyāt fī ʿilm al-mīqāt* (Book of the Collection of Beginnings and Results in the Science of the Determination of Time). The time on sundials was measured not in astronomical hours equal to 1/24th of the day and night but in temporal hours equal to 1/12th of the day.

In later times oblique (not horizontal or vertical) sundials called *al-munḥarifa* were often used. Of particular interest is the treatise on these sundials written by the *muwaqqit* of the mosque al-Azhar in Cairo Sibṭ al-Māridīnī (1423–ca. 1495) *Risāla fī'l-munḥarifa wa ʻl-shākhis* (Treatise on an Oblique [sundial] and a Pole).

Surgery in Ancient Egypt

HEDVIG GYŐRY

In ancient Egypt, because a majority of the population had to endure hard physical toil, bone abnormalities such as arthritis, inflammation of the joints, bone attrition, kyphosis, osteo-arthritis, or tuberculosis were a common occurrence. None of these conditions were, however, considered surgical cases. The surgical repertory was limited. Both physical remains and written sources support the notion that operations were sporadic and minor, and that the emphasis was on physical treatment of fractures or dislocations, with a few cases of incisions or cuts into certain regions of the body. There were also various external organic alterations like abscesses, boils, fistulas, haemorrhoids, ulcers, and some superficial growths. Malfunctions of the nose, ear, and teeth were treated in this manner only occasionally. In treatment, the anatomical knowledge applied was taken from earlier medical observations and theories, not from the science of mummification. Good examples of this are the mummies examined by Regöly-Mérey: in seventeen cases, the brain was removed transnasally, in eight cases the frontal and facial sinuses were removed, and in five cases the pterygoid sinus had been opened up. Thus, these sinuses had to be penetrated with a hook, but none of these sinuses is ever mentioned in the medical treatises.

Sources

If we consider surgery (from the Greek *cheirourgia* meaning 'hand work') as a medical specialty that treats illness by operative manual and instruments, its most important characteristic is wound management. Looking at the ancient Egyptian word for physician, we find the *swnw* written with an arrow-shaped hieroglyph. It has been suggested that the arrow shape has its origin in the fact that the primary occupation of physicians was treating injuries received in combat. Physicians were experienced in removing arrows, similar to the god Thot, or perhaps they used arrowheads to lance abscesses. But a very limited number of pictures and only relatively few passages in the medical papyri describe surgical wound management in ancient Egypt. The Ebers papyrus (855–77), Hearst papyrus (217–27, 245, 260), London papyrus (29, 43–4) and, the most extensive, a complete scroll – the Edwin Smith papyrus – all contain descriptions.

References to surgical cases interspersed among prescriptions in the above-mentioned first three scrolls suggest that surgery was considered as part of any healer's art. This conjecture seems to be relevant for all three types of healers – physicians, priests, and magicians – since they are all named in the Smith papyrus when speaking about the examination of the patient's pulse. Ancient Egypt was, however, very advanced in medical specialisation and thus there might be a distinction among physicians dealing predominantly with surgical cases – as the priests of Sachmet are believed to have been specially trained surgeons (even for animals). Early distinction between surgery and pharmaceutical medicine is the most pronounced when looking at treatments of internal versus external cases: practically all the operations are directed at repairing external parts of the body, mostly for already existing damages.

The Smith papyrus was a manual for use by an army surgeon or practitioner for treating accidents or for teaching purposes. It is essentially a treatise on wounds, internal pathology, and bone surgery with meticulous clinical observations. It lists forty-eight cases of injuries and lesions along with the appropriate treatments. It follows the *a capite ad calces* (from the head to the calves) method, common in Western medicine until the Middle Ages. It starts with skull lesions, continues with caudal lying injuries on the head, in the neck, the clavicle, the humerus, the sternum, and the shoulders, and finishes with a description of the region of the spinal column, where it stops abruptly in the middle of the case of the fourth thoracic vertebra. But it was not the only ancient book in this field. It mentions, for instance, in case 5, another one, with the title 'On Wounds', the structure of which could be similar to that of the Smith papyrus. It contained case studies for medical treatment with explanatory glosses, but it might also have been a teaching book for anatomical and physiological features, since it is quoted as an explanation of a physical condition that results when the skull is splintered. The Smith papyrus is matter of fact and sober and would even fulfil today's requirements. The inductive process that deals with these cases is the oldest known example.

Case Study

The surgeon elicited information by questioning the patient or directing him to attempt certain movements or postures. His own ocular, olfactory, and tactile observations were then added. For case studies, conditions were closely observed, symptoms described and effective treatments noted in a remarkably scientific manner. These procedures were, however, accompanied by an equally important religious/magical rite, known from different sources. For instance, the ancient Egyptians believed that the illness passed into the bandage (called trap in Eb. 2) and thus, with the removal of the bandage, the illness was also thought to be removed.

Wound Repair

The ancient Egyptians regarded symptoms of infection as part of the recovery process. They also realised pain, but interestingly, they never mention anaesthesia for use in surgical interventions, although they had means for it. The silence can be the consequence of both its non-existing (e.g., holding the patient down) or having methods which were trivial – e.g., being drunken. Its only possible occurrence is an Old Kingdom circumcision scene (see a comprehensive description in the article Wound Healing).

Ancient practitioners were more deeply concerned with arresting haemorrhages, since the *mtw* (Eb. 871), tumours (Eb. 875), and wounds were susceptible to bleeding. The main wound repairing methods were bandaging with an ointment or poultice, scorching (Eb. 872, 876) and surgery. In doubtful cases, enforced bedrest and normal diet were often recommended to the patient until he reached the decisive moment when the healer could give either a positive or negative prognosis.

In many cases, as mentioned in Eb. 510–42, injury treatment was restricted to various medicaments. For instance, a typical first-day treatment was to put raw meat on the fresh wound, which induced haemostasis. A suppurating wound was likely to be cured by honey (Eb. 513), which is hygroscopic (capable of easily absorbing moisture) and stimulates the production of white blood cells, or by astringent herbs such as acacia leaves (Eb. 527). They also used wound dressings which combined, for example, honey and *snṯr* (incense, Eb. 515) or wax and *mrḥ.t* (grease/oil, Eb. 518), providing protection and promoting healing. Discharge and suppuration might also be treated by fat, ground peas and fermented barley bread, causing an antiseptic and hygroscopic effect (Eb. 522) – and, in the case of bread, possibly yielding penicillin. These last materials were given in sequence: (1) ox fat on the first day to induce the wound to become foul; (2) barley bread for drying it; then (3) several other things alone or in combination on the following 4 days. Thorn pricks (Eb. 726–32) were treated with poultices or ointments. Similar treatments could also certainly be applied to artificial wounds.

We do not know the criteria the surgeon used to determine the place for an operation, i.e., *ḏw-ᶜ* – 'knife-treatment'. Neither is a special operating theatre mentioned thus far, which may mean that the operation was performed at the patient's home.

Main Surgical Categories

Trauma (By Accident or Combat)

Based on many relatively good healing settings, we can assume that ancient Egyptian bone setting was advanced. Among the skeletal remains from ancient Egypt, there are innumerable completely healed limbs with good realignment of the bone, but most other bone settings often show gross shortening and misalignment. Since fractures of the femoral bones often healed without complication, it may indicate, on the one hand, that the virulence and incidence of pyogenic pathogens was lower than they are today, although their existence is proved by the frequency of osteomyelitis. On the other hand, based on the skeletal remains of pyramid workers and other Egyptians, it is obvious that fractured limbs were splinted using an advanced technique suitable even by modern standards. Cleverly, if only one of the bones of the lower leg or forearm was broken, the remaining intact bone could serve as a splint for the broken one, and healing was satisfactory. In instances where the damage was so severe, however, amputation was an alternative course of action.

Representations of injuries are relatively infrequent. Two of them are accurate enough to mention: the accidents drawn on the wall of the tomb of Ipui which happened in the joiner's shop and the pictures of the battle of Qades in various temples. Moreover, medical papyri, especially the Edwin Smith papyrus, are very accurate and detailed in the description of various types of injuries and their treatments. They tell us that the healer was able to characterise the most important types of injuries, impressive even by today's standards. They differentiated among various types of swellings, fractures, and joint injuries.

Besides the superficial wound (*wbnw*), they cured the *wbnw kft* – a deep gaping wound, as, for instance, in Sm. 28, where the most important clinical sign for an open oesophagus, drinking water regurgitating through the wound, is mentioned. The axillary could also be open (Sm. 47). The most common complaints, swelling and fever, indicate that wounds were often infected. In the special case of perforation, the word *thm* is used.

Wounds were often surgically treated by suturing with *jdr* stitching (Sm. 3, 10, 14, 23, 26, 28, 47) and/or bandaging (Sm. 2, 9, 10, 27, 47). Basic medicaments for curing were honey and fresh animal meat, but, in specific cases, many other ointments and poultices were also applied (Eb. 510–42). Sometimes a sequential approach was used (Eb. 522).

In the case of fractures, the ancient Egyptians differentiated a simple closed *sḏ*-fracture, where the bone is broken in two, from a commuted compound or impacted *pšn*-fracture, where the bone is broken in several places. As a diagnostic clinical sign of fracture, *nẖbẖb*, meaning, in all probability, 'crepitation', is mentioned. The standard procedure for the reduction of fracture was traction (Sm. 12, 35, 36). And, indeed, many humeri were found in graves still set in splints. The first procedure was, after realigning the broken limb, to set it either with a splint wrapped in bandages, or encased in a healing poultice cast that could be made of various (often unidentified) materials; as, for instance (just to mention some known substances), cow's milk mixed with barley (H 219) or acacia leaves bound together using gum and water (H 223). For reducing a fracture of the clavicle (Sm. 35), the ancient Egyptians also used a method still applied, but first described among Greek physicians by Hippocrates, by stretching the patient 'on his back with a folded cloth between the shoulder blades' and pulling 'on his two shoulders until the fracture falls into position'. Among the neurological complications, as in the case of an impacted fracture of the cervical vertebrae (Sm. 33), aphasia, unconsciousness and tetraplegia, are mentioned.

Concerning injuries to joints, dislocations (*wnẖ*) and sprains (*nrw.t*) were treated. In the tomb of Ipui in Deir el-Medineh, there is a picture of industrial accidents. Among them the use of Kocher's method for dislocated shoulders can be clearly discerned.[1] Other methods are described in the Smith papyrus, e.g., treatment for the dislocation of a jaw (Sm. 25). For neurological complications resulting from the dislocation of a cervical vertebra the inability to move the limbs, priapism, urinary incontinence, and intestinal dilatation with gas secondary to paralytic ileus are given (Sm. 31). In another case, a positive Lasague sign is described, i.e., pain due to a sprain of the vertebral column when the legs are extended (Sm. 48), which indicates a prolapsed lumbar intervertebral disc with nerve involvement.

Based on two ivory slabs bearing the names of kings Aha and Djer (both 1st Dynasty), some specialists assume the use of tracheotomy, a procedure that opens the airways to maintain breathing. The slabs represent a man kneeling, with his hands tied behind his back and with a pointed instrument directed at his throat. As the man holding the tool is seated, the scene is unlikely to be a battle scene, and, since the process is not repeated in later representations and the situation is not described in later medical texts, an interpretation of ritual execution (?) is also possible.

Skull Surgery and Trepanation

According to the Edwin Smith papyrus, the ancient Egyptians recognised brain disorders and performed skull repair. They were also the first in the history of medicine to identify the inner parts of the cranium, as *tpw*, the falx cerebri, or protruding dura mater[2] – based on the description, or as *ntnt*, the meninges (Sm. 6). They also provided vivid descriptions of the brain and cerebrospinal fluid.

Parallel to the development of weapons, the number of head injuries increased (Fig. 1), thus causing a discussion of the many cranial injuries in the Smith surgical treatise. The dominant factor in healing,

Surgery in Ancient Egypt. Fig. 1 Head of Seqenenre Taa II, showing multiple injuries acquired in battle. Source: LECA, A–P. La médecine égyptienne au temps des pharaons, Paris 1971, fig. 94, p. 372.

[1] For information on Kocher's method, see ►http://www.tki.unibe.ch/theodor.htm.

[2] The dura matter is the tough fibrous membrane covering the brain and the spinal cord and lining the inner surface of the skull. It is the outermost of the three meninges that surround the brain and spinal cord.

however, seems to be the *vis mediatrix naturae*, the expectant healing power of nature. This is also manifest by the signs of treatment on heads with cranial injuries found by Elliot Smith, Wood Jones, Courville, and, recently, Nerlich, which are far from adequate if any medical treatment's sign is present. A successfully recovered head injury to Amenemhab, who saved Thutmosis III from an attacking elephant in Nij/Mitanni, is known from literary tradition, while Breasted published the results of a palaeopathological examination of the mummy of General Ossi-numph-neferu, with a 7.5–cm long, caved-in, but completely healed, left side frontotemporal bone wound. This recovery is a great achievement even by current standards of surgical knowledge.

Craniotomies were well known in ancient Egyptian practice. A special treatment was trepanation, which is essentially making a hole in the skull without damaging the cerebral membrane. Today, only a few unquestionable cases are known of perfect healing at the edges that testify to a longer life, and, based on its absence in the Smith papyrus, it was certainly not regarded at that time as a medical treatment. But many other interventions were considered surgical, and some of them are given in the Smith papyrus with a modern scientific approach of clarity and diagnostic accuracy.

The first eight cases in the Smith papyrus deal with various injuries of the skull (for details, see *Wound Healing in Ancient Egypt*). Pathological descriptions give clues to the identification of symptoms such as meningeal irritation, cerebral prolapse, nuchal rigidity (stiff neck), trismus (lockjaw), tetanus, contracoup (brain injury), or hemiplegia (weakness on one side of the body). Complex case studies indicate a basic medical understanding of the function of the brain. They also knew their limits very well – when a cure was hopeless, palliative treatment was undertaken.

Plastic and Prosthetic Surgery

In some cases, wound treatment meant not only the healing of the wound but also the reconstruction of an earlier structure. Typical examples are Sm. 11–2 cases with plastic surgery of the nose. Besides the treatment of the fractured bone, by the usual means of application of *mrḥ.t* (oil/grease), honey and fibres, two fabric *ads* soaked into *mrḥ.t* were introduced into the cavity and applied to the bridge of the nose. Then the nose was bandaged above two linen pads, which protected the nostrils from distortion. The same reasoning led to the fixing of the auricle by means of a small cushion after the suturing of the ear in Sm. 23. Following local applications, a supportive bandage was also recommended for an ear wound in Eb. 766.

A surprising innovation in ancient Egyptian medicine was the use of prostheses (artificial limbs). We know that long ago there was a post-mortem nose prosthesis, for instance, on a Ptolemaic period Gamhud mummy, clearly shown by the fact that the straps are above the mouth and the chin, which then go to the base of the cranium where they are tied in a knot. Consequently, for a long time it was thought that restorative surgery was only used by embalmers to maintain physical integrity for eternal life.

There were doubts about the earliest prosthetic contrivance, two 4th Dynasty teeth fixed together by a golden wire, found in the Gisa cemetery. After a long debate, the conclusion seems to be that it was made for a dead person (The next artificial teeth, the holding of a maxillary bridge by a silver wire, were found in the Ptolemaic period.).

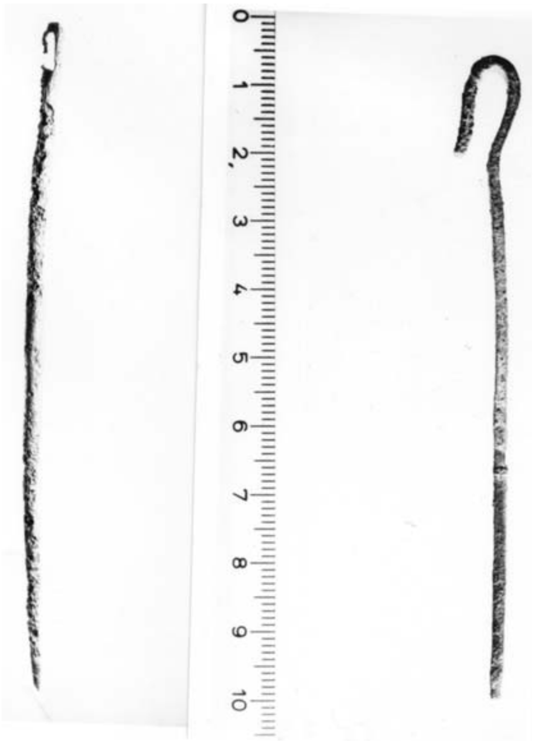
A prosthetic big toe, however, recently discovered in Thebes on a mummy of the 21st/22nd Dynasty in Tomb 95, was certainly made for a living person (Fig. 2). The linen-wrapped foot and leg show evidence that the amputation was cleaned and prepared for this device. The amputation is completely healed, and the wooden prosthesis, made up of three separate components, is worn on the sole, which indicates that the owner lived long using the prosthesis after the accident (As a reason for amputation of the toe, ischaemic gangrene has been suggested.). Another (in this case cartonnage[3]) toe prosthesis from Thebes around the same period, kept in the British Museum, was applied also to a living person; again, wear and subsequent refurbishment can be observed.

Pathological Extensions

Pathologies were well differentiated: several sorts of tumours, abscesses, cysts, swellings, boils, etc. (*ḥnḥn.t*, *ᶜ.t*, *sfṯ*, *ᶜnw.t*, *šfw.t*, *ḥsd*, *tw.w*, *bsj*, *ḥm*, *sẖ*, *bnw.t*, *wnm-snf*) are mentioned in the Ebers, Hearst and Berlin papyri, with very brief medical instructions. These might have been treated in the following ways:

- Medicaments, for instance, Eb. 51–581, 855–62, H 41, 132–33, 136–39, Bln. 52–7 or the last step in Eb. 877;
- … treat it similar to the treatment of the *s-ḥmm* "(firebolt?-man)" for scorching the skin-like flesh-protrusion in Eb. 863 or the (umbilical or epigastric?) hernia in Eb. 864;
- *ṯḥn* – piercing with the *Hmm* as in Eb. 865 for the ascites (fluid in the abdomen);
- *ḏw-ᶜ*-'knife-treatment', meaning, probably, excision, as in Eb. 866 for a vascular tumour (haemangioma?), Eb. 867 for a presumably subcutaneous lipoma; Eb. 868 for a possible sebaceous tumour with metastasis

[3] Cartonnage was papyrus or linen soaked in plaster, shaped around a body. It was used for mummy masks and coffins.



Surgery in Ancient Egypt. Fig. 2 Hook and needle in the Egyptian Collection of the Museum of Fine Arts, Budapest.

(*ʿ.t nt s*); Eb. 869 for an abscess; Eb. 870 for a swelling, the identification of which has several possibilities, such as a dermoid cyst lined with skin appendices, pilonidal sinus located in the midline or sebaceous cyst of the scalp, as, for instance, atheroma; Eb. 871 for an abscess in the axillary lymph glands;

- *ḏw-ʿ*-'knife-treatment' with heated (*sšmm*) knife as in Eb. 872 for a probable haemangioma;
- Either excision or scorching according to the state of the tumour, as in the first two cases in Eb. 876; or
- The tumour was left untreated, as Eb. 874. This might have been leprosy, or in Eb. 873, a possible cavernous haemangioma, or a twisted vascular swelling forming knot (in this case, however, the *mtw* should be straightened). The first two steps in Eb. 877 are still unidentified although cancer, cutaneous leprosy, bubonic plague, or neurofibromatosis have already been suggested. In the last step in Eb. 876, the ball-shaped extensions have tentatively been identified by Regöly-Mérei as varicosities.

In all the above cases, procedures are not described and thus nothing definite is known. The only complex and detailed surgical process is given in the Ebers papyrus (Eb. 875) – with various knife and forceps devices – and is, in all probability, the month-long treatment for dracunculiasis[4] (which may be the origin of the caduceus, the medical emblem with snakes), and thus a very atypical surgical invention.

Circumcision

Herodotos (II.37) wrote: 'They practice circumcision for cleanliness, for they set cleanliness above seemliness', but we find no mention of it in any medical or iatromagical text, and its two representations hint at a sort of feast for ritual initiation, probably for procreative purposes. Conceivably, the traditional practitioners had religious ties, and were most probably priests, since the fulfilling of the cleanliness doctrine was the most important one for temple workers. Based on a representation of the tomb of Ankhmahor, it was performed by a scalpel or some sort of blade. Following the Ptolemaic rule, physicians could do it, too, as later the use of Roman instruments, such as forceps and scalpels, was common in this field.

There is only one mention in the First Intermediate Period stele of Uha of circumcision being performed on females in Pharaonic times, where a crowd of men and women are participating in the cultic rites that accompanied the procedure. It seems, based on this mention of a communal feast, that female circumcision was also primarily ritualistic and it has been hypothesised that it was also associated with temple activities, although I think it was primarily the same sort of fertility rite as that for men – at least the above communal feast hints at it. We do not know, however, how popular the act was, or when, how or why it came into existence. In any event, it must have lost its festive side, as it never appeared again as a public act. It must not have been obligatory, since virgins were also referred to as *ʿmʿ.t*– 'uncircumcised', from the Middle Kingdom on. Based on the state of preservation of the pubic area on mummies, the fulfilment or non-fulfilment of the act of circumcision cannot be definitively determined. According to written sources, however, in Graeco-Roman times, nymphotomy/clitoridectomy seems to have been a widespread custom in Egypt. Soranus (2nd century BCE) first recommended the process for girls with excessively large clitorises. He gave as the reason for the operation the shame that results from its erection and the girl's excessive desire for sexual indulgence caused by the abnormality. According to Aetios, who used Hellenistic and Roman imperial sources, the ancient Egyptians excised the clitoris especially around the time when the girl was about to be married.

[4] Dranunculiasis, also known as Guinea worm disease, is a painful and debilitating infestation contracted by drinking stagnant water contaminated with Guinea worm larvae that can mature inside a human's abdomen until the worm emerges through a painful blister in the person's skin.

Burns

In the Ebers papyrus, there is a complete book on wounds originating from burns: 482–509. No. 482 lists a sequence of remedies which, it says, should be applied consecutively. In other cases, remedies applying an ointment or a bandage are the same during the entire treatment. Similar to cases in the London papyrus (15–21, 46–8, 53–61) and also among the Ebers papyrus prescriptions (482–500), magic spells had to be cast, referring to Horus having been burnt in the desert. According to the incantation of Eb. 499 which had to be recited with mother's milk, Isis used 'water in her mouth' and 'Nile springing between her thighs'. Mother's milk, gum, and ram-fur (having a high cholesterol content) were put on the burnt wound. As for surgical procedures, Eb. 504 speaks about opening a blister with a sharp thorn, and Eb. 501 mentions an incision on a blister sandwiched between two prescriptions, but, as usual, without any details.

Various Types of Bites

According to the Brooklyn herpetological papyrus, snakes and the effect of their bites were accurately identified, and their bites treated with rational medical care. The treatments comprised the application of a bandage with salt and natron,[5] both being antiagglutinant[6] and antihaemolytic[7] thus impeding the absorption of the venom; drinking of emetic remedies with various materia to get rid of venom by vomiting; fumigation as adjuvant; magical spells for general and specific divine help and/or the *ḏw-ʿ* 'knife-treatment' and the *tštš*-incisions in the swelling.

Other types of bites, such as those from crocodiles (Eb. 436, H 239–40, 243), lions (H 244) and humans (Eb. 432–35, H 21), were treated like any other wound, preferably by applying fresh meat on the first day and, subsequently, honey, wax, and *mrḥ.t* as in Eb. 435 or by using other herbal remedies, occasionally with the addition of some animal ingredients.

Dental Surgery

Dentistry is among the earliest medical fields in ancient Egypt. Even the first known Egyptian physician, Hesira, was a dentist. A wide range of dental treatments is listed in the medical papyri, such as filling teeth, treating gums or abscesses, and reducing halitosis. But no surgical inventions are mentioned, although an alveolar process using piercing to drain an abscess under the first molar has already been found in a mandible from the fourth Dynasty. Neither is tooth extraction described, and, based on the many abscesses and cysts found on mummies, was rarely, if ever, practiced.

Surgical Devices

There were several specialised surgical devices (Fig. 3), as various types of knives for cutting tumours, needles for suturing, several types of spatulas for applying the medicaments, 'fire drills', and metal cauteries for operations and disinfection. They made splints and bandages very skilfully, having specialised books on this topic – primarily for the embalmers, but as the Smith papyrus says, physicians used them as well. Hooks and forceps were probably also often common with the embalmers, although such devices as the small leather forceps, called *hnw*(*ḫ*) must have been a surgical speciality. They also used several natural objects, such as acacia thorns for cutting up blisters and the bulrush knife for removing elastic foreign bodies. Seemingly they were adapted to the various functions surgeons had to accomplish during the various stages of different types of operations. Parts of the instruments

Surgery in Ancient Egypt. Fig. 3 Prosthetic big toe from Thebes.

[5] Natron was a salt (sodium carbonate and sodium bicarbonate) that was used in the mummification process to dry out the body of the deceased in order to assist in its preservation.

[6] An antiagglutin is a substance that makes particles (such as bacteria or cells) stick together to form a clump or a mass.

[7] Haemolysis is alteration, dissolution, or destruction of red blood cells in such a manner that hemoglobin is liberated into the medium in which the cells are suspended, e.g., by specific complement-fixing antibodies, toxins, various chemical agents, tonicity, or alteration of temperature.

were also used for cosmetics; ointments were made and applied the same way for both purposes. The execution could have been of different quality according to the demand, although they are mostly primitive. The problem is, however, that only a few surgical devices survived (often unprovenanced), and representations are missing – the Kom Ombo temple relief originates from the Roman times, so ancient Egyptian and Roman medical instruments are already mixed. We do not have detailed knowledge of pharaonic surgical devices.

Surgeons

The practitioners of all the above procedures might have been very different people. Surgeons, i.e., medical practitioners specializing in surgery, seem not to have existed in the modern sense during Pharaonic times. Operations were performed by the practitioners, dentists, priests, or magicians. For combat/battle injuries there was a military physician, problems with teeth were handled by a dentist, complications of the ear or nose were treated by the specialist or by a general practitioner. For bites, the *ḫrp Srḳt*, the 'controller of Selket' was responsible, while circumcision might be the task of the *kz*-priests.

Surgical procedures are, however, attributed by Egyptologists most often to the priests of the lioness goddess, Sechmet, who were veterinarians (as the ancient Egyptian said: 'one who knows bull') too. Aha-nakht, a colleague of the *swnw* Hery-shef-nakht, of the Middle Kingdom introduced his picture in his Hatnub graffito with the words: 'The scribe of the hall of judgement, Aha-nakht. I am a wab priest of Sekhmet, capable and skilled of his brotherhood, who places hand on a man when he knows it (i.e., the illness), skilled in examining strongly and one who knows bulls', thus attesting to a medical connection for these priests. The *ḏw-ʿ* – knife-treatment, however, is said in Eb. 501 to belong only to the *swnw* physician as the secret knowledge of the beating of the heart belongs as well to the *swnw* as to the *wʿb* priest of Sekhmet and to the magician.

The account given in this article represents the state of surgery during the New and, probably, the Middle Kingdom periods in Egypt, since our sources date mainly from these periods, but it was probably not very different during the preceding and following periods. Wound management has always been an important part of human life and thus probably the first medical books (see Medicine in Egypt, especially the note on Egyptian Medical Papyri) already contained appropriate instructions. It is unknown, however, how much they differed from the Middle Kingdom methods, where the latest research places the original of the texts of the Smith papyrus. The concept was probably the same, as we find in the few New Kingdom Berlin papyrus prescriptions for bite and the very complex 30th Dynasty (?) Brooklyn Museum herpetological papyrus. A great transformation seems to have taken place only later, with the gradual fusion with Greek medicine via the Alexandria School.

Surgery would be used in ancient Egypt only if a cure could not be achieved by means of prescriptions or other methods, and if the patient was not in a terminal condition, when only palliative steps were taken. And, indeed, it was often the best solution as success would certainly not be guaranteed even in standard operations, in spite of the relatively advanced methods, due not only to imperfect anatomical knowledge, but also to the lack of both effective anaesthetics and of antiseptics and the low level of hygiene, which could lead to septicaemia.

Surgery in Ancient India

A. R. Sankhyan

Ancient surgical practices included trepanation (also called trephination or trephining), the craniotomy or drilling and cutting through the skull vault. It was practiced either on the living person (antemortem) or just after death (postmortem). Squier (1863–1865) and Broca (1876, 1867) were probably among the first to draw attention to the antiquity of this practice in Peru. Piggott (1940) thought that it had begun in Europe around 5,000 years ago. In Asia trepanation is evident from around 4,000 years ago in the Bronze Age of Jericho in Palestine (Parry and Starkey 1936; Giles 1953). In the Indian subcontinent, trepanation was known among the Bronze Age Harappans (ca. 4300 BP) people of the Indus Valley Civilization (Sarkar 1972). He attributed a squarish hole on the right temporal skull of a child of 9–10 years skull found at Lothal, a Harappan site. Roy Chowdhury (1973) noticed the evidence of trepanation in two Harappan skulls (No. H 796/B and H 802/B from Cemetery R37), adding that a Kalibangan skull (another Harappan site) in Western India, was probably also trephined. This practice was also followed during the Iron Age of India, since a megalithic skull (M30) from Maski in Karnataka, South India, also showed evidence of trepanation in the form of two circular holes of 22 and 15 mm, respectively, on the either side of the sagittal[1] suture of the vertex (the top of the head) (Sarkar 1972). A Neolithic skull excavated at Burzahom in Kashmir shows more convincing evidence of trepanation (Roy Chowdhury 1973; Sankhyan and Weber 2001; Sankhyan 2004) practiced over 4,000 years ago. Although Āyurveda, Indian traditional medicine, talks about brain surgery during ancient times, unequivocal evidence of trepanation has not been discovered.

According to Brothwell (1994) trepanation as a surgical operation was widely established in many ancient societies of the Americas, Europe, Africa, and Asia. He assigned a time bracket of 4,000–5,000 years ago. He observed similarities in the techniques of trepanation across all continents; this suggests the transfer of surgical skills from one society to another.

The author drew specific attention to a multi-trephined skull from the Neolithic pit-dwellers of Burzahom in the Kashmir Valley of the northwestern Himalayas, as a more authentic case in the subcontinent contemporaneous with the Indus Valley civilization.

[1] The sagittal plane is a vertical plane passing through the standing body from front to back. The midsagittal, or median, plane splits the body into left and right halves.

The Site and Its Age

Burzahom is located about 10 km northeast of Srinagar in the Kashmir Valley, on a terrace of Late Pleistocene–Holocene Karewa deposits. The site was excavated over six seasons between 1961 and 1968 and has yielded ten human skeletons of different cultural stages: Neolithic, Neolithic–Megalithic, and early historic cultures. The early phase I of the Neolithic at Burzahom has not yielded any human skeletons; C^{14} dating has yielded an earliest possible date of 4,375 ± 120 BP. The C^{14} dates by Agrawal and Kusumgar (1965) and Agrawal et al. (1966) suggest ca. 4300–2000 BP dates for the various burial sites. The Neolithic Phase II burials, including the trephined Burzahom skull, fall into the 4300–4000 BP time bracket. The Neolithic Phase II has yielded seven human skeletons in burials (Basu and Pal 1980) including the trephined skull (SKL 7, BZH-3), known here as the Burzahom skull. The remaining three skeletons belong in the later Neolithic–Megalithic cultural complex.

The burials of Burzahom are of a type called pit burials. The burial of the trephined Burzahom skull had animal bones, antler horn pieces, and a circular soapstone disc associated with it. The skeleton was in its primary articulation and in a crouching position, oriented NE–SW and was found at a depth of 7 ft 4 in. (2.24 m) from the surface level. The skull was reportedly covered with red ochre; the author, however, finds no trace of this. The trephined side of the skull was lying upward, facing the surface.

The seven skeletons of the Neolithic Phase II were excavated from different burials of varying depths, ranging from 3 ft 9 in. (1.15 m) to 10 ft 7 in. (3.22 m) from the surface. Four were in primary articulation and three in secondary articulation or partially articulated, nearly in NE–SW orientation, some with and some without grave furnishings. One burial contained an earthen pot, two had barrel-shaped carnelian beads, and one had a circular stone bowl. One burial of the Neolithic–Megalithic phase had a dog skull along with the human skeleton. Burying a dog with a human is said to have been a practice among early Chinese (Roy Chowdhury 1973).

Anthropological Analysis

Among the ten Burzahom skeletons, five are of adult males, three of adult females, one of a juvenile, and one of a child. The trephined Burzahom skull is of a female aged 26–30 years. All crania are markedly dolichocranic (having a relatively long head) with great calvarial (relating to the skullcap) heights and with cranial capacities ranging between 1,469 and 1,493 among adult males, and between 1,353 and 1,413 cc among adult females. Average stature is 169.6 cm. The dental condition of all skeletons is good.

The trephined Burzahom skull has a cranial volume of 1,353 cc. The cranium shows left-sided swelling or exaggeration. The forehead is low, slightly receding and with a distinct postglabellar (the space between the eyebrows) depression. The nose was long. The cranium is much more elongated. The face is very narrow with a medium height, and the skull has a look typical of a female. All the skeletons from this site represent a homogeneous population. Greater proximity is shown toward mature Harappans (excavated from Cemetery R37) and toward the modern Punjabi people of northwest India.

Trepanation and Surgical Operation

A trepanated skull was first noticed by Allchin and Allchin (1968), but it was first studied by Roy Chowdhury (1973). Basu and Pal (1980) studied the skeletal features and also commented on Roy Chowdhury's work by questioning the use of trepanation for medical purposes. Here I reexamine the original skull and the arguments and counterarguments.

Observations

The skull shows multiple trepanations. In all 11 attempts at trepanation are evident on the cranium. Barring a minor depression on the top of the right parietal,[2] all attempts are on the left parietal bone. Depending on the nature and depth of the depressions and holes, we have distinguished at least four successive attempts or stages/sittings in the trepanation of this cranium. There are six completed perforations, which represent the final stage of trepanation. All holes are nearly circular or oval in outline, ranging in maximum diameter from 5 to 14 mm. Trepanation was probably begun at the posteroinferior end of the left parietal and at the top of the right parietal. These depressions are very shallow and elongated where only the outer table of the bone has been removed, probably for the initial treatment of the patient. Then trepanation was attempted (probably in a second sitting) at sites nos. 9 and 10 where the depressions are deeper with the outer table of the bone removed into the diploic (the central layer of spongy, porous, bony tissue between the hard outer and inner bone layers of the cranium) space, leaving the inner table intact. The next attempt was made at site no. 8 where a much deeper depression was created. A hole was not probably intended since another minor stroke here would clearly puncture the skull. In the final attempt at actual trepanation, six holes were made, apparently in a triangular fashion, three on the inferior and three on the superior parietal region.

[2] Either of two large, irregularly quadrilateral bones between the frontal and occipital bones that together form the sides and top of the skull.

Probably nos. 2, 3, and 5 were made first, followed by nos. 1, 4, and 6. This sequence is speculative but may be deducted from the nature of the holes. The first three are very neatly and very carefully made and are almost of the same size and outline. The same instrument most likely made them and there are no fracture lines emanating from them. The holes nos. l, 4, and 6, on the other hand, are bigger and were most likely made with a different single instrument. It is probable that the later holes were created at the terminal stage, with less care and more force, even blows; the vault was fractured as is seen from the fracture line connecting the three.

No instruments that could have been used in trepanation were found at the Burzahom site. However, other flint and bone instruments (but no bronze instruments typical of the roughly contemporaneous Indus civilization to the south) have been recovered. It is likely that drills or sharp flint knifes of various diameters were used on the skull for cutting or drilling. It is an attractive but purely speculative thought that at least an Indus civilization surgeon could have performed some of the trepanation on this skull.

It seems that the whole series of operations was performed in quick successive stages of short duration. No clear evidence of healing of the bone (osteogenesis and sclerosis) is visible inside or outside the punctured holes. Roy Chowdhury, however, believed that there is evidence of a ring of sclerosis (callous) around one hole, unfortunately failing to specify the hole. Basu and Pal (1980) did not recognize any evidence of sclerosis and came to the extreme conclusion that it was not a surgical operation either performed while alive or after death. Bone healing or callous formation is expected in an *antemortem* operation if the patient survived for a sufficient time to allow the process of bone formation. But, as argued above, the patient probably did not survive the last traumatic operation. Alternatively, the ring of sclerosis, which Roy Chowdhury reported but of which we have found no trace, could have grown during a relatively brief period between operations and so be slight enough for its existence to become a matter of opinion. Positive evidence for a surgical operation may be taken if the left increase in size of the skull is interpreted as an anomaly or cranial disease. We need not necessarily accept the argument of Basu and Pal that such an anomaly is within the normal range of cranial variation. No similar case has been found in other Burzahom crania. If even the very existence of cranial disease cannot be established without doubt, it is still less likely to establish what symptoms the afflicted owner of the skull might have exhibited. As it is, we can only speculate that the Burzahom woman with the at least slightly abnormal skull may have been insane, epileptic or otherwise "different" and such people were regarded with awe and fear in most early societies. As it is, we simply do not know. This is unfortunate, as it would have allowed some general conclusions to be reached on the reasons for this and other trepanations.

Basu and Pal (1980) believe that trepanation at Burzahom was done with the sole purpose of taking out roundels for cranial amulets, to be used for ritual or other votive offerings or magico-religious practices. They draw this inference from parallels in Oceania (de Morgan 1924) and Michigan (Gillman 1882) and further argue that the left portion of the trepanated side of the skull was facing upward and that the skeleton was treated with red ochre. The present author contests these arguments. First, there is evidence of red ochre treatment in most of the Neolithic Phase II skeletons at Burzahom, not only of humans but also of animals. As Basu and Pal themselves note "a distinctive feature of the human burials of phase II was the use of red ochre on bones of both human and animals" (1980:3). Another relevant point is that the skeleton of the trephined Burzahom skull SKL7 was in primary articulation, i.e., not disturbed by any agency after burial. Why were six holes cut and five more left as depressions? Neither figure 6 nor 11 is known to have had any religious significance in the area, then or now. Not much care is needed for cutting roundels from the skull of a dead person nor have other trepanated crania been found at Burzahom. If roundels were desired, we would find deep cuts around the circumference of incomplete holes, which is not what we find in nos. 7–11. Finally, there is no evidence of prehistoric or contemporary tribal or nontribal people of northwest India or of India in general using cranial roundels as amulets or for other purposes.

The very carefully performed trepanation at Burzahom with the strong likelihood of several different stages/sittings on a possibly anomalous skull does, in the opinion of the present author, argue for a clear case of surgery performed for predominantly medical reasons on a living person who has not survived the procedure. It should be borne in mind, however, that most primitive societies regard disease as an invasion of spirits, which are usually, but not invariably thought to be evil. Also, medical and surgical procedures in such societies are so closely intertwined with belief, ritual, and magic that they cannot neatly be separated. Cases of mental illness, epilepsy, and others are also widely regarded as messengers of the gods with the afflicted often given a very special, even sacred, position in society. Trepanation in the case of the Burzahom skull and elsewhere could merely represent the surgical part of a much more elaborate medico-ritual ceremonial procedure of which only the trepanated skull has come down to us.

Tello (1929), a Peruvian archaeologist, remarked, "Trepanations were done for spiritual, magical reasons, including perhaps cases of mental illness, epilepsy, or headache." The skull of the long-suffering Burzahom woman may throw some light on the riddle of how the centers of prehistoric trepanation came to use such remarkably similar techniques and procedures despite the enormous gaps in space and time separating them.

Acknowledgments

The author thanks the Director, Anthropological Survey of India, Kolkata, for research facilities and to S. R. Walimbe, a paleopathologist at Deccan College, Poona (India), for useful discussions. G. H. J. Weber (Switzerland) prompted the author to carry out this work and made the literature available besides taking much pain to get the critical comments and helpful suggestions of Prof. Th. Böni of the Universitätsklinik Zurich, Switzerland and cand.med. B. Hunger.

Surveying

FRANK J. SWETZ

Surveying is the mathematical science that incorporates the application of geometric principles with concepts of measurement in order to delineate the forms, position, and extent of terrestrial features or man-made structures. It is an ancient activity that has been used by all urbanized societies. The establishment and maintenance of land boundaries, the construction of walls, and the lay out of irrigation systems and aqueducts rely on the use of some kind of surveying. Extent structures such as Stonehenge in England, the Great Wall of China, Machu Picchu in the Andes of Peru, the Great Pyramids of Giza, or the temples of Angkor in Cambodia testify to their builders' knowledge and use of surveying. However, all too often, in the ancient world, surveying activities were the closely guarded prerogative of an elite, members of a priestly or bureaucratic class. Knowledge of their mathematical discipline was usually transmitted orally from master to student. Such practices, combined with the ravishes of time, account for few existing documented records of old surveying practices and techniques. Therefore, much of what can be gleaned about surveying in early non-Western societies is speculative in nature and rests on extant archaeological and architectural evidence.

The most basic of surveying activities include the determination of straight horizontal and vertical lines and the establishment of a level plane upon which structures can be erected or reference slopes established. Instruments to achieve these goals are strikingly simple: straight horizontal lines can be obtained through the use of sighting poles or stakes and retained by the use of stretched cords or ropes; straight vertical lines are obtained by the use of a plumb bob, a weight suspended from a string, and a level plane can be constructed with the assistance of a leveling device such as a water-filled trench.

Rope Stretching

Herodotus (ca. 484–425 BCE), the Greek historian, attributed the origins of geometry to the Nile Valley of Egypt, where priest-surveyors stretched ropes to mark out land boundaries. These "rope-stretchers," or as Herodotus called them *harpedonaptae*, are the first historically recognized surveyors. Rope stretching activities also took place in Babylonia where ancient clay tablets mention the act of "stretching a field," that is using a rope to determine the dimensions of an agricultural field and denoting a particular individual as "the dragger of the rope," a surveyor. It appears that these early Egyptian and Babylonian land measuring activities were prompted by the need for royal levies. However, in the early Indus Valley civilization, rope stretching served another need. The *Śulbasūtras* (Rules of the Cord), compiled between the fifth to eighth centuries BCE, supply geometric prescriptions for the construction of ritual altars. These prescriptions were based on rope-stretching and were carried out by the Vedic priests. Later Pali literature makes mention of "rope holders" (surveyors) in reference to land measurements. In all early urbanized societies, rope stretching provided the basis for surveying.

Egypt

Surveying activities in Egypt certainly preceded the fifth century BCE observations of Herodotus. An inscription on the Palermo Stone dating from the Old Kingdom period of Egyptian history (ca. 3000 BCE) notes the existence of land surveys. Tomb inscriptions of about the same period mention the existence of land registry offices. A wall scene in the tomb of Menna at Thebes depicts surveyors at work. The scene shows two men measuring a field of corn with a long cord on which knots are marked at intervals of about 4 or 5 cubits. A standard measuring cord or rope of this period was 100 cubits (52.5 m) long. To obtain accurate vertical lines as well as to sight over long distances, Egyptian surveyors use the *merkhet*. This instrument also existed in Egypt from the earliest times; it consisted of a short plumb-line and plummet hanging from a holder that contained a sighting slit. Thus alignments could be made on distant objects. Merkhets were employed in the orientation of temples in a process called the "stretching of the measuring cord." Egyptian surveyors also employed two types of levels, the water level via a water filled trench which was suitable for large scale leveling, and the plumb-bob level erected with the aid of a wooden, right isosceles triangular frame work. Modern surveys have affirmed that the ancient Egyptians obtained very accurate results using their simple tools: the foundation for the Great Pyramid of Giza is almost perfectly level; boundary markers on the sides of the Nile River are aligned over long distances and a very accurate system of nilometers (flood gauges), were established along the Nile from its delta to the First Cataract, a marvelous feat of leveling.

Babylonia

Large scale construction projects existed in the Tigris-Euphrates region as early as 2300 BCE. The accomplishments of Gudea of Lagash, an engineer or architect of this time, is commemorated by statues which depict him holding a tablet containing scaled plans for a structure. These plans are superimposed on a rectangular grid. Both the use of scaling and a rectangular reference grid indicate the existence of a high level of surveying skill at this time. Further, extensive systems of irrigation channels relied on the establishment of adequate gradients or slope determined by leveling techniques. Fragments of Babylonian clay astrolabes dating back to the second millennium BCE have been found. With such instruments, observers of the time could determine angles of inclination; however, it is believed that these astrolabes were employed for astronomical sightings rather than terrestrial surveying.

Ancient India

Archaeological evidence from such sites as Mohenjo-Daro and Harappa, cities of the early Indus civilization (3500–2500 BCE) indicate that city planning principles were followed. Buildings were uniform in appearance, and roads were laid out at right angles to each other. The existence of sewerage systems as well as flowing aqueducts testify to a knowledge and use of leveling principles. Builders of the cities of Mohenjo-Daro and Harappa knew surveying. Linear measuring scales found at excavation sites in the region indicate the early Indus peoples employed a decimal system of measurement. This system was based on a "Mohenjo-Daro inch" of 0.67 cm. Further, at Lothal, the remains of a sighting instrument were found. The instrument consists of a hollow shell with four slits cut into its sides. These slits are situated at right angles to each other and allow for perpendicular sighting as would be necessary in surveying a rectangular road system. During the later *Śulbasūtra* period (800 BCE), bamboo poles, *saṇku*, were used for measuring and laying out circular regions, and a standardized chain or measuring rope, *rajju*, was employed. The *Śulbasūtra* texts describe an extensive mathematics supporting its rope stretching surveying techniques. Included in this mathematics was a theory of similar triangles.

While works of later Indian mathematical authors primarily concerned applications of mathematics to astronomy, some also included mathematical information for surveyors. Āryabhaṭa I (476–550) in his *Āryabhaṭiya* (ca. 499) discusses procedures for finding areas and volumes of plane figures and solids. Brahmagupta (ca. AD 628) in his *Brahmasphutasiddhānta* (Correct Astronomical System of Brahma) provides much information relevant to the needs of surveyors including specific computation procedures necessary for working with a shadow gnomon, a sighting staff employed for inclined sightings, thus incorporating a concept of angle into surveying activities.

China and the Far East

Early Chinese society was river based. Settling along the banks of the Yangtze and Hwang Ho rivers, the Chinese people harnessed and controlled the rivers by a system of dikes, canals, and irrigation channels. These construction projects required a knowledge and use of land surveying. Surveying was openly recognized as an important societal activity; folk hero Fu Xi and legendary emperor–engineer Yu the Great were often depicted holding surveying instruments.

Discussions and illustrations in extant texts and reference works provide some knowledge of the instruments used by early Chinese surveyors. Calibrated sighting poles, *biao*, were used in conjunction with sighting tubes, *wang tong*, or sighting boards, *ce shi pai*. A water level, *zhun*, was employed for leveling and a bamboo measure tape, *bu che*, devised for chaining land. A primary surveying instrument was the L-shaped set square or gnomon, *ju*. The earliest documented reference to surveying is found in the *Zhoubi Suanjing* (The Arithmetical Classic of the Gnomon and the Circular Paths of Heaven, ca. 100 BCE–AD 100) where in a fanciful conversation between Zhou Gong, a duke of the Zhou dynasty (ca. 1030–221 BCE) and the Grand Prefect Shang Gao, the duke advises the Prefect in the use of the set square. More substantial information on the mathematics of surveying is supplied in *Jiuzhang suanshu* (The Nine Chapters on the Mathematical Art, ca. 100 BCE). The work contains nine chapters on specific applications of mathematics. Chap. 1, "Field Measurements"; Chap. 5, "Construction Consultations" and Chap. 9 "*Gougu*"(right-triangle) are directly concerned with surveying computations (Fig. 1).

In AD 263, the scholar-official Liu Hui wrote a commentary on the *Jiuzhang* and revised much of its contents. He paid particular attention to the ninth chapter and extended its collection of problems to allow for more surveying situations which involved the obtaining of measurements to inaccessible points. Liu stressed a technique called *chong cha* (double difference) requiring two distinct sighting observations from separate locations. At the beginning of the Tang dynasty (AD 618–906), Liu's problems involving double differences were separated from the *Jiuzhang* and made into an independent mathematical work on

surveying, the *Haidao suanjing* (Sea Island Mathematical Manual). In AD 656, the Royal Academy established an official curriculum to be used for the training of state officials. The *Haidao* was included among the ten mathematical works to be studied. Later, this curriculum was adopted in Japan and Korea where the instructions of the *Haidao* provided the basis for surveying. One of the most accomplished feats of early Chinese surveying was begun in the year 724 when the State Astronomical Bureau of the Tang dynasty initiated the first meridian survey in the ancient world. Under the supervision of the scholar Yixing, 13 observation stations were established near the meridian 114°E and between latitudes 29°N to 52°N. Observations were taken over a period of several years. The expedition determined the angular attitude of the north celestial pole above the horizon and recorded the length of shadows at noon for the summer and winter solstices and equinoxes.

The *Haidao suanjing's* problems became the basis of later works which considered surveying computations. In 1247, the mathematician Qin Jiushao published *Shushu jiuzhang* (Mathematical Treatise in Nine Sections). Three of its nine chapters concerned survey applications: Chap. 4 was entitled "Surveying"; Chap. 7, "Architecture"; and Chap. 8, "Military Matters" which concerned the use of surveying techniques for observing an enemy from a distance. His contemporary, Yang Hui wrote *Tian mu bi lei cheng chu jie fa* (Practical Rules of Arithmetic for Surveying). Toward the end of the Ming dynasty, Western influence began to penetrate China. In 1582, the Italian Jesuit Matteo Ricci arrived in Macao and eventually made his way to Beijing where he used his mathematical and scientific knowledge to win favor with the court. Ricci collaborated with the scholar Xu Guangqi to publish *Celiang fayi* (Essentials of Surveying) (1607–1608). This book introduced contemporary European survey and land measurement methodology to China. Xu himself was a skilled surveyor and wrote an appendix to the *Essentials of Surveying*. It appeared in 1608 under the title *Celiang i tung* (Similarities and Differences [Between Chinese and European] Surveying Techniques). From this period onward, surveying in China combined both European and traditional theories and practices.

The Islamic World

Islam did not emerge as an intellectual and political force until about AD 726 with the establishment of the ʿAbbasid Caliphate. From their capital in Baghdad, the early ʿAbbasid caliphs patroned the collection of scientific works and used this acquired knowledge to consolidate their religious and political empire. Their era was marked by the building of new canals, bridges and aqueducts and by the reconstruction of old Babylonian irrigation systems. Surveying was used in this work. While Muslims became the heirs of

Babylonian, Egyptian and Greek surveying theory, they soon became accomplished practitioners and innovators in their own right. Religious prescriptions required daily prayers toward Mecca; in turn, mosques had to be constructed facing Mecca. Thus determining the *qibla*, or direction of Mecca from a given location, became an important task for surveyors.

Muslim surveyors used several methods of leveling: the plumb-bob level was employed as well as leveling poles. Al-Khāzinī (ca. 840) and Ibn-al-ʿAwwām wrote on the use of leveling poles. The latter wrote a handbook for farmers that included the layout of fields. Right angles were laid out with the use of an L-shaped square, *kunija*. Abu'l Wafā (940–998) wrote about the use of such a square. The most complete early Muslim treatise on surveying was written by Muḥammad ibn al-Hassan al-Hasib al-Karajī (ca. 1000). It was entitled *Kitāb al ʿuqūd wa'l abniyah* (Of Vaults and Building). Al-Karajī discussed both the mathematical and practical aspects of surveying and provided specific instructions for the surveying of tunnels and underground aqueducts, *qanat*. Later writer Abū Saqr al-Qabisi introduced trigonometric methods into surveying computations.

The one area of surveying in which Muslim scientists and craftsman excelled was the design and utilization of measuring instruments. Their knowledge of the astrolabe was obtained from the works of Ptolemy. The first noted Muslim maker of astrolabes was al-Fazārī (d. ca. 777) who worked under the patronage of al-Mansur. By the end of the eighth century a number of scholars were producing works on the construction and use of the astrolabe. The most famous of these scholars was Māshā'allāh (762–ca. 815), a Jew who worked under Islamic patronage. His *Kitāb sana ʿat al-asturlāb wa l-ʿanal bihā* (Book of the Construction of an Astrolabe and Its Use) became the authoritative reference of its time. At a later date (ca. 1380), Chaucer used Māshā 'allāh's theories in his European introduction of the astrolabe as a scientific instrument. It was Muslim efforts that resulted in the astrolabe becoming a valued instrument in land surveying activities. Similarly, the Jacob's staff, a popular medieval instrument for determining planar angles, is believed to have reached Europe via Muslim sources and may have had its origins in navigational methods used by early Muslim traders. The oldest actual description of this instrument comes from a navigator's manual, the *Mohit*, written by Sidi al-Chelebri, captain of the Turkish fleet under Sultan Suleimann in 1554.

Pre-Columbian America

Although no written records exist to document the surveying knowledge of early native American civilizations, archaeological sites testify to these peoples' application and understanding of surveying techniques and principles. The city planning and construction carried out by the Olmec, Maya, Teotihuacan, Toltec, and Aztec peoples of South and Central America indicate that they undertook some surveying activities. For example, the Aztec capital of Tenochtitlan was laid out according to a grid system. It contained markets, palaces and streets and canals and held a population of approximately 200,000 people in the year 1521. Temples and ball courts were oriented to the four cardinal directions. Aqueducts brought fresh water into the city from many miles distant. Some of the Aztec surveying instruments are known by name; plumb line, *temetzlepilolli*; the water level, *atezcath*; set square, *tlanacazanimi*; measuring scale, *tlahuahuanoloni* and the construction compass, *tlayolloanaloni*.

Surveying in Egypt

Hans Barnard

The English verb "to survey" refers to a variety of activities, two of which will be discussed here with an emphasis on the way in which these were practiced in Ancient Egypt. The first can be provisionally defined as the techniques to reduce reality to fit onto a map or a model, the second as the techniques to transfer the information and ideas reflected on a plan or a model to the real world. Up until very recently a surveyor would go into the field with two instruments, one to measure angles, such as a transit or a theodolite; and one to measure distances, such as a measuring tape or an electronic distance-measuring device (EDM). Modern technology has combined these two instruments into one, therefore referred to as a "total station," which can perform both functions. The underlying principles of surveying, and the fact that these are based on the accurate measurement of angles and distances, were already mostly understood in Ancient Egypt. It must be kept in mind that the Ancient Egyptian civilization lasted for more than 3,000 years and did change slowly but continuously. The technology and methodology of surveying will have been different during the various periods of Egyptian history (Table 1). From the available evidence it is not possible to determine an exact chronology of the discipline of surveying in Ancient Egypt and the following discussion will be thematic rather than sequential.

This evidence comprises a number of tools used for surveying, several plans and maps, inferences from marks and modern measurements in extant structures and a few surviving texts on the subject. The Moscow (or Golenischev) Mathematical Papyrus, probably written during the eleventh Dynasty (unknown provenance, now in the Pushkin State Museum of Fine Arts in Moscow), discusses a series of problems of the area and volume of complex shapes, including a curved surface (problem 10) and a truncated pyramid (problem 14). The Rhind (or Ahmes) Mathematical Papyrus, written around 1550 BCE but claiming to be a copy of a twelfth Dynasty text (found in Luxor, now in the British Museum in London) deals with a series of problems of area and volume, including the area of a triangle (problems 4 and 51), a rectangle (problems 6 and 49) and a circle (problems 38 and 50) as well as the volume of a cylinder (problems 41 and 43).

Surveying would have been needed in Ancient Egypt, from the Old Kingdom onward, for at least two important applications. First was the construction of the famous tombs, temples and pyramids, some of which still stand today and testify to the accuracy of the measurements. Second, and with a larger impact on daily life, were the measurements to restore the outlines of the agricultural fields after the yearly inundation of the Nile in July and August. The maximum height of the inundation, measured in Nilometers at several places, differed from year to year and with that the area of arable land. The available land needed to be redistributed each year and taxes were levied accordingly. This can be illustrated by the following remarks of the Greek historian Herodotus, who traveled through Egypt in the fifth century BCE.

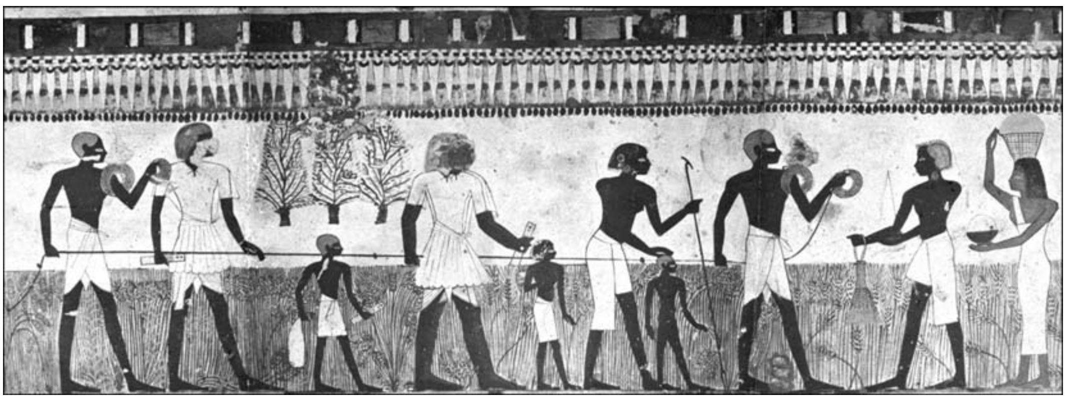
> The King would send men to inspect and measure the loss of cultivated land in order that from then on some of the tax, proportionate to the report of the loss, might be remitted. I attribute the invention of geometry to this cause and from Egypt it spread to Greece (Herodotus, *History 2.109*, translation Shore 1987: 125).

Measuring distances in Ancient Egypt was done in the same way as it is still done today: by comparing an unknown with a known distance indicated on a tape measure or a ruler. Several ancient measuring rods have been preserved, most of them dating to the New Kingdom or later. Two were found in the tomb of Kha, the architect of the Pharaoh Amenhotep II (eighteenth Dynasty), in Deir al-Medina (near Luxor) and are now kept by the Museo Egizio in Turin. One was gilded and probably a gift not meant for daily use; the other is hinged and was most likely used by its owner during his work (Arnold 1991). Longer distances were measured with a rope that had knots at regular distances, an activity known as "stretching the cord" (Shore 1987). This rope, reminiscent of "Gunter's chain" used by 17th–19th century surveyors, is often depicted ending in the ram's head of the god Khnum, indicating the importance attached to the measurements and their accuracy. A depiction of land surveyors in action can be found on the top register of wall 5 in the tomb of Menna,

S

Surveying in Egypt. Table 1 The chronology of Ancient Egyptian civilization following Baines and Malek (2000: 36–37)

Period	Dynasties	Date
Early Dynastic Period	1st–3rd Dynasties	2950–2575 BCE
Old Kingdom	4th–8th Dynasties	2575–2150 BCE
First Intermediate Period	9th–11th Dynasties	2125–1975 BCE
Middle Kingdom	11th–14th Dynasties	1975–1640 BCE
Second Intermediate Period	15th–17th Dynasties	1630–1520 BCE
New Kingdom	18th–20th Dynasties	1539–1075 BCE
Third Intermediate Period	21st–25th Dynasties	1075–715 BCE
Late Period	25th–30th Dynasties	715–332 BCE
Greco-Roman Period	Macedonian and Roman rulers	332 BCE–395 CE



Surveying in Egypt. Fig. 1 Fragment of the top register of wall 5 of the 18th Dynasty tomb of Menna, showing land surveyors in action (photograph by Robert L. Mond and Ernest J. Mackay, 1914–1916, used with the kind permission of the Griffith Institute, Oxford, UK).

an administrator who lived during the reign of Pharaoh Tuthmosis IV or that of his successor Amenophis III (eighteenth Dynasty) (Fig. 1).

No single Ancient Egyptian unit of length can be given, as this not only varied over time, but also by purpose and place. Several systems existed simultaneously, as they did in Europe until very recently (the "Convention of the Metre" was signed in 1875 and the "International System of Units" in 1954 but neither are implemented, or even adopted, by all countries). The basis for the Ancient Egyptian unit of length was the cubit, the length from the elbow to the tip of the middle finger (Arnold 1991; Gillings 1982; Skinner 1954). A cubit was divided into seven "palms" and 28 "fingers" (one palm being four fingers). Two cubits seem to have been in use, the "royal cubit" and the "short cubit"; the former was most often about 524 mm (20.6 in.), the latter 449 mm (17.7 in.). A finger was therefore either approximately 19 mm (0.74 in.), when taken from the royal cubit, or approximately 16 mm (0.63 in.), when taken from the short cubit (Gillings 1982). It is possible that at times the short cubit was divided into only six palms, and 24 fingers (Skinner 1954). The royal cubit would then be close to one short cubit plus four fingers (one palm) long. A hundred cubits, 52.4 m (171.9 ft) in length, was called a *hayt*, a *khet* or, in the Greco-Roman period, a *schoenia*. An area of 100 × 100 cubits (a square hayr, khet or schoenia) was called a *setat* or, in the Greco-Roman period, an *arura*.

A remarkable additional unit was the *remen*, defined as half the diameter of a square with sides of one royal cubit in length. The length of this diameter is $\sqrt{2}$ cubits, which can not be written as the sum of reciprocal fractions (such as $\sqrt{2} = 1 + 1/3 + 1/13$), the notation system used in Ancient Egypt, but only as an unending decimal fraction (like $\sqrt{2} = 1.41421\ldots$). A remen would be about 371 mm (14.6 in.) or, by coincidence, almost exactly 19.5 fingers (Table 2). The advantage of the remen was that it allowed areas of land to be halved, or doubled, while preserving the proportions simply by changing the unit. A square with sides of a cubit, for instance, has twice the area of a square with sides of a remen and half the area of a square with sides of two remen (a "double-remen"). To calculate the area of a

Surveying in Egypt. Table 2 Overview of the most important ancient egyptian units of length

	Fingers	Cubits	mm	Square (cubits^2)	Square (mm^2)
Remen	19.5	$1/2 \times \sqrt{2}$	371	1/2	137,288
Cubit	28	1	524	1	274,576
Double-remen	39	$\sqrt{2}$	741	2	549,152

circle π (pi) was approximated as $(2 \times (1 - 1/9))^2 = 16^2/9^2 = 256/81$, which equals 3.16049... (whereas the correct value of $\pi = 3.14159...$).

Less is known about how angles, the second basic element of surveying, were understood in Ancient Egypt. There is ample evidence of the use of plumb bobs, often combined with a set-square or another device that could have served as a sight, which essentially create a 0° angle with the vertical (and a 90° angle with the horizontal). Some of these instruments were apparently used to establish levels (Arnold 1991; Lehner 1997). Marks representing different elevations are preserved in several structures amongst which are the fourth Dynasty Mastabet al-Fara'un, the burial complex of Pharaoh Shepseskaf, in Sakkara (near Cairo), the fifth Dynasty pyramid of Niuserra in Abusir (near Cairo) and the eleventh Dynasty temple of Mentuhotep in Deir al-Bahri (near Luxor). It has been suggested that water in channels cut for this purpose was used to create a level plain (Edwards 1993), which can be considered a 0° angle with the horizontal (and a 90° angle with the vertical).

It is unclear how a right angle on a given base line, essential for many surveying tasks, was constructed. There is no evidence that the special case of the theorem of Pythagoras, which proves that a triangle with sides of 3, 4 and 5 units will have one right angle, was employed (Gillings 1982). Over short distances a right angle could have been constructed by sighting over a set-square (Arnold 1991; Edwards 1993). The accuracy of this method could be improved by several techniques, but probably not sufficiently to account for the results evident from the surviving structures. Another way to construct a right angle is by establishing two large equilateral triangles with one side, and two corners, in common. The diagonals of the resulting rhomboid, one of which would correspond with the base line, will be at a right angle (Arnold 1991). What techniques were used to achieve the observed level of accuracy with the tools available at the time remains enigmatic, but the ancient surveyors could draw on generations of experience with the layout of agricultural fields and canals.

There is some archaeological and textual evidence about angles other than 0° and 90°, relating to the inclination of pyramids, pylons and the walls of buildings. This includes a set of preserved marks in the foundation trenches of Old Kingdom mastaba number 17 in Maidum (Arnold 1991) and problems 56–60 of Rhind Mathematical Papyrus (Gillings 1982). The angle of the face of a structure was described using the *seqet*, which can be defined as the length of the setback of the building from the vertical at a height of one cubit or, in modern terms, as the cotangent of the angle of the wall with the horizontal (Gillings 1982). A vertical wall has a seqet of zero and a wall with an inclination of 45° has a seqet of one cubit. The Great Pyramid in Giza, built by Pharaoh Khufu (Cheops) of the fourth Dynasty, rises at an angle of 51°52′ with the horizon and consequently has a seqet of 0.79 cubit (about five palms, two fingers). The measurements by the ancient surveyors were sometimes transferred to the structures under construction by elaborate means, such as the mud-brick walls under the outer court of the twelfth Dynasty pyramid of Senwosret in Lisht, believed to indicate the desired level to which the court had to be built up, or the lines of rock-cut postholes surrounding the Great Pyramid (Arnold 1991).

Measurements were not only needed to ensure a practical and secure structure, but often also to make it correspond to religious beliefs or cultic necessities. Despite a dearth of concrete information, the latter has become subject of much speculation. Many proportions of structures and angles of shafts are assumed to have had a special meaning, but these are rarely fully understood. The orientation of the pyramids according to the cardinal points is generally thought to have been motivated by stellar elements in the Ancient Egyptian religion. This orientation was most likely achieved by astro-surveying, performed by priests rather than surveyors. One instrument that was probably used for this is the *bay*, part of a palm rib with a slit at its base through which stars, or the sun, could be observed. A bay was used in combination with a merkhet, which doubled as a plumb bob and a sundial. A set of these instruments (now in the Staatliche Museum Charlottenburg in Berlin, found in Abydos?) once belonged to Hor, a priest of the twenty-sixth Dynasty. According to the inscription on the merkhet it "... knows the motion of the two discs (sun and moon) and every star..." (translation Wells 1999: 37). An inscription on the bay indicates that it is "... for indicating the commencement of a feast..." (translation Wells 1999: 37). With these relatively simple instruments it is possible to observe, through the slit in the bay, the passing of a star across a vertical line, established by the plumb bob attached to the merkhet. In the day, the bay would cast a shadow that could be aligned rather accurately because of the slit in the top. Either could be used to find true North, for instance by bisecting the angle of the rising and setting of a celestial body over a horizontal plane (Edwards 1993; Lehner 1997), or by observing the alignment of a pair of selected stars (Spence 2000). Surveyors would then again be needed to transfer the observations to the actual building under construction.

Celestial observation were also used for the first known attempt to calculate the circumference of the earth, by Eratosthenes during the reign of Ptolemy III Euergetes (246–221 BCE). Eratosthenes was born in Cyrene (Libya) and brought to Egypt as a tutor for the son of Ptolemy III and a librarian of the library of Alexandria (with about 500,000 'books'). Alexandria was the capital of Egypt during the Greco-Roman period and, at the time, the most powerful and influential city in the region. Thanks to the patronage of the Ptolemaic rulers and the renowned library, scholarly and scientific knowledge advanced greatly. Basing his calculations on the difference, on the same day, in the height of the sun in Alexandria and in Aswan, Eratosthenes came surprisingly close to the actual figure (Berthon and Robinson 1991).

Sūryasiddhānta

K. V. Sarma

The *Sūryasiddhānta* is a complete work on Hindu astronomy and is more popular and widely studied in North India than in the South. In order to enhance its prestige and antiquity, it is stated in the text itself (1.29) that it had been communicated by a representative of the God Sun to Maya, several thousand years ago. However, both internal and external evidence show that the work was composed between AD 600 and 1000. In about 500 verses, distributed through 14 chapters, the work deals with all aspects of Hindu astronomy, and also cosmology, geography, astronomical instruments, and time-reckoning. It follows the midnight day-reckoning.

The contents of the work are comprehensive. Chapter I speaks about the circumstances that led to the composition of the work, the aeons and aeonary revolutions of the planets, the principles underlying the computation of the planets and the nodes, the position of the planets at the beginning of the current aeon, the Prime meridian and local time, and the inclination of the orbits of the planets. The time units given in the work are more in conformity with the *Purāṇas* than with other texts on Hindu astronomy. Chapter II deals with the computation of the true motion and the true longitudes of the planets. Chapter III is devoted to the determination of the directions, place and time, and also the calculation of the precession of the equinoxes. It is noteworthy that the *Sūryasiddhānta* is the earliest available Indian text which contains a discussion of the calculation of the precession of the equinoxes. Chapters IV and V deal in detail with lunar and solar eclipses and their computation. Chapters VII and VIII are concerned with the conjunction of one planet with another, and a planet with a star, including their observation. Chapter IX deals with the determination of the heliacal rising of the planets and Chap. X with the phases of the moon. Chapter XI is concerned with the phenomenon of *pāta*. Cosmology and geography of the worlds and of the earth occur in Chap. XII. The construction of the armillary sphere and its working, and a mention of the main astronomical instruments form the subject matter of Chap. XIII. Chapter XIV enumerates and defines nine types of reckoning time, such as lunar, solar, siderial, tropical, etc.

The *Sūryasiddhānta* is indebted to earlier astronomers like Āryabhaṭa (b. 476) and Brahmagupta (b. 598) in certain matters like the inclination of the planetary orbits, the tabular Sines, etc. It is also to be noted that the *Sūryasiddhānta* does not include chapters on arithmetic, algebra, or astronomical problems, which are generally included in texts of this type.

The popularity of the *Sūryasiddhānta* is clear from the very large number of manuscripts of the work found throughout the land. About 35 commentaries on the work, written by scholars from different regions of India, and about 20 works, including planetary tables and manuals, based in the *Sūryasiddhānta*, have been identified. The popularity of the work is also reflected by the number of almanacs prepared on the basis of the *Sūryasiddhānta*.

Suśruta

Guy Mazars

Suśruta is not the original author of the medical 'Compendium' which bears his name, the *Suśrutasaṃhitā*, which constitutes the major source of information about ancient Indian surgery. The treatise is supposed to contain the teaching of the god Dhanvantari, who was incarnated as Divodāsa, a king of Benares. Therefore it is not the personal work of Suśruta who had only recorded an already constituted medical tradition. The date of its redaction is not known. The basic text is supposed to have been revised and enlarged by an author called Nāgārjuna, which adds to the confusion, since there are several people named Nāgārjuna in Indian literary history. It is possible that the attribution of this name to the reviser of the text is but an echo of the legend which had the great Buddhist philosopher Nāgārjuna (first to second centuries AD) as a physician and alchemist. In any case, the teaching of Suśruta must already have been fixed at the time of the *Carakasaṃhitā* which refers moreover to the disciples of Suśruta for surgical treatment. The 'Suśruta's Compendium' was the object of very elaborate commentaries whose purpose was to clarify and add precision to the contents. The principal commentaries of the *Suśrutasaṃhitā* are those of Jejjaṭa (before the ninth century), Gayadāsa (eleventh century) and especially that of Ḍalhaṇa (eleventh to twelfth centuries) entitled *Nibandhasaṃgraha*.

In its present form the *Suśrutasaṃhitā* consists of 186 chapters which are divided into six large sections (*sthāna*):

1. Forty-six chapters in the *Sūtra* section deal with general questions such as medical training, diet or surgery.
2. Sixteen chapters in the *Nidāna* section deal with the diagnosis and prognosis of important ailments.
3. Ten chapters in the *Śārīra* section deal with the creation of the universe, embryology and anatomy.
4. Forty chapters in the *Cikitsā* section deal with therapy.
5. Eight chapters in the *Kalpa* section deal with poisons.
6. Sixty-six chapters in the *Uttara* section deal with diseases of the eye, ear, nose, and throat, paediatrics, seizures by evil spirits, dentistry and internal diseases in general.

The *Suśrutasaṃhitā* describes surgical operations which reveal the skill and the daring of the surgeons of that period: the lowering of cataracts with a needle, grafts for repairing the nose and the earlobe, procedures for the removal of stones in the urinary tract, resections of scrotal elephantiasis, Caesarean sections and surgical removal of a dead foetus from the womb.

Swidden

Karl H. Schwerin

Swidden, also known as "slash and burn," "long fallow," and *roça* in Brazil, is a system of agriculture that involves clearing small areas within a forest, burning the slash (Figs. 1–4), and planting for 1–5 years (Figs. 5 and 6). The plot is then abandoned for 25–200 years – long enough for the forest to reclaim the cleared area. In contemporary Latin America this system may support as many as 50 million people.

In spite of the labor involved in clearing the forest, it is less than that required in clearing brush or turning under grass sod. This explains why fields are abandoned until the forest has regrown. In the tropics most nutrient and organic matter is locked up in the plants and trees, rather than in the soil. Thus, ash from the burned slash also frees nutrients for the crops.

A typical swidden planting mimics the diversity of the forest, with a variety of crops interspersed among each other, or planted in closely spaced zones within the field. In the Amazon–Orinoco drainages one may encounter 10–15 crops being grown together (Fig. 7). Once crops are planted, they require only one or two weedings before harvest (Fig. 8). In the tropics, harvest can extend over many months; just enough is taken from the field to provide for a few days or a week at a time. In a sense, then, the crop is stored in the field, rather than in a storehouse (Figs. 9–11). The labor required in swidden is minimal, averaging 2–4 h a day (though perhaps concentrated into 5 or 6 h two or three times a week).

Swidden crops are often limited to starchy staples, vegetables, and fruits, producing little protein. Thus subsistence is typically supplemented by fishing and/or hunting. Only in Mesoamerica, where beans are important, is the need for supplementary animal protein reduced somewhat.

Swidden agriculture is often characterized as unproductive and destructive of soil fertility. In fact, during the first 1–3 years it is generally more productive than most permanent fields. The ash provides ready nutrients and there is little competition with other plants. The return on labor investment is even more rewarding.

After a few years productivity typically declines. Traditionally this was blamed on exhaustion of the soil. Extensive research indicates that this is due not so much to declining soil fertility, as to invasion by weeds and grasses which compete with crops for space and

nutrients. A further motivation for abandonment is that this tangled growth becomes a magnet for vermin, insects, and disease. Thus the farmer logically seeks out a new spot in virgin forest to clear another plot free of problems (Fig. 12).

Contrary to popular belief, this does not necessitate periodic village movement. Robert Carneiro has shown that 500 people practicing swidden agriculture could subsist permanently on 6,000 acres located within a 3-mile radius of their village. Other explanations based on social, political, or religious factors must be sought for the practice of moving villages.

There is much debate about the “backward” and “deleterious” effects of swidden agriculture. When practiced by a sparse, widely dispersed population, it does not seem to harm the ecosystem, and may in fact prove beneficial by opening up the forest canopy and stimulating new growth. Some ecologists believe that the equilibrium state under aboriginal conditions was grounded on periodic swidden clearing. On the other hand, when population growth intensifies clearing to a point where the forest can no longer regenerate itself, the result will be widespread environmental degradation. Throughout Latin America recent programs of development have led to widespread deforestation, replacement of swidden agriculture with more extensive systems such as livestock pasturing or machine cultivation, and resulting ecological degradation.

Takebe Katahiro

JOCHI SHIGERU

Takebe Katahiro was born in 1664 at Edo (now Tokyo). His father, Takebe Naotsune, was a *Yuhitsu* (secretary) of the Shogun. In 1676, when he was 13 years old, he and his elder brother Takebe Kataaki (1661–1716) became pupils of SEKI Kowa (d. 1708) and studied mathematics. The Takebe brothers and Seki Kowa were colleagues in the Shogun's government, and their families were the same rank: 300 *koku*.[1]

Takebe's mathematical works are in three fields. One concerns completing the *tenzan-jutsu* or *endan-jutsu* (lit. addition and subtraction methods, Japanese algebra system), which was created by Seki Kowa. In the second work Takebe created the *tetsu-jutsu* (inductive methods). Using these methods he obtained the formula of $(\arcsin\theta)^2$. In the third, for computing the approximate value of fractions, he solved the Diophanine equations using the *reiyaku-jutsu* (continual division method). Takebe also worked in astronomy and geography.

In 1683, Takebe wrote his first work, *Kenki Sampo* (Studies for Mathematical Methods). The book provided counter-arguments for Saji Ippei's *Sampo Nyumon* (Introduction to Mathematical Methods, 1680). Saji had criticized Seki Kowa's *tenzan-jutsu* system in the *Hatsubi Sampo* (Mathematical Methods for Finding Details, 1674) and solved Ikeda Masoki's problems in the *Sugaku Jojo Orai* (Textbook of Mathematical Multiplication and Division, 1672). Takebe made good use of the *tenzan-jutsu* method for solving Ikeda's remainder problems.

Takebe commented on Seki Kowa's *Hatsubi Sampo* and published the *Sampo Endan Genkai* (Commentaries for Japanese Algebra System), in 1685. This is one of the best books for studying the *tenzan-jutsu* method.

Chinese mathematicians in the Song and Yuan dynasties used counting rods to solve higher degree equations of more than the fourth degree. There were two color symbols in the counting rods: red rods were plus and black were minus. They had no symbols to express power; the position of the rods on the counting board indicated the powers. Therefore, the system could not indicate complex expressions. For example, $1/(x-1)$, that is $(x-1)^{-1}$, was very difficult to indicate by that system. Seki Kowa abandoned the counting rods system and created algebraic symbols, which used Chinese characters for calculation with figures. This might be the first example of creating Japanese mathematics from the Chinese.

Takebe commented on the most important Chinese algebraic text in Japan at that time, *Suanxue Qimeng* (Introduction to Mathematical Studies, Zhu Shijie, 1299). He published the *Sangaku Keimo Genkai Taisei* (Complete Works of Commentaries on Suan Xue Qi Meng) in 1690. Seki Kowa and the Takebe brothers started to compile an edition of the mathematical works of *Seki-ryu*, Seki Kowa's school. After Seki died, Takebe Katashiro continued this work and published *Taisei Sankyo* (Complete Mathematical Manual) about 1710.

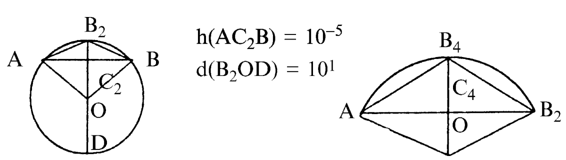
Takebe's main work is the *tetsu-jutsu* method, a sort of inductive method. He computed small natural numbers and then predicted infinite numbers. The computation was helped by the algebraic symbols of the *tenzan-jutsu* method. Using these methods, Takebe obtained the formula of $(\arcsin\theta)^2$. He computed the length of curve AB (hereafter s) using the diameter d and the length of straight line AB (h).

Takebe set up $d = 10$ and $h = 10^{-5}$. Then letting the half point of straight line AB be C_2, and the half point of curve AB be B_2, he computed the length of AB_2 (h_2). Then he computed the length of AB_4 as h_4, and continued to compute h_8, h_{16}, h_{32} and h_{64}. Takebe computed h_∞ using a sort of infinity series *zoyaku-jutsu* (extra division method), and obtained h_∞.

$$\left(\frac{s}{2}\right)^2 = 10^{-4} \times 1.000\,000\,333\,333\,411\,111\,225\,396\,906\,666\,728\,234\,776\,947\,959\,587\ldots$$

$$h(AC_2B) = 10^{-5},$$

$$d(B_2OD) = 10^1.$$



[1] His annual salary was 300 *pyo* (1 pyo was 60 kgs of rice), which is the same as a landlord of 300 person village.

Second, he indicated this value using h and d. The power 10^{-4} is h by d, and the approximate value of the coefficient is 1. Therefore,

$$\left(\frac{s}{2}\right)^2 = 1hd + 10^{-10} \times 0.333\,333\,511\,111\ldots.$$

Then he used the same method. The power 10^{-10} is h^2, and the approximate value of the coefficient is 1/3 using the *reiyaku-jutsu* method,

$$\left(\frac{s}{2}\right)^2 = 1hd + \frac{1}{3h^2} + 10^{-16} \times 0.177\,777\,992\ldots.$$

Takebe continued to compute as above, and he set the series as

$$\left(\frac{s}{2}\right)^2 = A_0 + A_1 + A_2 + A_3 + A_4 + \cdots.$$

He obtained

$$A_0 = hd, \quad \frac{A_1}{A_0} = a_1\left(\frac{h}{d}\right),$$
$$\frac{A_2}{A_1} = a_2\left(\frac{h}{d}\right), \quad \frac{A_3}{A_2} = a_3\left(\frac{h}{d}\right), \ldots$$
$$a_1 = \frac{1}{3}, \quad a_2 = \frac{8}{15}, \quad a_3 = \frac{9}{14}, \quad a_4 \frac{32}{45}, \ldots$$

He expanded them to the general series of a_n, which was

$$A_n = \frac{2n^2}{(n+1)(n+2)}.$$

Therefore Takebe obtained the formula

$$\left(\frac{s}{d}\right)^2 = 2\sum_{n=0}^{\infty}\left(\frac{(n! \times 2^n)^2}{(2n+2)!} \times \frac{h^{n+1}}{d^{n-1}}\right).$$

Takebe had no notion of triangle functions. However, if we set

$$\theta = \sqrt{\frac{h}{d}},$$

we can obtain arcsin $\theta = s/(2d)$. Therefore, his formula has the same value as the formula

$$(\arcsin\theta)^2 = 2\sum_{n=0}^{\infty}\frac{(n! \times 2^n)^2}{(2n+2)!} \times \theta^{2n+2}.$$

This work was described in the *Fukyu Tetsu-jutsu* (Inductive Methods) in 1722, and the special manuscript was sent to to Shogun in 1730.

The key method of *tetsu-jutsu* was computing the approximate value of decimal fractions. He named it the *reiyaku-jutsu*, which used the Euclidean algorithm to compute the value of continuing fractions. For example, to try to compute the approximative value of π using this method, we set;

$$\pi_n = 3.1415926, \quad \text{or} \quad 3 + \frac{1,415,926}{10,000,000}.$$

First, divide 10,000,000 by 1,415,926; the quotient q_1 is 7 and the remainder r_1 is 88,518. Next, divide the former divisor 1,415,926 by the remainder r_1; the quotient of q_2 is 15 and the remainder r_2 is 88,156. Next, divide the former divisor r_1 by the newer remainder r_2, and the quotient q_3 is 1 and the remainder r_3 is 362. Continuing this algorithm, the quotients are:

$\{q_1, q_2, q_3,\ldots, q_n\} = \{7, 15, 1, 243, 1, 1, 9, 1, 1, 4\}$,

$p_1 = 3 + 1/7 - 22/7 > \pi_n$,

$p_2 = 3 + 1/(7 + 1/15) = 333/106 < \pi_n$,

$p_3 = 3 + 1/(7 + 1/(15 + 1/1)) = 355/113 > \pi_n$.

$p_{2k} = q_0 + 1/(q_1 + 1/(q_2 + 1/q_3 + 1/(q_4 + + 1/q_{2n} + 1))) < \pi_n$,

$p_{2k+1} = q_0 + 1/(q_1 + 1/q_2 + 1/(q_3 + 1/(q_4 + + 1/q_{2n} + 1))) > \pi_n$.

The value of p_1 and p_2 had already been computed by the Chinese mathematician, Zu Chongzhi (429–500). Takebe concluded that Zu Chongzhi also invented the same method as his own *reiyaku-jutsu* and Zu Chongzhi's significant figures were seven decimal places, the same as the above computation. He admired Zu Chongzhi and named his book *Fukyu Tetsu-jutsu*; the title was connected with Zu Chongzhi's *Zhui Shu*.

In 1723, Takebe made a map of Japan under the order of Tokugawa Yoshimune, the eighth Shogun, this map is now lost. That year Takebe became a *Yoriai* (adviser) of the Shogun.

Shogun Yoshimune already permitted the import of foreign scientific books in 1720, if they were not related to missionaries. Knowledge of Western astronomy was imported in some Chinese translations. Takebe and his student, Nakane Genkei (1662–1733) translated Mei Juecheng's *Li Suan Quan Shu* (Complete Works of Calendar and Mathematics, 1723) and sent the manuscript (Japanese name *Rekisan Zensho*) to Yoshimune in 1733. It was published and read by many Japanese scholars. Kepler's newest opinion, the elliptical orbit of planets, however, was hidden by the missionaries who advised Mei Juecheng. It became known to the Japanese after Asada Goryu (1734–1799) translated Kepler's (Part 2 of) *Li Suan Quan Shu*.

Takebe was held in honor by Yoshimune, and he became a *Hoi* (Knight), and held successively better positions. In 1733, he retired, and he received a life annuity of 300 *pyo*. He died on July 20, 1739 (August 24, 1739 in the present calendar) at Edo.

Takebe was one of the best mathematicians in Japan. The Mathematical Society of Japan has presented the Takebe Katahiro Prize since 1996.

Tang Shenwei

HONG WULI

Tang Shenwei was a medical practitioner of the eleventh century. He was a native of Chongqing, Sichuan Province with the surname Shenyuan, and later he moved to Chengdu in the same province. He was born to a family of many generations of physicians and was an expert in medical science. During the Yuanyou period (1086–1094) of the Song Dynasty, his tutor was Li Duanbo. Tang inherited his tutor's medical knowledge and became quite adept at treatment. He was very virtuous, also he responded to any patient's call and never refused to see a patient, whether rich or poor. The only payment he asked was knowledge about a certain herb or an effective recipe (Tang 1957).

He was especially conversant in the herbal art. He compiled a 32-volume *Materia Medica of Classified Syndromes* which was based on the combination of two other existing herbological works, the *Jia you ben cao* (*Jiayou Materia Medica*) and *Tu jing ben cao* (*Illustrated Classic of Materia Medica*). He added a large amount of new material extracted from the classics of philosophy, history, and other branches of the natural and social sciences, as well as the Buddhist canon, with a total number of 1,746 herbal drugs (Tang 1904). In the field of traditional pharmacology, in addition to absorbing the knowledge inherited from earlier practitioners, he was full of initiative and creativity. Most of his experience was derived from his own long-term practice. He enriched the traditional herbological work by adding processing methods and effective recipes for each herb. Meanwhile, he was also a proficient clinical physician. He created a new style of combining medical practice with herbal knowledge to form the principle of "verifying the drug by recipes", which was quite helpful to clinical practitioners, thus pushing medical science forward a step further. His work was treated as an officially promulgated book on materia medica and circulated for several hundred years (Shang 1989). His working methodology and epistemology were praised and copied by later scholars in the same field. Tang exerted an especially profound influence on the work of the great naturalist of the Ming Dynasty, Li Shizhen.

Tao Hongjing

FABRIZIO PREGADIO

The Daoist (Taoist) master, alchemist, and pharmacologist Tao Hongjing was born in 456 near modern Nanjing. He served in various positions at the courts of the Liu Song and Qi dynasties until 492. In that year he retired to Mount Mao, the seat of Shangqing or Supreme Purity, a Daoist tradition based on meditation and visualization techniques. The retreat he built on the mountain was to remain the center of his activities until his death in 536.

After his initiation into Daoism around 485, Tao set out to recover the original manuscripts, dating from about one century before, that contained the revelations at the source of the Shangqing tradition. Tao authenticated and edited the manuscripts, and wrote extended commentaries on them. This undertaking resulted in two texts completed in ca. 500, the *Zhengao* (Declarations of the Perfected) and the *Dengzhen yinjue* (Concealed Instructions on the Ascent to Perfection, only partially preserved). These and other works make Tao Hongjing the first systematizer of Shangqing Daoism, of which he became the ninth patriarch.

Since the establishment of the Liang dynasty in 502, Tao enjoyed the favor of Emperor Wu (r. 502–549), on whom he exerted remarkable influence. Shortly after, he began to devote himself to alchemical practices under imperial patronage. His main biographical source, written in the Tang period, has left a vivid account of these endeavors. Along with scriptural sources they testify to the importance of alchemy within the Shangqing tradition, which represents the first known instance of close links between alchemy and an established Daoist movement.

A third text on which Tao Hongjing worked during his retirement on Mount Mao was the *Bencao jing jizhu*, a commentary on the earliest known Chinese pharmacopoeia, the *Shennong bencao*. The original text contained notes on 365 drugs. To these Tao added 365 more, taken from a corpus of writings that he refers to as "Separate Records of Eminent Physicians." Tao's arrangement of the materia medica was also innovative. He divided drugs into six broad categories (minerals, plants, mammals, etc.), and retained the three traditional classes of the *Shennong bencao* only as subdivisions within each section. In a further group he classified the "drugs that have a name but are no longer used [in pharmacology]." Tao's commentary discusses the nomenclature, notes changes in the geographical distribution, and identifies varieties; it also includes references to the Daoist *Xianjing* (Books of the Immortals) and to alchemical practices. With the exception of a manuscript of the preface found at Dunhuang, the *Bencao jing jizhu* is lost as an independent text, but has been reconstructed based on quotations in later sources.

Taqī Al-Dīn

Sevim Tekeli

Taqī al-Dīn, Muḥammad al-Rāṣid ibn Maʿrūf, was a mathematician and astronomer. He was born in Damascus in 1521 and died in about 1585. He wrote several books on mathematics, astronomy, optics, and theology.

The most important of his books are: *Jabr wa'l-Muqābala* (Algebra), *Bughyat al-Ṭullāb min ʿilm al-Ḥisāb* (The Desire of Students for Arithmetic), *Sidrat al-Muntahā fī al-Afkār* (The Nabk Tree of the Extremity of Thoughts), and *Ālāt-i Raṣdīya li Zīj-i Shāhinshāhīya* (Observational Instruments of the Emperor's Catalogue), *Al-Kawākib al-Durrīya fī Bengamāt al-Dawrīya* (The Brightest Stars for the Construction of Mechanical Clocks).

From the point of view of the history of Ottoman science, the most important event of the sixteenth century was the foundation of the Istanbul Observatory, which Taqī founded under the sponsorship of Murād III (1574–1595). This observatory was an elaborate building which contained dwelling places, a library, and offices for the astronomers. It was conceived as one of the largest of the observatories of Islam and was comparable to Tycho Brahe's (1546–1601) Uranienborg Observatory built in 1576, equipped with the best instruments of his time in Europe. There is a striking similarity between the instruments of Tycho Brahe and those of Taqī al-Dīn.

The instruments of the observatory included the following. First there were those originally constructed by Ptolemy: the armillary sphere, the parallactic ruler, and the astrolabe. Then there were those invented by Muslim astronomers, such as the azimuthal and mural quadrants. Taqī al-Dīn invented the *mushabbaha bi'l manāṭiq* (sextant, an instrument with cords for the determination of the equinoxes), which was also an important invention of Tycho Brahe. In addition, he built a wooden quadrant for the measurement of azimuths and elevations, and clocks for the measurement of right ascensions of the stars. The latter was one of the most important discoveries in the field of practical astronomy in the sixteenth century, because in the beginning clocks were not accurate enough to be used for astronomical purposes.

In *The Astronomical Instruments of the Emperor's Catalogue* the author says, "The ninth instrument is an observational clock." The following statement is taken from Ptolemy: "I could have freedom of action if I were able to measure the time accurately. Now our master Taqī al-Dīn, with the help of God, upon the instructions of the Sultan, planned the observational clocks." *In The Nabk Tree of the Extremity of Thoughts* Taqī al-Dīn says, "We constructed a mechanical clock with three dials which show the hours, the minutes, and the seconds. We divided each minute into five seconds." On the basis of his observations, Taqī al-Dīn prepared astronomical catalogues and books.

Hipparchos (second century BCE) used the intervals of seasons for the calculation of the solar parameters. But the variation of the declinations around the tropics in 1 day rendered difficult the correct determination of the beginning of the seasons. In spite of this difficulty, the method was used for a long time. After him, al-Bīrūnī (d. ca. 1048), Copernicus (1473–1543), and Tycho Brahe were interested in this subject, and used a new method called "three points observation." Taqī al-Dīn, a contemporary of Tycho Brahe, says the following in *The Nabk Tree*: "The moderns follow the method of three points observation, two of them being in opposition in the ecliptic and the third in any desired place." This method was an important contribution to astronomy. By using this method, Copernicus, Tycho Brahe, and Taqī al-Dīn calculated the eccentricity of the orbit of the Sun, and yearly mean motion of the apogee. According to Copernicus the eccentricity is 1p 56′; according to Tycho Brahe it is 2p 9′, and according to Taqī al-Dīn it is 2p 0′ 34″ 6‴ 53⁗ 41′⁗ 8″⁗. As compared to modern calculation, Taqī al-Dīn's is the most accurate value. According to Copernicus the annual motion of the apogee is 24″; to Tycho Brahe it is 45″, and to Taqī al-Dīn it is 63″. Its real value is 61″. As far as world astronomy is concerned, Taqī al-Dīn's results can be said to be the most precise in the calculation of solar parameters.

The next important contribution of Taqī al-Dīn concerns the use of decimal fractions, the system of numerals formed from initial letters, used in the Hellenic world. This system hindered the development of algebra.

Al-Khwārizmī (d. 801) presented the decimal system which was inspired by Indians to the Islamic world. The application of this to fractions started with Abū'l-Ḥasan Aḥmad ibn Ibrāhīm al-Uqlīdīsī and continued with al-Kāshī (d. 1437). But its application to astronomic and trigonometric tables was realized by Taqī al-Dīn. Thus the tables of his *zīj* named Kharīdat al-Durar (*unbored pearl*) and a *zīj* were prepared using the decimal system and decimal fractions.

Technology

Arnold Pacey

The development of technology has usually been socially determined, changing in direction as different social formations have emerged. For example, there are important distinctions to be made between, first, small communities of farmers or dispersed groups of hunters with technologies outstanding chiefly for their adaptation to local *environments*; second, the larger kingdoms and empires, whose technology tended to be *engineering-centered*; and third, trading communities and merchants or entrepreneurs with *production-centered* technologies.

An initial problem in discussing technologies of the first kind is nomenclature. Weiner, who has discussed the remarkable protective clothing developed by the Inuit for life in the Arctic, has described these people as "the great pioneers of microclimatological bioengineering." This tribute to the control of body heat loss achieved by Inuit clothing is well deserved but places the skills of Arctic people within the wrong frame of reference. Their technology was environment-centered, not engineering-centered. On the one hand, they were adapting to a very demanding environment; on the other, they were making very efficient use of environmental resources. Thus, the animals hunted for meat were also a source of oil for lamps, bone for making needles and other tools, and the skins, intestines, and fibers from which clothing was made.

Archaeological evidence suggests that the invention of tailored skin clothing adequate to enable people to winter in the Arctic was accomplished in Siberia around 2000 BCE. After that, it was several centuries before oil lamps, houses built of snow, and dog sleds were developed by the people of the Dorset Culture, based on Baffin Island. Later still, improved boats and harpoons were developed by the Alaskan Inuit.

All these inventions, quite clearly, were the work of small, dispersed groups without centralized organization, and all were responses to an exacting environment. Perhaps what we ought also to remember is that for the Inuit, as for most non-Western peoples, the environment was endowed with personal and spiritual meanings, and with magical qualities. It was not merely the object of detached, if concerned, analysis that it has become for most Westerners. Thus, their technology was based on an organic world view.

The same points can be made about peoples inhabiting other environments, such as rainforests, deserts, steppes, or coastal and island situations. The efficiency with which resources were used by such people is illustrated by the estimate that in AD 1500 the Amazon basin supported a somewhat larger population than it did in 1990, yet without the extent of destruction of forest and fishery resources now taking place. Fruits, nuts, leaves, seeds, and roots were gathered for use as food and medicine. Fish and animals were caught, often using poison tipped spears, but with less ecological disturbance.

In some rainforests, notably in Central America as well as in Asia and Africa, people developed a form of agriculture in which a great variety of crops was raised while extensive tree cover was retained. Cereals such as corn in the Americas or rice in Southeast Asia were grown in forest glades with shade tolerant vegetables under trees. Those trees that were left unfelled or were newly planted would be selected according to whether they produced fruit, nuts, timber, fodder, or *materia medica*. Thus, an artificial rainforest was formed in a system often referred to as forest farming, forest interculture, layered gardening or, more recently, agroforestry. The key point – whatever the name – is that there would always be tree cover, and usually other vegetation, to protect the soil from erosion and to retain plant nutrients. By contrast, where rainforest is cleared for conventional western style agriculture, soils become degraded very rapidly.

In Africa, rainforest crop production became widespread only after the banana and Asian yam were introduced on the east coast by Indonesian traders and colonists around AD 400–500. In quite a short space of time, these crops were adopted by many gardeners across the continent, enabling populations in forested areas to increase considerably. In Central America, archaeologists have now shown that the Maya culture used forest farming with high yielding nut trees and manioc (cassava) as major crops around AD 600–900.

Other environment-centered technologies were those of people living in hot, dry, semidesert conditions who evolved sophisticated water conservation techniques. Some of these made use of small structures, such as check dams in gullies and spreader dikes on flatter ground – for example, in northern Mexico and Arizona – or else stone lines on contours (in the African Sahel). Others practiced the careful planning of fields in relation to rainwater catchment areas, and the construction of bunds to channel water and hold it on the land. Among the most elaborate rainwater harvesting systems of this kind were those of Nabataean farmers in the Negev Desert in Israel from about 200 BCE, and comparable systems in Morocco and elsewhere in North Africa. Small dams, river diversions, and the Persian *qanat* (wells linked by a tunnel) were other means of providing irrigation water to crops on a small scale.

Consideration of environment-centered techniques such as these offers a distinct perspective on early technology quite unlike the conventional view based on the materials from which tools were made, namely, stone, bronze, and iron. That view seeks to discover a pattern of tool use and metal-working skill common to all human societies, and ignores the environmental particularism emphasized here. It parallels the modern assumption that the principles of technology are independent of cultural values and underestimates the different ways in which human societies explored the varying surroundings in which they lived. By contrast, a perspective based on environmental adaptation allows one to recognize the extraordinary sophistication of some peoples who nominally remained in the "Stone Age" even in the early twentieth century, including the Inuit and some rainforest communities.

Viewed from another angle, however, the Neolithic period in the later Stone Age does seem to have been a time of particularly important innovation, at least for western Asia. It is associated with the first domestication of crops and livestock, and hence the invention of agriculture, probably associated with the earliest use of some of the water conservation techniques previously discussed. Complementing these innovations were others, such as pottery (and soon after, the potter's wheel), grain milling, tool-making, and textiles (with the looms on which they were woven). Many of these innovations relate to the domestic sphere of life, and it is likely, therefore, that many of the inventors concerned were women.

It would be a mistake, however, to assume that the invention of agriculture, the domestication of plants, and the appearance of pottery or textiles were unique events, each occurring only once in human history, in one part of Asia and then diffusing to other regions. Independent inventions undoubtedly occurred, just as different crops were domesticated in various places and at different times. For example, about 1500 BCE, corn (i.e., maize) and pottery were both known in Mexico, but not in Peru, where beans and peppers were cultivated. Thus, the two cultures may have developed agriculture independently of one another. Moreover, some plants were still being newly domesticated in the twentieth century, for one reaction to deforestation in Africa has been to cultivate a number of fruits and vegetables that people had collected from the wild until the loss of forest cover threatened their existence.

Reports from Kenya show how modern gardeners, usually women, have selected from wild varieties and have produced strains adapted for garden conditions.

Engineering-centered technologies developed in a very different context. They were characteristic mainly of kingdoms or empires whose labor resources and administration made large scale construction works possible. One view of the origins of engineering is that once agriculture was established, irrigation became necessary in many of the warm, dry countries of western and southern Asia to produce sufficient food for growing populations. The dams and canal systems necessary for irrigation could not have been constructed, it is argued, without recruiting a large labor force, and that in turn could not have been done except in centrally organized kingdoms. In this view, the need for irrigation canals and other hydraulic works dictated the formation of centralized government administrations with the coercive power and management skills needed to organize large scale construction works.

This theory about how hydraulic civilizations evolved does not apply everywhere, however, since empirical evidence shows that in many areas where irrigation was practiced, farmers did the essential earth moving and engineering work themselves, or with their neighbors through local systems of cooperation, but without central organization. This seems to be true for rice culture in China, according to Francesca Bray. Some of the biggest centrally organized engineering schemes prior to AD 605, involving thousands of laborers, were not for irrigation but for construction of transport canals for carrying grain to the capital. However, flood control and irrigation in north China did depend on large scale works, so the evidence is not clear cut.

In Mesopotamia and Egypt, much early irrigation was also on a small scale, dependent on manually operated water raising devices such as the *shaduf*. The type of crops grown and the seasons of cultivation meant that water requirements in early agriculture were much less than after the agricultural revolution of the Islamic period (after AD 700), when crops that demanded more water (including rice) were more widely grown. In Mesopotamia, large scale works were needed at an early date, but in most places it is hard to argue that the requirements of hydraulic management were sufficiently exacting to determine the development of centrally organized states. On the contrary, the prior existence of centralized political power made possible a wide range of construction programs that included fortifications, monuments, and temples, as well as hydraulic works, and it is impossible to say which kind of engineering came first. One of the earliest sites to provide evidence is Jericho, where defensive walls, but also big water tanks, have been found dating from before 6000 BCE. The pyramids of Egypt were among the largest construction projects ever conceived when they were begun about 2600 BCE. But a comparable amount of labor may have gone into embankments and canals built at about the same time for flood control and irrigation by the Sumerians in Mesopotamia. Thus, the evidence does not give a clear picture of hydraulic requirements, rather than other construction works, forcing the pace in either administration or engineering.

That brings us to a second hypothesis about how engineering-centered technologies evolved, suggested by Lewis Mumford and some like-minded commentators. This is the view that such technologies were related to the invention of institutionalized warfare. In early societies, conflicts were sometimes wantonly violent, but some groups had customs that enabled one side to signal a surrender before serious injuries were inflicted. Among a few isolated peoples in Africa and Oceania, conflicts between communities were still like this until recently, and observers note that, if somebody was killed, the combatants were so shocked that fighting immediately stopped. A ceremonial burying of spears and an exchange of cattle or captives would then settle outstanding issues.

Organized, lethal warfare had to be invented, perhaps during the Neolithic period, and possibly following the invention of agriculture, since agriculture made possible denser populations within which tensions could be greater. Also, agriculture produced the economic surplus needed to pay for arms and fortifications. The suggestion is that military institutions evolved from about this time and provided a model of how large bodies of men could be recruited, disciplined, and supervised while constructing fortifications, pyramids or hydraulic works. Many instances can be quoted of the administration of hydraulic installations based on military routines. In later times, at Marv in northern Iran, a water storage dam below the city was looked after by 400 “guards” who minutely regulated and recorded all outflows of water. The head of the water office had more authority than the local police chief, and when repairs to the dam or canals were necessary or when new works were needed, he could call up 10,000 people to do the work.

The development of warfare provided much other stimulus to engineering-centered technology. Mechanized fighting may be said to have begun with the clumsy, four-wheeled Sumerian chariot of about 2400 BCE. The Hittites, whose empire overlapped Asia Minor and Syria, invented some of the first effective siege engines around 1600 BCE and introduced the first iron weapons soon after. Horses were initially used mainly for drawing chariots, their full potential for warfare only emerging much later with the invention of the stirrup and its associated harness. This freed the rider’s arms to use weapons while he remained securely in the saddle.

The most famous of military inventions was, of course, gunpowder, known by AD 900, used in rockets by about 1100, and in guns before 1288. These inventions, developed within Chinese military institutions, were stimulated by earlier Indian discoveries about the chemical behavior of saltpeter, and by the use of incendiary weapons for naval warfare in Southeast Asia. The latter often depended on petroleum, obtained from surface oil seepages on the island of Sumatra. Although guns evolved more rapidly in Europe after 1300, China was the source of many ideas for gunpowder siege weapons used in the Arab world, and there were transfers of Chinese firearms technology to Korea and Thailand.

Considerable resources were needed for manufacture of the heavy cannons that had become widespread by 1500, and only the larger Asian empires could afford them in any number – but those that could were then able to expand their territory and consolidate their power. In India, the Mughal Empire's arsenals and gun-casting capability were important for its expansion between 1526 and 1700 In Persia also the new technology had a centralizing, consolidating influence during the reign of Shah Abbas (1587–1627), though his empire depended less on guns than did the powerful Ottoman or Turkish Empire, an exporter of guns and know-how. Given that most cannon were cast in bronze, McNeill has called this period a "second bronze age", referring to "gunpowder empires" not only in connection with Turkish, Persian, and Mughal rule, but also in relation to China and the Russian Empire in Asia.

The ships used in naval warfare and trade in Southeast Asia were of sewn construction, with rattan fiber holding together carefully fitted timbers in a flexible hull suited to landing on sandy beaches. They usually had outriggers and tripod masts to support sails, and regularly crossed the Indian Ocean. The Chinese, meanwhile, were building larger ships whose wooden hulls were held together with iron nails and had watertight bulkheads. China was also developing inland water transport on a large scale. The canals had ramps and spillways for moving boats between one level and another, but also incorporated the first pound locks and lock gates, introduced in AD 983 (a precisely dated invention).

One Western bias in understanding technology is a tendency to focus on the wheel and machines using wheels. But wheels did not always mean progress. Wheeled vehicles were used in the north and west of Africa around 500 BCE, regularly crossing the Sahara Desert. Yet they went out of use later when the camel was introduced, because camels provided much more efficient means of transport in a region with sandy deserts and no paved roads. For parallel reasons, wheeled vehicles were not much used in southern Asia. In Central America, rollers and wheeled toys have been found, but in a region where there were not animals capable of pulling carts, no purpose could be served by developing such devices.

The potter's wheel (and later lathes working on similar principles) were probably the first machines, around 3000 BCE, to use the wheel. Much later, a basic water powered corn mill evolved, with a vertical axle and propeller like blades below the millstones. One view is that this was a Greek invention made about the time of Alexander the Great. Another view, however, is that it arose out of the Hittite tradition of engineering which had earlier pioneered so much military equipment. After the Hittite empire collapsed around 1200 BCE, some aspects of its culture survived in Syria, and itinerant craftsmen perhaps reached Mesopotamia and Iran. It was probably in one of these countries that water mills originated. Since the same type of mill appeared in China not long afterwards, one might reasonably look for its origins close to trade routes with China. As for the introduction of the mill into Greece, this could be a by-product of Alexander's expedition through Iran to the Indus River in 330–323 BCE.

Some thousand years later, Iran was certainly where an early type of windmill was invented. It worked in much the same way as the vertical axle water mill, though mounted in a tower with vents in the walls to catch the wind.

Mumford sees these inventions as part of the tradition of innovation stemming from small dispersed communities rather than from centrally organized states. However, at Baghdad, which had about one million inhabitants in AD 1000, corn milling was carried out by a series of floating mills on the Tigris River which operated continuously, night and day. The water wheels were of the later undershot type, driving millstones through wooden gears. Other uses of water power in Iraq and Iran by AD 1000 were in sugar cane crushing mills, fulling mills, and mills for preparing the pulp for papermaking. Paper manufacturing had been introduced at Baghdad in AD 794, probably with the help of Chinese workmen, and pulping was water powered from about AD 950.

In all these instances, it would seem, we are no longer dealing either with the environment-centered technology of dispersed communities, nor with the labor intensive engineering of powerful centralized states. Rather, we are seeing the emergence of production-centered technologies in expanding industries. An even more striking example can be cited from northern China, associated with the use of blast furnaces for iron production. Methods of achieving high temperatures in furnaces were highly developed in China's porcelain industry as well as in metal smelting. Chinese iron masters had pioneered blast furnaces capable of melting large batches of metal, and output rose steadily to a peak in AD 1078. Moreover, the furnaces were owned and run by independent entrepreneurs whose market oriented, proto-capitalist operations are seen by McNeill as marking a turning point in world history.

More evidence that technology in China was moving into a new phase is provided by the great flowering of mechanical devices that were introduced there in the three or four centuries prior to 1250. They included spinning wheels, silk winding machines, and most striking of all, water-powered mills for spinning and winding thread of a local type comparable to linen. Some improvements in textile technology were due to women innovators, and many businesses were run in an independent, entrepreneurial style.

By contrast, much manufacturing in the major Asian empires was directed toward meeting state requirements for armaments, or the needs of royal palaces for luxury textiles, porcelain, and furniture. The most characteristic unit of production was the royal factory or *karkhana* in Mughal India, or the specialist porcelain factory or arsenal in China. At one time, 4,000 silk workers were employed in karkhanas in Delhi. Some may have been conscripted, and the factories were run in rather the same way as the labor intensive, state-run engineering works mentioned previously. Such factories were highly successful in meeting government requirements for arms or the court's demand for luxury goods, but could not respond readily to a varying market demand. Production for purposes of trade, and especially for export, flourished most markedly where merchants and other entrepreneurs could function independently. By 1700, India had become the world's greatest exporter of textiles, sending its cotton cloth to Europe, Africa, and many destinations in Asia. Both Indian and foreign merchants were involved, sometimes financed by the many Parsi and Gujarati bankers to be found in ports such as Surat.

It should not be thought, though, that proto-capitalist industrial organization was always favorable to the use of machines, water powered or otherwise. The high quality of Indian textiles was achieved by painstaking handwork and a very fine division of labor. British observers noted that cotton cloth would sometimes be worked on by four people for every one employed on the same tasks in Europe. Thus, the remarkably fine muslin produced in Bengal was the result of many detailed processes which would be simplified and reduced to a single operation in the West.

Indian cloth was also noted for the fastness and brilliance of the colors with which it was dyed, mostly using vegetable dyes, such as indigo and madder. However, some inorganic substances were also needed as mordants, and this gave rise to a significant chemical industry. For example, the alum used in madder dyeing was produced in Rajasthan by processing broken shale tipped as waste around copper mines. The shale was steeped in water. Aluminum compounds were separated from copper salts by differential crystallization. Then a reaction with saltpeter produced the alum. These chemical processes were operated on a substantial scale but using labor intensive methods and minimal equipment. Merchants and banks had ample funds to invest in the textile trade, but because wages were low, there was little advantage in financing better production equipment. Instead, most of the capital available was put into building ships to carry exported cloth. Thus, Indian shipbuilding developed to a very high level in the eighteenth century. Ships were built for Indian merchants and foreign traders, and from 1800 for the British navy. Meanwhile, cotton cloth, dyestuffs, and chemicals continued to be produced by laborious manual techniques.

Similarly in China, there were many flourishing industries, often organized on proto-capitalist lines, but the interest in mechanization evident before 1300 was not sustained, and indeed, some machines went out of use. Silks, porcelain, and cotton goods were produced in quantity, but mainly by labor intensive methods in an economy where wages were tending to fall. But, as in India, the production technologies involved are of considerable interest. Moreover, they are quite distinct from the environment-centered and engineering technologies discussed earlier. It is of particular relevance to observe that printing evolved as a production technology in China, and by 1600 had export markets in Korea and Japan. But the content of the books being printed was dominated by the literary interests of the bureaucrats who served the imperial government. Thus, relatively few books were of significance for the dissemination of technical information. It is worth recalling, though, that the first known printed book, the *Diamond Sūtra*, an extract from the Buddhist scriptures, dates from AD 868, and that by the eleventh century a few books on agriculture were being printed. In AD 1044, Zeng Gongliang published the *Wujing zongyao* (Collection of Military Techniques) that quoted the formula for a weak gunpowder mixture, and in 1313 a remarkable work appeared – *Nong Shu* (Treatise on Agriculture) by Wang Zhen – which, among other things, described water powered spinning mills.

But whatever limited writings there were on technical subjects, either in Islamic manuscripts or Chinese printed books, technology depended far more on knowledge, skill, and technique passed from one craft worker to another through processes of observation, personal contact, and apprenticeship. Nonverbal habits of thought and of getting the "feel" for how a process should work were undoubtedly central for innovation and learning.

Nonverbal communication, often in the form of a visual or experimental dialogue, was also the means whereby techniques were passed from one community or culture to another. Confronted with an unfamiliar product or process, a craft worker would not always copy it directly, but would "question" it to try and work out how the same result might be achieved by more familiar means, or how it might be reinterpreted to suit his or her community's culture or resources. Moreover, this dialogue or questioning approach could at times prompt entirely new lines of thought or innovation. For example, between the sixth and tenth centuries AD, the Chinese picked up ideas from India and Persia about chemistry, dyestuffs, textile printing, windmills, suspension bridges, and other matters. These were developed in entirely new ways as a result of being questioned and reinterpreted rather than being copied, and so contributed to some of the best known of Chinese inventions, including gunpowder and printing.

Between 1100 and 1800, and especially after their voyages of discovery began around 1450, Europeans were continually picking up ideas from other cultures: about water clock mechanisms, chemistry, cooking, and glassmaking from Islamic sources; about gunpowder, firearms, printing, and porcelain manufacture from China; and about metallurgy, cotton textiles, and dyestuffs from India. Few of these techniques were directly copied in any detail, but they became part of a dialogue in which Westerners did most of the questioning and learning – and in which they reinterpreted many techniques in terms of the Western enthusiasm for machines and mechanization.

This source of stimulus contributed significantly to the technology of the European industrial revolution, but that in turn brought a change in attitudes and relationships. A sense of technological superiority coincided with a tendency to use non-Western countries as markets for factory made goods and as sources of raw materials. Local manufactures in many parts of the non-Western world therefore declined. One striking feature of the late twentieth century has been a new openness in the West for dialogue with the environment-centered technologies practiced in the rest of the world. But, again, Westerners are reinterpreting everything they learn in terms of their own outlook, discarding the organic and holistic world views of other peoples and fitting everything into an analytical, scientific frame of reference. Thus, Inuit technology has been discussed in terms of "ice alloys" and "bioengineering" whilst indigenous rainforest technologies are being reinvented as "ethnobotany" and "agroforestry".

Technology and Culture

Claude Alvares

General accounts of the history of science and technology (or, more narrowly, of inventions) are scarce. The few that are available are also of fairly recent origin: obviously, the idea of a history of science (where science has been identified with Galilean science) and technology (identified with industrial technology) could not have appeared much earlier than this century. Not many people even know that the word "scientist" was first used by William Whewell in 1833.

Also, most available histories have remained the work of western scholars. This has not been an entirely happy circumstance. On the contrary, it has afflicted these histories with certain methodological and other infirmities which have had the effect of reducing them to mythological works. This is especially so when they are studied with regard to aspects of the history of science, technology, and medicine in the non-Western world.

One of the first is a history of technology and engineering written by Dutch historian Forbes. Forbes's work appeared in 1950 under the title *Man the Maker*. In it, he conceded that technology was the work of humankind as a whole, and that "no part of the world can claim to be more innately gifted than any other part." A few years thereafter, Forbes produced his rich and prodigiously detailed *Studies in Ancient Technology* which set out a remarkable description of the different technologies of Asia, Africa, pre-Colombian America, and Europe. However, it is in *The Conquest of Nature* that his Eurocentric assumptions came to the fore: in that work (as the title itself indicates), Forbes went on to subsume the technological experience of people from diverse cultures under a philosophical anthropology that was unmistakably Western, if not Biblical – the domination of nature myth originating in Genesis. And after a discussion about the grievous consequences of a seriously flawed modern technology, he ended his book promising redemption from the technological genie through the Christian event of Easter. How does one prescribe a text like this to Hindu, Chinese, or Arab readers?

Another influential work of about the same period is *A History of Western Technology* by a German scholar, Friedrich Klemm. In it, Klemm provided a picture of technological development in the West in which non-Western ideas and inventions had no hand at all. The English translation which appeared in 1959 barely mentions Joseph Needham's work on China in the bibliography. Klemm could not have substantiated his interpretation of Western technological development unless he consciously played down non-Western technology. In fact, the only quote on Chinese technology in Klemm's book is from the *Guan yin zi*, the work of a Daoist mystic of the eighth century AD: Klemm used it to prove why the alleged religiously colored oriental rejection of the world in China could not have provided a stimulus for the emergence of science and technology in that country.

This distorting Eurocentric perspective continued to hold sway even over the more standard (five volume) *A History of Technology* edited by Charles Singer, Holmyard and Hall. The first volume of this work appeared in the same year as Joseph Needham's *Science and Civilisation in China*, and the editors themselves acknowledged that up to the period of the Middle Ages in Europe, China had the most sophisticated fund of technological expertise. Three of the Singer volumes dealt with preindustrial technology, where logically China (and India) should have been given major space and Western technological development would have appeared in proper perspective in the nature of an appendix. However, Chinese, Indian, and other technologies were ignored and Western technology made the focus of the exercise.

In addition to manifesting such ignorance of non-Western science and technology, these histories suffered from another methodological limitation: they restricted themselves to a record of artifacts and machines disembodied from the latter's social and cultural contexts. The problem was eventually recognized by some Western scholars themselves.

These histories are evidence that the western scholars associated with them proved incapable of stepping out of their cultural cages, either knowingly or involuntarily. Either way, this eroded the credibility of their work as it exhibited both their lack of objectivity and their general incompetence when called upon to deal with societies other than theirs.

They show that our dominant descriptive and evaluatory ideas of technology and culture both in the Western and non-Western world have been formulated over the past couple of centuries with reference to the West's experience of these phenomena. Concepts and categories reflected from a limited area of human experience have been indiscriminately used to explain and assess the rest of the world.

New frameworks are therefore inevitable. We are in the posttraditional, postcolonial, and postmodern age. But unless the outmoded intellectual environment that engendered this subjective and tunnel-visioned output is rigorously dissected, analyzed, and then jettisoned, the new frameworks needed for the alternative histories and encyclopaedias intending to take their place are in danger of turning into copies of the old.

There are two preliminary aspects of this intellectual mal-development that need elucidation. First, there is the perception of humankind as *homo faber*, a tool-making animal, which is basically a reflection of fairly recent Western experience with the machine. Fascinated by the bewildering profusion of tools and machines, Western historians began to look at the ability to produce these as a special field with its own history and set out to create a distinct species of man in the image of *homo faber*. This scholarly creation had its repercussions in encouraging the overestimation of the singularity or uniqueness of Western culture in comparison with others (although all cultures are unique and incommensurate). The elaborate, embarrassing exercise in culture-narcissism soon became routine since it was not to be challenged for nearly a century. (It is important to point out that the *homo faber* idea is quite recent to humankind: it is consistently absent in not just other cultures, but even within a large part of the West itself.)

For instance, it was taken for granted that the system of production that got generated in the last century and a half in the West was the only one with any significance simply because in the light of the present – and to all appearances – it had apparently emerged as the dominant one. Therefore, its past was the only one worth considering. This notion was in turn bolstered by another: a self-generating model of technological development in which the historian attempted to trace the evolution of modern science and technology by working backward to the experiences and ways of thinking characteristic of Mediterranean antiquity. Thus the roots of modern technology were shown to be exclusively founded on the work of Greek and Roman thinkers, mathematicians, engineers, and observers of nature with no input from any other culture areas or people.

This brings us to the second aspect we have alluded to above, and this concerns the relationship between knowledge and power and the impact of this on interpretations of technology and culture. Throughout history, knowledge has generally remained closely linked with interests. Even when encyclopaedias, for instance, have traditionally sold themselves on the Francis Bacon principle that "knowledge is power", they too have continued to reflect an undeclared, equally influential, political principle – that "power is knowledge".

The intrusion of Europeans into non-European societies and the gradual establishing of political dominance and inequality between societies stimulated the inauguration of a new discourse about such societies. Political dominance came to be as routinely and unabashedly expressed in the form of knowledge as it was through the barrel of guns. Edward Said has already written on the invention of the discourse on "Orientalism" and its direct political uses. But there are less controversial discourses that have had even larger repercussions only now being acknowledged. As a result, much academic knowledge in the Western world about the non-Western world, particularly the latter's technology traditions, remains not only distorted or contaminated by the ethnic concerns, goals, theories, obsessions, and peculiar assumptions of Western scholars and universities; it is still largely defined, legitimized, and decided by them irrespective of whether there is any concurrence from the non-Western world.

The combination of these two aspects proved deadly: the emerging conception of Western man alone as *homo faber*, once it took firm roots within the situation of political dominance, rendered any appreciation of technique elsewhere – technique not necessarily reflected only in tools or machines – difficult and often impossible. In fact, the combination helped inaugurate its very own dark age. For it generated among Western (and not a few non-Western) scholars several major assumptions concerning technology and culture. We shall discuss three of these.

The first emerged in relation to Western man's attitude toward the past, particularly with regard to preindustrial technology. *Homo faber* exercised his new found power over the past by deriding it: this is reflected in the rewriting of history from today's perspective in which the past is seen as mere prelude to the present. Earlier technological innovations are considered primitive precursors of later developments. Here we have a good example of the parochialism of the modern/Western mind as it proceeds to take experiences of technology and culture exclusive not just to the late twentieth and early twenty-first centuries but to extremely small segments of the world population and makes these the basis for investigating, analyzing, assessing, and judging the general activities of human societies over hundreds of years. This was the case even when such societies were not so technologically enamored, dependent, or controlled as some of them seem to be now.

The second assumption relates to humankind's so-called unique propensities for technology when compared with that of the animal world, an uncritical theory best summed up in a single word: speciesism. After deciding on the issue of the comparative technological competence of all living species in its own favor, the West came to the conclusion that the rest of creation, because inferior, was expendable if so required to further its own scheme of things.

But it is the third assumption that concerns us most seriously here: it is the idea that Western man can be equally distinguished from non-Western societies as well on the ground that the latter, like the animal and other "lower" species, also lacked technological development as it emerged in the West.

This idea was appropriately reflected in academia in the emergence of two new sciences: the discipline of sociology, which focused on so-called advanced societies and their flair for technology; and the subject of anthropology which occupied itself with non-Western cultures, limited to primitive or preindustrial tools. Anthropology's political origins have been blandly asserted by Claude Levi-Strauss in his controversial Smithsonian lecture:

> Anthropology is not a dispassionate science like astronomy, which springs from the contemplation of things at a distance. It is the outcome of a historical process which has made the larger part of mankind subservient to the other, and during which millions of innocent human beings have had their resources plundered and their institutions and beliefs destroyed, whilst they themselves were ruthlessly killed, thrown into bondage, and contaminated by diseases they were unable to resist. Anthropology is daughter to this era of violence: its capacity to assess more objectively the facts pertaining to the human condition reflects, on the epistemological level, a state of affairs in which one part of mankind treated the other as an object.

It is within such an imperialist context that the histories and technological experience of non-Western societies could be written off or ignored: the latter, after all, were conquered peoples. When technology is seen through an anthropological prism, the emerging picture is bound to be far removed in character from a scenario that emerges from a sociological perspective. What is more, it is bound to be even more far removed from reality itself.

Some impression of that reality is discernible in the period before political dominance began to corrupt the objectivity of knowledge. Before the so-called "voyages of discovery," though non-Europeans were conceived as fantastic, wild, opulent, even monstrous, they were rarely considered inferior or backward; and even the actual European encounter with the scientific, technologic and medical traditions of non-Western societies was different from what eventually became the stuff of politically directed myths. In fact, from the day that the Portuguese mariner Vasco da Gama landed in India until almost three centuries later, Asia had a larger and more powerful impact on Europe than is normally recognized. Donald Lach has appropriately titled the first volume in his *Asia in the Making of Europe* "The Century of Wonder". It was not without reason that an Englishman of the time addressed the Indian Emperor by describing himself as "the smallest particle of sand, John Russel, President of the East India Company with his forehead at command rubbed on the ground." Nor can we forget that the first presents offered by da Gama to the King of Calicut included some striped cloth, hats, strings of coral beads, wash basins and jars of oil and honey. The king's officers naturally found them laughable.

It would take a few more decades before the Europeans landing in the Indian subcontinent would notice anything beyond gold and spices. But by 1720 and for a period of up to a 100 years, a new category of observers came visiting, some from newly formed learned societies in England. Their detailed reports were a result of the European quest for useful knowledge in different fields.

In his pioneering volume, *Indian Science and Technology in the Eighteenth Century*, the Indian historian Dharampal includes several accounts from these observers which describe among others the Indian techniques of inoculation against smallpox and plastic surgery. (While the first was eventually banned by the English, the latter was learnt, adopted, and developed.) The accounts also document Indian processes like the making of ice, mortar, and waterproofing for the bottoms of ships; water mills, agricultural implements like the drill plough, water harvesting and irrigation works, and the manufacture of iron and of a special steel called *wootz*.

More techniques (like those involved, for instance, in the manufacture of Indian textiles) are described in *DeColonizing History* (Alvares 1991) and *Science and Technology in Indian Culture* (Rahman 1984). But even this documentation, impressive as it is, is now recognized to be but the tip of the proverbial iceberg.

The Chinese, like the Indians at Calicut, had a similar experience with an embassy and its gifts from London. The edict of Qian Long to the embassy is worth quoting: "There is nothing we lack, as your principal envoy and others have themselves observed. We have never set much store on strange or ingenious objects, nor do we need any of your country's manufactures" (Fairbank 1971).

Immediately after the encounter, the graph of European reaction rises with esteem and wonder; and then, as political conquest and overlordship increase, the graph alters course and begins to record increasing denigration. A remarkable transformation of image thus takes place as the political relationship between Europe and non-European societies changes to the advantage of the former, rendering the Europeanization of the world picture almost an act of divine will.

By 1850, political dominance over the non-Western world was clearly installing distorted ideas not only about that part of the world but rebounding to distort Western man's image of himself as well. Already by 1835, for instance, the British had acquired a flattering notion of their own civilization (Victorian England was seen to be at the top of the pyramid of civilization) and a thorough-going contempt for Asia.

This contempt finds expression in the famous Minute of Lord Babington Macaulay:

> I have never found one amongst them (the orientalists) who could deny that a single shelf of a good European library was worth the whole native literature of India and Arabia… It is, I believe, no exaggeration to say that all the historical information which has been collected from all the books written in the Sanskrit language is less valuable than what may be found in the most paltry abridgment used at preparatory schools in England. In every branch of physical or moral philosophy the relative position of the two nations is nearly the same.

Dharampal has produced an interesting record of these assessments of science and technology in India among Western observers as the relationship between India and Britain changed to Britain's advantage.

Regarding the question of Indian astronomy, he discusses the case of Prof. John Playfair, Professor of Mathematics at the University of Edinburgh and an academician of distinction. Playfair studied the accumulated European information then available on Indian astronomy and arrived at the conclusion that the Indian astronomical observations pertaining to the period 3102 years BCE appeared to be correct in every text. This accuracy could only have been achieved either through complex astronomical calculations by the Indians or by direct observation in the year 3102 BCE. Playfair chose the latter. Opting for the former would have meant admitting that "there had arisen a Newton among Brahmins to discover that universal principle which connects, not only the most distant regions of space, but the most remote periods of duration, and a De La Grange, to trace, through the immensity of both its most subtle and complicated operations."

Similar attitudes prevailed concerning the knowledge of how Indians produced *wootz*. Heath, founder of the Indian Iron and Steel Company and later prominently connected with the development of the steel industry in Sheffield, wrote "... iron is converted into case steel by the natives of India, in two hours and a half, with an application of heat that in this country, would be considered quite inadequate to produce such an effect; while at Sheffield it requires at least four hours to melt blistered steel in wind-furnaces of the best construction, although the crucibles in which the steel is melted, are at a white heat when the metal is put into them, and in the Indian process, the crucibles are put into the furnace quite cold."

However, Health would not admit that the Indian practice was based on knowledge "of the theory of operations," simply because "the theory of it can only be explained by the lights of modern chemistry."

By the beginning of this century, the Western mind had already convinced itself that Western science and philosophy were the only approach to metaphysical truth ever attained by the human species and that the Christian religion provided wisdom and insight incumbent on all people everywhere to believe.

The result is reflected in the output of academia: a "history of art" turned out to be nothing but a history of European art and a "history of ethics" a history of Western ethics. While European music was music, everything else remained mere anthropology. The contemporary evaluation of human activity in the West as compared with the non-Western world was unabashedly provided by the late Jacob Bronowski in the Ascent of Man in words almost echoing Macaulay in 1837:

> We have to understand that the world can only be grasped by action, not by contemplation. The hand is more important than the eye. We are not one of those resigned, contemplative civilizations of the Far East or the Middle Ages, that believed that the world has only to be seen and thought about and who practiced no science in the form that is characteristic for us. We are active; and indeed we know, as something more than a symbolic accident in the evolution of man, that it is the hand that drives the subsequent evolution of the brain. We find tools today made by man before he became man. Benjamin Franklin in 1778 called man a 'tool-making animal' and that is right.

Now, there were obviously perverse consequences of such a view: scholars in several non-Western societies, schooled in an educational system imposed on their societies through the colonial establishment, readily incorporated similar ideas about their own histories. In an article in *Nature* 35 years ago, Joseph Needham had to chide a native scholar of Thailand for claiming that his own people had not made any contribution to science despite compelling evidence to the contrary. Nevertheless, the colonization project succeeded in convincing many non-European intellectuals and scholars that only the West was active. They facilely accepted the idea that activity per se was desirable compared to judicious or necessary activity; that only the West was capable of thinking in the abstract sense. If this opinion were carried to its logical conclusion, it would appear that if the rest of humankind had survived for hundreds of years, this must be due to some form of manna falling providentially from the heavens.

The damage done by these years of extremely ideological scholarship and a ruinous ethnocentrism to the history of technology was bad enough. Predictably, the impression of an empty technological wilderness invented by Western scholarship about non-Western societies had a parallel, simultaneous, destructive impact on the assessment of their cultures as well. So insidious was the nature of this outrageous assumption regarding Western and non-Western abilities, that even Joseph Needham, Mark Elwin, Abdur Rahman and a host of other scholars participated in pointless debates which often took it for granted. One major debate, for example, focused on why China (and India) did not produce either modern science or an industrial revolution on the European pattern, especially since Chinese technology had already reached a level of sophistication not yet attained in any other part of the world as late as the fifteenth century.

Attempted answers compared and contrasted the internal conditions within Chinese society with those within Europe; the argument eventually succeeded in establishing the conclusion that no scientific or industrial revolution occurred in China because the social conditions in China were not the same as those within Europe. Thereafter, a host of cultural and social factors were dragged out of context and labeled probable "obstacles" either to the development of technology or modern science.

A critique of the three assumptions we have surveyed above therefore becomes compelling and inevitable, if we are to eschew their myriad fallacies in future. We shall take each in turn.

The idea that the past was merely a prelude, and a primitive one at that, may come naturally to anyone who has begun to feel that the present era of technical change is inevitable. Yet future societies may assess their past (our today) basing themselves on values other than those celebrating mere technical change. Already mindless technical change and built-in technological obsolescence have been assaulted by several global thinkers on the ground of ecological unsustainability and resource scarcity. It would also be wrong to think that because man did not have technology as he now does, he was necessarily impoverished. If there is anything the past gives us it is this positive impression of survival in all kinds of environmental scenarios. There is also evidence of more widely dispersed creativity when man was not submerged by technology than there is today. In many areas of human experience, we are yet to match even the technological achievements of the past which were driven by values other than mere complexity for its own sake or profit.

A similar argument may be used against the assumption that humankind is the only tool-making species there is. Several naturalists and ethologists have documented the diversity of nature's schemes at fabrication; most notably, Felix Paturi in his *Nature, Mother of Invention* and Karl von Frisch in *Animal Architecture*. Scholars like Lewis Mumford have gone further in stating quite bluntly that in their expression of certain technical abilities other species have for long been more knowledgeable than man.

> Insects, birds and animals, for example, have made far more radical innovations in the fabrication of containers, with their intricate nests and bowers, their geometric beehives, their urbanoid anthills, and termitaries, their beaver lodges, than man's ancestors had achieved in the making of tools until the emergence of homo sapiens. In short, if technical proficiency alone were sufficient to identify and foster intelligence, man was for long a dullard, compared with many other species.

Niko Tinbergen, another ethologist, after years of close observation of other species, has come to the following conclusion: "It was said that (1) animals cannot learn; (2) animals cannot conceptualize; (3) cannot plan ahead; (4) cannot use, much less make tools; (5) it was said they have no language; (6) they cannot count; (7) they lack artistic sense; and (8) they lack all ethical sense." All of these statements, says Tinbergen, are untrue.

It cannot be said therefore that, in contrast with other species, humankind alone is a tool-maker. Thus the attempt to distinguish man from other living species because of his tool-making capacity is now seen to be a result of limited knowledge and unwarranted assumption of qualitative discontinuities between human beings and other species. It will also be useful to recall here that the ability to fabricate and organize is not a singular human trait – it is an intrinsic feature of nature since nature can exist only in a given form, whether at its most primary constituents at the subatomic level or even at the level of crystalline structures or the multiple tiers of a primary forest.

However, it is the third assumption – concerning the West's genius for technology and the rest of the world's incompetence in the same department – that contains the greatest mythological component of them all.

As we shall presently see, such an assumption has not only no historical basis, it is in fact contrary to historical and even to contemporary evidence. As for the gift of Greek rationality, suffice it to say that for 2,000 years it gave no technological advantage to those who had it over those who did not. On the contrary, major scientific concepts, technological artifacts, tools, and instruments emerged in cultures that had nothing to do with either Greece or Rome.

The other problem with this assumption is it cannot even cope with the long established view that the science and technology traditions of most societies, particularly so of the West, are in significant ways mixed traditions. Even the little that we know about it indicates that the cross-cultural borrowing of technics and technology is impressive. Thus a very large number of critical inventions from both India and China helped fill significant gaps in the technological development of the West. A simple example from Francis Bacon's work will suffice to illustrate this point. He wrote:

> It is well to observe the force and virtue and consequences of discoveries. These are to be seen nowhere more conspicuously than in those three which were unknown to the ancients, and of which the origin, though recent, is obscure and inglorious; namely, printing, gunpowder, and the magnet. For these three have changed the whole face and state of things throughout the world, the first in literature, the second in warfare, and the third in navigation; whence have followed innumerable changes; inasmuch that no empire, no sect, no star, seems to have exerted greater power and influence in human affairs than these mechanical discoveries.

Now all these three mechanical discoveries were Chinese. Yet here again Western scholars have found it hard to acknowledge their origin. Borrowing of techniques from India is easily documented as well.

The documentation of technology in other cultures is only beginning. For example, it was only in 1974 that Sang Woon Jeon's *Science and Technology in Korea* appeared. There is as yet no major record of technology in Africa or South America though there is now available a large volume of documented evidence that both areas were rich in tools and techniques, from metallurgy to textiles.

In India, the other large storehouse of useful and appropriate tools (some still in productive use), the most extensive documentation of technology has only recently commenced, sparked in part by Dharampal's *Indian Science and Technology in the Eighteenth Century* and the work of scholars like Abdur Rahman.

The immediate impact of these reinvigorated investigations, stimulated largely by political independence, is a fresh debate over the issue of technology and culture: the old assumption of one technology and one culture in which others are seen to make a few, presumably inconsequential, contributions, is in tatters. Whatever its own pretensions to be the only viable culture, the West is finally being seen by non-Western societies as only one among several: a certain balance between cultures gets restored even though economic inequality persists. In fact, in some cases the pendulum has swung to the other side with cultures unabashedly resuming their traditions. There has naturally been a reverberation in the climate of ideas.

Changes in perception of this kind have already come about in other academic disciplines. To cite just one example, world histories were once written as if Europe were the center of the planet, if not the cosmos. There has been progress since: Geoffrey Barraclough and Leon Stavrianos, for instance, have both succeeded in producing comprehensive histories which avoid the older Eurocentric perspectives.

But even assuming we are able to produce, culture by culture, a fairly objective and comprehensive record of science, technology, and medicine, we would still be uncomfortably close to the pet obsession and perception of the present epoch. If there is anything the recent past has shown us, it is that we can be all too zealous judges in our own cause. We continue to celebrate uncritically our technological feats even when we know that the principal criterion of success for any species (and the human species is no exception) is primarily its ability to survive.

Therefore, it may be best not to get trapped in the debates on what is basically a subhistory: the history of slave-machines or automation or the recent machine-propensity of some cultures. After all, the *homo faber* concept is itself a distorted reflection of the natural endowments of the human species, an example of reductionist thinking. We know now that reductionism readily distorts knowledge, often pauperizes it, but rarely enhances it.

What is required in the circumstances then is a paradigm shift. I would like to suggest this can be achieved by replacing the heavily loaded term "technology" (too close identified with externalized objects) with the more neutral word, "technique." Technique has a larger ambit than technology and does not necessarily express itself only in the form of tools or artifacts. For the moment, we may define it briefly as every culture's distinct means of achieving its purposes. The natural propensity of human beings is to rely on technique, not technology, for while it has been proven that we can survive without technology, we cannot survive without technique.

Thus there can be no technique without culture, no culture without technique. An investigation into a culture's techniques is bound to be considerably more difficult than the recording of a culture's artifacts. The important gain here would be that we would begin with a more democratic assumption: that there is no culture without a system of techniques. Such a postulate would inoculate us effectively against methodological, ethnocentric, and other fatal flaws the *homo faber* concept was both parent and heir to. It would nip in the bud any undesirable future forays into cultural narcissism or ethnocentric discourse.

If this is indeed so, the more logical assumption would be that every culture has relied on a corresponding system of techniques that has guaranteed survival. Understood in this way, it makes far better sense to talk of Western technique (even though today largely expressed in the form of technology), or African, Indian, Chinese, Maya, or Arabic techniques of survival (in which technology may not be given that importance for fairly valid reasons). But even a relatively low importance given to technology could never mean a poverty of technique. The idea that the human species is technique-natured could be empirically falsified if a human society could be found that lacked technique – and not just machines or artifacts.

Technique, then, is nothing but the permanent but dynamic expression of an individual culture. Cultures can only express themselves or survive through technique: the alternative is chaos. Nonhuman species may be guided in the exercise of technique by inflexible inborn patterns of behavior. But the human world is as rigorously bound by the controls imposed by the symbolic universe that emerged as a substitute for weakened instinctual patterns. Myth, for instance, is technique. Interaction with (or manipulation of) nature may take place either through myth-making, scientific construction, and myriad other ways. All are expressions of the symbolic universe human beings inherit because they are human beings.

Thus we share the necessity of functioning through technique – not just through tools – with other living species – from the mammoth geobiological processes of Gaia to the cross-pollination of the rice plant to species of bird and animals, some of which, like the bower bird, are more prone to technology than others. Thus the so-called potter-wasp is known for its technique in constructing what we human beings culturally recognize as pots: however, the small vessels are the conclusion of technique: without it, there would be no "pot", no propagation and, therefore, no survival.

This will also explain why so-called primitive societies are often more complex in their socio-cultural arrangements – their rich fund of botanical knowledge, slash-and-burn techniques, elaborate myths are as much an expression of technique – than modern societies.

Our new paradigm – based on a thorough-going analysis of technique – will enable us to concentrate more effectively on those aspects of human experience in non-Western societies where there may be appropriate development of technology (as in India and China) but a superabundance yet of technique. A large number of these, particularly in India or in the Islamic cultures, may be located squarely within the domain of the sacred. They would be unintelligible outside such a framework of understanding.

We shall also observe in such societies that even where there is sophisticated technology, it retains an unobtrusive (not invasive) character. This can be seen from the merged outlines of Arab architecture to the irrigation works of South India or Sri Lanka.

An encyclopaedia of non-Western science, technology, and medicine may restrict its scheme to a bare description of the evolution of machines or artifacts incompetently covered by earlier conventional Western works, but it must do so guided by the background of the larger canvas of technique. Here the scholar will eventually examine theories of language in the same detailed manner as he would the culture and preparation of food or the control of breath – all extremely detailed sciences in India and China; he would examine irrigation and animal husbandry techniques, the domestication of cultivars of crop plants, record the elaborate knowledge of plants and of the human body, and seek to understand theories of cosmic phenomena and of the behavior of annual events like the monsoons.

The aim of the historian is to describe the nature of this individual system and not place it within a hierarchical ordering of societies. His task is to document this immense richness, not endeavor to swamp and drive it into oblivion on the questionable assumption that Western technology is the only direction that human technique will take. The growing anxiety over Western technology is closely associated with the threat it is perceived to pose to the fate of the planet and to survival. We may have to examine its history clinically to diagnose why it has generated the kind of problems it poses for humankind. Here, only a proper study of technique and culture within non-Western societies (and not as Forbes hoped, the event of Easter) will bring some balance and provide urgent clues to the origins of what Jamal-ud-din described as the illness of occidentosis, the plague of the West.

Technology and Environment

Arnold Pacey

The development of technology has usually been socially determined, changing in direction as different social formations have emerged. For example, there are important distinctions to be made between, first, small communities of farmers or dispersed groups of hunters with technologies outstanding chiefly for their adaptation to local *environments*; second, the larger kingdoms and empires, whose technology tended to be *engineering-centred*; and third, trading communities and merchants or entrepreneurs with *production-centred* technologies.

An initial problem in discussing technologies of the first kind is nomenclature. J. S. Weiner, who has discussed the remarkable protective clothing developed by the Inuit for life in the Arctic, has described these people as "the great pioneers of micro-climatological bioengineering". This tribute to the control of body heat loss achieved by Inuit clothing is well deserved but places the skills of Arctic people within the wrong frame of reference. Their technology was environment-centred, not engineering-centred. On the one hand, they were adapting to a very demanding environment; on the other, they were making very efficient use of environmental resources. Thus, the animals hunted for meat were also a source of oil for lamps, bone for making needles and other tools, and the skins, intestines, and fibres from which clothing was made.

Archaeological evidence suggests that the invention of tailored skin clothing adequate to enable people to winter in the Arctic was accomplished in Siberia around 2000 BCE. After that, it was several centuries before oil lamps, houses built of snow, and dog sleds were developed by the people of the Dorset Culture, based on Baffin Island. Later still, improved boats and harpoons were developed by the Alaskan Inuit.

All these inventions, quite clearly, were the work of small, dispersed groups without centralized organization, and all were responses to an exacting environment. Perhaps what we ought also to remember is that for the Inuit, as for most non-Western peoples, the environment was endowed with personal and spiritual meanings and with magical qualities. It was not merely the object of detached, if concerned, analysis that it has become for most Westerners. Thus, their technology was based on an organic worldview.

The same points can be made about peoples inhabiting other environments, such as rainforests, deserts, steppes, or coastal and island situations. The efficiency with which resources were used by such people is illustrated by the estimate that in 1500 CE the Amazon basin supported a somewhat larger population than it did in 1990, yet without the extent of destruction of forest and fishery resources now taking place. Fruits, nuts, leaves, seeds, and roots were gathered for use as food and medicine. Fish and animals were caught, often using poison tipped spears, but with less ecological disturbance.

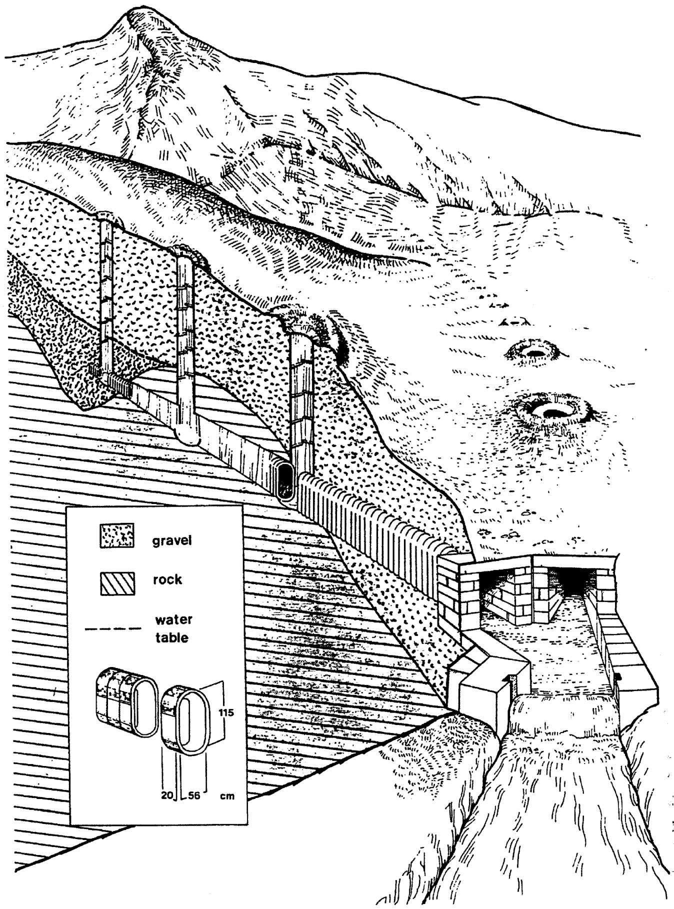
In some rainforests, notably in Central America as well as in Asia and Africa, people developed a form of agriculture in which a great variety of crops was raised while extensive tree cover was retained. Cereals such as corn in the Americas or rice in Southeast Asia were grown in forest glades with shade-tolerant vegetables under trees. Those trees that were left unfelled or were newly planted would be selected according to whether they produced fruit, nuts, timber, fodder, or *materia medica*. Thus, an artificial rainforest was formed in a system often referred to as forest farming, forest interculture, layered gardening or, more recently, agroforestry. The key point – whatever the name – is that there would always be tree cover, and usually other vegetation, to protect the soil from erosion and to retain plant nutrients. By contrast, where rainforest is cleared for conventional western style agriculture, soils become degraded very rapidly.

In Africa, rainforest crop production became widespread only after the banana and Asian yam were introduced on the east coast by Indonesian traders and colonists around 400–500 CE. In quite a short space of time, these crops were adopted by many gardeners across the continent, enabling populations in forested areas to increase considerably. In Central America, archaeologists have now shown that the Maya culture used forest farming with high yielding nut trees and manioc (cassava) as major crops around 600–900 CE.

Other environment-centred technologies were those of people living in hot, dry, and semi-desert conditions who evolved sophisticated water conservation techniques. Some of these made use of small structures, such as check dams in gullies and spreader dikes on flatter ground – for example, in northern Mexico and Arizona – or else stone lines on contours (in the African Sahel). Others practiced the careful planning of fields in relation to rainwater catchment areas, and the construction of bunds (embankments or dikes) to channel water and hold it on the land. Among the most elaborate rainwater harvesting systems of this kind were those of Nabataean farmers in the Negev Desert in Israel from about 200 BCE, and comparable systems in Morocco and elsewhere in North Africa. Small dams, river diversions, and the Persian *qanat* (wells linked by a tunnel; Fig. 1) were other means of providing irrigation water to crops on a small scale.

Consideration of environment-centred techniques such as these offers a distinct perspective on early technology quite unlike the conventional view based on the materials from which tools were made, namely, stone, bronze, and iron. That view seeks to discover a pattern of tool use and metalworking skill common to all human societies, and ignores the environmental particularism emphasized here. It parallels the modern assumption that the principles of technology are independent of cultural values and underestimates the different ways in which human societies explored the varying surroundings in which they lived. By contrast, a perspective based on environmental adaptation allows one to recognize the extraordinary sophistication of some peoples who nominally remained in the "Stone Age" even in the early twentieth century, including the Inuit and some rainforest communities.

Viewed from another angle, however, the Neolithic period in the later Stone Age does seem to have been a time of particularly important innovation, at least for western Asia. It is associated with the first domestication of crops and livestock, and hence the invention of agriculture, probably associated with the earliest used of some of the water conservation techniques previously discussed. Complementing these innovations were



Technology and Environment. Fig. 1 Two *qanat* tunnels in a typical landscape, where rainwater running off mountains replenishes groundwater beneath the sand and gravel of the lower slopes (water-bearing gravel is shown darker than the dry gravel layer above). The ground penetrated by one of the *qanats* is shown in cut-away section to demonstrate how the tunnel gives access to water trapped by impervious rock. The section also shows how the tunnel is lined with earthenware rings when passing through sand or gravel layers which might otherwise cave in. *Qanat* tunnels were excavated from the bottoms of a series of well shafts, with the "mother well" at the upstream end dug first to prove the existence of water. The tunnels were sometimes several kilometres long with their route evident on the surface from the line of well shafts, as on the right of the picture (illustration by Hazel Cotterell based on sketches by Arnold Pacey; reproduced from Pacey 1990: 86).

others, such as pottery (and soon after, the potter's wheel), grain milling, tool-making, and textiles (with the looms on which they were woven). Many of these innovations relate to the domestic sphere of life, and it is likely, therefore, that many of the inventors concerned were women.

It would be a mistake, however, to assume that the invention of agriculture, the domestication of plants, and the appearance of pottery or textiles were unique events, each occurring only once in human history, in one part of Asia and then diffusing to other regions. Independent inventions undoubtedly occurred, just as different crops were domesticated in various places and at different times. For example, about 1500 BCE, corn (i.e. maize) and pottery were both known in Mexico, but not in Peru, where beans and peppers were cultivated. Thus, the two cultures may have developed agriculture independently of one another. Moreover, some plants were still being newly domesticated in the twentieth century, for one reaction to deforestation in Africa has been to cultivate a number of fruits and vegetables that people had collected from the wild until the loss of forest cover threatened their existence. Reports from Kenya show how modern gardeners, usually women, have selected from wild varieties and have produced strains adapted for garden conditions.

Engineering-centred technologies developed in a very different context. They were characteristic mainly of kingdoms or empires whose labour resources and administration made large-scale construction works possible. One view of the origins of engineering is that once agriculture was established, irrigation became

T

necessary in many of the warm, dry countries of western and southern Asia to produce sufficient food for growing populations. The dams and canal systems necessary for irrigation could not have been constructed, it is argued, without recruiting a large labour force, and that in turn could not have been done except in centrally organized kingdoms. In this view, the need for irrigation canals and other hydraulic works dictated the formation of centralized government administrations with the coercive power and management skills needed to organize large-scale construction works.

This theory about how hydraulic civilizations evolved does not apply everywhere, however, since empirical evidence shows that in many areas where irrigation was practiced, farmers did the essential earth moving and engineering work themselves, or with their neighbours through local systems of cooperation, but without central organization. This seems to be true for rice culture in China, according to Francesca Bray. Some of the biggest centrally organized engineering schemes prior to 605 CE, involving thousands of labourers, were not for irrigation but for construction of transport canals for carrying grain to the capital. However, flood control and irrigation in North China did depend on large-scale works, so the evidence is not clear-cut.

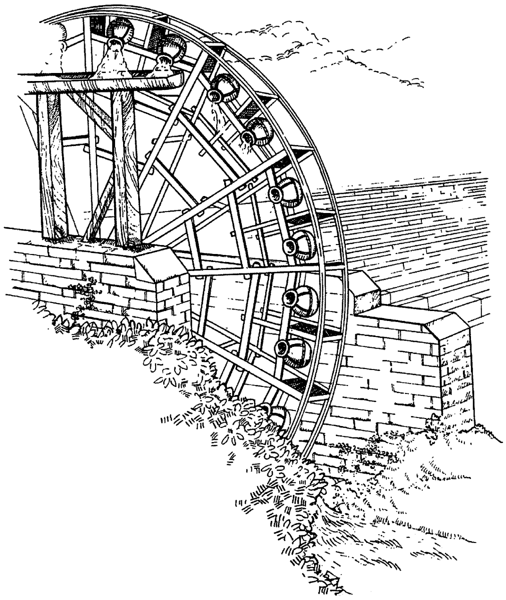
In Mesopotamia and Egypt, much early irrigation was also on a small scale, dependent on manually operated water-raising devices such as the *shaduf* (a device consisting of a long suspended pole weighted at one end and having a bucket at the other end). The type of crops grown and the seasons of cultivation meant that there were fewer water requirements in early agriculture than after the agricultural revolution of the Islamic period (after 700 CE), when crops that demanded more water (including rice) were more widely grown. In Mesopotamia, large-scale works were needed at an early date, but in most places it is hard to argue that the requirements of hydraulic management were sufficiently exacting to determine the development of centrally organized states. On the contrary, the prior existence of centralized political power made possible a wide range of construction programs that included fortifications, monuments, and temples, as well as hydraulic works, and it is impossible to say which kind of engineering came first. One of the earliest sites to provide evidence is Jericho, where defensive walls, but also big water tanks, have been found dating from before 6000 BCE. The pyramids of Egypt were among the largest construction projects ever conceived when they were begun about 2600 BCE. But a comparable amount of labour may have gone into embankments and canals built at about the same time for flood control and irrigation by the Sumerians in Mesopotamia. Thus, the evidence does not give a clear picture of hydraulic requirements, rather than other construction works, forcing the pace in either administration or engineering.

That brings us to a second hypothesis about how engineering-centred technologies evolved, suggested by Lewis Mumford and some like-minded commentators. This is the view that such technologies were related to the invention of warfare, for indeed, organized lethal warfare had to be invented, and this may have happened during the Neolithic age, possibly following the invention of agriculture. The reasoning here is that agriculture made possible denser populations within which social tensions were inevitable and from which large bodies of fighters could be recruited, while at the same time, agriculture produced the economic surplus needed to pay for arms and fortifications. It is suggested, also, that centralized governments and military institutions began to evolve about this time, and provided a model of how large bodies of people could be organized and supervised, not only in combat, but also in constructing fortifications – or dams, canals, and pyramids.

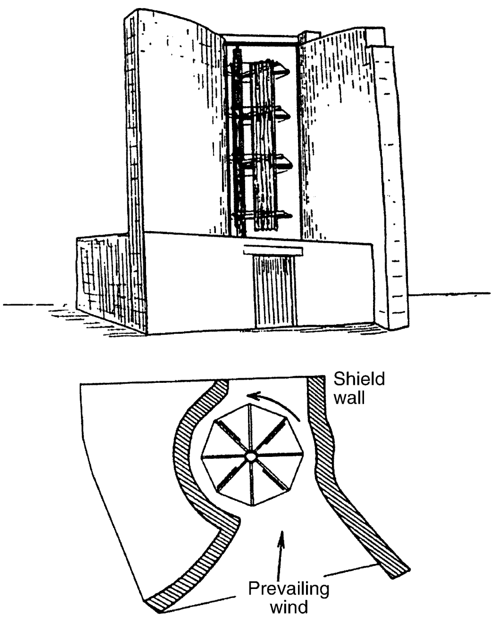
Needless to say, the development of warfare provided other stimuli to engineering-centred technology. Mechanized fighting may be said to have begun with the clumsy, four-wheeled Sumerian chariot of about 2400 BCE. The Hittites, whose empire overlapped Asia Minor and Syria, invented some of the first effective siege engines soon after. Horses were initially used mainly for drawing chariots, their full potential for warfare only emerging much later with the invention of the stirrup and its associated harness. This freed the rider's arms to use weapons while he remained securely in the saddle.

Engineering-centred technologies in ancient civilizations can appear to be focused very largely on large-scale hydraulic works and on military engineering. In addition, one bias in the western understanding of technology is a tendency to focus on the wheel, and on machines using wheels, such as the early chariots just mentioned. But wheels did not always mean progress. Wheeled vehicles were used in the North and West of Africa around 500 BCE, regularly crossing the Sahara Desert. Yet they went out of use later when the camel was introduced, because camels provided much more efficient means of transport in a region with sandy deserts and no paved roads. For parallel reasons, wheeled vehicles were not much used in southern Asia. In Central America, rollers and wheeled toys have been found, but in a region where there were no animals capable of pulling carts, little could be gained by developing such devices.

The potter's wheels (and later, lathes working on similar principles) were probably the first machines to use the wheel, around 3000 BCE. Much later, a basic water-powered corn mill evolved, with a vertical axle



Technology and Environment. Fig. 2 Water-raising wheel of the type known as the *noria*. This is an undershot water wheel, driven by the flow of water in the stream running underneath it. The jars tied to the rim fill from the stream and then empty into the trough at the high level (illustration by Hazel Cotterell; reproduced from Pacey 1990: 11).



Technology and Environment. Fig. 3 Persian-type windmill showing how shield walls were designed to funnel wind onto the sails, which rotated on a vertical shaft. The way the mill worked is most clearly seen from the plan (lower illustration). The perspective view shows how the shield walls of later mills formed a towering open structure built of sun-dried bricks with a small room containing the millstones underneath. The earliest mills seem to have been of different design with the millstones supported by the shield walls at the top of the structure (illustration by Arnold Pacey, based on photographs by Dick Day of a windmill in Afghanistan; reproduced from Pacey 1990: 12).

and propeller-like blades below the millstones. One view is that this was a Greek invention made about the time of Alexander the Great. Another view, however, is that it arose out of the Hittite tradition of engineering which had earlier pioneered so much military equipment. After the Hittite empire collapsed around 1200 BCE, some aspects of its culture survived in Syria, and itinerant craftsmen perhaps reached Mesopotamia and Iran. It was probably in one of these countries that vertical-axle water mills originated. Since the same type of mill appeared in China not long afterwards, one might reasonably look for its origins close to trade routes with China. A related invention of the same period was the water-raising wheel or *noria*, a basic water wheel with a horizontal axle and pots or buckets attached to its rim in which water could be raised (Fig. 2).

Some thousand years later, Iran was certainly where an early type of windmill was invented. It worked in much the same way as the vertical-axle water mill, though mounted in a tower with vents in the walls to catch the wind (Fig. 3).

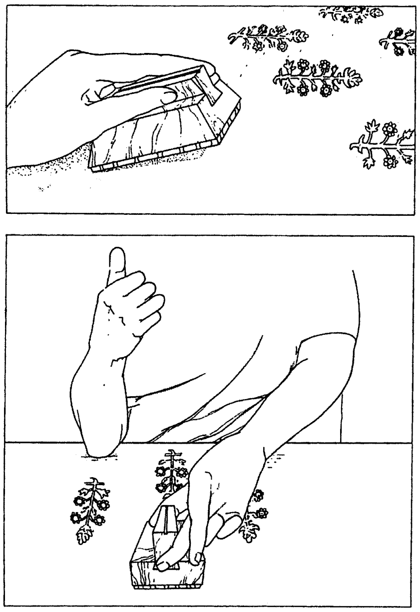
In both Iran and Iraq extensive use was made of water wheels of several types, and some large dams were erected. Other uses of water power in this region around the year 1000 CE were in sugar cane crushing mills, fulling mills, and mills for preparing the pulp for papermaking. Paper manufacturing had been introduced at Baghdad in 794 CE, probably with the help of Chinese workmen, and water wheels were used to work hammers that made pulp from 950 CE.

Production-centred technologies can be said to include devices such as corn mills, or iron smelting, or the porcelain industry which developed in China. Other evidence of production technologies in China includes several inventions that first appeared there in the three or four centuries prior to 1250. They include spinning wheels, silk-winding machines, and water-powered mills for spinning and winding thread.

Much production of pottery and textiles would be carried on in a domestic context, but there were also instances of large-scale production, of which the most characteristic unit in South Asia was the *karkhana* of Mughal India, or the specialist porcelain factory in China. At one time 4,000 silk workers were employed in karkhanas in Delhi, some of them conscripted.

Production for purposes of trade had to be more flexibly organized and flourished most markedly where merchants could function independently. By 1700, India had become the world's greatest exporter of textiles, sending its cotton cloth to Europe, Africa,

T



Technology and Environment. Fig. 4 Indian technique for printing designs on cloth using a wooden block, applied by hand to transfer a mordant (rather than the dye itself) to the cloth. Mordants are chemical substances that made the cloth receptive to dye. First the wooden block carved with the flower pattern being printed is carefully placed in position (top), and then it is struck sharply with the right hand to transfer the mordant solution from the block to the cloth (illustration by Hazel Cotterell based on sketches by Arnold Pacey; reproduced from Pacey 1990: 85).

Technology and Environment. Fig. 5 Alum production in Rajasthan, India, about the year 1800 CE. Shale tips associated with copper mines provided the raw material and can be seen in the background on the right. Shale was steeped in water in rows of pots on the tips. The liquid was then brought to the boiling house seen to the left where some water was evaporated off and the pots left to stand. Blue crystals of copper sulphate formed and were removed. After decanting the liquid and boiling it again, saltpetre was added. The alum was formed by reaction of the saltpetre with aluminium salts in the solution, and crystallized at the bottom of the pots (illustration by Hazel Cotterell based on sketches by Arnold Pacey; reproduced from Pacey 1990: 122).

and many destinations in Asia. Both Indian and foreign merchants were involved, sometimes financed by the many Parsi and Gujarati bankers to be found in ports such as Surat.

It should not be thought, however, that proto-capitalist industrial organization was always favourable to the use of machines, water-powered or otherwise. The high quality of Indian textiles was achieved by painstaking handwork, as in the printing of designs on cloth (Fig. 4), and sometimes by a very fine division of labour. British observers noted that cotton cloth would sometimes be worked on by four people for every one employed on the same tasks in Europe. Thus the remarkably fine muslin produced in Bengal was the result of many detailed processes which would be simplified and reduced to a single operation in the West.

Indian cloth was also noted for the fastness and brilliance of the colours with which it was dyed, mostly using vegetable dyes such as indigo and madder. However, some inorganic substances were also needed as mordants, to help dyes bond with textile fibres and often modifying the colour, and this gave rise to a significant chemical industry. For example, the alum used in madder dyeing was produced in Rajasthan by processing broken shale tipped as waste around copper mines (Fig. 5). These chemical processes were operated on a substantial scale but using labour-intensive methods and minimal equipment. Merchants and banks had ample funds to invest in the textile trade, but because wages were low, there was little advantage in financing more productive equipment.

Technology is too often equated with engineering and hence with structures, machines, or equipment. However, a deeper understanding of technology in non-Western cultures demands awareness of subtleties in responses to the environment by which human survival was guaranteed in very varied conditions, and subtleties in the use of materials (such as dyes and mordants) by which high-quality production was achieved without machinery.

Thus while engineering-centred technologies that are easy to illustrate with pictures of machines are central to most people's image of what technology is about, a more fundamental view of technology must take account of responses to the environment that cannot easily be illustrated, such as rainwater harvesting or agroforestry where there are no machines to illustrate.

Technology in the Islamic World

Donald R. Hill

Hydraulic engineering was the most important technology of medieval Islam. Irrigation schemes supported a thriving agriculture and such schemes involved the construction of canals and *qanats* (see below), dams and water-raising machines. At the other end of the chain, water power was needed to process the raw agricultural products. In this article, we will begin with a survey of hydraulic engineering which will give us an overview of many of the significant aspects of Islamic technology.

Following this, a brief summary of a few other technologies will help us to appreciate the richness and diversity of Islamic material culture. The brevity of this summary is because of limited space and should not mislead readers into thinking that these technologies were insignificant, either in the social life of Islam or in the history of technology.

In Egypt, basin irrigation was in general use. This consists of leveling large plots of land adjacent to a river or canal, and surrounding each plot by dikes. When the river reaches a certain level the dikes are breached, allowing the water to inundate the plots. It remains there until the fertile sediment has settled, whereupon the surplus is drained back into the watercourse.

The regime of the Nile, with the predictable arrival of the flood, made Egypt particularly suitable for basin irrigation. Elsewhere in the Islamic world, however, perennial irrigation was, and is, practiced extensively on all the major river systems. As the name implies, it consists of watering crops regularly throughout the growing season by leading the water into small channels which form a matrix over the field. Water from a main artery – a river or a major canal – is diverted into supply canals, then into smaller irrigation canals, and so on to the fields. In many cases the systems operate entirely by gravity flow, but water-raising machines were used to overcome obstacles such as high banks, whether they were natural or artificial. Perennial irrigation from wells, again using water-raising machines, is also extensively practiced in the Islamic world.

After the advent of Islam a number of existing systems were extended in order to cater for the needs of newly founded cities. Completely new systems were also constructed. In central Iraq the Muslims inherited the network constructed by their predecessors, the Sasānid dynasty of Persia. The major expansion occurred after the foundation of Baghdad in AD 762. The great Nahrawān canal, which left the east bank of the Tigris a short distance below Takrīt, was extended southward.

The rivers ʿUzaym and Diyāla, which discharge into the Nahrawān from the east, were dammed by the Muslim engineers to provide water for a huge irrigated area. Further south, to the west of the Shaṭṭ al-ʿArab, the city of Basra was founded in the seventh century. Originally it was simply an army encampment consisting of reed huts, but soon it grew into a great city which had no rival in Islam before the foundation of Baghdad. Gradually, in the last decades of the seventh and the first decades of the eighth centuries a vast network of canals was constructed to serve the demands of a thriving agriculture.

Other important systems were based upon the rivers in the province of Khurāsān, then much larger than the eastern Iranian province of the same name. Some of the most impressive networks were based upon the river Murghāb, upon which stands the city of Marv. In the tenth century the system was controlled by a specially appointed Amir who had 10,000 men under him, each with an appointed task. This Amir is said to have had more authority than the prefect of Marv. Other important schemes in the east were those centered on the cities of Bukhārā᾽ and Samarqand and on the lower reaches of the Amu Darya (Oxus) river.

In Spain, the Muslims greatly extended the irrigation schemes that had been constructed by the Romans and Visigoths. Syrian irrigation technology – large contingents of the conquering armies were from Syria – was applied in Spain, where the climatic and hydraulic conditions of the rivers of the north were very similar to those in Syria. The irrigation systems, such as those along the Gudalquivir river and those in the province of Valencia, were the basis of the agricultural prosperity of Muslim Spain. Indeed, systems such as that in Valencia, basically unchanged since Islamic times, continue to serve the needs of the province to the present day.

A particular technique, originating in Armenia about the eighth century BCE, and still in widespread use in modern Iran, was the *qanat*, an almost horizontal underground conduit that conducts water from an aquifer to the place where it is needed. For the preparatory work an experienced surveyor carefully examines the alluvial fans, the terrestrial equivalent of a river delta formation, in the general location of the proposed *qanat*, looking for traces of seepage on the surface and often for a barely noticeable change in vegetation, before deciding where the trial well is to be dug. When a successful trial well has been excavated, it is now known as the mother well. The surveyor levels from this point to the outlet of the qanat, marking the positions and levels of the proposed ventilation shafts at 30–50 m intervals. These shafts also provide for excavation of the spoil. A skilled artisan (*muqannī*) then begins work with his assistants by driving the conduit into the alluvial fan, starting at the mouth. At first the conduit is an open channel, but it soon becomes a tunnel. Another team sinks ventilation shafts ahead of the tunnelers, and laborers haul up the spoil to the surface through these shafts by means of a windlass. The tunnel is about 1 m wide by 1.5 m high; in soft soil hoops of baked clay, oval in shape, have to be used as reinforcement. As the work nears the mother well, great care has to be taken in case a muqanni misjudges the distance and strikes the full well, in which case he might be swept away by the sudden flow.

The construction of canals, qanats, and other public works required the assistance of skilled surveyors. The earlier methods of leveling were rather slow and tedious. This involved stretching a string between two staffs divided into graduations and held vertically. A level was suspended to the center of the string. One type, for example, was an inverted isosceles triangular frame suspended by hooks to the string. Fixed to the center of the horizontal leg was a plumb line. One end of the string was moved up or down the staff until the plumb line passed through the inverted apex of the triangle, at which point the string was level. The difference in level between the two staffs was noted. In the eleventh century a level was introduced akin to our modern instrument but without, of course, any telescopic or electronic aids. A thin copper tube rotating on a circular plate that was suspended to a "gallows" was aimed horizontally on to a level staff. The reading gave the difference in level between the two points. The rises and falls along the route of the survey, summed algebraically, gave the level difference required. Triangulation, by which the heights and distances of objects, whether accessible or not, could be determined was usually carried out by the astrolabe. Quantity surveying methods were very similar to those in use today. The amount of excavation for a canal, for instance, was first calculated. Then, by applying known unit rates, the engineer worked out the number of excavators, laborers, foremen, and supervisors. From these results he prepared a Bill of Quantities which was used for measuring progress and paying the contractor.

The main purpose of dams was to divert water from rivers into irrigation systems. Our knowledge of Muslim dams comes from two sources: reports in the works of Muslim geographers, and the examination of Muslim dams which have survived to the present day. In the east, one of the most impressive dams, known as the Band-i-Amir, was built in 960 over the river Kūr in Iran, between Shirāz and Persepolis. As described by the tenth-century geographer al-Muqaddasī, it was used to irrigate 300 villages. At each side of the dam, downstream, were ten water-raising wheels and ten water mills, all given extra power by the head of water impounded behind the dam. The dam was constructed throughout of masonry blocks, and the joints were made of cement mortar strengthened with lead dowels. The dam still exists and it is not surprising, given the solidity of its construction, that it has had such a long and useful life.

Also in Iran, at Kebar, about 15 miles south of Qum, is a dam which is very important in the history of dam construction. Built in the thirteenth century, it is the first known example of the true arch dam. It did not depend for its resistance to water pressure on gravity but was built as an arch, its convexity pointing upstream, and its sides were anchored securely into the rocky sides of the gorge in which it was built. The forces were transferred to the abutments, and it was considerably more slender than a gravity dam across a similar river.

A number of important Muslim dams were built in the Iberian peninsula. These included the dam at Cordoba with an overall length of 1,400 ft. Downstream from the dam were three millhouses that each contained 4 mills, as the geographer al-Idrīsī reported when he saw them in the twelfth century. Also below the dam is a large waterwheel. There are a series of eight dams on the river Turia in the province of Valencia. They are very securely built in order to withstand the sudden dangerous floods to which the river is subjected. They are also provided with desilting sluices, without which the canal intakes would soon become hopelessly choked.

These dams and their associated canals continue to provide for the needs of the province at the present time. It has been shown in modern measurements that the eight dams and their associated canals have a total capacity slightly less than that of the river. This, of course, raises the question whether or not the Muslims were able to gauge a river and then design their dams and canals to match. There seems no reason to doubt that they indeed had that capability.

Given that dam building had been an established practice since the times of the Sumerians and ancient Egyptians, it is not easy to isolate those elements that were Muslim innovations. On present evidence, it seems certain that the introduction of desilting sluices, the arch dam and hydropower were all Muslim inventions. The Muslims also probably perfected the technique of gauging rivers.

All the main water-raising machines were in existence in the Middle East before the advent of Islam. These included the Archimedean screw, the well windlass, the *shādūf*, the *sāqiya* and the *noria*. Because of their survival right up to the present day, and/or their importance in the development of machine technology, the last three of these are the most significant. The *shādūf* is illustrated as early as 2500 BCE in Akkadian reliefs, and it has remained in use throughout the world until now. Its success is due to its simplicity and its efficiency. It can be easily constructed by the village carpenter using local materials, and for low lifts it delivers substantial quantities of water. In consists of a long wooden pole suspended at a fulcrum to a wooden beam supported on columns. At the end of the short arm of the lever is a counterweight made of stone or clay. The bucket is suspended to the other end by a rope. The operator lowers the bucket and allows it to fill. It is then raised by the action of the counterweight and its contents are discharged into an irrigation ditch or a head tank.

The *sāqiya* was invented in Hellenistic Egypt, probably in the third century BCE. It is operated by an animal, usually a donkey, walking in a circle. On its shoulders and neck the animal wears a collar harness that transmits the power through two traces to a doubletree fastened to a drawbar. The drawbar passes through a hole in an upright shaft. This shaft carries the lantern-pinion, which is a type of gear-wheel consisting of two wooden discs separated by pins, the spaces between the pins being entered by the cogs of a vertical gear. This vertical gear has the cogs on one side of its disc and these protrude from the other side to form the wheel that carries the chain-of-pots, or potgarland. The component is therefore known as the potgarland wheel. It is erected on a horizontal axle over a well or other water source. The pots fill with water at the bottom of their travel and discharge at the top, like the shadoof, into a head tank or irrigation ditch. The saqiya was transited by the Muslims from the Middle East to Spain and eventually to the New World. In some areas it has retained its popularity to the present day.

The *noria* is perhaps the most significant, from a technical viewpoint, of the traditional water-raising machines. Being driven by water, it is self-acting and requires the presence of neither man nor animal for its operation. Essentially it is a large wheel constructed of timber. At intervals, paddles project outside the rim of the wheel, which is divided into compartments. The noria is provided with an iron axle and this is housed in bearings that are installed on columns over a running stream. As the wheel is rotated by the impact of the water on its paddles, the compartments fill with water at the bottom of their travel and discharge their contents at the top, usually into an aqueduct.

The point of origin of the noria is unknown, but it was certainly known in the Roman world and in China by the first century BCE. There is a possibility, therefore, that it was invented somewhere in the highlands of southwest Asia. The large noria at Murcia in Spain is still in operation, as are norias in various parts of the world, where they are often able to compete successfully with modern pumps.

Water wheels, as used in mills, were of three types: vertical undershot, vertical overshot, and horizontal. The first type was a paddle wheel mounted directly in a running stream. In the overshot wheel the rim was divided into compartments into which the water was directed from above, usually from an artificial channel or leat. Both vertical wheels required a pair of gears in order to transmit the motion of the water wheel to a vertical axle that led up to the millstones. In the horizontal type a jet of water from a reservoir was directed on to the vanes of the wheel, on the top of whose axle the millstones were installed. Various methods were used to increase the power and hence the output of mills. The wheel could be located in the piers of bridges or on boats moored on rivers, in both cases to take advantage of the increased rate of flow in midstream. In the Basra area in the tenth century there were mills that were operated by the ebb tide – about a century before the first mention of tidal mills in Europe. Apart from the production of flour from grains, water mills were also used for industrial purposes such as papermaking, the fulling of cloth and the crushing of metallic ores.

Bridges of all types were important in the Islamic world not only for communications but also for protecting the banks of canals from damage due to fording people and animals. In the mountains of Central Asia, such as the Tien Shan and Hindu Kush ranges, both cantilever and suspension bridges were used for crossing ravines. The great rivers of Egypt, Iraq, and Transoxiana were usually crossed by bridges of boats. In many cases, however, rivers and other obstacles were crossed by masonry arch bridges built of dressed stone or, sometimes, especially in Iran, of kiln-burnt bricks.

Two bridges in western Iran, built in the tenth century, are constructed with pointed arches. This type of arch, which was to be such an important element in European Gothic architecture from the twelfth century onward, had appeared in Syria and Egypt during the seventh and eighth centuries, but only as a decorative feature. These Iranian bridges are the earliest known occurrence of the pointed arch as a load-bearing component.

Chemical technology was a highly developed profession in medieval Islam. The most important writer on the subject was Muḥammad ibn Zakariyyāʾ al-Rāzī. Although he wrote a number of alchemical books, his major work, *Kitāb al-asrār* (The Book of Secrets), written early in the tenth century, leaves us with the impression of a powerful mind, much more interested in practical chemistry than in theoretical alchemy. *The Book of Secrets* contains a comprehensive list of pieces of equipment, many of which are still in use today. The chemical processes described or mentioned by al-Rāzī include distillation, calcination, solution, evaporation, crystallization, sublimation, filtration, and amalgamation. Arabic works were undoubtedly an important influence upon the development of European chemistry. Evidence for this influence is the abundance of Arabic words in the chemical vocabularies of European languages. Examples in English are alkali, alchemy, alcohol, elixir, naphtha, and many others.

Mining played an important part in the economic life of the Islamic world. Spread throughout this vast area were mines for all the important metals, precious stones and essential commodities such as salt, coal and petroleum. The oilfields at Baku were exploited by the Muslims on a commercial scale by the ninth century. In the thirteenth century Marco Polo reported that a 100 shiploads could be taken from Baku at one time.

Iron and steel were, of course, the most important metals for many industrial and military purposes. Cast iron was described about 1040 by the great scientist al-Bīrūnī – it was exported to many countries as a raw material. There was also an extensive steel industry which produced, among other grades, the famous Damascus steel. As far as we can ascertain at present, this came from a number of Islamic centers in the Middle East and Central Asia. But it was certainly produced in Damascus itself.

We have been able to mention only the more important areas in which Muslim engineers and technologists were pre-eminent for several centuries. In many cases Islamic ideas were transmitted to Europe, but it is important not to evaluate Islamic technologies only with regard to their contribution to their European counterparts. Technologists in the Islamic world were responding to the needs of society and were extremely successful in a number of fields.

Technology in the New World

Aaron Segal

The indigenous peoples of the New World were excellent builders. Although their construction tools were limited they managed to produce pyramids, temples, and other public buildings in the Andean Highlands, the lowland jungles of Central America and the Yucatan, and the central highlands of Mexico. There were ceremonial ballcourts built throughout the Caribbean as well as in what is now Mexico, Guatemala, and Belize. Construction in North America included the mound sites of the Midwest and the Southeast and the cliff dwellings of the Southwest. While estimated populations at these sites varied from the hundreds to the thousands these were all urban societies and civilizations.

These master builders relied on their own concepts, designs, craftsmen, and techniques. In spite of claims of trans-Pacific, trans-African and other exogenous contacts, the evidence is sparse and less than convincing. The civilizations of the New World evolved on their own with only limited contacts with one another over space and time. Their achievements as well as their failure are entirely their own, including matters of technology.

The New World societies concentrated on identifying, applying, and improving instrumental technologies, whether for agriculture, irrigation, construction, crafts, or other utilitarian uses. The legacy that has survived is one of warrior-kings, royal courts, artisans cum farmers, priests and scribes, builders and artists.

The peopling of the New World began approximately 15,000 years ago when climatic changes made migration from Siberia and East Asia possible across the Bering Straits. It took another 8,000 years for these small wandering human bands to reach Patagonia and spread throughout most of Middle and South America. Somehow they managed to keep fertility above infant mortality as they diffused on foot throughout the New World. Hunters and gatherers, they relied on stone age worked flint edges to kill, strip, and consume their prey. Their principal weapon, originating in Asia, was the *atlatl* or spear thrower improved with flexible sheets and stone weights. Bows and arrows were introduced later, also perhaps from Asia via the Arctic, and became a favorite weapon for hunting bison on the Great Plains. When the Tainos paddled island by island from Lake Maracaibo up the Caribbean Archipelago (AD 1000–1400) they were armed with an array of bows, arrows, stone, bone, and flint knives, *atlatls* and other weapons.

Those who undertook the Great Journey throughout the New World survived through environmental adaptation as they fanned out across two continents. Those who adapted to the Amazon Basin continued in a hunter–gatherer mode, learning the skills needed to survive in the tropical rain forest. The Arawaks, Tainos, and other voyagers to the Caribbean also relied primarily on hunting and gathering adapted to coastal fishing. Latecomers who remained in the Arctic or sub-Arctic turned to hunting, fishing, shelter, and other technologies to survive harsh winters.

Agriculture probably arose about 3000 BCE simultaneously in the Andean highlands and Central Mexico, first as a supplement to hunting and gathering and as a response to growing populations. Gatherers observed which seeds yielded what plants and began to cultivate on a trial and error basis. Teosinte, a high-protein precursor of corn, was first cultivated in Mexico, while potatoes were an early ecologically suitable cultigen in the colder Andes. The list of cultivated edible plants soon expanded to include manioc, squash, peppers, pineapples, and other New World originals, especially several varieties of beans. The Tainos learned to grow tobacco and to cure it as snuff in their Caribbean islands, which became valuable trade items.

Agricultural technologies evolved to include the use of digging sticks, irrigation canals, terracing and ridging, intercropping, and seed beds. Lacking draught animals fires were set to clear new land. The most sophisticated technique was that of the *milpas* practiced by the Aztecs who built silted mounds of fertile run-off materials.

Food processing and storage technologies were also innovated and widely diffused. The stone *metate*, or mortar and pestle, became the basic Mesoamerican tool for crushing corn. Ethnobotanical experience produced a variety of herbs, spices, and for the Mexicans chocolate to add to largely vegetable diets. As towns and cities grew, especially in the Andes and Mesoamerica, hunting declined in favor of limited domestication of chickens, turkey, pond fish, and small animals. However, animal protein was hard to come by in all the predominantly agricultural societies which relied on trade and food storage to supplement local corn, beans, manioc, and other staples.

Transport was a severe obstacle for all the New World peoples. Dogs were used to pull sleds and traverse with limited loads in the Arctic and on the Great Plains. Alpacas and llamas were semidomesticated and used for limited local transport in the Andes. However, everywhere terrain was rugged, surfaced roads were few and far between, and runners and headloads were the primary mode of transport. Sailing vessels were unknown and the canoes of the Tainos and others had to hug shorelines for safety. Although the concept of the wheel was known, and toy wheels were used in the Andes, the lack of roads and the natural obstacles impeded the development of wheeled vehicles. The Spanish introduction of the horse and the cow revolutionized transport in the New World. Trade previously was confined to what could be carried on men's backs. Thus the Aztec long-distance traders, *pochotes*, specialized in high-value items such as jewelry, ceremonial feathers, and weapons.

Confined to limited home markets, New World societies tended to invest their agricultural surpluses in exquisite crafts. As royal courts developed around ceremonial centers so did specialized artisans capable of meeting quality demands, as well as items for daily use. The oldest discovered textiles date back 3,600 years to the Peruvian coast and were made of cotton with intricate woven designs. Dyed cotton for personal clothing became widely diffused with pendants and ornaments often added. Excavation of Andean and other tombs has revealed the importance attached to clothing and jewelry and the high skills of the artisans. The Olmecs of the Mexican Southeast were the first to work in jade and turquoise as well as to create massive stone carvings. Metallurgy, especially in the form of masks, was highly accomplished in Mexico as well as among the peoples of what is now Costa Rica, Colombia, and Peru.

Ceramics and basket and gourd work were closely associated with the emergence of agriculture. Initial demands were for items used for carrying and storage. However, in the Andes and Mexico, as techniques improved, ceramics became an important ceremonial art form. Funerary jars, urns, water carriers, ceremonial masks, and other items are regularly depicted in sculptures and paintings and found in Aztec, Maya, and other tombs. Pre-Incan and Incan Andean societies also took pride in their varied and elaborate ceramics, baskets, and gourds.

Ceremonials were held largely outdoors, while palaces were for storage purposes. Most common people, including craftsmen, lived, ate, and slept in simple mud and brick dwellings. Their lords and masters lived in larger and more solid enclosures but with similar creature comforts. Building skills were directed at large-scale public constructions to honor the deities and/or fortresses for defense purposes. While kings lived in palaces with a few of their retainers many members of the court had to accept more humble accommodations. The benign tropical climate of the Caribbean contributed to nearly everyone's relying on hammocks and huts made of straw.

The Aztecs alone tackled the sewage and other waste disposal problems of man-made cities. They instituted barges along the canals of their capital at Mexico City, and also made an effort to keep water potable. At the Inca capital of Cuzco public hygiene was minimal as it had been in the Maya city-states. It may have been the scarcity of domesticated animals that reduced disease vectors in these highly crowded urban sites.

As builders the peoples of the New World concentrated their efforts on specific times and places. These included the Olmec (1000–600 BCE), Tectihuacan (AD 0–650), Toltec (1000–1300 BCE), and Aztec (AD 1400–1530) civilizations in Mexico, the Mayas (AD 0–900) in Guatemala and Mexico, and the Moche (AD 0–600), the Nazca (AD 0–600), the Chimu (AD 1300–1420) and the Inca (AD 1400–1530) in Peru. They were able to construct magnificent and lasting buildings in environments as different as lowland jungles and highland mountains. They moved massive amounts of stone and carved and fitted it exactly with simple tools, as well as working with wood. Their architects designed vast open spaces and compelling interiors. Their multistory edifices reached up to the heavens, and served sometimes as astronomical observation sites, while commanding the world below. Their equivalents are neither the medieval cathedrals of Europe nor the Acropolis of Greece. Instead they are the most significant continuing testimony to the uniqueness of the these New World civilizations and peoples.

While we can directly experience and marvel at these sites it is much more difficult to penetrate the intellectual worlds of their builders. The Mayas, prior to their collapse in AD 800–900, had a sophisticated writing system which was lost, as were many of their ideas about astronomy and mathematics. Similarly, the Nazcas of coastal Northern Peru who vanished around AD 600 may have had more advanced ideas about astronomy than their predecessors. The unevenness of historical experience and its inherently nonlinear nature is one of the sobering lessons of the history of science and technology in the New World. The Mayas alone invented a writing system which took nearly 450 years after the European Conquest to decipher. The Incas adapted a system of counting called the *quipu* for purposes of accounts and storage but never extended it into a mathematical base. The Aztecs excelled at urban planning, irrigation, and public health but showed little interest in writing.

The peoples of the New World were builders, agriculturalists, and craftsmen rather than scholars or theologians. The European conquerors came from an age of iron and steel with wooden ships, navigation, steel swords, guns, explosives, and literacy. They brought horses, cattle, and smallpox, measles, diphtheria, trachoma, whooping cough, chicken pox, bubonic plague, typhoid fever, scarlet fever, amoebic dysentery, and influenza.

Telescope

Julian A. Smith

The telescope is an optical instrument used to make distant objects appear nearer and larger; it consists of one or more tubes with a series of lenses, mirrors, or both (refracting, reflecting and catadioptric models, respectively), through which light rays are collected, brought to a focus, and magnified. Despite their great variety, all telescopes have two basic parts: the objective, which intercepts and focuses the incoming light, and the mounting, which supports the objective. The telescope, which revolutionized astronomical research in the seventeenth century, is usually considered to be a European invention, though parallel discoveries occurred elsewhere, and some of its elements were developed earlier by other cultures.

The traditional Western account of the telescope's invention is quite complex. The use of hollow sighting tubes without lenses to observe stars had been known to the ancient Greeks, being recorded by Aristotle (384–322 BCE) and the geographer Strabo (ca. 63 BCE–ca. 19 AD). Lenses are mentioned by the playwright Aristophanes (ca. 450–388 BCE), and mirrors were investigated by Heron of Alexandria (ca. 60 AD). The geometer Euclid (ca. 300 BCE) and the engineer Archimedes (ca. 287–212 BCE) studied both. The investigation of lenses, mirrors, and sighting tubes continued throughout the Medieval period. The invention of spectacles, an important telescope precursor, occurred between 1285 and 1300 by an unknown Italian glassmaker, but Alexandro della Spina (d. 1313) and his friend Salvino d'Armati (d. 1317) are most often credited. Meanwhile, English Franciscan friar Roger Bacon (1211–1294) wrote extensively of spectacles and other optical devices, and influenced many later scientists with his research into the laws of reflection and refraction.

An enormous number of sixteenth century figures developed various combinations of perspective glasses and mirrors to enlarge distant objects, including the English father and son surveying team of Leonard (ca. 1520–ca. 1571) and Thomas Digges (1546–1595), mathematician William Bourne (d. 1583), Italian natural philosopher Giambattista della Porta (1534/5–1615), and Dutch mathematician Cornelius Drebbel (1572–1634). But the lack of documentary evidence has thus far left historians divided over whether these instruments were true telescopes or just magnifying glasses.

The first unambiguous accounts of the European telescope come from Holland around 1608. Most credit the Middleburg spectacle maker Hans Lippershey (ca. 1570–1619) with the first refracting telescope; but there are rival claims by Middleburg optician Zacharias Jansen (1580–ca. 1638), and Alkmaar inventor Jacob Metius/Adriaanzoon (1571–1635).

Early telescopes were first applied to military operations. But over the winter of 1609–1610, Italian physicist and astronomer Galileo Galilei (1564–1642) dramatically improved Lippershey's primitive device and turned it to the sky. His announcements of lunar valleys and mountains, sunspots, the phases of Venus, the moons of Jupiter, and much more (published in the March, 1610 *Sidereal Messenger*) thoroughly shook the ancient earth-centered cosmology of Alexandrian astronomer Claudius Ptolemy (ca. 150 AD). Similar observations were made between 1609 and 1612 by English polymath Thomas Harriot (1560–1621). The word "telescope," meanwhile, was coined in 1611, and was first printed in Julius Caesar Lagalla's (1576–1624) *Lunar Phenomena* of 1612.

Early Galilean telescopes, with one biconvex and one biconcave lens, suffered from both chromatic and spherical aberration, which left blurry images. The German astronomer Johannes Kepler (1571–1630) designed the improved Keplerian telescope of two biconvex lenses in 1611, but problems remained. It was not until 1636, when the Minorite friar Marin Mersenne (1588–1648) suggested replacing lenses with mirrors, that real progress could be made. Reflecting telescopes were designed by Scottish mathematician James Gregory (1638–1675) in 1663, and built a few years later by both Isaac Newton (1642–1727) and French physicist Guillame/Nicholas Cassegrain (fl. 1672); these models (Newtonian and Cassegrain) are still widely used today.

During the period 1610–1650, the telescope was carried by European explorers to all regions of the earth; frequently Jesuit missionaries exported it to non-Western cultures. However, there is evidence that other societies developed both the telescope and its various parts independently of Europe. Glass originated in Egypt about 3500 BCE and was first produced on a large scale by the Phoenicians, and lenses dating back to pre-Greek times (2000 BCE) have been discovered in Crete and Asia Minor/Mesopotamia.

Meanwhile, Arabic astronomers played a significant role in paving the way for the telescope. The mathematical laws of optical reflection and refraction in glass and other media were thoroughly investigated and extended by the physicist–astronomer Ibn al-Haytham (Alhazen, 965–ca. 1040). Ibn al-Haytham knew how to use spherical glass segments to magnify objects, and was familiar with spherical aberration and techniques to calculate the focal lengths of lenses and mirrors. Much of this knowledge was subsequently transmitted to Europe through Latin editions of his work, and especially through the texts of his Polish disciple, Witelo of Silesia (ca. 1230–ca. 1275). Bacon also learned much from Ibn al-Haytham.

Sighting tubes were also early employed by Arabic astronomers; al-Battāni (858–929) used them in his Raqqa observatory. Naṣīr al-Dīn al-Ṭusī attached one to a sextant at his Maragha observatory in 1259 to study the sun.

Meanwhile, Needham argues that Chinese opticians may have discovered the elements of the telescope either before, or parallel to, the Europeans. Though glass was developed fairly late (ca. 500 BCE), quartz rock-crystal had been in use since ancient times and lenses of both materials were employed to focus solar rays to start fires. Needham also claims the Chinese used smoky rock-crystal to observe sunspots and eclipses. An important text of Tan Qiao (the *Hua Shu* or Book of Transformations of about AD 940) records the use of planoconcave, planoconvex, biconcave, and biconvex lenses to make objects larger, smaller, upright, and inverted. Spectacles have often been considered a Chinese invention, but this is based on a garbled text; they were brought overland from Europe by 1300. As for catoptrics, Mohist opticians of the fourth century BCE studied both concave and convex mirrors, and were familiar with real and inverted images, focal points and refraction in different media. The use of concave mirrors to ignite tinder by focusing sunlight goes back to the Chinese Bronze Age; one of the earliest citations is dated 672 BCE.

Chinese sighting tubes made of bamboo are similarly old; the most important early reference is the (approximate) sixth century BCE *Shu Jing* (*Historical Classic*). By the *Huia Nan Zi* (*Book of Huai-Nan*) of 120 BCE, they were widely used in land surveying and triangulation; and by the twelfth century, they were standard navigational equipment for taking astronomical observations aboard ships.

Though many of these developments were contemporaneous with European discoveries, there are two parts of the telescope in which Chinese scientists can claim undisputed priority: the invention of equatorial mounting, and the development of clock drives, both of which are standard equipment on today's telescopes.

Astronomer Guo Shoujing (fl. 1270) developed the equatorial mounting now used on all modern telescopes for his "simplified instrument", which was basically a dissected armillary sphere related to the torquetum, an Arabic invention which had been recently imported (ca. 1267) to China from Persia. With an equatorial mounting, a rotation about only one axis (one parallel to the earth's polar axis) was needed to follow the curved paths of the stars.

Chinese physicists and engineers anticipated the fourteenth century mechanical clocks and clock-driven astronomical instruments of Europe by over a 1,000 years. Mathematician, geographer and astronomer Zheng Heng (ca. 78–ca. 142) constructed what Needham calls the "grand ancestor of all clock drives," a rotating bronze armillary sphere powered by a system of gears attached to a waterwheel. This device was used to predict the positions of various stars and planets. The later clock-driven armillary sphere of Su Sung (AD 1090) added a sighting tube to permit direct observation of a star as it moved over prolonged periods, resulting in a true "clock drive" for astronomy.

But despite Chinese priority in clockwork and mounting, just as in Europe, it was not until the seventeenth century that the disparate elements of the telescope were joined together. Though Chinese texts describe European telescopic discoveries from 1615 onwards, and Jesuit Father Terrentius/Johannes Schreck brought a telescope to China in 1618, Needham maintains that enough documentary evidence exists to assert a parallel, independent discovery by Suchow opticians Po You and Sun Yun Qiu. Between about 1620 and 1650, this pair constructed not only early telescopes, but also compound microscopes, magnifying glasses, searchlights, magic lanterns, and other instruments. Meanwhile, Sun Yun Qiu wrote a text on these and other optical devices, entitled *Jingshi* (*History of Optick Glasses*). But the first Chinese book on the telescope specifically was the *Yuan Jing Shuo* (*Far Seeing Optick Glass*) of Tang Ruo-Wang (Adam Schall von Bell) in 1626. *Yuanjing* became the standard term for the telescope, and by 1635 it was being widely used by Chinese artillery in battle.

Telescopes appear to have come to Indian astronomers fairly late. Indian craftsmen made glassware, lenses, and mirrors throughout the ancient and medieval periods. And *gola yantra* or armillary spheres, first mentioned in the *Āryabhaṭīya* of Āryabhaṭa I of Kusumpura (b. 476 AD), had clock-drives (powered by clepsydra) for stellar observation by the *Bhatadipika* of Parameśvara (ca. 1432).

But it was not until the seventeenth century that primitive telescopes were used in India. The celebrated astronomer and instrument-maker Sawai Jai Singh (1686/8–1743) employed telescopes to "show that Mercury and Venus get their light from the Sun as the Moon does" (*Zica-i Muhammad Shahi*); and though they revealed Saturn to be an irregularly shaped "oval," these telescopes were apparently not good enough to resolve the rings, which had already been accomplished by Dutch physicist Christiaan Huygens (1629–1695) several decades previously, in 1659. Indian achievements in this area thus far appear to be rather derivative, but much research still needs to be done in this area.

Textiles in Africa

GLORIA T. EMEAGWALI

Historians of African textiles now have at their disposal a wide range of oral and written documented sources. These describe significant centers of textile production over time, the raw materials, implements, and techniques used by the various cloth producers, varieties of fabric and techniques of dyeing and coloration, symbolic expression as reflected in the finished products, and the many functions for which the latter were used. The process of technological transfer within various parts of the continent and the elaborate structure of guilds and schools of apprenticeship are also better known to us as a result of the systematic collection of oral history in some areas.

From the Northeast African Nile region to West Africa and elsewhere, travel reports, missionary reports, and even autobiographies have provided details about aspects of the development of cloth making techniques. Herodotus in his travels in Egypt as far as the first cataract obtained specific knowledge about the implements used by the Egyptians and the existing division of labor. Such information has complemented the archaeological evidence brought forward by teams of Egyptologists as they continue to come in contact with numerous reams of cloth in the mummified corpses and burial goods which the Egyptian nobility, like some of their counterparts in West Africa, sent along with the dead to the afterlife.

In the case of Ethiopia, travel reports by missionaries, explorers, and travelers such as Francisco Alvarez, Jerome Lobo, Charles Poncet, James Bruce and Henry Salt, provide direct and indirect information on the variety of textiles in the Axumite and post Axumite realm. For West Africa in the eighteenth and nineteenth centuries, Mungo Park, Barth, and Baikie complement the perspectives diffused in the missionary reports of Trotter, Allen, and Crowther, who emphasized that the people of Onitsha, Eastern Nigeria, like their counterparts elsewhere, "manufacture their own clothes generally plain or fanciful with cotton grown in their farms" (Crowther 1968).

Archaeological reports have been no less useful than the eyewitness travel and missionary accounts cited. Reams of linen and cotton have been found in Egyptian tombs, and the Sudan, also one of the Nile Valley kingdoms, has yielded cloth and looms dating back to 500 BCE. The Igbo-Ukwu finds of Eastern Nigeria included thousands of artifacts, among which was cloth dated to the ninth century. The Bandiagara cliffs of Mali have yielded textile products dated to the eleventh century. The evidence from the excavated pits complements the various collective recollections reflected in poetry, song, and narrative accounts no less than the honorific codes and titles and range of linguistic terms accorded textile specialists and their products. Some city states and towns in the African continent gave their names to a product line, as was the case of Akwete and Okenne in Eastern and Central Nigeria, West Africa.

Whether in renowned Nigerian textile centers such as Kano, Iseyin, Bida or Akwete and Okenne, or in the Wolof empire of Senegal, the Bambara kingdoms of Mali, the Mossi Empire of Burkina Faso, or the Baule polities of the Ivory Coast, we can identify some basic raw materials, production instruments and techniques, as well as common tendencies relevant to textile not only in West Africa, where the latter regions were located, but also in Central, East, and Southern Africa. Raw materials were derived from vegetable or animal products and generally involved wool, camel hair, flax, cotton, the leaves of the raffia palm (*Raphia rufia* or *Raphia vinifera*), silk from cocoons, and bark from the baobab tree. In all the above cases, with the exception of bark, which was hammered into shape, there developed over time sophisticated spinning, weaving, and dyeing techniques which included the gradual invention and improvement over time of vertical and horizontal frames, lower and upper beams, beaters, shed sticks, hecklers, shuttles, and templars, all various components of the horizontal and vertical looms produced across the continent.

African textiles, by the nineteenth century, included a wide range of fabrics, each influenced by the base material from which the thread was made, the texture of the thread, the width of the strip woven cloth, the alignment of the thread, and the intensity of inlays and the dyeing procedure, whether starch resist or not. Indigo, guinea corn stalk, the bark of the locust tree, the leaves of the tombolo tree, combined with ash potash and any of a long list of colorants were used to produce blue, red, buff, rust, or brown and other colors. Dyes were derived from experimentation with vegetable and other products. The famous *Kente* cloth of strip woven silk (sometimes interlaced with threads of gold and very often confined to the Ashanti nobility), *Sanyan*, Western Nigeria's silk derived fabric, *Adrinkra*, the hand-printed cloth of the Ivory Coast, and *Sotiba* of Senegal, are some of the various types of textile products which have become household names in the continent.

A wide range of symbols was reflected in cloth through the representation of motifs of special shapes, figures, dimensions, and sizes. These were either impressionistically done by the use of geometrical shapes and symbols or were made to reflect naturalistic images derived from African cosmologies and indigenous belief systems. It was common for Dahomean quilts to portray images of the founding fathers of particular dynasties. A lion represented King Gelele and a buffalo King Gezo, whilst a representation of a ship was the symbol of King Agaza – all historic figures in the making of the Dahomean (Beninois) state. More recently, worldly events ranging from the American soap opera Dallas to statements about the prevailing economic reform programs have been coded into fabric. A study of African textile over the centuries yields information not only about changes in technical expertise and accretional gains made from the intraregional and interregional exchange of ideas, but also the prevailing lifestyles, philosophies, and world views of Africans in various parts of the continent. Textiles in themselves provide a rich source of historical information. They were associated with many activities and had many uses. They were a medium of exchange in barter, or units of currency in a wide range of commercial transactions. Tax payment was collected in the form of textiles and so too tribute. Since fabric differed in cost and the degree of technical expertise associated with various types, it was easy for it to become a symbol of wealth, extravagance, and conspicuous consumption. Cloth very often was a symbol of class affiliation. Saddle cloth and the overall accoutrements of the horse included specialized fabric, as did the panoply associated with Ashanti royalty. Cloth had special burial functions. Specialized fabric was associated with shrines of the dead. Marital gifts, whether prenuptial or not, tended to include cloth as part of the expected dowry. Decorative and symbolic objectives were matched by functional and practical ones. Cloth was used for protective purposes against the elements, as sheets and covers, and also to make rice bags, purses, or tents.

The reproduction of knowledge systems was done through institutionalized apprentice systems of guilds, each of which adhered to strict codes of conduct and behavior. Fees in cash or kind were paid by the apprentice who was expected to "gain freedom" after periods agreed to in the context of elaborate ceremonies. These guilds themselves had a hierarchy of officials who in many cases were of significant political clout. The teaching and training of spinners, weavers, and dyers was therefore organized in the context of established custom and practice, even though there was a general tendency for specialization to be restricted to specific lineages within various regions.

There is evidence that Africans imported cloth in the context of the trans-Saharan trade as well as the trans-Atlantic, but these importations were complementary to a wide range of indigenous textile products. It was not unusual for various political elites to flaunt some of the imported textiles along with indigenous products, or for textile specialists to unravel an epic of imported fabric with the objective of isolating particular reams of thread. The British industrial revolution had specific implications for African textiles, given the fact that factory produced cloth was cheaper with the mechanization of spinning and weaving. The successful transfer of textile technology from India to Britain by the nineteenth century meant that the British factory system was able to churn out some relatively attractive textile products for the African consumer. This, however, did not lead to the destruction of the indigenous textile sector which continued to be a dominant component of the informal sector well into the twentieth century, despite some ill-intentioned legislation and policies during the period of colonial rule.

Contemporary Africa is home to a wide variety of indigenous textiles. Local factory-produced cloth has had to compete with Taiwanese, Indonesian, and Dutch imports, most of which are imitations of indigenous African fabric. IMF and World Bank conditionalities tend to call for the removal of duties on imports and therefore undermine those local textile centers, some of which lack the productive capability to compete on the open market. In spite of these trends, however, there is every indication that African textile producers will continue to have a large share in the market and continue to experiment, innovate and produce the high quality textiles historically associated with the continent.

Textiles in China

DIETER KUHN

A textile is here understood as a woven fabric made from a wide range of raw materials. Some of these were silk, cotton, wool, and the bast fibers ramie (*Boehmeria nivea L.*), hemp (*Cannabis sativa L.*), and the bean- or vine-creeper (*Pueraria thunbergiana*), which possessed the greatest economic and cultural importance in pre-Mongol (prior to AD 1279) China. The development of textiles is described here on the basis of archaeological evidence and from the view of its cultural importance.

The origin of weaving can be traced back to basketry and matting techniques from the Neolithic. Impressions on ceramic sherds and fragments from the archaeological sites of Banpocun near Xi'an in Shaanxi and from Hemudu in Yuyao county in Zhejiang prove that they existed in China as early as the fifth millennium BCE. The earliest finds of textiles are from southeast China. There is a complicated fragment of fabric, made of *Pueraria thunbergiana*, found at Caoxieshan in Jiangsu province and dated to the fourth millennium BCE. Its structure features a combination of hand twining and loom weaving techniques. A number of silk belts, a piece of silk, and a scrap of ramie cloth were discovered in a bamboo box excavated from the site of Qianshanyang in Wuxing in northern Zhejiang, dated to ca. 2750 BCE.

Small stone-cut and jade figures were found in various Anyang sites from the the Shang period (sixteenth–eleventh centuries BCE). They clearly show "textile ornaments" which give an impression of Shang clothing and fashion. Apart from furs and leather, especially suitable as winter clothing and used for ceremonial occasions, hemp and silk were tailored. Tailoring does not mean cutting pieces of fabric so as to make them fit but simply sewing pieces of fabric together, only allowing a few corrections. It was probably the Shang people who introduced right side fastening and a hair-dressing style which could be distinguished from the barbarians. Most garments including lined garments were buttoned on the right side under the right arm. Very often the overlap of a robe was unbuttoned. *Obi*-like waist-belts kept the coat and the undergarments in position. Women's dress included a skirt. Women had their hair styled in a cylindrical shape, and flat rather high round caps were common. Upperclass people wore gaiters and shoes that curled upwards to the toe. Geometrically patterned fabrics (*T-, hui* and *lozenge*-patterns) were exclusively used as borders of garments, at the openings of the sleeves, at the collar, and along the overlap, for girdles and waist-belts, caps and hats. Colorful painted and embroidered silk was available to the higher echelons of Shang society. Certain important weaving techniques were applied to produce silk fabrics as early as Shang times:

1. Tabby weaves with threads of almost identical diameter and a thread-count of warp and weft between 8 : 7 and 75 : 50 cm^{-1};
2. Warp-faced tabby, also called rep or rib, where the number of warp-threads is roughly double the number of weft-threads per centimeter;
3. Monochrome tabby patterned with twill (3/1), very often named twill damask (*wenqi*). The ground weave is a tabby weave, and the pattern is woven in twill weave with the warp-threads forming the pattern;
4. Tabby crêpe (*zhou* or *hu*) with a thread-count of ca. 30 : 30 cm^{-1}. The warp-threads show a twist with 2,500–3,000 twists per meter. The weft-threads are twisted together from several threads in an *S*-twist showing 2,100–2,500 twists per meter. The strong twisting of the threads causes the crêpe effect;
5. crossed-warp weave technology was known and used.
