Flow-through EIX/EaIX experiments demonstrate the regenerability of the EaIX material without the use of highly oxidizing solutions. Breakthrough curves for a 0.2-ppm Cs^+ feed stream are shown in **Figure 10**. Here, the EIX/EaIX system was operated in the conventional IX mode in the uptake cycle. The breakthrough curve for the first flow test shows that the breakthrough point (where the concentration of Cs^+ in the effluent stream is one-half the feed concentration) occurs after ~ 110 bed volumes were passed in the first flow test. In subsequent flow tests, each following regeneration of the NiHCF electrodes, the breakthrough capacity was reduced to ~ 40 bed volumes and the breakthrough profiles were consistent.

Regeneration cycles were carried out by potential cycling in a solution of sodium nitrate. The reasons for the diminished breakthrough volume after the first cycle are presently unclear. It is speculated that this is a 'plugging' issue. One hypothesis is that because of the great affinity of NiHCF for Cs^+ and strong binding in the cubic lattice, migration of Cs^+ to all sites within the film is hindered, and therefore, some Cs^+ are permanently bound in the NiHCF. The most noteworthy point is that regeneration of the EaIX material is reversible (starting with the second cycle) without the need for strong oxidiz-

Figure 10 Breakthrough curves for a feed stream of 0.2-ppm Cs in an EaIX bed consisting of eight NiHCF-coated porous nickel foam electrodes operated in IX mode. The electrodes were regenerated electrochemically in concentrated NaNO_3 solution between each test. Experimental conditions: $80 \text{ pores inch}^{-1}$ or $\sim 60 \text{ cm}^2 \text{ cm}^{-3}$ nickel foam; CsNO_3 solution flowed at 24 mL min^{-1} ; bed volume of $\sim 39 \text{ mL}$; and maximum ion capacity $\sim 2.0 \text{ C}$.

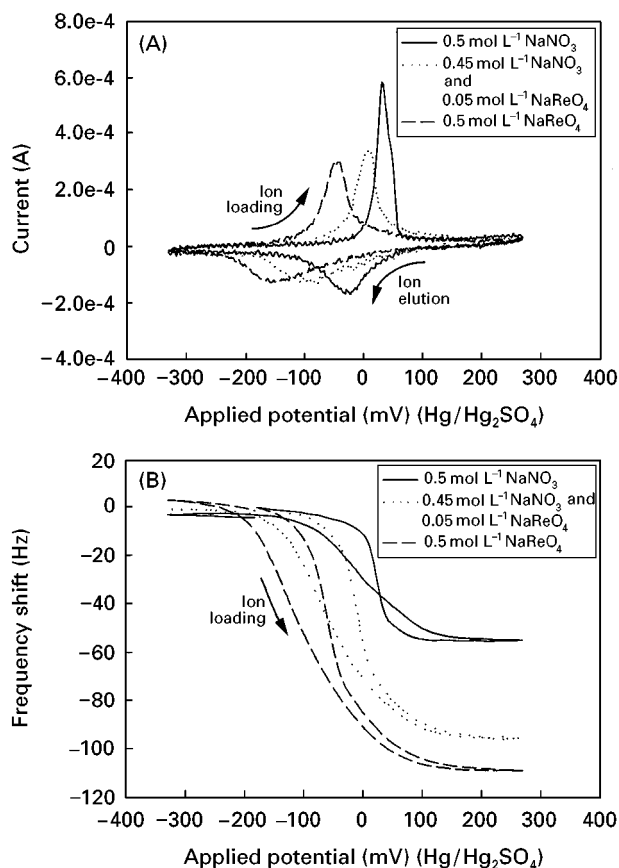

Figure 11 EQCM results for a series of $0.5 \text{ mol L}^{-1} \text{ NaNO}_3$ and $0.5 \text{ mol L}^{-1} \text{ NaReO}_4$ solution mixtures demonstrating selectivity of a PVF film for ReO_4^- over NO_3^- : (A) cyclic voltammograms indicate sensitivity to ReO_4^- in solutions nine times more concentrated in NO_3^- ; and (B) QCM frequency shifts indicate greater mass changes as solutions become more concentrated in ReO_4^- and relatively more ReO_4^- is loaded into the film.

ing solutions (i.e., 8 mol L^{-1} nitric acid used by previous researchers).

Polyvinylferrocene

Polyvinylferrocene $[-(\text{Fe}^{\text{II/III}}(\text{C}_5\text{H}_5))(\text{C}_5\text{H}_4\text{CH}_2\text{CH}_2)^{1+/0}-]$, or PVF, is a well-studied organometallic polymer. In contrast to NiHCF, oxidation of PVF to the $1+$ state requires the uptake of anions to maintain electroneutrality (see Figure 3C), making PVF a suitable anionic EaIX material candidate. Recently, the preference of PVF for perrhenate (ReO_4^-) over nitrate (NO_3^-) was demonstrated. The uptake and elution reactions are analogues to that shown in eqn [2]. As with NiHCF, PVF can also be used as conventional IX materials. Specifically, the NO_3^- in $(\text{PVF}^+)(\text{NO}_3^-)$ is readily exchanged for ReO_4^- . Other possible applications for PVF include the extraction of arsenates and chromates.

PVF has been prepared through chemical, electrochemical, and plasma polymerization. Both plasma

and electrochemical polymerizations should be suitable for depositing PVF within porous substrate.

Applications The preference of polyvinylferrocene for perrhenate (nonradioactive chemical analogue of pertechnetate) anions over nitrate anions has been demonstrated. Nitrates are the main competing anions for separation of pertechnetate in radioactive tank wastes. The current and the frequency responses of a PVF-coated EQCM as a function of a cyclic potential scan are shown in Figure 11(A) and (B). (The frequency response is shown rather than the normalized mass change because of complications due to the less rigid PVF films compared to the NiHCF films.) The more negative (cathodic) potential peaks observed in the pure ReO_4^- solution and in the mixture, compared to a pure NO_3^- solution, indicate the preference of ReO_4^- over NO_3^- . In addition, the frequency responses shown in Figure 11(B) indicate a substantial mass gained in the PVF film upon oxidation in a solution containing both NO_3^- and ReO_4^- , more mass than can be attributed to NO_3^- alone. This supports the contention that ReO_4^- ions (which are heavier than NO_3^-) are preferentially taken up by the PVF. The data shown in Figure 11(A) and (B) correspond to a separation factor of 30.

Future Developments

EIX processes (using EaIX and nonelectroactive IX materials) are very promising methods for ion separation due to the potential savings resulting from minimization of secondary waste generation. Better understanding of system performance through large-scale (e.g., pilot-scale) studies still needs to be carried out as well as the development of new materials. For example, EaIX materials selective for strontium (Sr^{2+}) are of interest to the nuclear industry. Calcium (Ca^{2+}) selective materials are valuable for preventing scale formation in many industries. Finally, effective removal of NO_3^- and arsenate anions is critical for safe drinking water.

Introduction

Separations with synthetic membranes have become increasingly important; today membrane processes are used in a wide range of applications and their number will certainly increase.

A membrane is a permselective polymer, inorganic or metal phase which restricts the motion of certain species. By controlling the relative rates of transport of various species it gives one product depleted in certain components and a second product concentrated in these components. Membrane performance is characterized by two terms: flux and selectivity. Flux (or permeation rate) is the volumetric mass flow of fluid passing through the membrane per unit area of membrane and unit mass time. Selectivity is a measure of the relative permeation rates of different components through the membrane.

Processes may be classified according to the driving force used: (1) a pressure differential leads to micro-, ultra- and nanofiltration and reverse osmosis; (2) a concentration difference across the membrane leads to diffusion of a species between two solutions (dialysis); (3) a potential field applied to an ion exchange membrane leads to migration of ions through the membrane (electrodialysis, membrane electrolysis and electrochemical devices). This last category and more specifically electrodialysis is the subject of this section. This electrically driven process uses ion exchange membranes, a description of which follows.

Ion Exchange Membranes

Electrodialysis (ED) uses membranes containing fixed charged groups attached to the polymer backbone of its membrane. Two kinds of ion exchange membranes (IEMs) are used in ED: *homopolar membranes*

bearing fixed charges of the same sign and *bipolar membranes* bearing positive and negative fixed charges located on each side of the membrane.

IEMs are sheet-shaped materials through which a selective ion transport can be established under a driving force, generally an electric field and/or a concentration gradient.

Most of them are of a polymeric nature. They are constituted of reticulated macromolecular chains forming a tridimensional structure. In this network, ionizable functionalized groups are attached to the polymeric matrix and are at the origin of the membrane selectivity. For example cation exchange membranes (CEMs) contain fixed negative charges and mobile cations which can be exchanged with other cations present in an external phase in contact with the membrane. The ions balancing the fixed exchange sites are called counterions. The concentration of counterions is relatively high and therefore counterions carry most of the electric current through the membrane. The fixed charges attached to the polymer matrix repel ions of the same charges (co-ions). This exclusion, which is a result of electrostatic repulsion, is called Donnan exclusion, named after F. G. Donnan, who first reported the phenomenon in 1910. However, as the membrane selectivity is never ideal, the membrane material can be penetrated by a non-negligible amount of electrolyte. A schematic structure of such a homopolar CEM is depicted in **Figure 1**. Under an applied electric field, the CEM bearing sulfonic exchange groups ($-\text{SO}_3^-$) mainly allows the transport of counterions.

A bipolar membrane (BPM) is composed of two layers of ion exchangers joined by a hydrophilic junction. The diffusion of water from both sides of the BPM allows it to dissociate under the electrical field to generate protons and hydroxyl ions, which further migrate from the junction layer through the cation exchange and anion exchange layers of the bipolar membrane. Generally, the cation exchange groups are sulfonic and the anions are trimethyl quaternary

Figure 1 Schematic process of transport of counterion (Na^+) through a cation exchange membrane (CEM, bearing sulfonic sites).

ammonium groups ($-\text{N}(\text{CH}_3)_3^+$). The principle of this water-splitting phenomenon is depicted in **Figure 2**.

The requirements for suitability of homopolar IEMs for industrial applications are the following:

1. high ionic conductivity with a concentration of fixed charges as high as possible;
2. high ionic permselectivity combining simultaneously a high conductivity and a moderate water uptake;
3. chemical stability of the fixed ions and a good mechanical resistance;
4. reasonable price.

Bipolar membranes must have all of these requirements and, in addition, must have an experimental potential to achieve a water-splitting capability as close as possible to the theoretical one, equal to 0.83 V at 25°C.

Nowadays, superior styrene-divinylbenzene copolymer membranes can be easily purchased; perfluorinated membranes with great chemical stability

are now being marketed and BPMs with an industrial-scale lifetime are becoming available.

Principles of Electrodialysis

Electrodialysis with Homopolar Ion Exchange Membranes

IEMs can be organized into two-, three- or four-compartment electrodedialysis cells.

Two compartment electrodedialysis The principle of ED is depicted in **Figure 3**. Electrically charged membranes are used to remove ions from an aqueous solution. A number of anion exchange membranes (AEMs) and CEMs are placed in an alternative pattern between a cathode and an anode. When an ionic feed solution (for example, a sodium chloride solution) flows through the channels of the electrodedialyser, the positively charged sodium ions migrate to the cathode and the negatively charged chloride ions migrate to the anode. As the chloride ions

Figure 2 Schematic principle of water dissociation by a bipolar membrane (BPM).

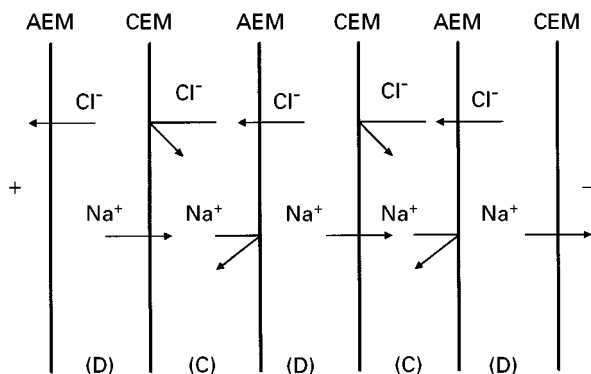

Figure 3 Schematic of two-compartment electrodialysis. AEM and CEM, anion and cation exchange membranes; (D), diluate; (C), concentrate.

cannot pass the CEM and the sodium ions cannot pass the AEM, the overall effect is a simultaneous ionic concentration increase in alternating compartments and an ionic concentration decrease in the other compartments. Consequently, alternate dilute and concentrated solutions are formed. A set of two compartments (dilute (D) and concentrated (C)) forms a cell pair. In commercial applications several hundreds of cell pairs are assembled in a stack.

Three compartment electrodialysis A three-compartment ED process is depicted in **Figure 4** and concerns the transformation of an electrolyte M^+X^- into its acid HX , which is weakly dissociated, according to the reaction:

The strong acid H^+A^- (HCl or H_2SO_4) is introduced into the feed compartment (F). Protons migrate to the substitution compartment (S) to transform the salt $(M^+X^-)_S$ into the weak acid $(HX)_S$. Simultaneously,

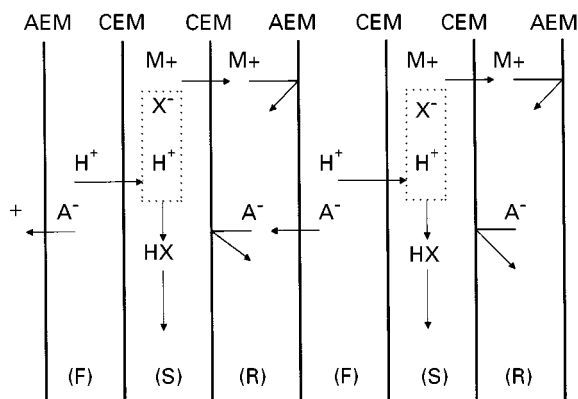

Figure 4 Schematic of three-compartment electrodialysis for the conversion of a salt M^+X^- into its weak acid HX .

Figure 5 Schematic of four-compartment electrodialysis for the double substitution reaction.

M^+ ions migrate to the recovery compartment (R) to form the salt $(M^+A^-)_R$.

Four-compartment electrodialysis A complex four-compartment ED process is depicted in **Figure 5**. The elementary cell is composed of four compartments and allows the reaction of double substitution according to

The electrolytes to be substituted, (B^+A^-) and (C^+D^-) , feed the diluates D1 and D2. In the first recovery compartment R1, A^- combines with C^+ to give C^+A^- , while simultaneously B^+ combines with D^- to give B^+D^- in the second recovery compartment.

Process parameters and limiting phenomena in electrodialysis The amount of ions transported through the membrane is directly proportional to the electric current (i) or current density, which is given by

$$i = \frac{ZFQ\Delta c}{\eta}$$

where z is the valency, F the Faraday constant, Q the flow rate, Δc the concentration difference between the feed and the permeate (diluate) and η the current efficiency. Theoretically, 1 faraday of current (96 500 coulombs) will transfer 1 mol of sodium ions to the cathode and 1 mol of chloride ions to the anode. Practically, the permeation of water through the ion exchange membranes and the fact that the membranes are not completely selective slightly reduces the current efficiency to an average of 0.90–0.95.

Electric current is related to electrical potential E by Ohm's law:

$$E = Ri$$

where R is the resistance of the total membrane stack. Increasing the current density leads to an increase in the number of ions transferred. However, current density cannot be increased by an unlimited amount. In the steady state, the flux of a species through a membrane can never exceed the flux of that species to the surface of the membrane. Concentration polarization is a well-known phenomenon arising at the interface between an IEM and an electrolyte solution when current passes through it. It is due to the difference in transport numbers of the counterion between the membrane and the solution. Gradients of concentration arise in the diffusion layer as depicted in **Figure 6**, and when the concentration of the counterions becomes negligible at the depleted solution-membrane interface a limiting current appears.

This limiting current density j_L is the current density when the flux of ions through the boundary layers has reached its maximum value and no further increase in ion flux (or current) is possible. It is given by the relation.

$$j_L = \frac{zDFC}{\delta(t_m - t_s)}$$

where D is the diffusion coefficient of the counterion in the solution, C the concentration of the bulk solution, δ the thickness of the diffusion layer (also named the Nernst layer or unstirred boundary layer), and t_m and t_s are the transport number in the membrane and the solution, respectively. If the current density is allowed to exceed j_L , then the current crossing the membrane must be carried by another ion and dissociation of water occurs at higher current density. The limitations of the rate of ion transport through a membrane can be seen from a current density versus voltage plot for the membrane as depicted in **Figure 7**. This current-voltage plot is composed of three regions: a first, ohmic one in which current is carried

Figure 6 Concentration profile in diffusion layers: depleted and concentrated regions (for a cation exchange membrane).

Figure 7 Current-voltage curve for an ion exchange membrane; limiting current.

by the ions of the electrolyte, a second plateau-shaped one corresponding to the limiting current, and a third region in which water splitting occurs. Because D/δ is equal to k , the mass transfer coefficient, j_L is strongly determined by the hydrodynamics of the system (cross-flow velocity, geometry of the cell). Moreover, the distance between membranes has to be very thin to reduce the ohmic drop due to the electrolyte thickness. Practically, separators of 0.8–1.5 mm thick acting as turbulent promoters are introduced alternately into membranes.

Electrodialysis with Bipolar Membranes

The conventional method for generating H^+ and OH^- ions from water utilizes electrolysis. Electrolysis also generates O_2 and H_2 , and the overvoltage for this generation consumes about half of the electrical energy of the process. Nowadays, special ion exchange membranes are available for splitting water directly into H^+ and OH^- ions without generating gases. Membrane water-splitting technology is a general-purpose unit operation for converting water-soluble salts to their corresponding acids and bases. The process uses BPMs in conjunction with conventional CEMs and/or AEMs, respectively). The separation and rearrangement of ions is effected by a direct current driving force. BPM electrodialysis (EDBM) is therefore an alternative method of electrolysis for the generation of H^+ and OH^- ions which can be used to generate acid and base from salts, without the production of oxygen and hydrogen gases.

The principle of water splitting by a BPM is illustrated in **Figure 8**. The diffusion of water from both sides of the BPM allows its dissociation under the electrical field to generate protons and hydroxyl ions, which further migrate from the junction layer through the cation exchange and anion exchange layers of the BPM.

Figure 8 Diffusion and dissociation of water in a bipolar membrane. AEL and CEL, anion and cation exchange layers.

The application of BPM reduces the energy costs associated with electrode polarization in the more conventional electrolytic approach.

The theoretical potential to achieve the water-splitting capability is 0.83 V at 25°C. The actual potential drop across a BPM is quite close to this, being in the range of 0.9–1.1 V for current densities between 500 and 1500 A m⁻², which is the general region of practical interest. The value of the membrane potential drops equate to theoretical energy consumptions of the order of 600–700 kWh per ton of NaOH. Of course, the actual energy consumptions are significantly higher because of the ohmic resistances in the other cell stack components, in practical operating units.

The configuration of the EDBM process depends on the application. Typical use of BPM is in the treatment of concentrated salt solutions such as Na₂SO₄ from the chemical industry to produce H₂SO₄ and NaOH. A cell system consists of an AEM, a BPM and a CEM as a repeating unit. In this case the configuration is a *three-compartment EDBM*, illustrated in **Figure 9**. This elementary cell is repeated

Figure 9 Generation of H₂SO₄ and NaOH from Na₂SO₄ solution (three-compartment cell).

and placed between two electrodes. The Na₂SO₄ solution flows between the CEM and the AEM. When direct current is applied, water will dissociate in the BPM to form the equivalent amounts of H⁺ and OH⁻ ions. The H⁺ ions permeate through the cation exchange side of the BPM and form H₂SO₄ with the sulfate ions provided by the Na₂SO₄ solution from the adjacent cell. The OH⁻ ions permeate the anion exchange side of the BPM and form NaOH with the sodium ions permeating into the cell from the Na₂SO₄ solution through the adjacent CEM. The final result is the production of NaOH and H₂SO₄ from Na₂SO₄ at a significantly lower cost than by other methods.

There are applications where it is not possible to obtain high purity of both acid and base, or may even generate problems during the process. For example, in the splitting of a salt from a weak acid (sodium acetate), the pure acid is weakly dissociated, so its conductivity is low. It would not therefore be practical to achieve the splitting of sodium acetate in a three-compartment cell. Instead, a two-compartment cell with the acetate solution flowing between a BPM and a CEM is recommended (**Figure 10A**). When the conversion of the salt stream reaches 95%, the conductivity becomes very low. Therefore it is not possible to pursue the EDBM more deeply. The EDBM is then stopped and the residual Na⁺ ions are removed using cation exchange resins. In a similar way, an ammonium or amine salt can be treated in a two-compartment cell with an AEM instead of a CEM (**Figure 10B**).

BPM can thus also be used in an alternative two-compartment cell configuration, regenerating only one base or acid. The cation/BPM two-compartment cell is useful for the processing of the salts of weak acids (or organic acids) to give a relatively pure base stream and a mixed acid/salt stream (**Figure 10A**), while the anion/BPM configuration is useful for converting salts of weak bases (e.g. ammonium nitrate) to a salt/base mixture and a relatively pure acid (**Figure 10B**).

Applications of Electrodialysis

Electrodialysis with Homopolar Membranes

Separation electromembrane processes such as ED are being applied to bioindustries and to the treatment of industry of wastewater. ED is a method which is used both for the removal of salts (e.g. to produce drinking water from brackish sources, to remove salts from foodstuffs) and for the concentration of salt solutions (e.g. for the manufacture of table salt from seawater, the concentration of process

Figure 10 Two-compartment bipolar membrane electro dialysis to produce only pure acid or base.

streams and the recovery of salts from effluents). An example of conventional two-compartment ED is depicted in **Figure 11** and some of the many applications of ED are listed in **Table 1**.

Figure 11 Schematic of a conventional two-compartment electro dialysis applied to the reconcentration/diffusion of NaCl solutions. C and D, concentrate and diluate.

The main application of ED is the production of potable water from brackish water whose salt content is close to 5 g L^{-1} . Beyond this value the reverse osmosis technique is more suitable. A new application of desalination is the reduction of nitrate content in drinking water. AEMs tend to selectively transfer nitrate in preference to other anions common in drinking water. Nowadays, electro dialysis plants produce several hundreds of cubic metres of potable water per day (reduction of nitrates to 5 mg L^{-1} and NaCl to 200 mg L^{-1}).

Another potential increasing area for ED is in the rough desalting of water that will be subjected to subsequent purification for use as boiler feed or rinse water in the electronics industry. Ion exchange has commonly been used for preparing waters with a very low salinity. However, the cost for regenerating and the magnitude of the waste disposal problem are proportional to the salinity of the feed water. A variant of ED which has achieved commercial success is electrodeionization. The depleted compartment is filled with an ion exchange material, generally an ion exchange resin. This material, providing high conductive paths for the ions, prevents the occurrence of the concentration polarization and a drastic increase of the electrical resistance. **Figure 12** illustrates the electrodeionization process with ion exchange resins. It allows the production of high resistivity water ($10\text{--}15 \text{ M}\Omega \text{ cm}^{-1}$) from water treated by reverse osmosis ($50\text{--}100 \text{ k}\Omega \text{ cm}^{-1}$). Ion exchange resins can be replaced by ion exchange textiles, which present a higher porosity and allow operation at high flow rates. Moreover, due to their sheet form, ion exchange textiles maintain their shape and dismantling of ED stacks for clearing or repair is easier.

The second historical application of ED is the concentration of recovered salts to high levels. That capa-

Table 1 Applications of electrodialysis with homopolar membranes

<i>Reduction of electrolyte content</i>	<i>Recovery of electrolytes</i>
Potable from brackish water	Pure NaCl from seawater

Potassium tartrate from wine	
Chloride purge in kraft paper process	<i>Miscellaneous</i>
Photographic developer regeneration	Ion substitution

bility has been used for the recovery of crystalline NaCl from seawater. There are several ED plants in Japan with 100 000 m² of ED membranes being used for NaCl recovery from seawater. Another important field of ED application has been in whey desalting. Whey is a by-product from cheese making containing useful quantities of proteins, lactose and lactic acid. However, the high mineral content makes it unacceptable for human consumption and of marginal value for animal feed. In terms of membrane area installed, this application is the third largest ED process. ED also has important applications in the pharmaceutical and biochemical industries, where gentle processing conditions are required for materials such as human blood plasma. The production of essential amino acids will require various demineralization steps. Certain waste streams in biochemical and pharmaceutical operations contain ammonium sulfate, urea and guanidine hydrochloride which can be recovered by ED. There are several other applications of ED for salt removal which include the production of protein fractions and the separation of amino acids into acidic, basic and neutral groups. Concerning this

latter example, amino acids are mainly produced from protein hydrolysates. The solutions obtained contain both natural amino acids and inorganic salts and therefore necessitate a demineralization step. **Figure 13** shows the two-compartment ED configuration for this operation. The hydrolysates to be treated are generally mixtures containing 2–3 mol L⁻¹ of amino acids and 2.5 M NaCl at pH 5–6.

The diluate containing hydrolysate is demineralized from 2.5 M to 0.2 M without significant loss of amino acids. Such a process is running on an industrial scale in Europe. The second step is the obtention of fractions of amino acids. This operation is achieved by a four-compartment ED as depicted in **Figure 14**. Charged amino acid forms are less mobile than the ions of the salts. During this operation pure anionic and cationic amino acid fractions are obtained in the concentrate compartments (C1 and C2, respectively), while the zwitterionic forms remain in the diluate D1. The zwitterionic fraction will then be purified using a BPM.

ED is also applied to the treatment of inorganic media. The metal-finishing industry offers numerous

**Figure 12** Schematic of the electrodeionization process. The ion exchange material (resin or textile) fills the diluate compartment.

Figure 13 Schematic of the demineralization of protein hydrolysates by electro dialysis. (Reproduced from Sandeaux *et al.*, 1998, with permission from John Wiley & Sons Limited.)

applications for ED in pollution control and material recovery. The rinse streams from such processes pose pollution problems. They are usually too dilute for direct metal recovery and too concentrated for disposal. For example, ED processing of a rinse stream from a nickel electroplating system allows the production of a dilute stream to be recycled in the rinse tank and a concentrated stream which can be recirculated in the electro dialysis to build up its metal content to a level that is useful for further recovery or direct return to the plating bath. Other similar applications concern the removal of phosphite from an electroless nickel bath or the recovery of HF and HNO₃ used to clean stainless steel.

Industrial countries are increasingly concerned with environment protection issues. The treatment of spent acids containing divalent metallic salts is a problem in several industries where these acids are used in pickling and surface treatment of metals. ED is an attractive technique for treating these waste acids because purified and reconcentrated acids can be obtained and reused. The advantage of this process

is not only the possibility of recycling acids but also the production of lower amounts of salt effluents or sludges. For example, the recovery of sulfuric acid from effluents containing metallic salts (Mg, Zn, Mn, 50 g L⁻¹) in an H₂SO₄ solution (200 g L⁻¹) from zinc hydrometallurgy is achieved in a two-compartment ED cell with modified CEMs having high selectivity protons/multivalent cations, and AEMs having a low proton leakage (Figure 15). A solution of 150 g L⁻¹ H₂SO₄ containing less than 0.5 g L⁻¹ of metals was so obtained.

Electro dialysis with Bipolar Membranes

A large number of applications have been identified. The applications have been classified under the broad categories of pollution control/resource recovery and chemical processing in Table 2.

The oldest industrial application of EDBM in pollution/control resource recovery is the recovery of HF and HNO₃ from a stream containing KF and KNO₃ generated from pickling baths in the steel plant.

Figure 14 Schematic of four-compartment electro dialysis for obtaining anionic forms (in C1), cationic forms (in C2), and zwitterionic amino acids (remaining in D1). (Reproduced from Sandeaux *et al.*, 1998, with permission from John Wiley & Sons Limited.)

Figure 15 Schematic of the recovery of an acid by electrodialysis. Diluate: H_2SO_4 and MSO_4 . Pure H_2SO_4 is obtained in the concentrate.

This first commercial use of BPM began operation in 1987 at Washington Steel in Pennsylvania. **Figure 16** illustrates the process. Spent pickling acid is neutralized with KOH to precipitate the heavy metals, which are then removed by filtration. The remaining neutral solution of $\text{KF} + \text{KNO}_3$ is then treated in a three-compartment EDBM cell in which the salts are split to form KOH, which is directed to the neutralization tank, and the mixed acids ($\text{HF} + \text{HNO}_3$),

which are directed to the pickling operation. The dilute salt solution from the salt compartment of the EDBM process is then reconcentrated by conventional ED and is then returned to the bipolar stack, while the diluate is used to rinse the filter cake.

The main application of EDBM in chemical processing is the recovery of organic acids which can be recovered from fermentation. The performance of fermentation is better when the pH is slightly higher

than the pK_a of the organic acid to be produced. This condition requires addition of a base to maintain this elevated pH. Thus, the product of the fermentation is a dilute salt of the organic acid. For example, in the case of lactic acid production, the conventional process requires many different ion exchange steps, resulting in a high volume of wastewater and organic solvents that have to be recovered. In addition, possible losses of product and a potential contamination

of the product have to be taken into account. The recovery of lactic acid from fermentation broth can also be performed by the use of two ED steps. In the first, the dilute sodium lactate solution is concentrated by a conventional two-compartment ED. This step also purifies the product because only the ionized components of the broth are transported by the current through IEMs. The other components of the broth are redirected to the fermentation reactor. In

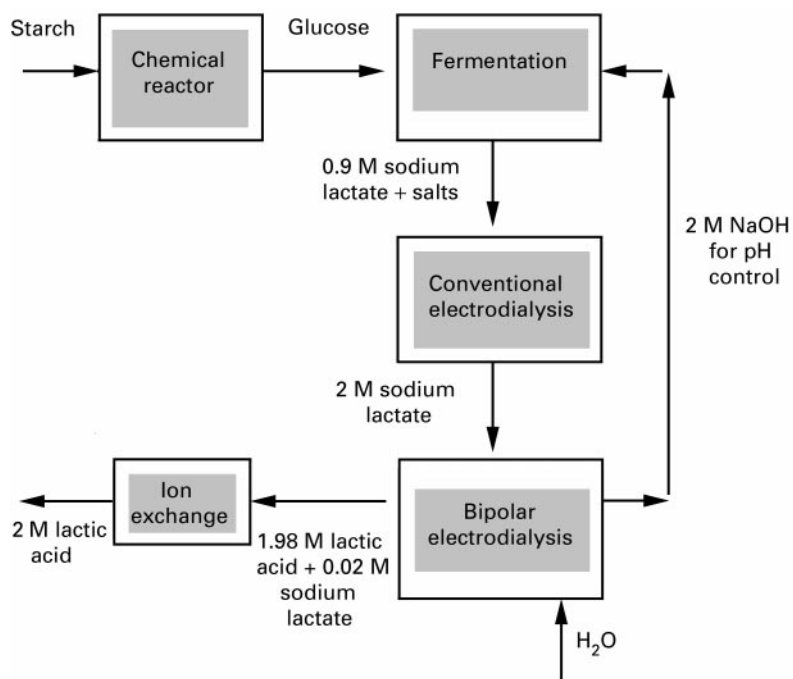

Figure 17 Schematic of the production of lactic acid from fermentation broth using both conventional electrodesialysis and bipolar membrane electrodesialysis. (Reproduced with permission from Davies *et al.*, 1997.)

the second step, the concentrated sodium lactate is split in a two-compartment bipolar ED with a CEM (configuration of Figure 10A) to generate lactic acid and NaOH. The acid stream, still containing Na^+ ions, is then purified by a cation exchange resin, while caustic soda is recycled to the fermenter for pH control. For economical reasons in the bipolar ED step, the conversion rate of sodium lactate is kept at 95%, but almost 100% could be easily achieved. A simplified schema of this process is reported in Figure 17.

Conclusion

ED with homopolar membranes was first developed several years ago, essentially for desalting brackish waters and reconcentrating brine for seawater. Conventional ED is also widely used on a large industrial scale in the dairy industry for demineralization of whey. The technical feasibility of applying ED with BPMs to a variety of commercially interesting processes has been demonstrated. ED techniques are very promising because they can be applied to environmental protection (depollution and recycling of chemicals) and to bioindustries (food, pharmaceuticals and biotechnology). For all these kinds of applications, special membranes have been elaborated showing adapted selectivity in ion transport under an electric driving force. For improvement of most of the other applications of ion exchange membranes, research is mainly focused on the membrane processes themselves rather than on the synthesis of new membranes.

ENVIRONMENTAL APPLICATIONS

Flotation

M. A. Burstein, NPACI Edcenter on Computational Science and Engineering, San Diego State University, San Diego, CA, USA

Introduction

Flotation is the selective separation of solid particles, liquid droplets, chemicals or ions, or biological entities from a bulk liquid, based on their surface properties. In the process two actions occur: the collision

between rising bubbles and matter suspended in the liquid, followed by adhesion of the particle to the bubble surface and separation of the resulting bubble-particle aggregate from that liquid. Environmental application of this technology includes the selective separation of specific solids or liquids from solid suspensions, liquids from liquid suspensions or certain dissolved species from solutions.

Separations which are based essentially on the adsorption from solution include colloidal suspensions of solid or liquid products, and the separation of certain dissolved substances and ions. In order to make a separation, there must be a drop in free energy for the removed substance when it attaches to the bubble. For selective separations this drop must significantly exceed those of the competing ions or colloids. In general, this results when the substance to

be removed is hydrophobic (if it is separate phase) or surface-active (if it is dissolved) and the substances to remain with the carrying liquid are hydrophilic.

There are many variations of flotation vessel that attempt to perform these actions, including induced air machines like flotation columns, agitated tanks and turbulent contact vessels; dissolved air flotation units; or electroflotation units where electrolytic bubbles are the carrier. The principal factor which influences the design is the ability of the unit to generate bubbles of a size that will maximize the likelihood of attachment of the dispersed particles and removal of bubble-particle aggregate from suspension.

Hydrocarbon Removal from Water

Flotation itself is not restricted by the concentration of the input contaminates, but the equipment used may be limited in its fractional removal and the purity of its products. Liquid hydrocarbons are generally highly hydrophobic and form very stable bubble aggregates. However, low density differences between the hydrocarbon and water mean that the droplet velocity relative to carrying water flow is low. As the relative velocity between the rising bubble and the settling droplet in a still suspension is low, flotation columns, with their quiescent collection environment are generally used to separate larger droplets, whereas mechanical cells can operate on smaller sizes and high intensity contact devices on yet smaller sized droplets. However, the high turbulence devices produce a large population of very small bubbles which, because of their low rise velocity, cannot easily be separated from the transport water. Depending on the droplet size distribution, with conventional units the residual hydrocarbon concentration in the water will be limited to purity levels between 10 and 30 p.p.m.

Recent designs specifically engineered to overcome the small bubble problem have produced aqueous underflow with less than 6 p.p.m. hydrocarbon content. This improvement trend is expected to continue as the principles behind fine bubble separation are better understood.

Some products that can be separated from water using this technology are diesel, motor oils and other automotive products, crude oil and tar sands products, creosote, polyaromatic hydrocarbon and polyaromatic phenol groups, chlorinated hydrocarbons, plant and animal oils, waxes, and many paints and organic solvents.

Usually, flotation is used after settling tanks for oil-water separation and prior to granular media filters. Typical applications are offshore platforms, oil refineries, large garages and vehicle service sta-

tions, and also at machinery plants where oil testing of production is used. On offshore platforms, natural gas is supplied instead of air to float hydrocarbon droplets and remove them to an oil pad.

Typically, for oil-water separation, a froth layer is not formed and oil is removed in a form of oil pad continuously or in batch mode by rising liquid level in the vessel.

Rendering By-Product Recovery

In the food industry, the processing of fish, fowl, wool or slaughterhouses produces a stream of liquid that carries animal oils and/or suspended solids. These streams have a high oxygen demand and often cause odour problems. The organic contaminants can be removed by flotation. This can be done by first screening and/or settling the process stream to remove larger products. The remainder is floated in a quiescent vessel to remove the larger products, followed by more intense flotation contactors to remove remnant oils. A properly designed circuit should recover all but approximately 10 p.p.m. of the organic wastes.

Reprocessing of Existing Mineral Waste Dumps

Flotation is used in the processing of secondary materials in mining industry. As high grade mineral deposits are exhausted, reprocessing of old tailings dams and ponds, stockpiles of low grade and oxidized ores as well as metallurgical slags becomes economically feasible with technical improvements in processing. It will also extend the lifetime cycle of mines and concentrators. Although this reprocessing of waste dumps and tailings dams will in turn produce new dumps and dams, they will be of a lower metal content so that acid damage will be reduced. In many cases, the grade of waste material from 50-100-year-old mines is higher than that of ores mined today, for example, copper content in old tailings dams is often over 0.8%, whereas its typical content in run-of-mine porphyry ores is 0.4-0.6%. Reprocessing of mine tailings usually does not require substantial expense because the particle size has already been reduced to the point that different mineral crystals are liberated from each other.

Site Run-off Treatment and Soil Decontamination

Many sites, such as pole treatment yards, truck and bus-washing facilities, and others which are still in use may be producing surface run-off or underground

plumes of contaminants. Most of these streams contain contaminants that are floatable. Also, flotation is becoming widely used for soil treatment at industrial and military sites, where soil contains substantial concentrations of oil or other chemical poisonous products.

Run-off water is collected by ditching and the contaminated feed is pumped to a processing facility. The first stage of separation is usually a gravity mixer settler, in which the resident liquid contains about 50% of organic matter, which effectively coalesces the finer organic droplets. The residence time of the suspension in the settling unit has to be sufficient to ensure that the coalesced droplets report to the organic-rich product stream. The required residence time is dependent on the hydrocarbons to be removed. The organic-rich stream is bled off and may be burned or shipped off site after passing through a further aqueous coalescing device. The aqueous stream, or underflow of the gravity separator, then passes through a hydrocyclone (high capacity streams only) followed by a flotation cell. The organic products of both the hydrocyclone and flotation device are recycled to the mixer settler for further processing. The aqueous stream, or underflow of the flotation device, is the final product to be returned to the environment.

The system for processing plume water is the same as run-off water, with the exception that a series of wells must be made to lower the water table locally, thus preventing water from leaving the contaminated site. This well water is then processed with the site run-off water.

Flotation systems can have very high capacities and produce a high purity final aqueous stream. However, they are more expensive than gravity units at low throughputs.

Possible Effluent Treatments

Ion flotation is widely used to extract ions from aqueous solutions. Bubbles can be stabilized by surfactants of various types. The bubble surface charge can thus be tailored to affect the preferential removal of a specific ion or ionic complex. Normally, some reagent (collector) is added to improve ion sorption at the gas-liquid interface. As ion flotation is a mass transfer process of dissolved substances, its rate is proportional to a specific bubble surface area. Therefore, minimizing the average bubble size is critically important; dissolved air, electroflotation, cavitation, or high turbulence are used to generate microbubbles. It includes saturation of feed stream with dissolved air at high pressure, and then releasing the pressure to atmospheric and discharging into a clarifier-type

vessel. Similarly, microbubble dispersions can be used to float colloidal solids, although it is usual to add coagulants to increase the size of the colloidal aggregates.

Flotation systems can operate under externally supplied electrical potentials which, by altering the surface charge of the particles in the field, will optimize bubble-particle attachment. As bacteria and other microorganisms such as microalgae, are normally hydrophobic, they potentially can be removed from water by microbubble flotation.

Flotation is used as the main method for de-inking of recycled paper. The aim of the process is to remove only the ink from wastepaper fibres suspended in a slurry. Under current practice using conventional mineral-processing mechanical cells, it is not possible to get a fibre-free ink-rich overflow product. The disposal of this as landfill is both expensive and environmentally objectionable. For these reasons, and because the partially de-linked product only has a limited use in low quality products, there is a need for the replacement of the existing cells by units specifically designed for this application.

Conclusions

The number of environmental applications of the flotation process has increased dramatically over the last 10 years. This trend will continue in the foreseeable future, as increased environmental concerns are manifested with respect to the treatment of liquid effluents and solid waste materials.

The treatment of these effluents will lead to the development of unconventional devices and methods for flotation of ultra-fine particles, ions and aggressive media.

The relatively low capital and operational costs of flotation make it attractive for industrial use as an integral part of the flow sheet.

Gas Chromatography–Mass Spectrometry

N. Scott and G. Gutnikov, California State Polytechnic University, Pomona, CA, USA

Introduction

Increasing public concern over environmental pollution reflects the heightened awareness of the toxicity of a large number of chemicals that find extensive application in wide-ranging fields. The consequent impetus to reduce chemical contamination of the environment has generated a growing body of legislation and mechanisms for enforcement via specific regulatory agencies. For example, following the discovery of trihalomethanes in chlorinated drinking water in the 1970s the Safe Drinking Water Act (SDWA) was passed that directed the United States Environmental Protection Agency (US EPA) to undertake a comprehensive study of the contaminants present in drinking water. The pre-eminent technique employed in these investigations was gas chromatography with mass spectrometric detection (GC-MS). The distinctiveness of the mass spectra of the target analytes and their volatility were two vital characteristics required for GC-MS. As the studies initiated by the SWDA yielded results, GC-MS has been recommended for analysis of many environmental contaminants.

Since many pollutants occurring at trace levels in complex matrices are either volatile or amenable to derivatization to volatile products, GC-MS has proved to be an effective means for verification of compliance with environmental regulations. GC and MS play complementary roles in the analysis of mixtures. Volatile constituents of complex mixtures may be conveniently separated by GC but not identified unambiguously with conventional detectors. MS provides much more definitive structural information that permits identification. The sample sizes necessary for GC and MS are also comparable and sample volatility is necessary for both.

The utility of GC-MS for environmental analysis has been further enhanced by the development of relatively inexpensive table-top instruments that has

brought the technique within the reach of most laboratories. Computer-assisted operation of these instruments, including automated sample injection, data acquisition, online searches of mass spectral libraries and quantification by selected ion monitoring (SIM) has led to rapid, efficient and convenient analytical systems. These advances have made compact, rugged, portable GC-MS instruments available for field applications, thereby rendering GC-MS a vital technique in environmental analysis.

Sample Pre-Treatment

The low concentrations of pollutants and the complex matrices in which they frequently occur generally preclude direct injection of environmental samples into a chromatograph. Sample pretreatment is then necessary to remove components that would interfere in the analysis and to concentrate target analytes that are present at extremely low levels. Pretreatment varies considerably with the nature of the sample and the information sought. Pollutants are dispersed in air, water and soil.

Atmospheric samples may contain numerous species ranging from gaseous to nonvolatile substances adsorbed on particles. They are usually collected in highly polished SUMMA[®] canisters and Tedlar[®] bags or on sorbents or in an impinger solution. Specifically, the EPA Compendium Method TO-14 mandates SUMMA passivated canister sampling. Particles are commonly retained on membrane filters or impactors. Gaseous components and volatile organic compounds (VOCs) are collected by trapping, either cryogenically for the most volatile or on sorbents of increasing retentivity for the less volatile.

The constituents of particulates are separated into approximately organic and inorganic substances by Soxhlet extraction or ultrasonication with an appropriate organic solvent (methanol, dichloromethane, cyclohexane, etc.) or by supercritical fluid extraction (SFE) with CO₂. SFE is becoming increasingly accepted for the extraction of analytes because it is

more rapid, reliable and efficient for a variety of matrices than the older techniques and is environmentally friendly in reducing the need for organic solvents.

The soluble fraction comprises a complex mixture of various organic compounds that may require further fractionation prior to GC-MS analysis. This has entailed separation into fractions of different polarities by such techniques as liquid–liquid extraction or column chromatography following preliminary removal of the acidic and basic components. Solid-phase extraction (SPE) has become a popular alternative because of its simplicity, speed, improved sample clean-up, easy automation and the capacity to handle multiple samples simultaneously. More recently filter discs have been introduced to perform the same functions more conveniently.

VOCs are generally preconcentrated on adsorbent traps. Different traps are often necessary as no single sorbent performs satisfactorily over the entire range of organic volatilities and polarities encountered. Two (or more) sorbents are used in tandem, first

a weak one to adsorb the heavier organics, followed by strong one to retain all the remaining. The analytes are desorbed by flash-heating from weak adsorbents (primarily graphitized carbon black and Tenax); by solvent extraction from strong ones (activated charcoals), using carbon disulfide, dichloromethane, etc. (Figure 1).

For aqueous samples preconcentration and clean-up are often achieved concurrently. In the purge-and-trap (dynamic headspace sampling) technique, the volatile species that are present in water are swept out of solution by a stream of nitrogen or helium into a sorbent trap consisting of activated carbon, Tenax or silica gel. The analytes are desorbed thermally and transferred along with the carrier gas to the GC-MS instrument. If the number of volatile compounds is few, analysis of the headspace gases is possible directly but with the drawback that water vapour is likely to be injected into the instrument.

Semi-volatile species present in water must be first extracted into a suitable organic solvent or retained

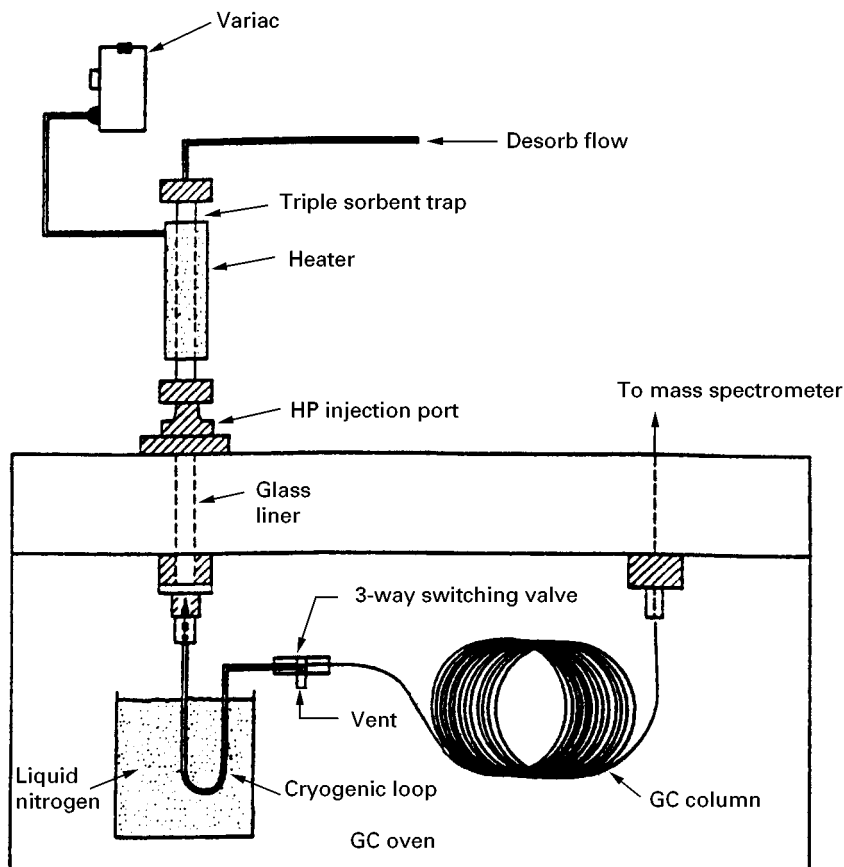

Figure 1 Schematic diagram for thermal desorption–gas chromatography–mass spectrometry system. (Reproduced from Ma C (1997) Performance evaluation of a thermal desorption/gas chromatographic/mass spectrometric method for the characterization of waste tank headspace samples. *Environmental Science and Technology* 31(3): 853–859, with permission from the American Chemical Society.)

on an SPE cartridge and then eluted for injection. The polarity of the organic stationary phase, which is bonded to a silica support, determines the retention selectivity.

For solid samples, VOCs are first extracted into methanol, which is then added to water for purge-and-trap. For extraction of semivolatiles from solid samples SCF is particularly advantageous. The extracted analytes collect in an appropriate solvent on reducing the pressure to atmospheric level.

Sample pretreatment is beset with a serious problem – the potential loss of analytes – which necessitates monitoring solute recovery by employing internal standards with similar properties. Also accumulation of water during preconcentration can affect the GC-MS instrument, especially the pumps necessary to maintain the vacuum. A remedy that has been attempted is the use of Nafion diffusion dryers, but this may cause the loss of small, polar organic compounds.

Instrumentation

Capillary columns (0.32 mm i.d.) of appropriate polarity are routinely used in view of their greater efficiency. However, for relatively high concentrations megabore capillary columns (0.53 mm i.d.) are preferred with connection to the mass spectrometer ion source being achieved via a glass jet separator for whose optimum functioning a stream of make-up gas is provided. This approach has been widely used for the analysis of ambient air samples; waste and solid samples; purge-and-trap analysis; as well as thermal desorption analysis of sorbent tubes.

The mass spectrometer of a GC-MS system must be capable of rapid response to monitor the solutes that are eluted from the chromatographic column in quick succession. Hence ion trap and quadrupole instruments are the most widely used mass analysers. The compact ion trap detector (ITD) also enhances the portability of GC-MS instruments for field analysis.

Calibration of a mass spectrometer is usually based on the diagnostic ions of either perfluorotributylamine (PFTBA) or perfluorokerosene (PFK). However the US EPA has introduced m/z abundance calibration for checking the performance of the entire GC-MS system, not merely of the mass spectrometer. Two compounds mandated for this purpose are bromofluorobenzene (BFB) for volatile analytes and decafluorotriphenylphosphine (DFTPP) for semivolatiles.

Electron impact (EI) ionization is the most widely used mode of ionization mainly because the databases available for mass spectral library searches (such as those provided by the National Institute of Science

and Technology and John Wiley & Sons) are compilations of EI-mass spectra. However, negative chemical ionization mass spectrometry (NCIMS) is used sometimes, e.g. for the analysis of positional isomers of nitropolycyclic aromatic hydrocarbons via high resolution mass spectrometry (HRMS). Organophosphates can be analysed by either EI or CI.

Quantification of very low concentrations necessitates operating in the SIM mode. SIM involves acquiring ion currents only at a few specified m/z values that are characteristic of the analyte(s). Data acquisition in this mode avoids sampling the barren regions of a full scan spectrum, thereby improving the ion counting and the sensitivity of detection. Internal standards are usually isotopically labelled compounds that may be purchased individually or as mixtures from agencies such as the National Institute of Science and Technology (NIST) or the EPA.

Despite enhanced sensitivity, SIM limits the detectable analytes to those producing ions of the specified m/z values. Hence, for identification, scanning the entire mass spectrum of each compound may be necessary. But this compromises the detection sensitivity. Therefore one strategy is to use GC with a multi-detector system (GC/MD) in conjunction with GC-MS. The multidetector system enables sensitive quantification while the mass spectrometer operated in the full-scan mode enables identification of some of the unknown pollutants. The primary quantification system is thus the GC/MD system that comprises conventional GC detectors such as FID, PID (photoionization detector) and ECD (electron-capture detector).

Applications

Environmental analysis serves different objectives, including routine monitoring, quality assurance, litigation and research. The list of target pollutants and the desired detection limits undergo continual revision in light of toxicological research. For the determination of a particular pollutant at the desired level of sensitivity, the same analytical technique is not adopted by all environmental agencies. GC-MS is sometimes mandated, sometimes suggested as an alternative method. Hence some examples that are presented in this article may not (yet) be approved by regulatory agencies but are nevertheless acceptable to environmental chemists as representing the wide applicability of GC-MS in this field.

The US EPA classifies organic pollutants into two classes: volatiles (compounds that exist as gases at room temperature and are easily removed from the sample matrix); and semivolatiles (compounds that can also exist as gases but need some form of extraction to be removed from the matrix). Both

classes of compounds occur in outdoor, indoor and workplace atmospheres as well as in soil and water, and their concentrations may range from 100 ppm in the vicinity of emission points to a few parts per trillion (ppt) in pristine environments. The components of a particular mixture are likely to occur at different concentrations, with the more toxic target compounds being at times at much lower levels than the less hazardous ones.

VOCs for which US EPA approved GC-MS methods of analysis exist cover a broad range of compounds, including highly volatile organics (carbon tetrachloride, chloroform, acrylonitrile, allyl chloride, etc.); semivolatile organics (benzene, nitrobenzene, chlorobenzenes, toluene, trichloroethane, etc.); *N*-nitrosodimethylamines; polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated biphenyls (PCBs); and a variety of miscellaneous compounds including chlorinated compounds and aromatics.

A major fraction of VOCs are hydrocarbons, especially by roadsides where traffic is heavy. For example, in West Los Angeles, petroleum residues are the main solvent-soluble organic fraction of carbonaceous aerosols. For analysis, these particles are collected on quartz filters and extracted by ultrasonication first with hexane and then with benzene/isopropanol. The extracted constituents are determined by high resolution gas chromatography-MS. A bonded OV-1701 (86% dimethyl/14% cyanopropylphenyl polysiloxane) column and a quadrupole mass spectrometer operated in the EI mode have been employed in such studies.

Hydrocarbon contamination of ground water and soil often occurs through leaking fuel tanks. In the California Leaking Underground Fuel Tank (LUFT) method GC-MS is preferred to GC-FID for monitoring such leakage without interference by other semivolatile species. The most abundant ions in the mass spectra result from the fragmentation of C_{10} – C_{23} *n*-alkanes and occur at m/z values of 43 and 57. They correspond to $C_3H_7^+$ and $C_4H_9^+$, respectively, and are regarded as qualifier and target ions for monitoring purposes.

GC-MS is an invaluable technique for chemical fingerprinting of crude oil spills in land or marine environments. Initial screening by fluorescence spectroscopy and GC is followed by GC-MS identification of specific compounds such as steranes, triterpanes, phytanes, pristanes, etc., that are most resistant to weathering. Similar analysis of tarballs, which are formed by highly weathered oils, may enable identification of the petroleum source (Figure 2). When considerably more components are monitored, multivariate and pattern recognition statistical analysis methods become necessary for data interpretation.

In order to avoid the cumbersome process of determining individual compounds, more convenient methods have been accepted as regulatory benchmarks. These include the GC-MS or GC-FID analysis of total petroleum hydrocarbons (TPH) or mixtures of benzene, toluene, ethylbenzene and xylene isomers (BTEX). In the TPH method the total area of unresolved and resolved chromatographic peaks is measured.

Interest in monitoring the indoor environment has been prompted by the well-known 'sick building syndrome'. The environment indoors can be worse than that outdoors because of the accumulation of volatile pollutants owing to poor air circulation. These pollutants not only enter from the air outdoors but are also released from building materials and furnishings, cleaners, air fresheners, gas-burning stoves, etc. GC-MS has been invaluable for their analysis following preconcentration on Tenax and thermal desorption. Separation has been achieved on a bonded SE-54 capillary column with temperature programming (Figure 3).

Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous environmental contaminants with carcinogenic properties and present an analytical challenge because of the complexity of the mixtures in which they exist as many different isomers of the parent compounds. Hence a separation step is indispensable but volatility requirements restrict the applicability of GC to compounds of low and moderate molecular mass, the heavier ones being analysed by HPLC with fluorescence detection. PAHs are isolated from airborne samples by a combination of a Teflon filter and polyurethane foam sampling; from solid matrices either by extraction with SCF employing carbon dioxide, or by microwave-assisted extraction (MAE) into an organic solvent. For concentration and sample clean-up SPE with combined C_{18} amino (NH_2) or cyano (CN) solid phases can be employed with subsequent elution being carried out with CH_2Cl_2 . Deuterated PAHs are available from US EPA to serve as internal standards. More than 60 compounds encompassing parent PAHs, their alkylated derivatives and heterocyclic analogues have been analysed at 5–100 ppb levels with a DB-5 capillary column employing both the scanning and SIM modes. Of even greater toxicological interest are the nitro-PAHs that have been ranked by the International Agency for Research on Cancer (IARC) as probable human carcinogens. Their analysis is even more difficult because of the much lower concentrations and the presence of many positional isomers. Moreover, unlike the parent PAHs, nitro-PAHs are not fluorescent, thereby limiting the sensitivity attainable by HPLC. Hence GC-NCI-MS is the technique of choice for the

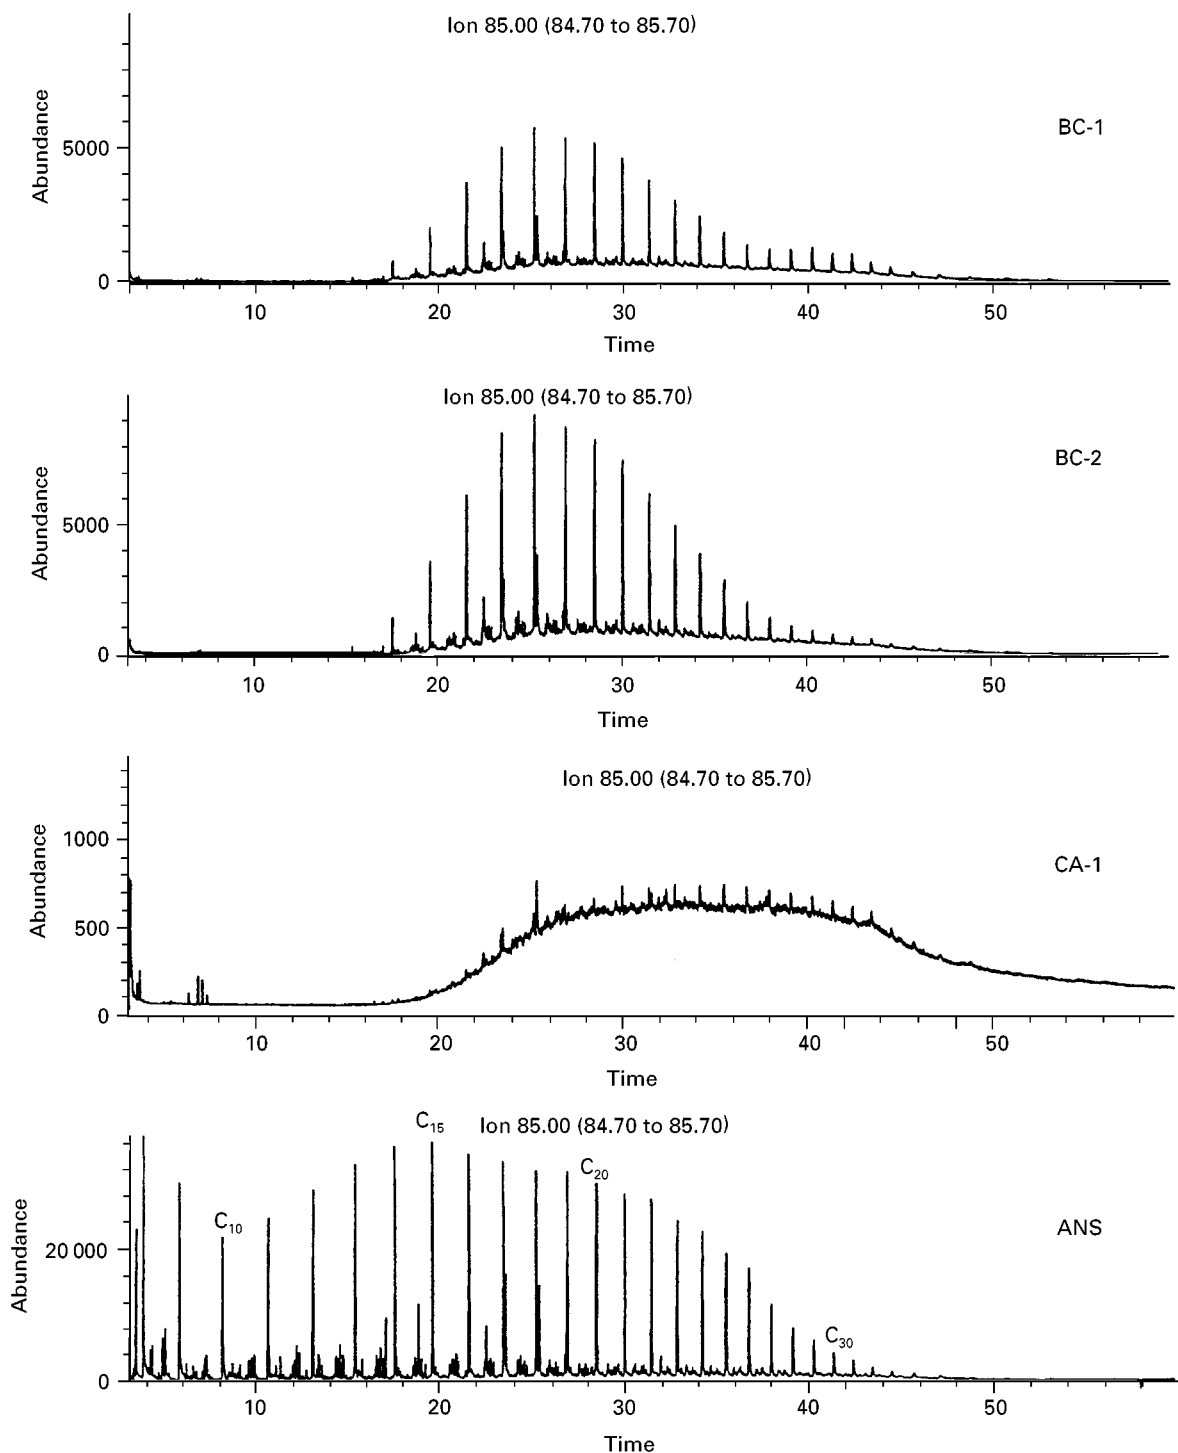

Figure 2 GC-MS *n*-alkane distribution patterns (m/z 85) for tarball samples BC-1, BC-2, CA-1 and ANS reference oil. (Reproduced from Wang Z *et al.*, 1998, with permission from Wiley–VCH.)

determination of nitro-PAHs. Polar or moderately polar capillary columns have been utilized for their separation with d_9 -1-nitopyrene or d_5 -dinitropyrene serving as internal standards for quantification.

Organochloro and organophosphate pesticides constitute another major category of toxic pollutants.

Chlorinated herbicides and pesticides are routinely analysed by capillary GC with MS or ECD. In view of the volatility of organophosphates GC is the technique of choice for analysis via phosphorus-specific detectors. However, MS detectors operated in the SIM mode are gaining popularity, especially with

Figure 3 Indoor air at a Swedish preschool. (Reproduced from Subramanian, 1995, with permission from Wiley–VCH.)

electron impact (EI) or chemical (CI) ionization for detection at low ppb. For characterization, CI is preferred because when CH_2Cl_2 is used as reagent gas the $(\text{M} + \text{Cl})^-$ ion is formed that gives a peak at a higher m/z value, thereby enhancing selectivity.

Insecticidal carbamates readily undergo thermal degradation and hence must be derivatized with heptafluorobutyric anhydride (HFBA) prior to GC-MS analysis. Ethylenethiourea, an environmental metabolite of carbamate fungicides and an accelerator used in synthetic rubber production, has been classified by the IARC as a potential human carcinogen. Its high polarity and water solubility require derivatization to a volatile compound and extraction into an organic solvent. This has been achieved by conversion to an *S*-alkyl derivative with *m*-trifluoromethylbenzyl chloride or 3,5-bis(trifluoromethyl)benzyl bromide. GC-NCI-MS on a D-1701 capillary column and the SIM mode has permitted sub-ppb detection limits to be realized.

Other organochloro compounds of great interest include the highly toxic, and environmentally persistent, polychloro-dibenzo-*p*-dioxins (PCDDs), -furans (PCDFs) and -biphenyls (PCBs), which are generated mainly during various combustion and manufacturing processes. They usually occur as very complex mixtures of a large number of compounds. For example, there are 22 isomers of tetrachlorodibenzo-*p*-dioxin (TCDD) alone, the 2,3,7,8-isomer being the most toxic. The very similar masses of these compounds demand high mass spectrometric resolving powers for peak separation. Hence much attention has been focused on simplifying the composition of the mixtures by appropriate sample extraction and clean-up prior to GC-MS. They are extracted from solids such as soil, sediments, dust, etc., into an organic solvent and the extracts are cleaned up via column chromatography on silica gel or alumina. Analysis is invariably carried out by GC-MS. A non-

polar column such as DB-5 enables determination of homologous groups of the dioxins but a polar column such as SP-2331 is necessary for separation of most of the 2,3,7,8-congeners. EI is the usual method of ionization and ^{13}C -2,3,7,8-TCDD is widely used as an internal standard in quantification. A mass spectrometer resolving power of even 10 000 is insufficient to separate a TCDD ($m/z = 321.8936$) that is coeluted with heptachlorobiphenyl ($m/z = 321.8678$). This difficulty underscores the importance of high resolution GC-high resolution MS. Despite this difficulty, by the mid-1980s GC-MS analytical methods had been developed for the separation of all TCDD isomers and quantification at the 10^{-15} level (Figure 4).

PCBs and polychloroterphenyls, which number over 200, are stable compounds that can cause serious toxicity through bioaccumulation. PCBs have been used in transformers, hydraulic fluids, etc. The method of choice for their analysis is GC-MS. In the EI mode, a PCB molecule can lose an ortho-chlorine atom giving a $(\text{M} - 35)^+$ ion, which facilitates distinguishing between two coeluted PCBs one of which lacks an ortho-chlorine atom. NCI, with methane as reagent gas, has improved detection sensitivities 10 to 100-fold not only for PCBs, but also for other organochlorine compounds such as toxaphene, chlordane, etc. In NCI, the base peak is usually either M^- or $(\text{M} - \text{H})^-$.

Large volume (100 μL) on-column injection capillary GC-MS has been applied to the determination of aliphatic and aromatic organochlorine compounds present in process water at low ppt levels. In the extraction of these solutes into hexane, the tedium of manual operation has been obviated by an automated procedure involving a laboratory robot. This has led to significant savings in extracting solvent, sample size, labour and time of analysis.

In recent years concern over the possible use of chemical warfare agents has generated interest in

Figure 4 Mass fragmentogram (m/z 320) of a composite sampling showing elution of all 22 TCDD isomers on (A) 55 m Silar 10C, (B) 50 m OV-17, and (C) 50 m OV-101 HRGC columns. Figure 5 Reconstructed ion chromatograms for (A) nerve agents GA, GB, GD, GF and sulfur mustard (SM) (1 ng injected) and (B) TBDMS derivatives of: 1, ethyl MPA; 2, iMPMA; 3, pinacolyl MPA; 4, cyclohexyl MPA; 5, 5-cyclohexyl MPA; and 6, TDG (500 pg injected). (Reproduced from Black *et al.*, 1994, with permission from Elsevier Science.)

their sensitive and reliable determination. The most common include 1,1-thiobis(2-chloroethane) (sulfur-mustard gas); O-ethyl-N,N-dimethylphosphorodiamidate (tabun); isopropylmethylphosphonofluoridate (sarin) and pinacolyl methylphosphonofluoridate (soman). Their degradation products include methylphosphoric acid (MPA); iP MPA; pinacolyl MPA; cyclohexyl MPA and dithioglycol (DTG). GC-MS is advantageous for their analysis since their mass spectra are well known and available for comparison. From samples such as clothing, soil, exhumed skeletons, etc., the parent compounds are extracted into CH_2Cl_2 ; the degradation products are extracted into water and converted to *t*-butyldimethylsilyl (TBDMS) derivatives. After preliminary screening by low resolution EI GC-MS, confirmatory evidence is obtained by one of two methods: (1) GC-MS with EI or CI with NH_3 as reagent gas or (2) GC-tandem mass spectrometry (GC-MS/MS), where a precursor ion further fragments in a collisional deactivation chamber. For confirming the presence of sarin at low ppb to ppm level, GC-MS/MS using both EI and NH_3 CI has been carried out, employing two columns of different polarity (Figure 5).

GC-MS has been extended to the analysis of highly polar compounds such as aliphatic glycols that are used as antifreeze in automobiles and in aircraft de-icing. Interest in their determination stems from the

acute toxicity of their metabolic products. Glycols form volatile *n*-butylboronate derivatives with the characteristic $^{10}\text{B} : ^{11}\text{B}$ isotopic ratio (1 : 4) assisting in identification. Employing a DB-1 column and an ion trap detector operated in the SIM mode, sub-ppm detection limits have been attained. Haloacids that are formed during disinfection of drinking water constitute another group of polar compounds that have been analysed by GC-MS. These acids are readily derivatized to their methyl esters with diazomethane.

GC-MS interfaced to inductively coupled plasma-mass spectrometry (ICP-MS) enables speciation of elements at trace levels and has been applied, in conjunction with isotope dilution, to the analysis of some environmentally significant inorganic species.

A knowledge of the total content of an element is of limited toxicological value since the toxicity is species dependent. Organometallic compounds of lead and tin have been reduced to their hydrides and sorbed on the GC column of a GC-ICP-MS unit and detection limits of $0.3\text{--}2\text{ ng mL}^{-1}$ for tin have been attained. Developing a convenient method for the analysis of mixtures of arsenic(III), arsenic(V), monomethylarsonic and dimethylarsinic acids continues to be a formidable analytical challenge. In a recent low resolution EI GC-MS method, which has employed hexachlorobenzene as internal standard, ppb detection limits have been attained following derivatization to methyl thioglycolates. However, arsenic(III) and arsenic(V) have been left unresolved (Figure 6).

Figure 6 Representative chromatograms of HCB and the TGM derivatives of DMAA, MMAA and As(III). (A) Calibration standard containing 10 ppb DMAA and MMAA and 20 ppb As(III). (B) River water spiked with 5 ppb DMAA and MMAA and 40 ppb total inorganic arsenic (As(III) and As(V)). SIM program: m/z 195 from 3.0 to 5.0 min, m/z 282 from 5.0 to 6.1 min, m/z 195 from 6.1 to 8.0 min, and m/z 285 from 8.0 to 9.3 min. (Reproduced from Claussen, 1997, with permission from Elsevier Science.)

Conclusion

Future developments of GC-MS in environmental analysis will encompass both sampling and instrumentation. Environmentally friendly extraction methods such as SFE and MAE that reduce or eliminate the need for organic solvents are likely to gain greater acceptance. A striking development in this trend is the solventless extraction technique of solid-phase microextraction (SPME), which concentrates the analytes on a stationary phase that is bonded or coated onto a fused silica fibre. Subsequent thermal desorption introduces the analytes into the injection port of the GC-MS unit. This method has been applied to the analysis of volatile organic solvents, organochlorine and organophosphate compounds and sub-ppb to ppt detection levels have been attained with ion trap mass spectrometry.

There is tremendous interest in developing miniaturized, field-portable GC-MS units to facilitate on-site, real-time monitoring. For unattended operation and reduced labour, the sampling, extraction and injection steps should be carried out by a robot, the

entire system being under computer control. A paramount consideration is the ability of the system to withstand shocks and vibrations during transport to and from the site(s). The greater speed, sensitivity and resolution needed for analysis of toxic pollutants produced in fast processes such as fires are continually the focus of developments in HRGC/HRMS. For faster analysis, short (1 m) capillary columns called ‘transfer lines’ and supersonic molecular beams for sampling and ionization have been employed. The low sample capacity associated with very short columns has been overcome via multicapillary columns. For monitoring solutes that are rapidly eluted from columns, mass spectrometer scan speeds must be increased significantly without compromising resolution. Alternatively, all masses must be scanned at the same time as is done in Fourier transform-MS (FTMS) and ITD. However, both these techniques operate in the pulse mode, making sample utilization inefficient. Hence other modes of array detection have been attempted, an interesting example being the development of an electro-optical ion detector (EOID) for microbore capillary column chromatography. In

Figure 7 Total ion chromatogram obtained from a mixture of compounds consisting of air (11), dichlorofluoromethane (16), chloromethane (19), bromoethane (28), chloroethane (30), dichloromethane (59), 1,1,1-trichloroethane (126), chloroform (162), benzene (188), and trichloroethylene (270). Each compound in the mixture has a concentration of 1 ppmv. A sample volume of 0.5 μL was injected, and a signal integration time of 250 ms was used for each frame. (Reproduced from Gutnikov G. (1991) Development of a miniaturized gas chromatograph-mass spectrometer with a microbore column and an array detector. *Analytical Chemistry* 63(18): 2012–2016, with permission from the American Chemical Society.)

EOID the electrons generated by a microchannel electron multiplier array are converted to photons by a phosphor screen and detected via an array of photodiodes (Figure 7). Very high sensitivities have been reported, with benzene being detected at 7.5×10^{-14} g levels.

Multidimensional gas chromatography (MDGC) is another technique that seeks to overcome the problems involved in the analysis of multicomponent mixtures of volatile constituents. It is based on the separation of the constituents via one column and isolating the coeluted species in one or more cryotrap to be separated by a second column of different selectivity. MDGC is usually coupled with detectors such as IR and MS for increased specificity.

GC-MS has emerged as one of the premier methods for the rapid, convenient and sensitive analysis of pollutants. This development is partly a result of the public concern and legislative pressure for reliable monitoring of environmental quality. The commercial availability of relatively inexpensive, computer-interfaced, bench-top instruments has rendered the technique almost routine for cost-effective analysis. Even greater speeds and resolving powers of the future generations of instruments will augment the significance of GC-MS in the environmental field.

Pressurized Fluid Extraction

S. R. Sumpter, DuPont Agricultural Products, Wilmington, DE, USA

Copyright © 2000 Academic Press

Introduction

Pressurized fluid extraction (PFE) is used to extract a wide variety of compounds from solid and semi-solid environmental samples. Soil is the predominant environmental solid extracted. Sediment samples are

also frequently extracted. Sludge, chimney brick, fly ash and urban dust comprise other materials that are extracted using PFE. There are several reasons to use pressurized fluid extraction for environmental samples. PFE methods are:

- automated
- easy to transfer
- environmentally friendly, consuming little solvent
- relatively fast

- simple, requiring little expertise
- acceptable to regulatory agencies.

Several PFE methods have been developed to extract compounds from environmental samples. These are listed in **Table 1**. These methods are summarized in the sections that follow. One promulgated method in particular has extensive applicability. This method is United States Environmental Protection Agency (EPA) Method 3545. It is suitable for the extraction of several compound classes from environmental solid and semisolid samples. Compound classes listed in **Table 1** that are extracted using EPA Method 3545 are noted.

The authors of EPA Method 3545 found the PFE method gives recoveries comparable to those obtained by rigorous Soxhlet extraction and other techniques, such as shaking, supercritical fluid and sonication extraction methods. Compared to these techniques, PFE takes less time (< 30 min) and consumes less solvent (15–30 mL). Using PFE, the method is applicable to the extraction of polychlorinated biphenyls (PCBs), semi-volatile base/neutral/acids (BNAs), organophosphorous pesticides (OPPs) organochlorine pesticides (OCPs), polycyclic aromatic hydrocarbons (PAHs) and chlorinated herbicides from soil. Of all of the extraction conditions, only the extraction solvent is changed when extracting different compound classes. For example, acetone–hexane is used to extract a sample when analysing for OCPs and PCBs, methylene chloride–acetone is used to extract a sample when analysing BNAs and OPPs, and acetone–methylene chloride acidified with phosphoric acid is used to extract a sample when analysing for chlorinated herbicides. Extraction conditions for Method 3545 are shown in **Table 2**.

Relative recoveries of the PFE method (Method 3545) compared to other methods such as shaking or sonication extraction are summarized in **Table 3**. In this work, relative recoveries are the quotient of PFE recoveries divided by shaking, sonication, or Soxhlet extraction recoveries.

The following sections summarize details of critical sample preparation steps that are necessary before PFE, as well as the conditions used to extract the compounds listed in **Table 1**.

Applications

Aliphatic Hydrocarbons

Aliphatic hydrocarbons are readily extracted by PFE using aqueous and organic extraction solvents. Using organic extraction solvent, pentane, nonane, decane,

undecane, tetradecane, and pentadecane are efficiently extracted using the conditions listed in **Table 4**. Due to its volatility, pentane recoveries are the lowest of these analytes. Pentane boils at 36°C, so special precautions are required to keep it from evaporating from the extraction cell before the extraction is performed. To prevent loss of pentane, extraction cells are cooled and aluminium retention discs are added into the tops of the extraction cells.

Water in the form of super-heated steam may also be used to extract aliphatic hydrocarbons. Dodecane, pentadecane, octadecane, heneicosane, tetracosane, heptacosane, triacontane, and tritriacontane are efficiently extracted from solid and semi-solid environmental samples using the conditions listed in **Table 5**.

Table 2 Summary of sample preparation and extraction conditions used in EPA Method 3454 to extract PCBs, semi-volatile BNAs, OPPs, OCPs and chlorinated herbicides from solid and semisolid environmental samples

<i>Extraction conditions</i>	<i>Extraction analysis conditions</i>
Sample preparation	Grind sample to 100–200 mesh (150–75 µm particle size)
Dispersing or drying agent	Mix sample with anhydrous sodium sulfate or diatomaceous earth
Sample size	Up to 30 g if a dispersing agent is not used
Extraction cell volume	11, 22, or 33 mL cell, depending on sample size
Extraction solvent	OCPs and PCBs: 1 : 1 acetone : hexane BNAs and OPPs: 1 : 1 methylene chloride : acetone Chlorinated herbicides: 2 : 1 acetone : methylene chloride acidified with phosphoric acid
Temperature	100°C
Heat step	5 min
Static time	5 min
Flow type	Static, dynamic, or mix of both
Number of cycles	1–5
Extraction pressure	2000 psi
Flush volume	60% of cell volume
Purge time	60 s

Alkylphenols

Alkylphenols are metabolites of alkylphenol ethoxylates: a class of non-ionic surfactants that were used as cleaning agents and still find use today. Alkylphenols are monitored in the environment as they pose potential risk to animals. Time, and the amount of organic solvent, are saved in the pressurized fluid extraction of alkylphenols from sediment. For the extraction, CO₂ extraction solvent is modified with organic solvent. Either methanol, ethanol, 1-butanol, 2-propanol, acetone, or dioxane may be used. Sediment spiked with heptylphenol and nonylphenol is extracted with 100% recovery after 15 min extraction times. Longer times are required to extract 100% nonylphenol from the sediment. A dynamic extraction time of 60 min with 27.5% methanol does not completely extract aged nonylphenol from soil. Table 6 shows a summary of sample preparation and extraction conditions for alkylphenols.

If the extractor does not allow the use of CO₂, 100% methanol, ethanol, 1-butanol, 2-propanol,

acetone, or dioxane may be used as the extraction solvent. Since the solvent is typically evaporated before analysis, the most volatile solvent should be used.

BTEX (Benzene, Toluene, Ethylbenzene, and Xylene)

BTEX (benzene, toluene, ethylbenzene, and xylene) mixtures are efficiently extracted from solid and semisolid environmental samples by PFE using organic and aqueous solvents. BTEX mixtures are extracted from sand spiked with BTEX by PFE using organic solvent and standard conditions described in Table 4. BTEX mixtures are also quantitatively extracted by subcritical water using the conditions listed in Table 5.

Ethoxylates

Alkylphenol ethoxylates are non-ionic surfactants used for cleaning that are monitored in the environment. Ethoxylates are extracted from sediment by

Table 3 Summary of pressurized fluid extraction validation data for EPA Method 3545. Reported relative recoveries for the various compounds are the results of the PFE method used divided by the U.S. EPA reference methods listed

<i>Compound class</i>	<i>U.S. EPA reference method</i>	<i>% Relative recovery</i>
Chlorinated herbicides	8150A (shake method)	113
Organochlorine pesticides	3541 (automated Soxhlet)	97

PFE. Extraction conditions for octylphenol-9,5-ethoxylate, nonylphenol-13-ethoxylate and decylphenol monoethoxylate are the same as those for alkylphenols (see Table 6). Using the modified CO₂ as the extraction solvent with dynamic extraction, 60 min longer are required.

Explosives

Explosives are another important class of compounds that are monitored in the environment. They are monitored in military site or decommissioned site soil

Table 5 Summary of sample preparation and extraction conditions used to extract aliphatic hydrocarbons, BTEX, PCBs, and PAHs from soil, sediment, sludge, and urban dust using water as the extraction solvent

Extraction conditions	Extraction analysis conditions
Sample preparation	Soil is homogenized
Dispersing or drying agent	None used
Sample size	0.2–0.5 g, cell void volume filled with sand
Extraction cell volume	0.5–0.8 mL (4.6 mm i.d. × 30 mm stainless steel HPLC column or 4.6 mm i.d. × 50 mm stainless steel SFE cell)
Extraction solvent	HPLC grade water purged two hours with nitrogen to remove dissolved oxygen
Temperature	250°C
Extraction time	15 min
Flow type	Dynamic, 1 mL ⁻¹ min ⁻¹
Number of cycles	1
Extraction pressure	73.5 psi for aliphatic hydrocarbons and 735 psi for BTEX, PCBs, and PAHs

Table 6 Summary of sample preparation and extraction conditions used to extract alkylphenols, ethoxylates, and linear alkylbenzene sulfonates from environmental solid and semi-solid samples

Extraction conditions	Extraction analysis conditions
Sample preparation	Water was separated from sediment by centrifugation. Sediment was dried at ambient temperature and ground to a particle size of less than 10 μm and water content was adjusted to 10% (w/w). After filling the cells, empty space in the extraction cell was filled with 3 mm diameter glass beads. Any remaining space, 2 mL was filled with modifier solvent.
Dispersing or drying agent	None used
Sample size	1 g
Extraction cell volume	5 mL
Extraction solvent	CO ₂ , modified with methanol, ethanol, 1-butanol, 2-propanol, acetone, or dioxane.
Temperature	100°C
Heat step	None
Static time	10 min
Flow type	Mix of static (10 min) and dynamic (5–60 min) extraction
Number of cycles	1
Extraction pressure	2200 and 2940 psi

Kreißelmeier and Durbeck (1996) *Fresenius Journal of Analytical Chemistry* 354: 921.

since the explosives can potentially contaminate water supplies. PFE extracts HMX (octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine), RDX (hexahydro-1,3,5-trinitro-1,3,5-triazine), TNT (2,4,6-trinitrotoluene), and DNT (2,4-dinitrotoluene) using the conditions shown in Table 7.

The extraction solvent used depends on the analytical technique preferred. Acetone is the best choice for GC and methanol is the best solvent for LC analysis. For the results shown in Figure 1, methanol was used as the extraction solvent. The extraction step takes 12 min per sample, resulting in 45 mL of extract.

Gasoline

Gasoline is extracted from spiked sand using the standard PFE conditions listed in Table 4. The average recovery of gasoline using these conditions is 94.4%, as determined by IR detection.

Linear Alkylbenzenesulfonates

Anionic surfactants are widely used for industrial as well as household cleaning and for pesticide formulations. Of the anionic surfactants, biodegradable

Table 7 Summary of sample preparation and extraction conditions used to extract explosives from soil

Extraction conditions	Extraction analysis conditions
Sample preparation	Soil is homogenized
Dispersing or drying agent	None used

Extraction pressure	1500 psi
Flush volume	60% of cell volume
Purge time	90 s

Extraction conditions from Ezzell (1998) *American Environmental Laboratory* January/February 24.

linear alkylbenzenesulfonates (LAS) are the most common and can be found in waste water systems and river water. From these water sources, anionic surfactants partition to sediment. LAS are selectively extracted from sediment by PFE allowing simple quantitation by high performance liquid chromatography. Extraction conditions for linear LAS [linear decyl- up to tridecylbenzenesulfonate (LAS-10 to LAS-13)] are the same as those for alkylphenols listed in Table 6. Methanol is the best CO₂ modifier (at 2200 psi) for these compounds.

Pesticides

Pesticides including herbicides, insecticides and fungicides are broadly applied throughout the world to

**Figure 1** Average percent relative recovery data of explosives extracted from soil spiked at 3 mg kg⁻¹ level. (Reprinted from Ezzell 1998. Soils were fortified with 50–500 and 500–5000 µg kg⁻¹. (Data from Ezzell *et al.* 1995.)

generate greater harvests and to protect food supplies. As pesticides are present in soil, sediment and water, they are an important class of environmental compounds. Pesticides are extracted by PFE using organic and aqueous solvents.

Sample preparation and extraction conditions for chlorinated herbicides, OCPs, OPPs in soil using EPA Method 3545 are shown in Table 2. The method (Method 3545) specifies the use of mixtures of organic solvents to extract a wide variety of organochlorine and organophosphate pesticides and chlorinated herbicides.

At least eight chlorinated herbicides (2,4-D; 2,4-DB; 2,4,5-T; 2,4,5-TP; dalapon, dicamba, dichloroprop and dinoseb) are extracted using this method. Extraction takes 12 min per sample, generating 15 mL of extract. Average relative recoveries for the

Purge time	60 s

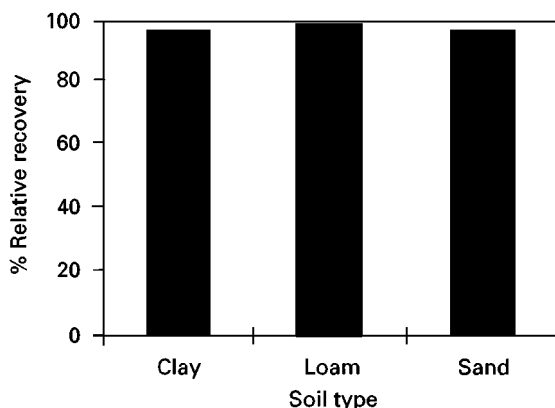

Figure 3 Average percent relative recovery data of organochlorine pesticides extracted from three soil types. Soils were fortified at 5, 50 and 250 $\mu\text{g kg}^{-1}$. (Data from Richter *et al.*, 1995. Copyright 1995 by International Scientific Communications, Inc.)

Figure 4 Average percent relative recovery data of organophosphorus pesticides spiked at low and high levels on three soil types and then extracted using EPA Method 3545. Soils were fortified with 250 and 2500 $\mu\text{g kg}^{-1}$. (Data from Ezzell *et al.*, 1995.)

eight chlorinated herbicides are shown in Figure 2. Relative recoveries are the quotient of PFE recoveries divided by shaker extraction recoveries.

Organic acids are extracted using organic solvents and by subcritical water. The advantages of using aqueous extraction solvent are (1) purchase and disposal costs are low and (2) it is environmentally friendly. Conditions used to selectively extract pyriithiobac sodium (the active ingredient in Staple[®] herbicide, used to control broadleaf weeds in cotton) are listed in Table 8.

Organochlorine pesticides (OCPs) are extracted using the conditions listed in Table 2. Average relative recoveries for the 20 OCPs are shown in Figure 3. Relative recoveries are the quotient of PFE recoveries divided by automated Soxhlet extraction recoveries.

Organophosphate pesticides (OPPs) listed in Table 9 are extracted from soil using the conditions listed in Table 2. Average relative recoveries for the 24 OPPs are shown in Figure 4. Relative recoveries are the quotient of PFE recoveries divided by Soxhlet extraction recoveries.

Fenthion	Tokuthion

Polychlorinated Biphenyls

Polychlorinated biphenyls (PCBs) are significant environmental pollutants that are routinely monitored in soil, sediment and sludge. PCBs are extracted from these matrices using organic and aqueous extraction solvents. PFE conditions using organic solvents are listed in Table 2; PFE conditions used for aqueous solvents are listed in Table 5. Although not listed in Table 2, acetonitrile and methylene chloride also provide adequate extraction of PAHs in environmental solid and semi-solid samples. Concentrations of PCBs extracted from soil, sediment, urban dust and sludge using PFE and exhaustive Soxhlet extraction are similar. This is true for both organic and aqueous extraction solvents in PFE.

Table 10 Summary of sample preparation and extraction conditions used to extract dioxins and furans from chimney brick, urban dust, fly ash and sediments

Extraction conditions	Extraction analysis conditions
Sample preparation	Grind soil to 100–200 mesh (150–75 μm particle size)
Dispersing or drying agent	Mix with anhydrous sodium sulfate or Hydromatrix TM
Sample size	4–10 g

Extraction solvent	Toluene, 15 mL
Temperature	180°C
Heat step	9 min
Static time	5 min
Flow type	Static, dynamic, or mix of both
Number of cycles	1–2
Extraction pressure	2000 psi

Extraction condition reproduced from Richter *et al.* (1997) *Chemosphere* 34: 975, with permission from Elsevier Science.

Polychlorinated Dioxins and Furans

Polychlorinated dibenzo-p-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs) are environmental pollutants that are extracted from chimney brick, urban dust, fly ash, soil and sediment using PFE. Conditions for the extraction of PCDDs and PCDFs are listed in Table 10.

PFE and Soxhlet extraction results of PCDDs and PCDFs levels found are essentially equivalent for the matrices tested. PFE required less time and solvent than Soxhlet extraction.

Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) are important environmental compounds being carcinogenic and mutagenic. They are extracted by organic solvents and by subcritical water. Using organic solvents, PAHs are extracted from urban dust, sediment and soil using the PFE conditions listed in Table 2. Subcritical water extraction requires the conditions listed in Table 5. Results from certified reference ma-

terials indicate that PFE efficiently extracts PAHs from these matrices. Figure 5 shows a comparison of the amounts of PAHs found in PFE extracts and certified values.

The following organic solvents also provide adequate extraction of PAHs in environmental samples: toluene/methanol 1 : 1 (v : v), toluene, methylene chloride, acetonitrile, hexane/acetone 1 : 1 (v : v) and water. Figure 6 shows the amounts of PAHs found in urban dust (SRM 1649) extracts comparing various organic and aqueous extraction solvents.

Semi-Volatile Base/Neutral/Acid Compounds

Semi-volatile base/neutral/acid compounds (BNAs) are extracted from solid and semi-solid environmental samples using the conditions listed in Table 2. Average relative recoveries for the 56 US EPA priority pollutants list (PPL) and target compound list (TCL) are shown in Figure 7. Relative recoveries are the quotients of PFE recoveries divided by Soxhlet extraction recoveries.

Figure 5 Comparison of amounts of PAHs found in PFE extracts and certified values. (Data from Richter, Jones, Ezzell *et al.* 1996.)

Figure 6 Recovery of PAHs from urban dust (certified reference NIST SRM 1649) extracted by PFE. Extraction solvents were water (250°C, 725 psi) and methylene chloride/acetone 1 : 1. (Data for water extraction from Hawthorne *et al.*, 1994.) Data for methylene chloride extraction (DCM 1) from Richter *et al.*, 1995. Data for methylene chloride extraction (DCM 2) from Schantz *et al.*, 1997.)

Total Petroleum Hydrocarbons

Total petroleum hydrocarbons (TPHs) are extracted from soil samples using the standard PFE conditions listed in Table 4. Levels of TPHs extracted by PFE and Soxhlet extraction are typically similar.

Future Applications

There are several reasons why analysts use PFE to extract analytes of interest from solid and semisolid

environmental samples. In comparing PFE to Soxhlet, sonication and shaking extraction methods, researchers find that the amounts of analyte extracted from solid and semi-solid samples are similar, but PFE requires less extraction time and less extraction solvent. PFE methods are easy to develop and to transfer. PFE provides automated sample extraction, allowing increased productivity of laboratory personnel. Finally, PFE methods are being accepted by regulatory agencies. Given these advantages, researchers

Figure 7 Average percent relative recovery data of 56 semi-volatile base/neutral/acid components extracted from three soil types using PFE. Soils were fortified at 250, 2500, and 12500 $\mu\text{g kg}^{-1}$. (Data from Richter *et al.* (1995) reproduced with permission from International Scientific Communications Inc.)

will continue to use PFE to develop many more environmental sample applications.

Solid-Phase Microextraction

T. Nilsson, Technical University of Denmark, Lyngby, Denmark

Copyright © 2000 Academic Press

Solid-phase microextraction (SPME) is a technique for the extraction of organic compounds from gaseous, aqueous and solid matrices such as many environmental samples. It is rapid and simple, which makes it ideal for automation and *in situ* measurements, and no harmful solvents are used. The principle of SPME is equilibration of the analytes between an organic polymeric phase coated on to a fused-silica fibre and the sample matrix. The parameters of importance for the equilibration process are described below and

various environmental applications are discussed. Traditionally, SPME has been combined with analysis by gas chromatography (GC), and mainly aqueous samples have been analysed. This combination has proved to be sensitive, accurate and precise for the quantitative analysis of volatile organic compounds and different classes of pesticides. Solid samples can also be analysed by SPME in spite of the stronger matrix effects, and recently SPME has been coupled with liquid chromatography (LC) for the analysis of polar pesticides.

Principle

The principle of SPME is that a fused-silica fibre is coated with an organic polymer and exposed to the

sample. The fibre is mounted inside a steel syringe needle for protection in order to be able to penetrate the septum of the sample vial and the GC injector without damaging the fibre. Subsequently, the fibre can be pushed out of the needle for exposure to the sample. The analytes will then diffuse into the fibre coating until equilibrium has been established.

Extraction Efficiency

Basically, the extraction efficiency is determined by the extraction time, the sample concentration and the distribution constant of the analyte between the fibre coating and the sample. The classical situation is extraction with the fibre immersed in a water sample.

The amount of analyte extracted by the fibre coating equilibrium n_1^∞ is determined by the expression:

$$n_1^\infty = \frac{KV_1V_2C_2^0}{KV_1 + V_2} \quad [1]$$

where K is the distribution constant, V_1 is the volume of the fibre coating, V_2 is the sample volume, and C_2^0 is the initial sample concentration.

Another SPME approach is sampling from a headspace above the sample in the vial. In this case, the amount of analyte adsorbed after infinite time n_1^∞ is given by the equation:

$$n_1^\infty = \frac{C_2^0V_1V_2k}{kV_1 + k'V_3 + V_2} \quad [2]$$

where V_3 is the volume of the headspace, k is the fibre coating–gas distribution constant, and k' is the gas–water distribution constant of the analyte. k' is directly proportional to Henry's constant and is usually relatively low for the compounds analysed by SPME. Thus, only if V_3 is considerable compared to V_2 , a lower sensitivity will be observed with headspace–SPME (HS–SPME). The advantage of HS–SPME is that equilibration times will be much shorter due to the fact that the diffusion is several orders of magnitude faster in the gas phase than in liquids. Another advantage of HS–SPME is that it can be applied for the analysis of solid and dirty samples. However, such applications are not so amenable to

a theoretical treatment because of unpredictable matrix effects.

Adsorption Kinetics

Basically, the kinetics of adsorption are governed by diffusion. A number of models have been reported for different situations, but they provide only approximate descriptions under ideal conditions. In practice, a number of factors will cause deviations from these conditions, thus a simple, empirical model has been described for practical purposes:

$$n_1 = n_1^\infty [1 - \exp(-t/\tau)] \quad [3]$$

where τ is a measure of the equilibration velocity, and n_1 is the amount adsorbed on the fibre coating at the time t .

Extraction

The extraction conditions are optimized in order to obtain a rapid and sensitive analysis. It is important to remember that SPME depends on diffusion and distribution. Thus, the required extraction time can be reduced by increasing the diffusion rates, and the extraction efficiency can be improved by increasing the distribution constant.

Choice of Fibre Coating

Various SPME fibres are commercially available (Table 1). The polydimethylsiloxane (PDMS) coating is recommended for the extraction of nonpolar compounds. Three different PDMS fibres exist with a coating thickness of 7, 30 and 100 μm , respectively. Usually, 100 μm coating is used due to its higher extraction capacity. However, for higher boiling compounds with high distribution constants and long equilibration times, the thinner coatings should be used. The 7 μm coating has the advantage that it is chemically bonded and can be used at temperatures up to 340°C.

Extraction Parameters

Reliable quantitative analysis can be performed under nonequilibrium conditions, but the sensitivity will be

Table 1 SPME fibres and their recommended use

<i>Fibre coating material</i>	<i>Abbreviation</i>	<i>Recommended use</i>
Polydimethylsiloxane	PDMS	Nonpolar compounds
Carboxen/polydimethylsiloxane	Carboxen/PDMS	Very volatile compounds
Polyacrylate	PA	General
Polydimethylsiloxane/divinylbenzene	PDMS/DVB	General
Carbowax/divinylbenzene	CW/DVB	Polar compounds
Carbowax/templated resin	CW/TPR	Polar compounds

better when the extraction time is sufficient to reach near-equilibrium. The equilibration time can be shortened by agitation or heating of the sample which increase the diffusion rates. Normally, an extraction time comparable to the time of the chromatographic analysis is chosen in order to maximize sample throughput. Rapid stirring using a magnetic bar is efficient, but may not always be very reproducible; vibration of the fibre is a valid alternative for small samples. At higher temperatures the equilibration will proceed faster due to the higher diffusion rates; however, the amount adsorbed at equilibrium will be lower.

An internally cooled SPME device has been developed for the purpose of maintaining favourable distribution constants while extracting from a heated sample. Sample heating may be necessary to release analytes that are adsorbed on solid matrices. Addition of a salt normally has a positive influence on the extraction efficiency due to the increased ionic strength of the solution. When acidic compounds are analysed, the pH should be below the lowest pK_a value, because ionic compounds are not extracted but the lifetime of the fibre is reduced at low pH values. A methanol content of less than 1% in spiked samples does not affect the SPME process significantly. It must always be borne in mind that relatively large amounts of other compounds in a complex matrix may have a significant effect on the distribution constant.

Desorption

In case of analysis by GC, thermal desorption is performed in the injector. For analysis by LC, the injection loop is replaced by a special SPME desorption chamber and the desorption is performed in the mobile phase or a solvent mixture. It is important to

optimize the desorption parameters in order to guarantee that the fibre can be used for subsequent analysis without intermediate cleaning. This is essential for automation purposes and for trace analysis. For GC analysis, desorption should be as rapid as possible. The best injection is obtained when the desorption temperature is sufficiently high to ensure an almost complete desorption within 1 min or less. However, a longer desorption time is often required to avoid carry-over, in which case cryogenic focusing may be necessary. For LC analysis, desorption using the mobile phase is the best solution and can even be performed in the flowing mobile phase (dynamic mode) if the desorption is rapid. However, a higher content of an organic solvent is often needed to obtain a satisfactory desorption. In this case, the desorption chamber is filled with the appropriate solvent mixture and desorption takes place (static mode) before the injection is performed by switching the valve. A high content of organic solvent may adversely affect the chromatography if the initial mobile phase is much weaker. Furthermore, the SPME fibres are not very resistant to organic solvents, so the coupling of SPME with LC is still at the experimental stage.

Analysis of Aqueous Samples

Numerous successful applications of SPME for the analysis of aqueous samples have been reported. The analytical conditions are summarized in Table 2, and the results for the different classes of compounds are discussed below. In most of the studies, only spiked samples have been analysed; however, considering the limited effect of suspended solids and humic substances at levels typical for lake, river and groundwater, such environmental samples can also be analysed. In more complex sample matrices, SPME can be used to measure the freely dissolved

Table 2 Applications of SPME for the analysis of aqueous samples

<i>Compound</i>	<i>Fibre coating</i>	<i>Analysis (alternative detector for some compounds)</i>
Volatile organic hydrocarbons	PDMS	GC-MS (FID)
Halogenated volatile organic compounds	PDMS	GC-MS (ECD)
Polychlorinated biphenyls, polyaromatic hydrocarbons and heteroaromatic compounds	PDMS or PA	GC-MS (ECD, FID)
Phenols and nitro-compounds	PA or more polar	GC-MS (ECD)
Organochlorine, organonitrogen and organophosphorus pesticides	PA or more polar	GC-MS (ECD, AED, NPD)
Fatty acids, phenoxy acid herbicides and amines	PA or PDMS/DVB	Derivatization/GC-MS (ECD, FID)
Organometallics and inorganic metal ions	PDMS	Derivatization/GC-MS
Phenoxy acid, sulfonyleurea, phenylurea, carbamate and other polar herbicides	CW/TPR	LC-ESI/APCI-MS (UV, DAD)

Abbreviations: MS, mass spectrometry; FID, flame ionization detection; ECD, electron capture detection; AED, atomic emission detection; NPD, nitrogen and phosphorus detection; ESI, electrospray ionization; APCI, atmospheric pressure chemical ionization; UV, ultraviolet absorption; DAD, diode array detection.

compounds. While the traditional techniques extract the total amount, only a small amount is extracted by SPME, so the equilibrium with the matrix is not perturbed. By addition of an internal standard, e.g. a deuterated surrogate, the total concentration and the distribution of the analytes can be determined. Unless an isotope-labelled analogue of the analyte is used, the benefit of an internal standard in SPME analyses is very limited because even similar compounds may behave differently in the SPME process.

Volatile Organic Hydrocarbons

The analysis of benzene, toluene, ethylbenzene and *m*-, *o*- and *p*-xylene (BTEX compounds) by SPME has been studied extensively. Many other gasoline and fuel-related hydrocarbons have also been analysed. Generally, the standard deviation of replicates is around 5% and detection limits are in the low $\mu\text{g L}^{-1}$ range for the lightest compounds down to low ng L^{-1} level for the higher boiling analytes with the PDMS fibre coating.

Halogenated Volatile Organic Compounds

Numerous applications of SPME for the analysis of halogenated volatile organic compounds have been reported. The PDMS fibre coating performs well for these compounds. The precision and sensitivity are similar to those reported for the volatile organic hydrocarbons.

Polychlorinated Biphenyls, Polycyclic Aromatic Hydrocarbons and Hetero-Aromatic Compounds

Polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs) have been analysed in spiked water samples and in groundwater. The equilibration times were approximately 60 min with the PDMS fibre coating. However, detection limits in the low ng L^{-1} range can be obtained with an extraction time of only 10 min. The relative standard deviations of these analyses are around 20% for the PCBs and 10% for the PAHs. Possibly, better precision could be achieved by increasing the extraction time in order to approach equilibrium. Pyrazines and several other heteroaromatic compounds have been analysed successfully with detection limits from low $\mu\text{g L}^{-1}$ levels for the volatile analytes down to low ng L^{-1} levels for the semivolatile analytes. The precision is in the range from 3 to 14% relative standard deviation. The extraction efficiency is strongly enhanced by salt addition.

Phenols and Nitro-Compounds

Usually, salt addition has a positive effect on the extraction of phenols and nitrophenols, and for analytes with pK_a values below 7 the extraction effi-

ciency is higher at low pH values. Typically, detection limits are in the low $\mu\text{g L}^{-1}$ range and the relative standard deviations are from 5 to 12%. The sensitivity and chromatography can be improved for most of the phenols by aqueous-phase acetylation prior to extraction. Nitrotoluenes, nitroanilines and nitrobenzenes have also been analysed successfully by SPME.

Organochlorine, Organonitrogen and Organophosphorus Pesticides

In several studies, the analysis of organochlorine pesticides has been examined. Generally, equilibration times range from 30 to 90 min, detection limits are in the low ng L^{-1} range with electron-capture detection (ECD) and mass spectrometry (MS), and standard deviations vary from 5 to 20%. For the organonitrogen and organophosphorus pesticides, similar precision and equilibration times have been observed, and the detection limits are at very low ng L^{-1} level with MS and nitrogen and phosphorus detectors.

Fatty Acids, Phenoxy Acid Herbicides and Amines

Fatty acids can be analysed directly from aqueous samples by SPME. However, for short chain fatty acids the detection limits are in the high $\mu\text{g L}^{-1}$ range with the polyacrylate fibre coating and worse with other fibre coatings. However, the sensitivity can be considerably improved by derivatization. Different derivatization procedures have been examined and detection limits below $\mu\text{g L}^{-1}$ can be obtained in the best cases. Similar detection limits are obtained for phenoxy acid herbicides and amines by derivatization-SPME.

Organometallics and Inorganic Metal Ions

SPME has mainly been applied for organic trace analysis. However, a few applications for inorganic metal ions and organometallics have been reported: bismuth was extracted using an experimental SPME fibre coated with a liquid ion exchanger; aqueous-phase derivatization with tetraethylborate followed by SPME has been applied to analyse methylmercury and labile Hg^{2+} in river water, and the same derivatization approach can be used for the analysis of tin and lead. The detection limits are in the low ng L^{-1} range.

Phenoxy Acid, Sulfonylurea, Phenylurea, Carbamate and Other Polar Herbicides

SPME coupled with LC-electron spray ionization (ESI)/atmospheric pressure chemical ionization (APCI)-MS has been applied for the trace analysis of polar pesticides in spiked water samples and lake

water. Acidic, as well as neutral, priority pesticides representing all major pesticide classes can be analysed successfully with single ion monitoring (SIM) detection limits in the ng L^{-1} range. Detection limits in the low $\mu\text{g L}^{-1}$ range and standard deviations below 10% were reported when UV detection was used. Finally, SPME-flow injection-MS-MS has been developed for the purpose of rapid, target-oriented screening analysis.

Validation of Standard Methods for Routine Analysis

In order for SPME to be applied for routine analysis, two issues are very important: automation and quality assurance. Thus, an autosampler has been developed for SPME-GC analysis, and three interlaboratory studies have been performed to validate the quantitative performance of SPME. One study addressed the analysis of 12 organochlorine, organonitrogen and organophosphate pesticides at low $\mu\text{g L}^{-1}$ level in aqueous samples. In the other two studies, standard methods for the analysis of volatile organic compounds and triazine herbicides in aqueous samples were validated at low $\mu\text{g L}^{-1}$ levels and around the European limit of $0.1 \mu\text{g L}^{-1}$ for individual pesticides in drinking water. Subsequently, both methods were presented by the Italian Standardization Organization, Unichim. The validations were performed in accordance with the International Standardization standard method 5725-1994 concerning interlaboratory statistics. The results regarding accuracy and precision are given in Table 3. The 95% confidence interval of the gross average of the reported results always included the true concentration of the test sample, i.e. the accuracy of the methods was very good. The precision obtained would meet the requirements for most routine analyses.

In Situ Measurements

Many well-established extraction techniques have been applied for the analysis of groundwater samples

from wells. These methods require pumping of the groundwater to the surface, sampling into appropriate containers, and transport to the analytical laboratory. Sample loss and sample composition variation may occur during these steps. Thus, a number of downhole sampling devices have been developed. However, each has limitations with respect to flexibility of sample type and sample size, maximum operating pressures and depth, portability and adaptability to difficult field conditions. The characteristics of SPME make it ideal for field sampling, i.e. it is simple, robust, portable, independent of sample volume and instrument configuration, and it is impossible to plug the fibre with particulate matter. Thus, SPME sampling probes have been developed for use in monitoring wells (Figure 1) and for fitting to the head of a cone penetrometer. They were tested in a mobile laboratory for on-site measurements of volatile organic compounds in groundwater and soil gas. Comparison of results obtained by *in situ* SPME and SPME after traditional sampling from the same groundwater wells confirmed the feasibility of the *in situ* sampling approach. Slightly lower results were obtained in most cases after traditional sampling.

Solid Samples

The major complication in the analysis of soil samples is the strong sorption of the analytes to the matrix. A nearly complete exhaustive extraction could be achieved for the BTEX compounds from sand and clay matrices by heating the sample and using an internally cooled SPME fibre for the extraction. However, in the case of less volatile and more polar analytes, the sorption is stronger and the recovery is very dependent on the organic carbon content of the soil. Thus, calibration using a model matrix would only be acceptable for screening purposes, while calibration by standard addition is needed for reliable quantitative analysis. Addition of water to the sample helps to release the analytes from the sample matrix and improves the recoveries drastically. A nearly complete extraction of polyaromatic

Table 3 Interlaboratory validation of SPME for quantitative analysis

Analytes	Number of participating laboratories	Concentration of the test sample ($\mu\text{g L}^{-1}$)	Accuracy	Average repeatability (%)	Average reproducibility (%)
Volatile organic compounds	12	3	True values within confidence intervals	9.3	28.7
Organochlorine, organonitrogen and organophosphorus pesticides	11	2-25	True values within confidence intervals	11.5	28.3
Triazine herbicides	8	0.05-0.12	True values within confidence intervals	9.6	13.6

hydrocarbons from different soils has been achieved by high temperature or subcritical water extraction. Finally, the leachability of pesticides from soils has been studied by SPME.

Conclusion

SPME has successfully been applied for the quantitative analysis of most of the organic, environmental priority compounds, which can be analysed by GC, in aqueous samples. In more complex sample matrices, such as wastewater and soils samples, quantitative analysis by SPME may be difficult because matrix effects influence the distribution constants significantly. Standard methods have been developed and validated regarding sensitivity, precision and accuracy for the trace analysis of volatile organic compounds and several classes of pesticides in aqueous samples. Derivatization/SPME-GC and SPME-LC have been applied for the analysis of more polar

organic compounds. However, further development of these methods is needed before they can be applied for routine analysis. Especially, further research on the coupling of SPME and LC-MS may allow many new environmental applications. Inorganic metal ions and organometallics have been analysed as well, and the use of an ion exchange fibre coating may allow more applications in this field. The small volume and the noninterfering character of SPME are important factors for numerous applications. Finally, the easy handling and simple design make SPME a good choice for in-field analytical work.

Soxhlet Extraction

M. D. Luque de Castro and L. E. García Ayuso,

Copyright © 2000 Academic Press

The health of our environment is now a matter of great concern. This has stimulated an intensive search for an understanding of both the ways in which the natural environment works and the anthropogenic actions that bring about environmental changes. A large number of studies have been, or are in the process of being, developed in order to increase our knowledge of the processes causing environmental pollution and to propose clean analytical methods for monitoring and subsequent control. Thus, a high percentage of the studies developed so far fall within the field of analytical chemistry. There are a number of stages involved in any analytical method: definition of the aim, selection and establishment of an appropriate method, sampling plan, sample collection, sample handling and pretreatment, final measurements (detection/determination), method validation, assessment and interpretation of the results and, finally, safety.

In spite of the evolution of analytical techniques involved in some of the above mentioned stages (particularly detection/determination), the development

of some of these has not been as great as desirable. These steps constitute 'critical points' of an analytical method and, consequently, the main source of errors. The pretreatment step (including separation techniques) can be considered as a 'critical step'. Conventional Soxhlet extraction is currently one of the most frequently used pretreatment techniques, not only in environmental analysis, but also in many other fields. Its principles, performance, environmental applications and improvements are considered in more detail below.

Principles of Conventional Soxhlet Extraction

Soxhlet extraction is a very useful tool for preparative purposes in which the analyte is concentrated from the matrix as a whole or separated from particular interfering substances. Sample preparation of environmental samples has been developed for decades using a wide variety of techniques. Solvent extraction of solid samples, which is commonly known as solid-liquid extraction (also referred to as leaching or Lixiviation in a more correct use of the physicochemical terminology), is one of the oldest methods for solid sample pretreatment. Conventional Soxhlet extraction remains as one of the most

Figure 1 Soxhlet extraction apparatus. (Reproduced from Reeves RN (1994) *Environmental Analysis*. New York: John Wiley.)

relevant techniques in the environmental extraction field. This assertion is supported by the double use of conventional Soxhlet: (1) as an extraction step in a given method, and/or (2) as a well-established model for comparison of new extraction alternatives.

In conventional Soxhlet, the sample is placed in a thimble-holder and during operation is gradually filled with condensed fresh solvent from a distillation flask. When the liquid reaches an overflow level, a siphon aspirates the whole contents of the thimble-holder and unloads it back into the distillation flask, carrying the extracted analytes in the bulk liquid. This operation is repeated until complete extraction is achieved. This performance makes Soxhlet a hybrid continuous-discontinuous technique. Inasmuch as the solvent acts stepwise, the assembly can be considered as a batch system; however, since the solvent is recirculated through the sample, the system also bears a continuous character. **Figure 1** shows a scheme of a conventional Soxhlet device. As can be seen, Soxhlet extraction is a very simple technique. This simplicity makes the procedures for different samples very similar. For this reason, an overview of its extensive application in the environmental field during the last two decades is presented here, which cover the kind of samples, analytes, solvents, etc. used

and the role of Soxhlet extraction in the overall analytical process.

Table 1 summarizes the main characteristics of Soxhlet extraction, clean up and detection/determination for each group of pollutants discussed below.

Use of Conventional Soxhlet Extraction for Leaching of Organic Pollutants

Organic pollutants present in solid environmental samples from natural or man-made sources are most of the time properly extracted with organic solvents in a Soxhlet device. The following sections show how conventional Soxhlet extraction is used as a technique for separation of the analytes from the solid matrix. The pollutants are classified into three groups depending on the matrices in which they are present: air, solid and liquid samples. It is worth noting that, in spite of the solid character of particulates, the samples are classified as a function of the medium in which they are present. Thus, airborne and water particulates are classified as air and liquid samples, respectively.

Organic Pollutants in Air

Organic pollutants are in the gas phase of the atmosphere and are associated with airborne particulate matter. Sampling of organic pollutants is usually carried out by filters through which a large volume of air is circulated. After filtration, the filter is extracted with an appropriate solvent and the target analytes are removed in the extract. When the extract is not suitable for direct individual separation/determination a prior clean-up stage must be applied. These and other aspects are discussed below.

Polycyclic aromatic hydrocarbons Polycyclic aromatic hydrocarbons (PAHs) and their derivatives are among the most studied environmental pollutants. This is due to both their continuous emissions from combustion and their biological activities, such as toxicity, mutagenicity and carcinogenicity. Determination of PAHs from air requires a suitable sampling device, including an aspiration pump, which retains the air particulates on glass or quartz fibre, cellulose or paper filters. However, the filter is not the sole collection medium for PAH-containing small-size aerosols. Chemicals such as Tenax GC, PUFs (see **Table 2** for abbreviations) or Amberlite XAD-2 resins should provide a back up to these filters by retaining PAHs not trapped by the filter. A layer of activated charcoal between two filters is used for collection of gaseous components.

VOCs	Volatile organic compounds

The adsorbed compounds are extracted by Soxhlet into different organic solvents such as toluene, benzene, cyclohexane, tetrahydrofuran, dichloromethane and liquid CO₂. Clean-up extract procedures are mainly performed by the use of silica gel (SFC, LLE and LC are also used), and the individual separation/determination stage involves HPLC-UV and GC-MS. A less common technique for PAH determination is TLC-UV.

Polychlorinated dibenzo-dioxins (PCDDs) and polychlorinated dibenzo-furans (PCDFs) Analysis of dioxins has become an issue of major importance because of their carcinogenic nature. The main source of dioxin emission is combustion (in waste incineration and the steel industry). In comparison with the wide variety of methods used for the determination of PAHs from air, the method for determination of PCDDs and PCDFs is well established and only some minor modifications are found in the literature. These compounds are sampled by splitting the air into two phases. The split involves glass fibre filters, which retain airborne particulates, and PUF solid sorbents, which retain vapours. The PUF sorbents are fortified with a range of ¹³C-labelled PCDDs and PCDFs before sampling (sometimes spiking precedes the sampling step). The same spiked procedure is applied to

particulate phases before extraction. The filter and foam are then extracted by Soxhlet with toluene (benzene/ethanol and dichloromethane have also been used but less frequently than toluene), followed by an acid-base clean-up step, then drawing of the extract through micro-columns of silica gel, alumina and carbon (sometimes a chromatographic clean up is applied before). Individual separation of the analytes and determination are performed by high-resolution GC-EIMS-SIM.

Polychlorinated biphenyls (PCBs) and other chlorinated compounds A wide variety of pollutants other than PCDDs and PCDFs contain chlorine. This makes them very harmful due to their activity in the atmosphere. PCBs and other compounds (chlorinated solvents, halogenated methoxybenzenes (halogenated anisoles), polychlorinated naphthalenes, etc.) are the most representative chlorinated compounds in addition to OCPs (alpha and gamma hexachlorocyclohexane (HCHs), chlorothalonil, dichlofluanid, toxaphene, chlorpyrifos, alachlor, etc.).

Sampling of these compounds is similar to that described in the previous two sections and either the adsorbent used or the extraction solvent and post-extraction procedures applied are widely documented in the literature. Thus, the performance of different sorbents, such as Chromosorb 102, Porapak R, Supelpak-2, Amberlite XAD-2, Amberlite XAD-4, Carbonaceous Ambersorb XE-340 and polyurethane foam, has been evaluated with use of atmospheres containing known concentrations of OCPs. The most efficient trap for HCH and PCBs was found to be two cartridges containing PUFs-Tenax-GC sandwich traps, connected in series. Halogenated anisoles and hexachlorobenzene (HCB) have been sampled from air using a high volume sampling technique in which air was pumped through two layers of solid sorbent: the upper sorbent layer was a mixture of silica gel 60/ENVI-Carb or ANGI-Sorb 5B/ANGI-Sorb 10B and the lower sorbent layer was silica gel 60/ENVI-Carb or ANGI-Sorb 2.5B. These solid sorbents are Soxhlet extracted with organic solvents, mainly dichloromethane (but also with others such as petroleum ether, ethyl ether, hexane, acetone and mixtures) and, after the appropriate clean up, the detection/determination step is developed mainly by GC-ECD.

Other pollutants usually determined in air In addition to PAHs and chlorinated pollutants from the atmosphere, there are some other families of pollutants that have a significant effect on the environment. Thus, alcohols and phenols, organophosphorous compounds, anilines and benzidines, aliphatic hydrocarbons, etc., can be included in this

classification. The procedures for determination and the general characteristics of the chemicals and instruments used (solid sorbents, extractant, extraction time, clean up and detection/determination) are similar to those discussed in previous sections.

Organic pollutants in solid samples Organic pollutants are present in a wide range of environmental solid samples. Thus, soil, sediment, sewage sludge and ash are the most commonly studied matrices in the environmental field. All these matrices can be leached by conventional Soxhlet extraction. There are two criteria that solid samples must meet before extraction: (1) they must be finely divided (in order to improve the sample-solvent contact), and (2) sample moisture must be carefully controlled. After the extraction step by an organic solvent, a clean-up procedure is necessary due to the co-extraction of both fat residues and other interferent substances. The usual procedures for analytical processing of the most representative organic pollutants are as outlined below.

Polycyclic aromatic hydrocarbons Soil or sediment samples are dried to constant weight, ground, sieved and mixed with anhydrous Na_2SO_4 . Soxhlet extraction is performed with dichloromethane (chlorobenzene, benzene, cyclohexane and hexane/acetone are less common for this purpose) and the extract is reduced in a Kuderna-Danish concentrator, a rotary-evaporator or under a N_2 stream. Clean up (if needed) involves: (1) passing the extract through one or more microcolumns containing silica gel, alumina, C_{18} , Florisil, Amberlite XAD-2, etc., and/or (2) fractionation by semi-preparative normal-phase LC. The PAHs are determined either by HPLC (with UV, MS or fluorimetric detection) or GC (with FID or MS detection).

Fly ash is Soxhlet extracted with toluene (or benzene) and the extract is cleaned up by TLC on a plate coated with silica gel. Detection/determination involves the same techniques as those used in soil.

Sewage sludge is Soxhlet extracted with toluene. The extract is evaporated and then, liquid-liquid partitioned between cyclohexane, dichloromethane and H_2O . The cyclohexane extract is purified on a silica column. Separation of neutral and polar PAHs is performed by HPLC-UV with individual separation/determination by GC-FID.

Polychlorinated dibenzo-dioxins and polychlorinated dibenzo-furans As could be seen in the previous section, the extraction of PCDDs and PCDFs is usually performed in a single step. The special character-

istics of these compounds makes it mandatory to study them apart from the rest of the chlorinated pollutants. Despite the existence of papers on determination of dioxins and furans from solid matrices such as soil or sediment, the main source of emission in the literature is combustion processes. Here, the most important solid matrix is fly ash from incinerators. However, the procedure followed for fly ash could be applied to other matrices with minor changes of the sample preparation step. Fly ash samples are collected at the bottom of the electrostatic precipitators of the incinerator (this is why they are considered as solid pollutants; however, when ashes are in the atmosphere they are considered as air pollutants). The fly ash is treated with 1 N HCl, filtered, washed with H_2O and air-dried at room temperature. After addition of ^{13}C -labelled PCDD and PCDF internal standards, the sample is Soxhlet-extracted with toluene (benzene and hexane/acetone have also been used) and the extract is concentrated, then subjected to clean up involving partitioning with concentrated H_2SO_4 and sequential LC on multi-layered silica gel (containing acid-modified, base-modified, AgNO_3 -modified and neutral forms of silica gel), acid alumina and Celite/Carbopack stationary phases as described in US EPA Method 8280A. A portion of the resulting solution is analysed by high resolution GC-EIMS-SIM.

Polychlorinated biphenyls and other chlorinated compounds The large number of chlorinated pollutants in solid samples present in the environment makes their classification and study very difficult. However, it has been clearly demonstrated that there are three groups (PCBs, OCPs and polychlorinated phenols), which are the subject of most of the papers found in the literature. Despite that the following paragraphs are devoted to these groups of organic pollutants, the procedures described are also applicable to the rest of the chlorinated compounds (particularly with regard to Soxhlet extraction).

The first step of the analysis of chlorinated phenolic compounds in polluted soils is wetting of the sample with H_2SO_4 , followed by Soxhlet extraction with hexane/acetone or diethyl ether/petroleum ether. Different techniques can be used for subsequent treatment of the extract, the most representative being acetylation and LLE. After evaporation, the acetates are cleaned up on a deactivated silica gel column and subjected to GC (with ECD or MS detection). The chlorophenols are also individually separated/determined by LC-atmospheric-pressure-CIMS.

PCBs are among the most studied pollutants in solid samples in recent years. Their properties (resistance to oxidation, acids, bases, and other chemicals,

high thermal stability, dielectric behaviour, etc.) make them the most frequently used organic compounds and, consequently, the greatest environmental pollutant.

As the overall procedures followed for the determination of PCBs and OCPs are similar, both groups are usually determined together. Solid sample preparation is similar to that shown for the determination of pollutants from solid samples (see PAHs from soils). Soxhlet extraction is performed with either a single solvent (toluene or dichloromethane) or a mixture of solvents such as, hexane/acetone, pentane/dichloromethane, etc. Clean up usually involves sulfur removal by reaction with Cu or tetrabutylammonium sulfite and the use of silica gel, Florisil and fractionation by SEC if required. The most usual way for individual separation/determination of PCBs and OCPs is GC-ECD.

Other pollutants in solid samples There are some other pollutants that are frequently determined in solid samples. These compounds (in general, the same as those covered in Organic Pollutants in Air) are usually in trace amounts in the environment. Thus, organic pollutants such as aliphatic hydrocarbons, aldehydes, non-chlorinated phenols, cresols, anilines and benzidines, VOCs (mainly organic solvents), phthalates, amines, non-chlorinated pesticides, etc., are also determined due to their importance in the environment. Soxhlet extraction has shown its suitability as a technique for separation of these pollutants from solid environmental matrices.

Organic Pollutants in Water

Water is the most important liquid in the environment. A wide range of human activities, such as mining, coal and fuel combustion, industrial and agricultural processes, domestic sewage, etc, contribute to the pollution of the aquatic environment. However, the key contribution to water pollution is the solubilization of pollutants. Thus, the study of pollutants in water can be divided into pollutants that are solubilized in water (mainly inorganic pollutants) and those present as the solid phases of the aquatic medium, such as sludge, sediment, particulates and biological species (organic and inorganic pollutants).

The way in which sludge and sediment are Soxhlet extracted in order to isolate the analytes from the solid matrix has been discussed in previous sections. This section is therefore devoted to the analysis of organic pollutants (mainly PCBs and pesticides) from water and associated particulates. In spite of the fact that biological samples are also a part of the environment, they are considered to be a matter concerning

biochemistry and toxicology and, therefore, beyond the scope of this article.

It is obvious that Soxhlet extraction is not a suitable method for direct separation of analytes from liquid sample, but that it must be used after a previous filtration step. This procedure is very similar to that followed for air samples. The two phases existing in water within suspension matter samples (liquid and particulate) are split by filters (paper, glass-fibre or quartz-fibre) and solid sorbents (PUFs, granular activated carbon, Aquapak 440A, Separon SE, ODS gel and Amberlite XAD-2, -4 or -7 resins). The solid sorbents and the particulate matter constitute the solid sample to be subsequently extracted by Soxhlet. Collection of the solid matter by centrifugation is an alternative to filtration. Some of the procedures found in the literature are discussed below.

PCBs and OCPs are Soxhlet extracted from solid particulate matter with dichloromethane. After silica gel or Florisil clean up in the presence of activated Cu, analyses are developed by GC-ECD (or GC-MS). The determination of organophosphorus and organonitrogen pesticides in solid particulate matter from surface water is developed by dichloromethane Soxhlet extraction and GC-NPD. The determination of PAHs from water samples requires hexane/acetone Soxhlet extraction, cleanup on both an $\text{Al}_2\text{O}_3\text{-Na}_2\text{SO}_3$ column and silica column, and finally, individual separation by HPLC and fluorimetric detection.

Many aquatic organisms accumulate pollutants inside their tissues by bioaccumulation. This behaviour is used in pollution surveillance programmes, due to the following advantages it provides: (1) the analyses of soil, air, water, etc. yield levels of pollutants present at the time the samples were taken, whereas those observed in bioaccumulator species reflect the level over a period of time; and (2) pollutants concentrate in biological species at high levels, and can therefore be monitored by analytical techniques with relatively high detection limits.

The most relevant field in which biological samples are used is in the analysis of the aquatic environment. Fish, mussels and a number of other species are studied in order to evaluate pollution levels in the surrounding environment. The pollutants studied are the same as in previous sections, and Soxhlet extraction has great relevance as a pretreatment technique due to the solid character of the matrix. In spite of this, one of the most relevant drawbacks in Soxhlet extraction of these samples is their high water content (the presence of water in samples subjected to Soxhlet extraction constitutes a shortcoming whose importance is a function of the amount of water). Thus, it is necessary to macerate the sample initially with anhydrous Na_2SO_4 . After this, a conventional Soxhlet

extraction of the mixture with an organic solvent (depending on the nature of the analytes) is performed.

Use of Conventional Soxhlet Extraction for the Leaching of Inorganic Pollutants

The application of conventional Soxhlet extraction in the field of inorganic pollutants has been developed to a much less extent than that of organic pollutants. There are in the literature only a few applications of Soxhlet extraction to inorganic compounds. Soxhlet extraction is used mainly as a clean up step prior to the determination of inorganic pollutants with the aim of removing organic substances in the extract. As an exception to this, metals have been determined in the extract after a Soxhlet step. This is possible either when metals are forming organometal compounds or are concentrated by sorption on PUFs impregnated with an organic substance. However, the suitability of Soxhlet extraction for the isolation of inorganic pollutants is poor and some other techniques such as hydrolysis, digestion, distillation, etc. are recommended for this purpose.

Improvements in Soxhlet Extraction

Soxhlet extraction has been the most frequently used technique for isolation of organic pollutants from environmental samples for the last twenty years. However, the use of new extraction techniques that overcome the drawbacks associated with Soxhlet is, today, one of the most promising research lines in the field of solid sample treatment.

The most significant drawbacks of Soxhlet extraction are the long time required for the extraction and the large amount of organic solvent wasted, which is not only expensive to dispose of but which can cause environmental pollution itself. Moreover, the conventional device is not easily automated. There are two different ways in which to circumvent the drawbacks of conventional Soxhlet extraction, namely: (1) the use of one of the new alternatives (such as SFE, MAE, ASE, etc.); and (2) the improvement of conventional Soxhlet. As this article is devoted to Soxhlet extraction, the following sections discuss only the latter way, that is, improving the shortcomings of the conventional device while keeping its positive characteristics.

High-pressure Soxhlet extraction

High pressure in Soxhlet devices is achieved by placing the extractor in a cylindrical stainless-steel

autoclave or by the use of either commercial or laboratory-made supercritical fluid-Soxhlet extractors. Thus, PAHs and PCBs can be removed from environmental samples using HPS with liquid CO₂ in working conditions close to those corresponding to the supercritical state of the extractant. The main drawback of this alternative is the change from supercritical to liquid state of the extractant, which affects Soxhlet performance.

Automated Soxhlet (Soxtec HT and Büchi B811)

Commercial automated Soxhlet devices perform the extraction with similar precision to conventional Soxhlet but with a significant saving of time and extractant. The most relevant characteristic of a Soxtec system is the possibility of developing three different steps, namely, boiling, rinsing and recovery of the solvent, by switching a lever. The B811 extractor is able to perform the same steps as a Soxtec device but it can also work as a conventional Soxhlet. The overall performance of the B811 extractor is computer controlled. The analysis of organic pollutants from soil and sediments is an example of the methods developed for use with this device.

Focused microwave-assisted Soxhlet extraction (Soxwave and FMASE)

The Soxwave is a commercial system with an operational performance similar to that of Soxtec HT. The system performs the same three steps but with two significant differences: (1) a different heating source (microwave instead of electricity) is used; and (2) the sample is also irradiated with microwave energy, making it easier to rupture the analyte–matrix bonds. The main drawback of Soxwave is its dependence on the extractant dielectric constant. Thus, efficient extractions are only obtained with polar solvents (due to the characteristics of microwave irradiation) and, consequently, this device is not as universal as a conventional Soxhlet is. Moreover, the energy the analytes receive is at least as high as that necessary to reach the boiling point of the solvent, which can cause degradation of thermolabile analytes. Some applications of Soxwave have been developed in the environmental field and, due to its suitability for water-based extractions, quantitative extractions have been achieved in the isolation of metals from solid samples such as coal or soils.

FMASE is the last of the improvements carried out on the conventional Soxhlet extractor. In fact, the FMASE device works as a conventional Soxhlet, but the cartridge zone, where the extractant and sample are in contact, is placed in the microwave cavity of a specially designed focused microwave oven.

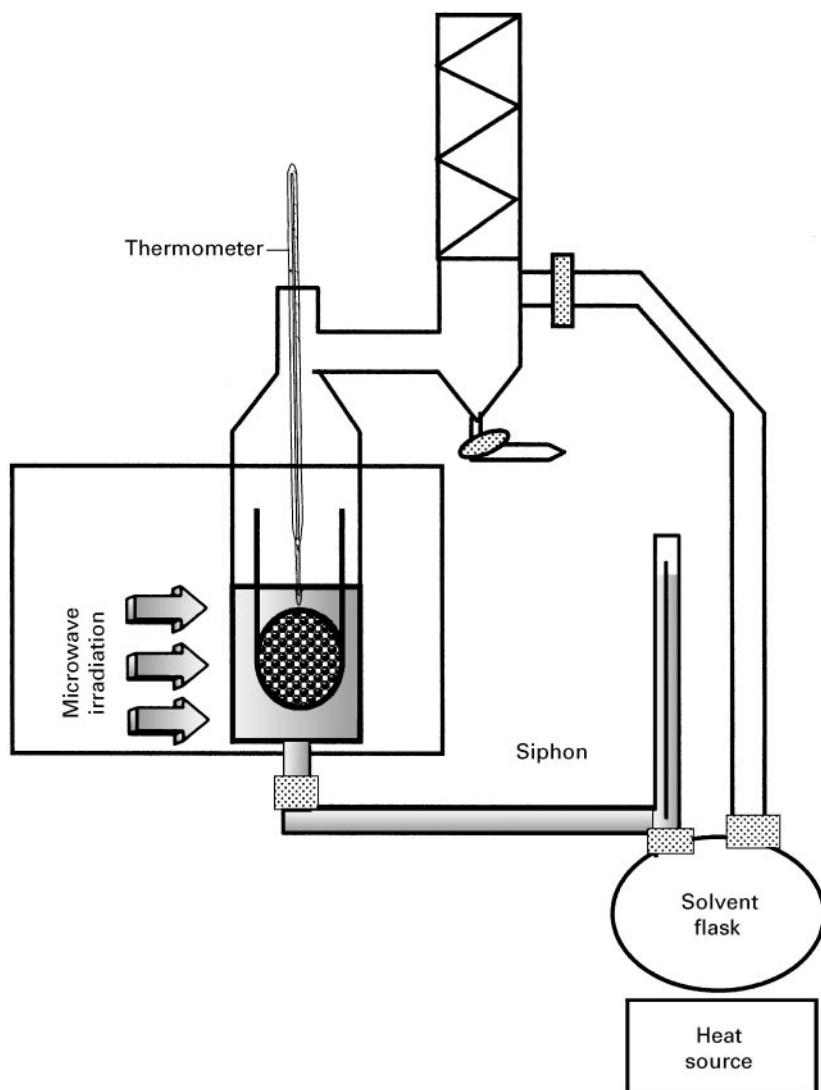

Figure 2 Scheme of the FMASE device. (Reproduced with permission from García-Ayuso LE and Luque de Castro MD (1999) *Analytica Chimica Acta* 382: 309.)

Figure 2 shows a scheme of the FMASE device. The similar performance with respect to its conventional counterpart makes FMASE a suitable alternative for almost all the applications developed in a conventional Soxhlet, that can be developed without changes, except in the time required for quantitative extraction.

FMASE maintains the advantages of conventional Soxhlet extraction while overcoming the limitations, such as the long extraction time, non-quantitative extraction of strongly retained analytes and unsuitability for automation. Solvent distillation in FMASE is achieved by electrical heating, which is independent of the extractant polarity, and recycling saves 75–85% of the total extractant volume. The main drawback in FMASE is the difficulty of using water as

extractant due to its design, as both thermal insulation and shortening of the present distillation device is mandatory for reception of water vapour on the sample-cartridge vessel, condensation there and dropping on the sample. A comparison between conventional Soxhlet and FMASE for leaching of PAHs, herbicides and n-alkanes from soil shows the advantages of the latter when compared with the conventional design. FMASE provides efficiencies similar to those obtained by conventional Soxhlet with extraction times at least eight times shorter.

Supercritical Fluid Extraction

V. Camel, Institut National Agronomique
Paris-Grignon, Paris, France

Copyright © 2000 Academic Press

There has been growing interest in supercritical fluid extraction (SFE) in the past few years due to its numerous advantages over liquid extraction (rapidity, low solvent volumes, nontoxicity of carbon dioxide, great selectivity by modifying the fluid density, low dilution of the extracts, possibility of online coupling with chromatographic techniques and automation).

Analytical applications of SFE began in the late 1980s, with particular focus on environmental samples. While early reports were on spiked matrices and/or highly contaminated samples, recent applications deal with samples containing low levels of incurred contaminants. It was soon found that extraction conditions are strongly dependent on both the solutes and the matrix, so that parameters need to be adjusted for every new application.

This article will focus on the main pollutants extracted, showing the important parameters that influence extraction recoveries, and illustrating the great potential of this technique together with its limitations.

Sample Preparation Prior to Extraction

To ensure better desorption of analytes from the matrix, several sample treatments can be performed, either physical (e.g. grinding) or chemical (e.g. addition of derivatization reagents).

Pretreatment of the Sample

This step is of prime importance, as it may greatly enhance the extraction efficiency.

Solids The moderate water solubility in supercritical CO₂ may lead to restrictor plugging; in addition,

water can be detrimental to the extraction of nonpolar compounds. Consequently, matrices with a high water content (typically 75%) require the addition of a drying agent to the sample (e.g. hydromatrix, a pelletized diatomaceous earth, magnesium or sodium sulfate). This also enlarges the surface area of the sample. However, the presence of residual water usually favours the extraction of polar compounds.

Grinding the sample should also enhance the extraction but, excessive grinding may lead to a pressure drop within the extraction cell, thereby decreasing the solubility of the analyte at the bottom of the cell. The pressure drop problem may be overcome by mixing the finely ground sample with a coarse dispersing agent.

Finally, the presence of sulfur in some matrices (e.g. sediments or sewage sludges) can cause lack of reproducibility and restrictor blockages. To overcome these problems, it is suggested to mix the sample with copper prior to extraction to act as sulfur scavenger.

Liquids A few studies have been performed on the direct SFE of aqueous matrices using a special extraction vessel. However, such analytes are mainly pre-concentrated on to a solid-phase extraction (SPE) disk or cartridge, before being eluted with the supercritical fluid. This SPE-SFE combination offers a greater selectivity compared to elution with an organic solvent (e.g. CO₂ at low density selectively extracts organochlorine pesticides from C₁₈ disks, while extraction at a higher density in the presence of methanol is required to elute organophosphorus pesticides).

Derivatization Reactions

Extraction of highly polar compounds may be improved by coupling derivatization reactions with SFE, to convert polar functions into less polar groups for better solubility in the fluid. This procedure affords extracted compounds that are readily amenable to

gas chromatography. Besides, the derivatizing agent may react with active sites of the matrix, leading to better desorption of solutes.

The three main reactions are alkylation (with acidic methanol, alkyl halides, tetraalkylammonium salts or Grignard reagents), acylation (mostly with acetic anhydride, in the presence of organic bases such as pyridine) and silylation (with hexamethyldisilazane and trimethylchlorosilane). As the latter requires relatively anhydrous conditions, matrices with moisture contents greater than 0.4% may reduce derivatization efficiency.

Derivatization may be performed prior to extraction or under supercritical fluid conditions (*in situ* derivatization). The latter approach is most common as it reduces sample handling. Pre-extraction derivatization is used for particular applications (e.g. alkylation with Grignard reagents due to their low solubility in CO₂). As complex environmental matrices contain many potential interferences that can be derivatized, excess quantities of reagent should be used.

Ion Pairing

SFE of ionic compounds may be possible by formation of an ion pair, which is soluble in the fluid. The ion-pairing reagent may also react with the matrix active sites, thus favouring the desorption of solute molecules.

Common Pollutants Extracted by SFE

SFE has been successfully applied to the determination of several pollutants from different matrices. The strong solute-matrix interactions usually impose proper modifier selection and elevated temperature. Typical extraction conditions for the main pollutants are given in Table 1.

Polynuclear Aromatic Hydrocarbons

Polynuclear aromatic hydrocarbons (PAHs) have commonly been extracted from environmental matrices, and SFE has recently been adopted as an official method (US Environmental Protection Agency method 3561).

These analytes are relatively nonpolar and should be extracted with neat CO₂. However, the delocalized π -electron system of PAHs can cause strong interactions with the active sites of the matrix surface, hindering their extraction. Extraction of high molecular weight PAHs from real samples therefore requires high pressure and temperature, as illustrated in Figure 1 for urban dust particulates. Elevated temperature are suspected to favour analyte desorption from the active sites of the matrix.

PAH solubility in supercritical CO₂ decreases with increasing number of fused aromatic rings, so addition of a modifier is recommended to achieve acceptable recoveries. Methanol is the most common modifier, but satisfactory results can be obtained with other modifiers. For example, toluene-modified CO₂ is efficient in extracting two to six fused aromatic ring PAHs from soil with high carbon content (50%); addition of toluene to the sample also improves the extraction of nitro-PAHs from diesel and air particulates. A combination of toluene, trifluoroacetic acid and triethylamine is an even better modifier for PAHs and nitro-PAHs; the additives are thought to block the matrix active sites, thus preventing possible re-adsorption of solute molecules. Extraction of PAHs from air particulate matter is also improved in the presence of diethylamine or acetonitrile, as illustrated in Figure 2.

The efficacy of the modifier is highly dependent on matrix characteristics. For example, the addition of methylene chloride as a static modifier allowed the quantitative extraction of PAHs from soil with CO₂; this modifier solubilizes the soil aggregates, thus increasing the contact between soil particles and supercritical CO₂.

The effect of increasing the temperature is always advantageous at constant density. Modifier and temperature effects are additive, so that extraction using CO₂ with modifiers at high temperature is usually the most rigorous SFE method for the extraction of particularly difficult samples such as urban air particulates, as shown in Figure 3.

Another approach has been the use of *in situ* chemical derivatization to determine PAHs from a harbour sediment. The derivatizing agent (Tri-Sil, a 2:1 (v/v) mixture of hexamethyldisilazane and trimethylchlorosilane) was added to the extraction vessel prior to the extraction step. As shown in Figure 4, results were improved compared with extraction with CO₂ or 10% methanol-modified CO₂. As PAHs cannot be derivatized, the effect of the reagent was to help displacement of the analytes from the matrix.

Although nitrous oxide modified with 5% methanol may be considered to be the most efficient fluid for extracting PAHs, its use should be avoided due to the possibility of explosion with this combination. Difluorochloromethane is also efficient but environmental concern discourages its common use. Subcritical water (250°C, 50 bar) seems a more viable alternative to CO₂ for the SFE of organic compounds with a wide range of polarities. The dielectric constant of water decreases as the temperature increases so that at moderate temperatures (50–100°C) polar compounds are extracted (e.g. phenols, amines), while nonpolar to moderately polar organics (including

Table 1 Typical applications of SFE to solid environmental matrices

Compounds		Matrices	Reagent added to the matrix	Fluid	Observations
Polyaromatic hydrocarbons		Soils, sediments, urban dust, fly ash	None	CO ₂ -CH ₃ OH (10%) CO ₂ -toluene (10%) CO ₂ -diethylamine (10%) Subcritical H ₂ O	Strong interactions with the matrix High temperatures recommended, as well as with addition of modifier Solubilization of soil aggregates by CH ₂ Cl ₂ Tri-Sil displaces the solutes from the matrix
			CH ₂ Cl ₂	CO ₂	
			Tri-Sil	CO ₂	
Polychlorinated biphenyls		Soils, sediments, sewage sludge	None	CO ₂ CO ₂ -CH ₃ OH (1-2%) CO ₂ -diethylamine Subcritical H ₂ O	Moderate temperatures (70-100°C)
Dioxins		Fly ash, sediments	None	CO ₂ -CH ₃ OH (2%)	Strong interactions with the matrix Better recoveries with a dry matrix Destruction of the matrix by the acid
			Strong acid	CO ₂	
Phenols		Soils, house dust	None	CO ₂ -CH ₃ OH (2-20%) CO ₂ -CH ₃ OH (32%)-H ₂ O (8%)	High temperatures recommended <i>In situ</i> acetylation of phenols
			Acetic anhydride and pyridine	CO ₂	
Pesticides	Organochlorine	Soils, sediments	None	CO ₂ -toluene	Toluene disrupts solute-matrix interactions
	Organophosphorus		None	CO ₂ -CH ₃ OH (5%) CO ₂ -CH ₃ OH (10-30%) CO ₂ -[CH ₃ OH + 2%H ₂ O] (10%)	Matrix moisture enhances the extraction
	Triazines		None	CO ₂ -CH ₃ OH (20%)	
Surfactants	Nonionic	Soils, sediments, sewage sludges	None	CO ₂	Ion pairing and methylation Methylation
			BF ₃ /CH ₃ OH	CO ₂	
	Anionic		H ₂ O	CO ₂ -CH ₃ OH (27.5%) CO ₂	
			None	CO ₂ -CH ₃ OH (40%)	
Metallic species	Cationic	Sediments	TAA salts	CO ₂	Ion pairing Methylation
			Methylation reagent	CO ₂	
	Organometallics		None	CO ₂ -CH ₃ OH (30%) CO ₂ -CH ₃ OH (10-20%)	
			Organic ligand ^a Derivatization reagent ^b	CO ₂ -CH ₃ OH (5%)	
	Metal ions	Sediments	Organic ligand ^c	CO ₂ -CH ₃ OH (5%)	Formation of a metal chelate Methanol increases the chelate solubility

TMPA, trimethylphenylammonium hydroxide; TAA, tetraalkylammonium.

^aOrganic ligands: dithiocarbamates (mainly sodium diethyldithiocarbamate and diethylammonium diethyldithiocarbamate).

PAHs) are extracted at higher temperatures (200–250°C), as illustrated in Figure 5.

PAHs have also been determined in water samples after their preconcentration on to C₁₈ disks and their further elution with supercritical CO₂.

Polychlorinated Biphenyls

Polychlorinated biphenyls (PCBs) are lipophilic and thereby highly soluble in CO₂. Hence, CO₂ alone or modified with a small amount of methanol (typically 1–2%) is efficient for their extraction. Figure 6 illustrates the effects of both pressure and temperature on the recovery of PCBs from river sediment using neat CO₂. Best recoveries are obtained at high temperature, whatever the pressure. Surprisingly, high molecular weight PCBs are more efficiently extracted, despite their expected reduced solubilities; in fact, this is in agreement with the tighter binding of low molecular weight PCBs to the sediment matrix.

Recovery rates may be improved by addition of modifiers, especially methanol, as illustrated in Figure 7. Thus, methanol-modified CO₂ allowed the SFE of PCBs and organochlorine pesticides at the part-per-trillion level in marine sediments. Water under subcritical conditions is also an effective extractant for PCBs.

Recently, a single SFE method for field extraction of PCBs and PAHs in soils has been developed with neat CO₂ (150°C, 400 bar) to avoid co-extraction of matrix material, allowing direct gas chromatography. The simultaneous extraction and clean-up of mussel samples can be achieved by adding Florisil on top of the sample, enabling the direct determination of 11 PCBs (as well as 15 organochlorine pesticides).

Dioxins

Dioxins (polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzofurans (PCDFs)) are of great environmental concern owing to their acute toxicity. Like PCBs, they are readily amenable to extraction by SFE. As these pollutants have been mainly detected in emissions from municipal incinerators, their extraction from fly ash matrices has been investigated. SFE gave satisfactory results, as compared to Soxhlet extraction. Despite the high solubility of these compounds in pure CO₂, it gave almost no extraction due to the strong matrix adsorption of the dioxins. Upon addition of 2% methanol to the CO₂, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin was efficiently extracted from a dry sediment; the presence of water in the matrix hindered its extraction. The suitability of nitrous oxide for the SFE of PCDDs and PCDFs

has also been described. Alternatively, the matrix may be destroyed by exposure to a strong acid, and further extracted with neat CO₂.

Phenols

Phenols are moderate to highly polar compounds. Thus, several approaches have been used for their SFE: direct addition of a polar modifier (e.g. water, acetonitrile, methanol) to the matrix, dynamic addition of the modifier to the CO₂, or *in situ* acetylation.

For example, addition of 2% methanol improved their extraction from soil. Enhanced-fluidity liquid extraction (CO₂ with 20% methanol) improved the recovery of phenols from house dust. Further improvements could be achieved using a methanol-water-CO₂ mixture (32.1/7.9/60 mol %), as water is supposed to swell the matrix material, allowing more efficient penetration and interruption of matrix-analyte interactions. Similar results have been obtained with sediments.

As illustrated in Figure 8, phenols are efficiently acetylated during SFE by means of direct reaction with acetic anhydride. Even though recoveries of phenols decrease as the activated charcoal content of

the soil increases due to stronger solute-matrix interactions, improvement upon derivatization is evident. In addition, extracts are cleaner because of milder extraction conditions.

Similarly, the SFE of pentachlorophenol and related compounds from soil samples can be achieved using *in situ* acetylation (with acetic anhydride and triethylamine at 80°C) followed by CO₂ extraction. Increasing the extraction temperature from 50 to 200°C resulted in higher recoveries of chlorophenols from an industrial soil.

Pesticides

Pesticides have a broad range of physical properties and chemical structures. Their solubility in pure CO₂ may be evaluated from their octanol-water partition coefficients. Organochlorine pesticides are highly soluble in pure CO₂, while organophosphorous compounds require a modifier; addition of a polar modifier becomes crucial for triazines. In the case of phenoxyacetic acids, an ion-pairing or derivatization reagent needs to be added.

Another useful parameter is the soil-water partition coefficient, as it is indicative of the pesticide's soil adsorption; recoveries have been shown to decrease

Figure 8 Recoveries of phenolic compounds from three garden soils with 2, 5 and 10% activated charcoal content, using SFE alone^a or SFE-derivatization^b. ^aCO₂, 90°C, 382 bar, 0.77 g mL⁻¹, addition of 100 μL methanol to the sample, 10 min static/15 min dynamic. ^bCO₂, 115°C, 0.4 g mL⁻¹, addition of 20 μL pyridine and 115 μL acetic anhydride to the sample, 5 min static/15 min dynamic. (From Llompart MP, Lorenzo RA, Cela R, Li K, Belanger JMR and Pare JRJ (1997) Evaluation of supercritical fluid extraction, microwave-assisted extraction and sonication in the determination of some phenolic compounds from various soil matrices. *Journal of Chromatography A* 774:243–251. With permission from Elsevier Science.)

as the soil organic content is increased, due to strong analyte–matrix interactions.

Nonpolar pesticides Despite their high solubility in CO_2 , the solute–matrix interactions may yield lower recoveries than expected from solubility alone. Thus, extractions of organochlorine pesticides from spiked soils were unsatisfactory, especially for soils with a high organic content. Modifiers have been tested to enhance the SFE of organochlorine pesticides from different matrices. For example, toluene added to a contaminated soil improved the extraction with CO_2 of hexachlorocyclohexane isomers.

Several organochlorine pesticides were also efficiently extracted from aqueous matrices using a combination of SPE (on to C_{18} disks and cartridges) and pure CO_2 SFE.

Moderately polar and polar pesticides Methanol-modified (5%) CO_2 is a common extractant for organophosphorus pesticides. The polar triazine herbicides require a higher percentage of methanol (10%) in CO_2 to increase their solubility and disrupt solute–matrix interactions. Methanol (10%) containing 2% water may also be used. The ternary mixture acetone–water–triethylamine (90/10/1.5 v/v/v) is also efficient. Water is suspected of increasing the surface area of clay containing soils by swelling. Thus, a direct correlation between diuron extraction from montmorillonite clay and the percentage swelling of the matrix (due to the modifier) was observed at different pressures and temperatures. In contrast, triethylamine should compete with solute molecules on to the active sites of the soil. Also, soil moisture has been reported to enhance triazine extraction, as well as addition of a surfactant (Triton X-100), which probably leads to the matrix swelling and the formation of nonionic reverse micelles.

Extraction of bound pesticide residues in soils may require more severe conditions (for example, extraction of triazine from a mineral soil entailed 30% methanol, 350 bar and 125°C).

Ionic pesticides Specific SFE conditions are required to improve their solubility and/or to overcome strong solute–matrix interactions. Addition of 20% methanol to CO_2 allowed the extraction of four herbicides (dicamba, 2,4-dichlorophenoxyacetic acid (2,4-D), 2-(2,4,5-trichlorophenoxy)propionic acid (2,4,5-TP) and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T)) from house dust (440 bar and 100 or 150°C). Pre-extraction of extraneous matrix material was achieved with CO_2 after hexane was added to the sample. The mixture acetone–water–triethylamine (90/10/1.5 v/v/v) also enhanced extraction of 2,4-D from soil.

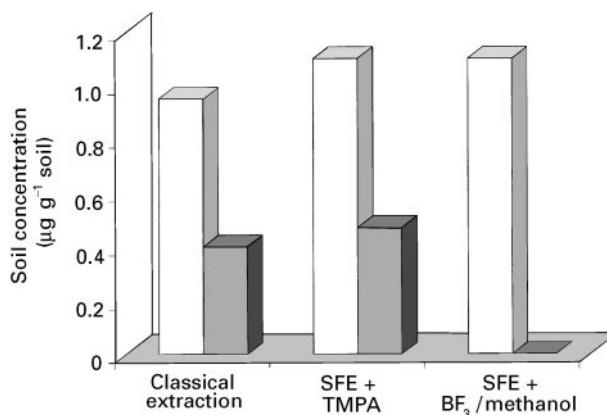

Figure 9 Extraction of native pesticides from an agricultural soil using either classical extraction (two sequential extractions with 0.5 mol L^{-1} KOH in 10% KCl/water) or SFE (with TMPA (three sequential extractions (each 15 min static/15 min dynamic), CO_2 , 400 bar, 80°C) or BF_3 -methanol (a single extraction (15 min static/15 min dynamic), CO_2 , 400 bar, 80°C) as derivatization reagents). Open bars, 2,4-D; filled bars, dicamba. (Reproduced with permission from Hawthorne *et al.*, 1992. Copyright 1992 American Chemical Society.)

The ion-pairing methylating reagent TMPA facilitated the CO_2 extraction of 2,4-D and dicamba from sediments. The presence of methyl iodide improved the recoveries of 2,4-D and 2,4,5-T from soil. Alkylation with methanol and BF_3 as a catalyst is also promising for the preferential extraction of 2,4-D over dicamba, as illustrated in Figure 9.

Surfactants

Nonionic surfactants (e.g. alkylphenoethoxylates) have been extracted from sediments with 27.5% methanol-modified CO_2 (450 bar and 100°C). Water-modified CO_2 (350 bar and 80°C) was also efficient in extracting nonylphenol polyethoxylates from dried sewage sludge, yielding recoveries higher than traditional techniques.

Quantitative extraction of anionic surfactants (linear alkylbenzenesulfonates) from soil, sediment and sludge can be obtained using 40% methanol-modified CO_2 (380 bar and 125°C). Also, TAA salts have been used as ion-pairing reagents to extract linear alkylbenzenesulfonates and linear alkylsulfonates from sewage sludge. Finally, derivatization of anionic surfactants into their methyl esters may also be performed to enhance their extraction.

The ditallowdimethylammonium cation was extracted from anaerobically stabilized sewage sludge and marine sediment using 30% methanol-modified CO_2 (380 bar, 100°C). No improvement could be obtained in the presence of ion pair reagents. Due to the ionic character of this surfactant, it was assumed that high concentrations of anionic surfactants ini-

tially present in the matrix allowed the formation of ion pairs with the cationic surfactant, thereby enabling its extraction.

Surfactants (e.g. alcohol phenol ethoxylate) were also extracted from aqueous samples with either direct SFE (by means of a modified extraction cell) or SPE-SFE. In the latter case, methanol-modified CO₂ was required for efficient elution from the C₁₈ discs.

Metallic Compounds

Metals exist in the environment as organometallic compounds, ionic species or inorganic compounds. Organometallic compounds are usually soluble in supercritical fluids and may be extracted directly. On the other hand, ionic species require the addition of a ligand to be extracted. Consequently, speciation can be achieved by SFE using sequential extractions (with proper selection of ligands). As an example, methylmercuric chloride and dimethylmercury could be extracted with neat CO₂ and 100 bar (50°C) from solid materials; a dithiocarbamate reagent was further introduced into the matrix to extract Hg²⁺ ions.

Organometallic compounds Several studies have investigated the use of SFE for extracting organometallic compounds from environmental samples. Thus, tributyltin has been successfully extracted from sediments using methanol (20% v/v)-modified supercritical CO₂. Methanol as a modifier provided the most favourable recovery of trimethyllead, triethyllead and diethyllead from sediment and urban dust, as compared to water and acetone (446 bar and 80°C, 10% modifier).

Other approaches have been tested: binding to an organic ligand, formation of an ion pair and *in situ* derivatization. Thus, with the addition of diethylammonium diethyldithiocarbamate as a ligand, di-, tri- and tetra-substituted organotin species could be extracted from soils and sediments using 5% methanol-modified CO₂ (while recoveries of monoalkyltins remained low). Monobutyltin was efficiently extracted from a reference sediment on addition of sodium diethyldithiocarbamate in the extraction vessel (Figure 10); increased extraction efficiencies of trimethyllead, trimethyltin, dibutyltin and tributyltin were also observed in this way.

Hexylmagnesium bromide as a derivatizing agent assisted the CO₂ extraction of monophenyltin, diphenyltin and triphenyltin from sediment. Dimethylarsenic acid and monomethylarsenic acid could be extracted from a solid sample by supercritical CO₂ after *in situ* derivatization with thioglycolic acid methyl ester.

Figure 10 Comparison of extraction efficiencies of organotin compounds from a reference sediment (PACS-1) using SFE with or without the addition of sodium diethyldithiocarbamate (NaDCC). Open bars, certified value; grey bars, no NaDCC; black bars, with NaDCC. (Reproduced with permission from Chau *et al.*, 1995, and with permission from Elsevier Science.)

Organotins in aqueous matrices were ethylated with sodium tetraethylborate, enriched on C₁₈ disks and further extracted with acid-modified supercritical CO₂. Alternatively, aqueous matrices containing butyl-, phenyl- and cyclohexyltin compounds were collected on a C₁₈ disk, before being derivatized via Grignard ethylation and extracted using supercritical CO₂.

Metal ions Extraction of free metal ions by supercritical CO₂ requires charge neutralization. This can be achieved by binding the metal ion to organic ligands, thereby resulting in neutral stable complexes that are soluble in CO₂. Obviously, rapid complexation kinetics and a high stability constant for the neutral complex will enhance the extraction process. A key factor is the solubility of the complex in the supercritical fluid.

Different organic ligands (dithiocarbamates, β -diketones, crown ethers and organophosphorus reagents) have been tested for their ability to extract heavy metals, lanthanides and actinides from several matrices. In particular, fluorinated ligands yield metal complexes with higher solubility in supercritical CO₂, making them more effective for the extraction of metal ions. In addition, alkyl substitutions in ligands may enhance the solubility of metal complexes in CO₂. As an example, diethyldithiocarbamates and fluorinated β -diketones are effective chelating agents for extracting transition metal ions from solid matrices, as shown in Figure 11 for Cd²⁺. Recoveries are improved with methanol (5%)-modified CO₂, as the solubility of the metal chelate is enhanced. As dithiocarbamates tend to decompose in supercritical

Figure 11 Recoveries of Cd²⁺ from spiked sand samples using SFE with dithiocarbamates or β -diketones as chelating agents. Open bars, CO₂; filled bars, 5% methanol-modified CO₂; 45°C, 250 bar; 15 min static/15 min dynamic. LiFDDC; bis(trifluoroethyl)dithiocarbamate; Et₂NH₂DDC; diethylammonium diethyldithiocarbamate; NaDDC; sodium diethyldithiocarbamate; APDC, ammonium pyrrolidinedithiocarbamate; TFA, trifluoroacetylacetone; TTA, thenoyltrifluoroacetone; HFA, hexafluoroacetylacetone. (Reproduced with permission from Wai *et al.*, 1996, and with permission from Elsevier Science.)

CO₂ in the presence of water, an excess of reagent is recommended to achieve good metal extraction efficiencies.

Addition of a proton-ionizable crown ether (*tert*-butyl-substituted dibenzobistriazolocrown ether) in methanol (5%)-modified CO₂ allowed the selective extraction of Hg²⁺ from sand if a small amount of water was present in the matrix (200 bar and 60°C). Other divalent metal ions (Cd²⁺, Pb²⁺, Co²⁺, Mn²⁺, Ni²⁺) remained in the sand under these conditions.

Very recently, fluorinated hydroxamic acids have been used for the SFE of Fe(III) with unmodified CO₂. Toxic metals (As, Cd, Cr, Cu, Pb) have been extracted from real contaminated soil and wood samples using the Cyanex reagent (*bis*(2,4,4-trimethylpentyl)-monothiophosphinic acid) as an extractant in supercritical CO₂ modified with 5% methanol.

Up to the present, most of the experiments conducted have focused on spiked samples and future studies need to be conducted with real environmental samples. In such samples, the active sites and natural ligands present may bind strongly to certain metal ions, thereby hindering their complexation with added ligands. Native metals can also be in highly insoluble forms (such as oxides and sulfides), leading to a fraction of the metals that may not be extractable by SFE. It seems that SFE may be used to evaluate the amounts of leachable metals in solid matrices.

Metal ions have also been directly extracted from aqueous samples. First, the supercritical CO₂ is passed through a vessel filled with the ligand. Next, the fluid saturated with the ligand passes through the aqueous phase. For example, CO₂ containing thenoyltrifluoroacetone and tributyl phosphate

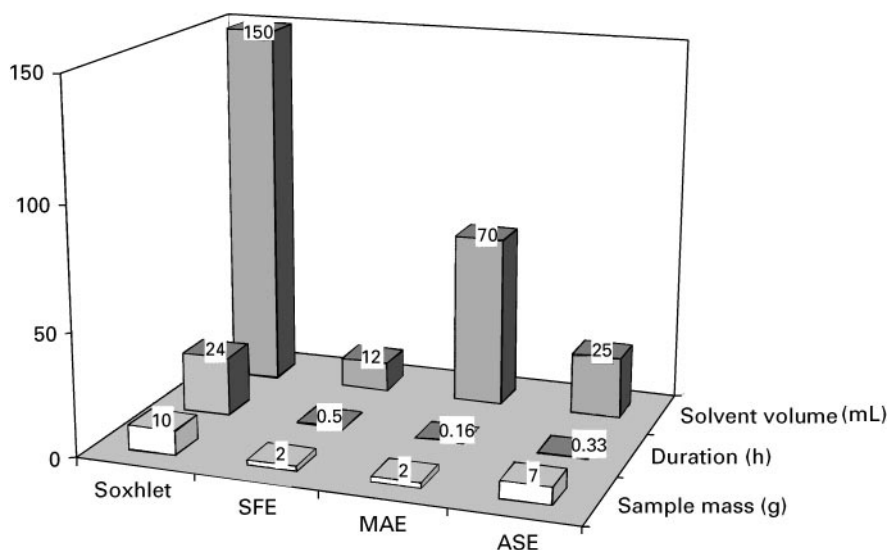

Figure 12 Comparison of extraction techniques for the determination of PAHs from contaminated soil: Soxhlet extraction (10 g sample mixed with 10 g anhydrous sodium sulfate; 150 mL dichloromethane; heating 24 h), SFE (2 g sample; 20% methanol-modified CO₂; 70°C, 250 kg cm⁻², 30 min), atmospheric microwave-assisted extraction (MAE) (2 g sample; 70 mL dichloromethane; heat 297 W; 20 min) and accelerated solvent extraction (ASE) (7 g sample; dichloromethane–acetone 1:1 (v/v); 100°C, 2000 psi; 10 min). (Reproduced with permission from Saim *et al.*, 1997, and with permission of Elsevier Science.)

extracted lanthanides (La^{3+} , Eu^{3+} and Lu^{3+}) from a buffered acetate solution.

Future Trends

Despite rapid growth in the past few years, SFE is still rarely used for routine applications. This is mainly because of the large number of parameters to control, as well as the influence of the matrix. The strong matrix-analyte interactions that may occur in environmental matrices frequently make the development of quantitative extraction conditions based solely on solubility considerations and spike recoveries invalid for real samples. In addition, its development is also limited by the high capital cost required.

Yet SFE has several advantages over other techniques (especially rapidity and low solvent volumes, as shown in **Figure 12**). It is successful in extracting a broad range of pollutants from numerous matrices. In particular, polar compounds and ionic species can be extracted through addition of a polar modifier, a derivatization reagent, an ion-pairing reagent or a ligand. These recent applications will be more thoroughly studied in the next few years, especially the possible speciation, due to selective extraction, of metallic compounds.

Subcritical water appears to be a very promising fluid, as it offers the opportunity to extract polar to nonpolar compounds by simply increasing the temperature. No doubt this fluid will be more common in future SFE applications.

Finally, extraction conditions will be optimized for numerous real environmental samples, including certified reference materials, thereby leading to wider use of this technique.

Separation and Determination in Physiological Samples

The determination of an absolute enzyme concentration in a physiological sample is principally straightforward; the main problem is the need for a purified sample to use as a standard.

Enzymes are proteins found in nature in complex mixtures, usually in cells which perhaps contain several hundreds of different enzymes. In order to understand and interpret enzyme data from complex biological systems in, for instance, a subcellular organelle (such as a mitochondrion), a cell or whole organism, we must try to understand its properties in as simple a system as possible. From studies of an isolated enzyme we can learn about its specificity for certain substrates, the kinetic parameters for the reaction and the possible means of regulation. All these parameters are useful for understanding the role of the enzyme in more complex systems. The ready availability of isolated enzymes has been of considerable value in a number of medical and industrial applications.

To study a given enzyme properly in physiological samples it must be purified. Maintenance of biological activity is the goal throughout the whole purification scheme. Extracellular enzymes usually withstand the variety of stresses they are exposed to during the purification. In contrast, when released from their natural protective environment, intracellular enzymes are very sensitive to various steps in the purification scheme. Integral membrane enzymes are especially vulnerable during solubilization.

Specific examples, together with trends in enzyme determination in physiological samples, will be discussed in this article.

Preparation of Enzymes with Biological Activity from Physiological Samples

Enzyme Activity Measurement Process

To elucidate enzymatic activity from physiological samples certain steps have to be performed.

1. Preparation of reaction mixture and enzyme, where the reaction mixture usually consists of a controlled substrate solution with the correct temperature, pH and any cofactors needed for catalysis. Enzymes often demand a more complex preparation methodology than substrates and the reaction mixture. This will be discussed later.
2. Initiation and incubation, which are usually started by adding the proper enzyme preparation to the reaction mixture or vice versa. All subsequent time measurements are related to this initial time.
3. Termination, which can be achieved in various ways. Normally, this means inactivation of the catalytic activity of the enzyme.
4. Separation of the enzyme products from the enzyme and its substrates.
5. Detection and identification of the enzymatically formed product(s) during specific incubation intervals.
6. Under certain conditions enzyme activity can be followed dynamically, i.e. by rate measurement ($\Delta f/\Delta t$, where f is temperature, absorbance, fluorescence, etc., and t is time).
7. Interpretation of the produced data.

Handling of Specimens and Samples (the Preanalytical Phase)

For all biological material (tissue, urine, cerebrospinal fluid, cell cultures, etc.) the same basic sequence of procedures applies.

1. Preparation of subject to be investigated.
2. Collection of specimen.
3. Separation of sample from specimen.
4. Transport of specimen and/or sample.
5. Storage of specimen and/or sample.
6. Pretreatment of samples for enzymatic analysis.

The specimen is defined as that part of the subject which is taken as representative for the analysis. The sample is the material that is actually analysed. The sample can be derived from, prepared from or be a part of the specimen which is homogenized for measurement of enzyme activities. Consequently the aliquot of homogenate that is analysed is the sample. Only under certain conditions is the sample identical to the specimen.

Sample Preparation Strategy

Two factors should be considered during preparation of enzymes with biological activity from physiological samples. The first factor for consideration is the selection of the biological sample that is to be used as the starting material for the purification. The samples can be subdivided into three groups, depending on their complexity (see Figure 1).

The first group (I) includes samples containing different cell types and extracellular compartments, e.g. samples containing organs, tissue, biological fluids, microbial cells, and unicellular organisms from a culture medium or fermentation broth. Initially cellular compartments have to be separated from noncellular compartments. The second group (II) consists of

different cell types within the cellular compartments being separated from each other. Group II samples are thus homogeneous populations of each type of cell. This becomes the starting material for samples where cell-surface activities can be directly assayed or the cells can be lysed (broken up), thus providing access to the activities in intracellular organelles and on cytoplasmic fragments.

The third group (III) consists of subcellular fragments liberated by lysis of group II samples. These fragments include organelles such as mitochondria as well as those operationally defined as the membrane fraction or a fraction containing soluble components. The initial steps within this group will be separation of different organelles and separation of soluble from insoluble material. This is followed by solubilization

Figure 1 Enzyme purification scheme. Samples can be divided into three groups, I, II and III, depending on their complexity. Samples in the different groups enter and leave the purification process at different points. The samples in group I are the most complex, consisting of both extracellular and cellular enzyme-containing material which must first be separated. Group II samples contain different types of cells, one of which contains the enzyme of interest. In group III the enzyme source is from only one type of cell, from which the 'right' subcellular fraction gives the 'right' enzyme. (Adapted from Rossomando, 1987.)

of membrane fractions and finally separation of molecular species from each other.

The second factor for consideration during the preparation of biologically active enzymes concerns to what extent the sample should be purified. The traditional end point of any purification scheme would be a homogeneous protein. The main goal should be to assay a single enzymatic activity without interference from other activities. However, for some studies it is advantageous or even necessary to assay the activity of interest in the presence of other activities.

Sample Obtained from Tissue or Organ

Tissues and organs (e.g. skin, liver) can be divided into at least two compartments, the cellular compartment and the extracellular compartment. The activity of interest could be localized in either of the compartments. Cell-sorting techniques should be used where whole undamaged cells are separated from the stable fibrillar matrix. Some cell damage is unavoidable with the harsh methods often used for disrupting the matrix, e.g. cutting or dicing with scissors, shearing in a blender, or grinding. Specific disruption of the matrix can be performed using purified enzymes, e.g. collagenase for mammalian tissues. Trypsin and other proteolytic enzymes have also been used with success. Such procedures result in a mixture of cells extracellular compartments including some insoluble fragments, and added enzymes (including reagents).

Samples Obtained from Tissue or Organ Culture

Cultured samples are usually treated in the manner described previously. Precautions must be taken to avoid errors due to the additional extracellular compartments and the culture medium, which may contain enzymatic activities originating from the medium itself or produced during sample growth.

Samples Obtained from Biological Fluids

Body fluids such as blood, cerebrospinal fluid and saliva contain cells as a normal component. However, in other fluids cells are a contamination. Cells in urine may indicate a disease process. The study of enzymes in such fluids also requires separation of the two compartments (cells from biological fluid). Because biological fluids do not contain fibrillar matrix material, the separation will, for instance, be a simple centrifugation step (5000 g for 15 min) which will produce a pellet containing most of the cellular material. The supernatant produced by centrifugation can be assayed for enzymatically active proteins.

Samples Obtained from Cell Culture

For cells grown in liquid culture, including mammalian cells, fungi, protozoa and bacteria, noncellular compounds should be separated from the cells before analysis takes place. Even here, a low-speed centrifugation is sufficient for separation of cells from culture media. The supernatant should be assayed for enzymatic activity and the cell-pellet material could be set aside for later assay or lysis.

Enzyme Activity Determination

Extracellular Enzymes

The extracellular fluid around tissues or the growth medium around mammalian cells, bacteria, yeast or fungi cells often contains the enzyme activity of interest. Several factors have to be considered before activity measurements can be started. Proteolytic enzymes must be inhibited early in the determination process, because otherwise they will degrade and destroy the enzymatic activity of interest. Another factor for consideration is the interference of small molecules, which could be erroneously measured as enzyme substrate or product. A special case is inhibitors which diminish enzyme activity. If a serum-free medium is not used during mammalian cell propagation, special care concerning serum enzymatic activity measurements and purification has to be taken.

Within the Cellular Compartment

After sample preparation, cells are separated from noncellular material in different manners depending on the complexity of the original sample (i.e. from which organ the sample originates). Because a number of different types of cells could remain, an assay of any complex sample should begin with the preparation of only one cell type.

Many separation methods utilizing different properties of the cells have been used. In sucrose gradient centrifugation, density differences between cell types are used and each cell type finds its equilibrium position in the sucrose gradient. Field flow fractionation can also be used for separating cells according to their size and shape. Adipose tissue cells will separate without centrifugation; they just float. Antibodies raised against any special marker on the cell surface could be explored for selection of that special cell type with various techniques. For example, using metallic iron coupled to antibodies a strong neodymium permanent magnet could be used for selecting a specific cell type. Selective chemical lysis of cell types that are not of interest followed by mild centrifugation will provide the cells containing the enzyme of interest. Even

homogeneous mammalian cells can differ in enzymatic activity if the age or nutritional status of the animals is not identical.

Intact Cells

When a reaction mixture consists only of one type of cell any assay of enzymes on the cell surface will only be straightforward if the cells are not disrupted during determination, because the presence of intracellular components could give rise to false results. For example, if cell-surface adenosine triphosphatase (ATPase) activity is to be measured it is suitable to monitor the product ADP (adenosine diphosphate). However, if the cells are lysed, intracellular ADP will affect the enzyme activity determination.

Subcellular Samples

Depending on the localization of the enzyme of interest, different strategies for the cell lysis have to be considered. A subcellular fractionation could be quite rewarding later in the enzyme purification route. Methods such as sonication, use of a French press, blending or homogenization are useful for the lysis of different types of cells.

For example, a French press is needed for the lysis of bacterial cells with rigid cell walls. The use of a Potter-Elvehjem homogenizer (PTFE (poly(tetra fluoroethylene)) pestle in a glass mortar) for the homogenization of cells with fragile cell membranes is a procedure that will merely break the outer cell membrane, leaving most of the cell organelles intact.

Table 1 Marker enzymes for different subcellular fractions

Subcellular fraction	Enzyme
Nuclei	DNA nucleotidyltransferase
Nuclei	Nicotinamide-nucleotide adenylyltransferase
Mitochondria	Succinate dehydrogenase
Mitochondria	Cytochrome <i>c</i> oxidase
Endoplasmic reticulum	Glucose-6-phosphatase
Lysosomes	Acid phosphatase
Lysosomes	Ribonuclease
Peroxisomes	Catalase
Peroxisomes	Urate oxidase
Plasma membrane	5'-Nucleotidase
Cytosol	Glucose 6-phosphate dehydrogenase
Cytosol	Lactate dehydrogenase
Cytosol	6-Phosphofructokinase

From Price and Stevens (1989), p. 369.

A subcellular fractionation scheme based on centrifugation for mammalian cells is outlined in **Figure 2**.

The enzymatic activity of interest can be followed, together with the activity of marker enzymes, through the subcellular scheme (**Table 1**). The subcellular localization is then predicted and further purification can be performed.

Enzyme Purification Methods

Maintenance of Biological Activity

Soluble proteins, either cytoplasmic or inside organelles, are present in highly concentrated soups

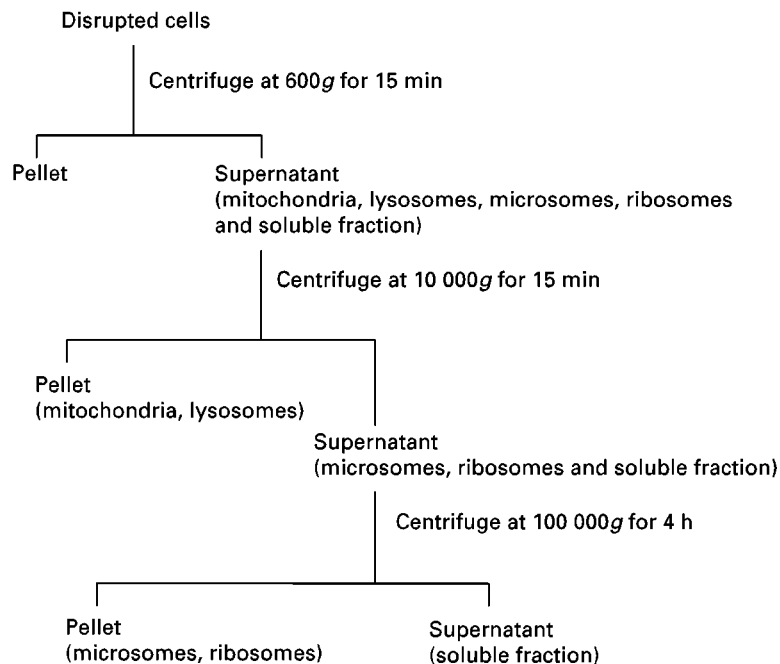

Figure 2 A subcellular fractionation scheme for mammalian cells by differential centrifugation. (From Price and Stevens (1989), p. 368.)

of proteins, with concentrations ranging from 100 mg mL^{-1} to as high as 400 mg mL^{-1} inside the mitochondrial matrix. Oxygen tension is low and different natural reducing compounds such as glutathione are present to maintain a high reducing potential. Other stabilizing agents are also present, such as different substrates and products. When the tissue is disrupted during purification proteins are released from their protective environment and proteolytic enzymes which are held in separate compartments are also released. As a consequence the enzyme of interest has to be protected from oxidation, proteolytic degradation and irreversible unfolding of their tertiary structure. This can be achieved in many different ways and should be tailor-made for each purification scheme and enzyme.

Denaturation during purification can be minimized if precautions are taken according to extremes of pH, temperature and organic solvents. The natural pH inside a cell is normally in the range 6–8. Using buffers within this pH range at appropriate ionic strength should protect against pH denaturation. Reducing the temperature by $15\text{--}25^\circ\text{C}$ decreases many degradation processes three- to five-fold. Reducing the temperature also slows down the processes involved in the separation method, for instance in size exclusion chromatography.

Enzymes in dilute preparations may denature due to adsorption onto the wall of the container or onto the chromatography matrix used. Enzymes with quaternary structure will dissociate and the activity of interest will be lost.

Adsorption and denaturation of dilute enzyme samples can be circumvented by using a carrier protein such as bovine serum albumin (BSA), or even better a commercial synthetic carrier protein with a simple and known structure at a concentration as high as 1 mg mL^{-1} . Care must be taken to avoid interaction between the carrier protein and the enzymes of interest. The molecular size of the carrier protein should also differ by at least a factor of two from the enzyme of interest, for easy removal by size exclusion chromatography if the pure enzyme protein is needed, for instance in amino acid sequencing.

Catalytic site inactivation by specific reactions is hard to avoid. Loss of cofactors can be prevented by including them in the purification buffer. Covalent modification of the active site which contains reactive amino acid residues responsible for the catalysis is common. The most troublesome amino acid is cysteine, which is very susceptible to modification. Sulfhydryl residues at the active site may be in the ionized form, which is prone to oxidation and can form disulfide bonds, or may be partially oxidized to

the sulfinic acid or irreversibly oxidized to the sulfonic acid.

These reactions can be suppressed by using different additives such as ethylenediaminetetraacetic acid (EDTA), which masks by complexation cations that would otherwise catalyse the formation of disulfide bonds with cysteine residues at the catalytic site. Other commonly used reducing agents are sulfhydryl-containing reagents such as β -mercaptoethanol, 2,3-dimercaptopropanol, thioglycolate, glutathione, cysteine and the dithio-analogues of the reduced C_4 sugars, threitol and erythritol (DTT, DTE). EDTA and other complexing agents often cannot be used for enzymes that have an essential metal ion in the active site.

Proteinases or proteolytic enzymes are contained inside living cells. In mammalian cells they are packed in lysosomes. In microorganisms they are often found between the plasma membrane and the cell wall. During preparation of an enzyme extract by cell homogenization, release of proteolytic enzymes will occur and their activity has to be inhibited. Depending on the wide scale of different proteinases present in the cell homogenate, many types of inhibitors have to be used.

Diisopropyl fluorophosphate (DFP) inhibits serine proteases. Note that DFP is dangerous to handle because it is volatile and attacks human acetylcholinesterase, vital in nerve conduction. Phenylmethylsulfonyl fluoride (PMSF) is a nonvolatile serine protease inhibitor and does not attack acetylcholinesterase. It inhibits some thiolproteases and some carboxypeptidases, but it has to be dissolved in acetone or isopropanol.

Pepstatin, leupeptin and antipain are peptide-based inhibitors that are very potent against acid proteases such as pepsin, cathepsin D and yeast protease A. Normal concentrations of inhibitors used in freshly prepared extracts are 5 mmol L^{-1} EDTA, 1 mmol L^{-1} PMSF, $10 \text{ }\mu\text{mol L}^{-1}$ pepstatin, $10 \text{ }\mu\text{mol L}^{-1}$ leupeptin and $10 \text{ }\mu\text{mol L}^{-1}$ antipain.

Other stabilizing factors during enzyme purification are some nonaqueous hydrophilic molecules. Owing to the high nonaqueous content in cell cytoplasm (10–15% w/v), the water around the protein molecules is not freely mobile and thus stabilizes the protein structure. To mimic this situation in prepared enzyme extracts glycerol is added at 10–50% (w/v). Below 30% the viscosity is not harmful for most methods used during enzyme purification except for ultrafiltration and centrifugation and in some ‘salting-out’ experiments because hydrogen bonding and hydrophobic forces decrease. Sugar or sugar alcohol solutions such as glucose, fructose, lactose and sorbitol and be used instead of glycerol. The mechanism of protection is similar.

Separation Methods Based on Size, Shape, Mass, Charge, Hydrophobicity, Solubility and Biological Recognition

The different physicochemical properties of the enzyme that should be utilized during a purification scheme include size, shape, charge, hydrophobicity, solubility and biological recognition. The salient points of various separation methods are listed in Table 2.

After each step in a purification scheme, a proper enzyme activity assay should be carried out and the amount of protein determined. If correctly done the specific activity (in units per milligram) (1 U is the

amount of enzyme that converts 1 μmol of substrate per min under defined reaction conditions) can be followed through the purification scheme – it should rise and then reach a plateau. Crude extracts should be concentrated by fractional precipitation with ammonium sulfate or poly(ethylene glycol) (PEG) or adsorbed and desorbed from a chromatographic matrix as soon as possible. Precipitated proteins, after dissolution in a small volume, are more stable because they are more concentrated. Centrifugation with field strength from 5000 to 50 000 g is widely used for subcellular fractionation and for ammonium sulfate and PEG-precipitated enzymes.

Table 2 Enzyme separation methods

<i>Physicochemical property</i>	<i>Method</i>	<i>Characteristic</i>	<i>Scale</i>	<i>Use</i>	<i>Enzyme activity recovery</i>
Size, shape or mass	Centrifugation	Moderate resolution; slow	Large or small	Partial fractionation	Good
	Gel filtration	Moderate resolution; slow	Small	Desalting, size determination, fractionation	Good
	Field flow fractionation	Good resolution; fast	Small	Size determination, fractionation	Good
	Ultrafiltration	Bad resolution; slow/medium	Large or small	Desalting, concentration	Good
	Dialysis	Bad resolution; slow	Large or small	Desalting, concentration	Good
Polarity (a) Charge	Ion exchange chromatography	High resolution; fast	Large or small	Fractionation, concentration	Good
	Chromatofocusing	Excellent resolution; fast	Medium	Fractionation, concentration	Poor
	Electrophoresis	High resolution; medium/fast	Small/medium	Fractionation, visualization	Medium/poor
	Isoelectric focusing	Excellent resolution; medium	Small/medium	Fractionation, visualization	Poor
	Capillary electrophoresis	Excellent resolution; fast	Extremely small	Fractionation, size determination possible	Good
	(b) Hydrophobic character	Hydrophobic interaction chromatography	Good resolution; fast	Large or small	Fractionation, concentration
Reversed-phase chromatography		Excellent resolution; fast	Large or small	Fractionation, concentration	Poor
Solubility		Change in pH	Medium resolution; fast	Large or small	Concentration, fractionation
	Change in ionic strength	Medium resolution; fast	Large or small	Concentration, fractionation	Medium/good
	Decrease in dielectric constant	Medium resolution; fast	Large or small	Concentration, fractionation	Medium
	Two-phase separation	Medium/good resolution; medium	Large or small	Fractionation, concentration	Good
Biological activity	Affinity chromatography	Excellent resolution	Generally small	Fractionation, concentration	Medium/good
Specific binding or structure features	Dye–ligand chromatography	Good resolution; fast	Large or small	Fractionation, concentration	Medium/good
	Immuno-chromatography	Excellent resolution; fast	Generally small	Fractionation	Medium/good
	Covalent chromatography	Medium/good resolution; fast	Medium/small	Fractionation	Medium

Field flow fractionation Field flow fractionation (FFF) is a chromatography-like separation technique which is designed for fractionation of macromolecules, colloids and particles. The principle is simple. A laminar flow of carrier liquid between two walls, separated by *c.* 0.1 mm, creates a parabolic velocity profile. The sample is injected into the carrier stream at the inlet of the channel and exits through the outlet end which is connected to a detector.

Sample retention is achieved when molecules are pushed to the accumulation wall (an ultrafiltration membrane) by an external field force (a cross-flow), so that they obtain different average distances from the wall and are placed at different heights in the parabolic flow profile. The different sample molecules are consequently transported down the channel at different velocities. Thus separation can be achieved.

The size range embraced by FFF is from small proteins (*c.* 10 kDa), up to organelles and cells with a diameter of several micrometers. FFF does not rely on a stationary phase, which makes it very useful for separation of labile enzyme molecules. Separation times are very short (3–10 min) and selectivity according to size is better than for gel filtration. Loadability is so far limited to *c.* 200 µg per separation run.

Examples of Enzyme Determination in Physiological Samples

Hormone-Sensitive Lipase from Adipose Tissue

Hormone-sensitive lipase (HSL, EC 3.1.1.3) is an amphiphilic enzyme and the key control of energy substrate flow in mammals. Its activity in adipose tissue determines the rate of hydrolysis of stored triacylglycerols and thereby the production of fatty acids for release as free fatty acids (FFAs) into the circulation.

The following parameters were considered during purification.

1. Development of a suitable assay procedure
2. Selection of the best source from which the molecule could be purified.
3. Solubilization of the desired molecule.
4. Development of a series of isolation and concentration procedures which includes stabilizing the molecule at each stage.

Lipase activity was measured against emulsified [³H]-oleic acid-labelled monooleoylglycerol (a diacylglycerol ether analogue). An enzyme activity of 1 U corresponds to the release of 1 µmol of fatty acids per minute at 37°C. The assay was performed between each purification step. The enzyme source was rat adipose tissue (epididymal fat pads).

A summary of the steps taken in the purification of HSL from rat epididymal adipose tissue is given in **Figure 3**.

Step 1. Fat pads frozen in 0.25 mol L⁻¹ sucrose, 1 mmol L⁻¹ EDTA, 1 mmol L⁻¹ DTE and 10 µmol L⁻¹ of leupeptin and antipain in liquid nitrogen were homogenized (Potter–Elvehjem homogenizer) in 30% (w/v) 0.25 mol L⁻¹ sucrose and partially delipidated by removing the fat floating after centrifugation at 5000 g for 10 min at 4°C.

Step 2. The supernatant was further delipidated and separated from the pelleted material by centrifuging at 100 000 g for 45 min (referred to as the ‘100 000 g supernatant’).

Step 3. The pH was lowered to 5.2 with acetic acid. HSL was precipitated over 30 min on ice and the pellet collected after 30 min of 10 000 g centrifugation. The pellet was resuspended in 20 mmol L⁻¹ Tris-HCl (2-amino-2-hydroxymethylpropane-1,3-diol hydrochloride), pH 7.0, containing sucrose as before (this fraction is referred to as ‘the pH 5.2 ppt fraction’). This fraction contains practically all the HSL and about 25% of the contaminating proteins. The preparation is stable for several months at –80°C.

Step 4. Further solubilization of the pH 5.2 ppt fraction was by sonication at 10°C in the nonionic detergent C₁₃E₁₂ (heterogeneous alkyl polyoxyethylene glycol type). The solubilized HSL was fractionated by gradient sievortptive chromatography on quaternary aminoethyl (QAE)-Sephadex, for a separation time of 12 h at 10°C. 70% of the recovered enzyme was pooled and concentrated 15-fold by ultrafiltration and referred to as the QAE-Sephadex fraction.

Step 5. This fraction was dialysed and concentrated three-fold further against 20 mmol L⁻¹ Tris-acetic acid, pH 7.50, containing 20% (w/v) glycerol, 15% PEG, 1 mmol L⁻¹ DTE, 0.2% C₁₃E₁₂ and 10 µmol L⁻¹ leupeptin for 8 h at 4°C, immediately followed by chromatography on a Mono Q column (polymer-based strong anion exchanger for liquid chromatography from Pharmacia) as described in detail in **Figure 4**. The enzyme peak fractions collected were immediately brought to pH 7.0 by addition of a potassium phosphate buffer to give a final concentration of 30 mmol L⁻¹ and the fractions were stored at –80°C in 50% (w/v) glycerol. This enzyme preparation is referred to as the ‘Mono Q enzyme’.

Step 6. The last step of the purification scheme consisted of Mono S chromatography (polymer-based strong cation exchanger for liquid chromatography from Pharmacia). Before chromatography the Mono Q enzyme was dialysed and concentrated three-fold for 3 h against 10 mmol L⁻¹ potassium

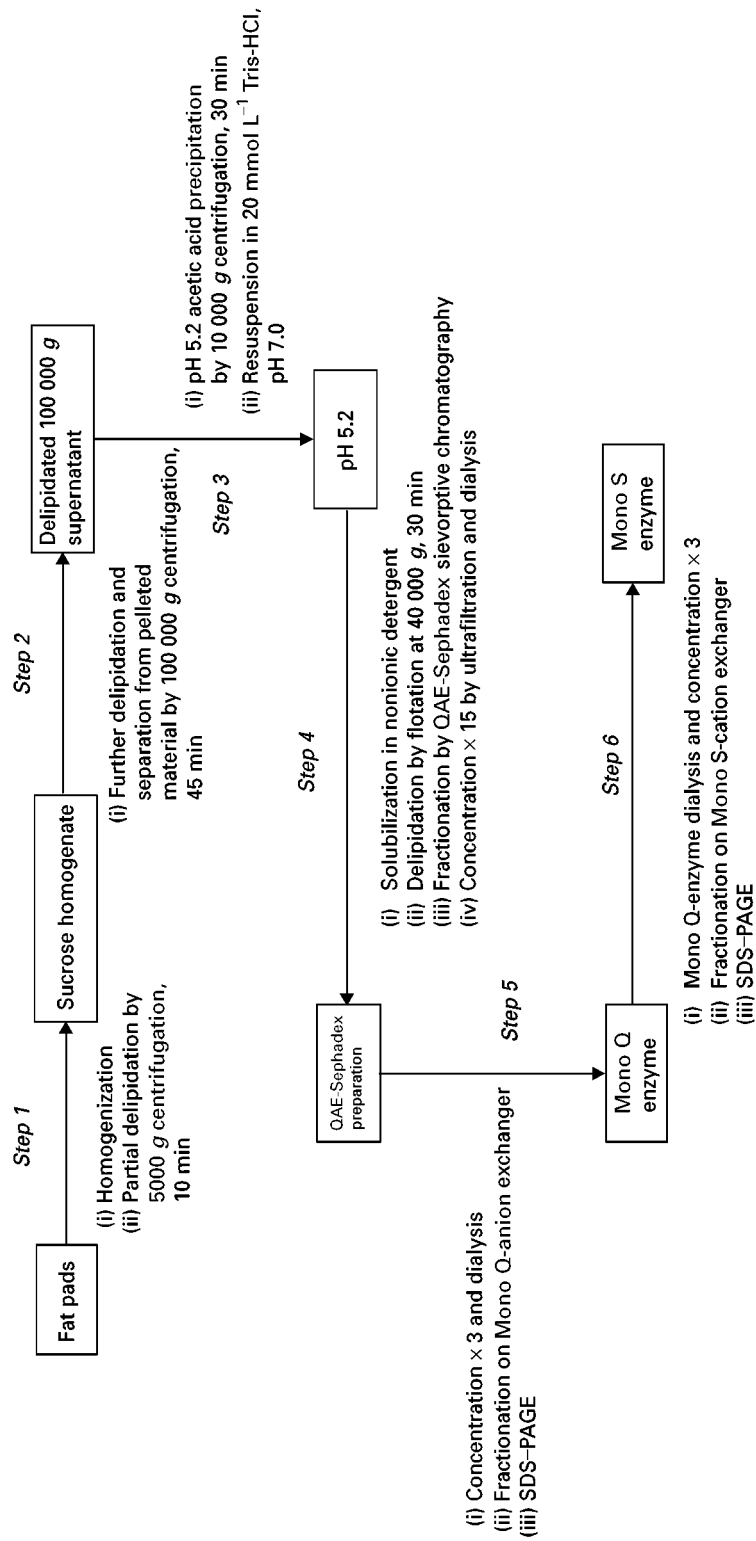

Figure 3 Purification scheme for HSL from rat epididymal adipose tissue. Enzyme activity was monitored at each step. (Reproduced with permission from Nilsson and Belfrage (1986).)

Figure 4 Fractionation of partially purified HSL by high-performance Mono Q anion exchange chromatography. (A) The sample, 7.5 mL of concentrated QAE-Sephadex enzyme (about 17 mg of protein), representing half of the preparation from adipose tissue of 500 rats, was applied to an 8 mL Mono Q column (fitted with a precolumn, flow rate 1.0 mL min^{-1} at a back-pressure of about 1.5 MPa) pre-equilibrated in 50 mmol L^{-1} Tris-acetate, pH 7.5, containing 1 mmol L^{-1} DTE, 20% (w/v) glycerol and 0.2% (w/v) of the nonionic detergent $\text{C}_{13}\text{E}_{12}$. (B) After adsorption the lipase was eluted (4.0 mL min^{-1} at a back-pressure of about 4.2 MPa) by the increasing salt and decreasing pH gradient obtained by addition of 0.3 mol L^{-1} sodium acetate, pH 7.0, as indicated by the conductivity and pH profile in the figure. HSL activity (shaded area) was measured towards an emulsified lipid substrate. One unit (U) of enzyme activity corresponds to $1 \mu\text{mol}$ of fatty acid released per minute at 37°C . The protein composition of the QAE-Sephadex enzyme sample applied to the column (lane a), and the indicated column fractions (lanes b-o), analysed by SDS-PAGE and Coomassie blue staining. Lanes to the extreme left and right are reference proteins; values are in kiloDaltons. Arrow labelled HSL signifies the HSL $M_r = 84\ 000$ subunit. Enzyme peak fractions corresponding to 70% of the total enzyme eluted were pooled for the next step. (Reproduced with permission from Nilsson and Belfrage (1986).)

Table 3 Purification of HSL from rat adipose tissue^a

Purification step	Volume (mL)	Protein (mg)	Enzyme activity ($\mu\text{mol fatty acids}$ per min)	Specific activity ($\mu\text{mol fatty acids}$ per min per mg protein)	Purification (-fold)	Yield (%)
100 000 g supernatant	790	4900	314	0.06	1	100
pH 5.2 ppt	50	1204	289	0.24	4	92
QAE-Sephadex	46	33	112	3.40	57	36
Mon Q LC ^b	16	2.1	58	27	450	18
Mono S LC ^b	8	0.2	34	154	2567	11

^aEnzyme was purified from about 600 g of epididymal fat pads from 500 rats. Enzyme activity was measured with monoacylalkyl-glycerol substrate at 37°C.

^bCombined enzyme from two identical chromatographic treatments of half the initial batch. Reproduced with permission from Nilsson and Belfrage (1986).

phosphate buffer, pH 7.0, followed by 3 h against the same buffer, pH 6.5, both containing the same concentration of glycerol, PEG, C₁₃E₁₂, DTE and leupeptin as used for the Mono Q chromatography. The enzyme peak fractions (70% of the enzyme activity recovered) were brought to pH 7.0 and glycerol was added to 50% (w/v). The results of the purification are illustrated in Table 3.

The obstacles encountered in the determination of enzymes in biological samples are well illustrated in this purification scheme for the enzyme HSL, which has been notoriously recalcitrant to purification because of its low tissue abundance, amphiphilicity and general lability. What are the necessary precautions that have to be fulfilled during the process? After every solubilization, fractionation or concentration step, the biological activity has to be estimated to detect any inhibition, destruction or loss of the enzyme of interest. To obtain optimum enzyme activity, certain precautions have to be taken in between every step as discussed previously, by adding reducing agents or stabilizers, lowering the temperature or speeding up the separations where possible. To elucidate the effectiveness of different fractionation steps used, protein purity must also be examined with a nonchromatographic method such as sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) or capillary electrophoresis. Another, not easy, problem of importance is the identification of the protein band on SDS-PAGE that corresponds to the enzymatic activity.

In the case of HSL, it was possible to carry out the identification in rather crude preparations because the enzyme was activated through covalent modification, i.e. phosphorylation. Then it was possible to 'tag' HSL with ³²P and identify the SDS-PAGE band by autoradiography. After the Mono Q purification step there was only one phosphorylated band.

A single band on SDS-PAGE with Coomassie blue, or even silver staining together with maximum enzyme activity, are not conclusive evidence for identification.

Plasminogen Activator in Gingival Crevicular Fluid

There is a correlation between plasminogen activator (PA) concentration in gingival crevicular fluid (GCF), which is an extracellular exudate occurring in the gingival crevice, and gingival inflammation. The concentration of plasminogen activator inhibitor (PAI) in GCF also plays an important role. The fibrinolytic system is activated by PAs, which are serine proteases that catalyse the conversion of the inactive proenzyme plasminogen to the active enzyme plasmin which then activates collagenase and thereby participates in the tissue destruction seen at inflammatory lesions.

Sampling of GCF was performed by placing small discs (Millipore GWVP-filter 0.22 μm , calibrated in size to absorb a determined volume) in the gingival crevice.

PA determination is performed by two different methods.

1. Enzyme-linked immunosorbent assay (ELISA), where the amount of protein is determined by placing the small discs in the wells of the microtitre plates used for ELISA (further details of ELISA are given elsewhere). This can be done providing monoclonal or polyclonal antibodies that have been raised against the enzyme, which in turn demands a relatively pure enzyme for immunization.
2. Gel lysis can be used for the determination of enzymatic activity of PA. The filter discs are placed on plasminogen-rich fibrin plates and incubated for 18 h. PA activity can then be derived from the size of the gel lysis.

Figure 5 Instrumental set-up for levitation single cell analysis.

Single Cell Analysis

The key step in future enzyme determination is miniaturization, combined with highly selective separation and detection methods. Separation and determination should be done simultaneously. The goal is to be able to study the molecular processes of life at the level of a single cell and its subcellular compartments, if possible without destroying the cell's integrity, and analysing for a specific enzyme. Capillary liquid chromatography and capillary electrophoresis are good candidates for single-cell analysis. In fact, small molecules such as catecholamines, dipeptides and proteins have already been determined in single viable cells. This can be achieved either by sucking a single cell into the capillary and causing cell lysis by use of a high ionic strength buffer, or penetrating the outer cell membrane with an ultrathin capillary (2 μm i.d.) and sucking in some of the cell contents.

By introducing a substrate for a specific enzyme during the separation, it is possible to follow its activity directly after cell lysis by studying the decrease of the substrate and increase of the product concentrations. In some cases the enzyme itself can be monitored during the separation if the amount is high enough. Detection techniques sensitive enough to detect substrates, products and enzymes at the concentration levels derived from a single cell experiment are laser-induced fluorescence or amperometric detection.

Single cell analysis can also be achieved using other miniaturized analysis systems. A very suitable method for studying living cells and biochemical reactions is acoustically levitated microdroplets. Cell studies have

for example been performed on freshly prepared, intact and living primary adipocytes. The instrumental set-up is shown in **Figure 5**. A single adipose cell in a 500 nL droplet is acoustically levitated. Stimulation of adipocytes with β -adrenergic agonists results in activation of adenylate cyclase, production of cAMP and activation of cAMP dependent protein kinase (PKA). PKA phosphorylates HSL, leading to activation of enzyme activity and increased lipolysis, resulting in FFA release and a consequent pH decrease in the surrounding buffer droplet. Addition of insulin antagonizes this effect and hence also the decrease in pH. The change in pH, i.e. the cell response in the droplet, is followed by a pH-dependent fluorophore continuously monitored by fluorescence imaging detection. Additions to the levitated droplet are achieved using continuous flow-through droplet dispensers. To counteract droplet evaporation, which affects the fluorescence intensities, a dispenser is used to continually add water, thus keeping the droplet volume constant. An image analysis computer program is employed to calculate droplet fluorescence intensities during experiments. The method is particularly useful for studying of dynamic events in natural cellular environments at the single cell level, e.g. for the screening of new drug candidates or for studying side effects and reactions between cells.

Subcellular fractionation at the single-cell level using a two-phase levitated droplet system is under development at the author's laboratory.

Introduction

Enzymes find applications in food, pharmaceutical and biochemical industries. They are found in combination with other macromolecules or various small molecules. Their uses require identification and purification of the enzymes. The nature, quality, and quantity of the desired enzyme are determined by its intended use. For example, the food industry needs enzymes in large quantities and the pharmaceutical industry requires ultra pure enzymes. High-performance liquid chromatography (HPLC) is widely used for the separation or purification of enzymes on a preparative or analytical scale. It is also used for the analysis of the enzymatic activity.

Properties of Proteins and Practical Implications

All enzymes are proteins. All proteins are macromolecules with molecular weights ranging from hundreds to several thousands. The sequence of amino acid in a protein is specific and this gives each protein unique properties. A protein with just amino acids as a building block is a simple protein; those that contain additional units, such as a nucleic acid, a lipid or a metal etc., are called conjugated proteins.

There are 20 naturally occurring amino acids found in proteins that vary in structure; thus, it is the amino acid sequence and composition that determine the properties of enzymes. Two distinct properties are the size and polarity of the protein, which are impor-

tant factors for understanding their separation. The size of a protein depends upon the number of amino acid units in the protein, whereas the polarity depends on the hydrophilic and hydrophobic units present.

A protein molecule contains one of the three groups: uncharged polar, potentially positively charged (basic side chain) or a potentially negatively charged (acidic side chain). These side chains are normally ionizable and this leads to proteins having characteristic isoelectric points. Since there are other issues governing the protein molecule, such as size, shape and nature of the solution (pH), the overall net charge and polarity depends upon the combination of these factors. In general, the chromatographic processes associated with the properties of enzymes can be summed up as indicated in Table 1.

High-Performance Liquid Chromatographic Techniques

Size-Exclusion Chromatography

Size-exclusive chromatography (SEC) is primarily used as a first step in purification when molecules

Table 1 Chromatographic processes associated with enzyme properties

<i>Enzyme property</i>	<i>Chromatographic method</i>
Net charge	Ion-exchange chromatography
Size	Size-exclusion chromatography
Substrate affinity and conformation	Affinity chromatography
Polarity	Reversed-phase chromatography and hydrophobic-interaction chromatography

differ significantly in size. This technique is used extensively in biochemistry for fractionation and molecular weight determination of proteins and enzymes. The basis of separation in SEC, as the name suggests, is the size of the molecules to be separated. Spherical beads made of a cross-linked gel of a polymer such as silica, agarose, or polyacrylamide are used as column packings. Small molecules can enter all pores and elute with a characteristic volume equivalent to the column hold-up volume. Large molecules are excluded from those pores with a smaller cross-section than the solute and elute in a smaller volume than the small molecules. Consequently, molecules passing through the column separate on the basis of their size and elute in order of decreasing molecular weight.

The resolution depends on gel bead size, pore size, column size, sample size, and flow rate of the mobile phase. Low flow rates of the mobile phase, long and narrow columns, and small gel bead sizes give the highest resolution. The pore size of gel beads is designed according to the size of the molecules of interest.

The nature of the mobile phase in SEC is very important in enzymatic separation as the protein (enzyme) conformation can be changed due to solvent polarity, pH, ionic strength, and salt concentration. Conformational change can change the whole chromatographic behaviour of an enzyme. In SEC, solute-stationary phase interaction is completely prohibited for better separation. However, the mobile phase may produce (ionic or hydrophobic or both) solute-stationary phase interactions. It is necessary to design an ideal mobile phase for chromatography to avoid the above problems. Most enzymes are stable in the pH range of 5–8. The desired pH of mobile phase in SEC is obtained by using buffers suitable for both the enzyme to be analysed and the stationary phase. Tris(hydroxymethyl)aminomethane salt solution or phosphate buffers are widely used for enzymes. Denaturing solvents are sometimes also employed for the chromatographic separation of enzymes. Protein denaturants, detergents in mobile phase, change the original proteins to random coil conformations.

Organic solvents such as acetonitrile can be used for SEC of enzymes. Using acetonitrile is very advantageous because it can be evaporated after elution to concentrate the enzyme solution. Acetonitrile is an ideal organic solvent if a UV detection method is used. However, the solubility of enzymes in acetonitrile solution limits its use in the mobile phase.

A prepacked column of cross-linked methacrylate gel (Ultrahydrogel from Waters) was used for preliminary isolation of fractions of peptidoglutaminase

Figure 1 Gel permeation of *Bacillus circulans* proteins on acrylate gel (300 × 7.8 mm) at flow-rate of 0.5 mL min⁻¹ using 2 mg (A) and 20 mg (B) of cell extract proteins. Pooled active peaks (0.1 mg) from (B) were reinjected (C). Reproduced from Hamada JS (1995) *Journal of Chromatography A* 702, 163–172, with permission from Elsevier Science.

(PGase) from *Bacillus circulans* cell extract (1). PGase sample loading was 2–30 mg in 0.05 M sodium phosphate buffer (pH 8.0) and the eluent was 0.05 M sodium phosphate at flow rate of 0.3 mL min⁻¹ (Figure 1). The pooled PGase peak from multiple injections was then further purified by anion-exchange chromatography.

Ion Exchange Chromatography

Ion exchange chromatography (IEC) is a widely used technique for enzyme purification because of the net charge characteristics of enzymes. In IEC, the charged functional groups are covalently bound to the solid surface of the matrix. Cellulose, silica or styrene-divinylbenzene is used as a matrix. Cation exchanger resins contain immobilized negatively charged functional groups (i.e. RSO₃⁻, RCO₂⁻, RPO₄⁻ and RO⁻) and anion exchangers contain immobilized positively

charged functional groups (i.e. quaternary ammonium groups). Resins containing sulfonyl and quaternary ammonium groups are strong ion exchangers and ionize at any pH, whereas weak ion exchangers containing functional groups like carboxyl and secondary or primary amines ionize within a certain range of pHs. When an ionized solute passes through an ion exchange column, the sample ions adsorb and displace counter ions on the surface. The adsorption process is reversible and adsorbed ions are eluted by a salt solution. Using a suitable mobile phase regenerates the resins.

The choice of the appropriate ion exchange resin for a particular enzyme separation depends on the isoelectric point of the enzyme to be separated. The isoelectric point of any molecule is the pH value at which the molecule has no net charge, i.e. an equal number of negative and positive charges. Enzymes are acidic at a pH above the isoelectric point and anion-exchange resins are used for separation of such enzymes. Similarly, cation-exchange resins are used for basic enzymes.

Column packing material, particle size and pore diameter of the support, column length, mobile phase, and temperature are some important parameters which affect separation of enzymes in IEC. In a column with smaller packing particle sizes, large enzyme molecules diffuse at a slower rate and this results in enhanced resolution and lower elution time. Most of the surface area of a support is confined within the pores and the diameter of pores affects the penetration of enzyme molecules into the column matrix and hence the mass transfer and loading capacity. Pore diameters of $\approx 300 \text{ \AA}$ are ideal for most enzymes with molecular weight up to 100 000, providing loading capacity and good resolution. Larger pore diameters are needed for higher molecular weight enzymes. The column length is not an important factor in the resolution of enzymes in IEC. Using short columns has many advantages, e.g. concentrated eluents, lower pressure and lower column cost. Lower loading capacity is a disadvantage of using a short column.

The pH, ionic strength and salt composition of mobile phase are also important factors in IEC separation of enzymes. Aqueous organic solvents are used as mobile phases. The amount of organic solvent in the mobile phase is determined by trial and error and depends completely on the nature of the molecules to be separated. Excessive organic solvent should be avoided because it can destroy the stability of enzyme molecules. The isoelectric point (pI) of enzymes determines the type of column used for separation (discussed earlier) as well as the pH of the mobile phase. The net charge on enzyme molecules depends on the

pH of the solvent. Ionization of ammonium groups occurs at any pH below the isoelectric point (pI) and contributes a positive charge on the enzyme. Similarly, a negative charge on the enzyme is obtained by a pH above its pI. The retention on ion exchange columns therefore depends on the net charge carried by the enzyme molecule to be separated and the pH of the mobile phase is chosen accordingly. The pH of the mobile phase should be slightly above the pI of the enzymes to be separated for anion-exchange columns and vice versa for cation-exchange columns. The nature of displacing counterion in the salt used also affects the enzyme retention on the column. Higher valent ions are stronger displacers than lower valent ions and thus give lower retention. The smaller size of ions also favours lower retention if the charge on the counterion is the same. Gradient elution based on ionic strength variation or pH changes is used in IEC. Chromatographic separation of most enzymes is carried out at a low temperature to preserve enzyme stability.

The quaternary methylamine resin from Waters (Accel Plus QMA) has been used for the separation of peptidoglutaminase from *B. circulam* cell extract. Enzyme load was 1.0 mg in 20 μL of 0.02 M phosphate buffer (pH 8.0) and the eluent used was 0.05 M sodium phosphate buffer and 0.1–0.8 M KCl at a flow rate of 0.5 mL min^{-1} for analytical separation and 1.5–10.0 mL min^{-1} for preparative separation (Figure 2).

Reversed-Phase Chromatography

Reverse-phase chromatography (RPC) is the most popular chromatographic method for the purification, separation, and analysis of the biological molecules because of its high resolution and ease of handling. Column packings are usually prepared from silica particles and hydrophobic long-chain alkylsilyl ligands. n-Butyl (C4), n-octyl (C8), n-octadecyl (C18), and alkylphenyl groups are used for separating enzymes. The nonhydrophobic molecules in the sample do not strongly interact with the hydrophobic stationary phase of the column and elute earlier, while hydrophobic molecules in the sample interact with the hydrophobic stationary phase of the column and elute later.

The column packing material, particle size and pore diameter of support, column dimension, mobile phase, and length of hydrophobic ligands, determine the effectiveness of an RPC procedure. Silica is the most widely used support because of its mechanical stability, efficiency, and ability to be bonded with hydrophobic ligands. However, silica supports are not stable under basic conditions (pH > 8). Small

Figure 2 Anion-exchange separation of *Bacillus circulans* proteins using (A) QM anion exchange (150×3.9 mm) column at 1.0 mg load and 0.5 mL min^{-1} flow rate, (B) 150×19 mm QM anion exchange column at 30 mg load and 5.0 mL min^{-1} flow rate, and (C) DEAE anion exchange (150×21.5 mm) column at 5 mg load and 5 mL min^{-1} flow rate. Reproduced from Hamada JS (1995) *Journal of Chromatography A* 702, 163–172, with permission from Elsevier Science.

support particles favour higher resolution, but high column backpressures and the large size of enzyme molecules to be separated do not favour the smaller particle sizes. A particle size of $\approx 20 \mu\text{m}$ is optimal for RPC column for enzymatic HPLC. A pore size of 300 \AA is the most commonly available size in commercial RPC columns. For large enzyme molecules use of a large pore size (≈ 1000 or greater) is suggested to avoid any diffusional problems.

The hydrophobicity of n-alkyl group attached to the silica decreases with decreasing chain length of n-alkyl group ($\text{C18} > \text{C8} > \text{C4} > \text{C2}$). Smaller n-alkyl group chains are favoured for highly hydrophobic samples and vice versa. More hydrophobic columns (e.g. C18) require a stronger mobile phase (higher amount of organic solvent). Organic solvents such as acetonitrile, methanol or isopropanol and ion-pairing

agents or buffers are added to the mobile phase to achieve reasonable retention times. The effectiveness of these organic modifiers depends on solvent polarity and increases with decrease in polarity. Isopropanol is a very good solvent for highly hydrophobic enzymes and methanol is better for hydrophilic enzymes. Acetonitrile is the most suitable organic modifier because it has intermediate polarity, low viscosity, and low UV adsorption. It is volatile and can be easily removed from the eluent. The function of added solvents is to decrease the interaction between the stationary phase and highly hydrophobic molecules and thus reduce the retention time. Ion-pairing agents or buffers set the eluent pH and interact with the enzyme to enhance the separation. Trifluoroacetic acid (TFA) is widely used as an ion pairing agent. Buffers such as phosphate or hydrochloric acid are also used. The mobile phase for RPC typically consists of water, organic solvent, and trifluoroacetic acid (0.1%) or phosphoric acid.

Capillary columns packed with nonporous (pellicular) supports have been used for fast separation of enzymes or proteins at high temperatures and at high flow rates. Packed capillary RP-HPLC columns have several advantages over conventional columns – fast separation, reduction in solvent usage and the ability to work with small samples. The mass transfer between the stationary phase and the mobile phase is fast with pellicular packings because the diffusional distances in the stationary phase are short owing to limited chromatographic interaction at the outer surface. Capillary columns are stable at higher temperatures and at higher pressures because of the solid, fluid-impervious core of the micropellicular packing. Rapid mass transfer resulting from the pellicular configuration and higher temperature is mainly responsible for the fast separation of enzymes. Higher temperatures may not be appropriate for the stability of some enzymes.

Fast separation of a mixture of four proteins was performed in 6 s at 120°C on a 3 cm column packed with $2 \mu\text{m}$ pellicular ODS-silica (Figure 3).

The biological activity of enzymes is sometimes lost due to high backpressures, mobile phase (low pH and organic modifiers) and a strong hydrophobic stationary phase. Hydrophobic interaction chromatography (HIC) has less harsh chromatographic conditions than RPC and can be used to preserve the biological activity of enzymes.

Hydrophobic Interaction Chromatography

The basis of separation in hydrophobic interaction chromatography (HIC) is the same as for RPC. These methods differ in the properties of the mobile and stationary phases. HIC is carried out with an aqueous

Figure 3 Fast separation of standard mixture of proteins: 1 = ribonuclease A; 2 = cytochrome *c*; 3 = lysozyme; 4 = lactoglobulin B. Column (30 × 4.6 mm) packed with 2 μm pellicular ODS-silica; 12 s linear gradient from 10 to 90% (v/v) acetonitrile (ACN) in water containing 0.1% trifluoroacetic acid (TFA), temperature = 120°C, flow rate = 5 mL min⁻¹ and column inlet pressure = 240 bar. Reproduced from Chen H and Horvath CS (1995) *Journal of Chromatography A*, 705, 3–20, with permission from Elsevier Science.

solution of higher salt concentration at neutral conditions and uses a weak hydrophobic stationary phase. The higher concentration of salt in the mobile phase

enhances the binding between enzymes and weakens the hydrophobic stationary phase.

Most separation variables in HIC behave in the same way as in RPC but the nature of the mobile phases and stationary phases differs in these two HPLC methods. The HIC performs separation under non-denaturing conditions whereas RPC denatures enzymes during separation because of the mobile phase conditions (organic solvent and highly acidic) and the highly hydrophobic stationary phase. The mobile phase in HIC is neutral and nonorganic and protects enzymes from denaturation. Salts such as sodium or potassium phosphate are added into the mobile phase to buffer it at pH ≈ 7. The bonded phase in HPHIC is an aryl or smaller alkyl ($n < 5$) group, weak hydrophobic ligands, attached to silica support.

The purification of *Chromobacterium viscosum* lipase has been studied using hydrophobic interaction chromatography. The stationary phase was prepared by covalent immobilization of polyethylene glycol on Sepharose gel (Sepharose CL-6B, Pharmacia). The extent of lipase was affected by the salt used and increases with increasing ionic strength in the eluent buffer and with higher pH value. The best recovery of lipase was observed when potassium phosphate was used as a salt compared to NaCl, Na₂SO₄ and (NH₄)₂SO₄ (Figure 4).

Affinity Chromatography

The basis of affinity chromatography (AC) is the selective adsorption of the molecule to be separated

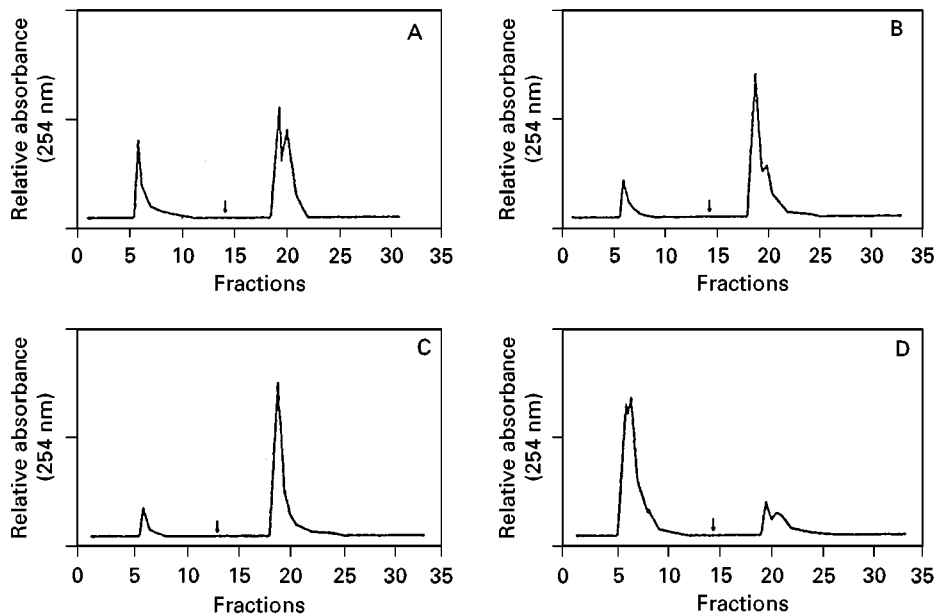

Figure 4 HIC on PEG 10000-Sepharose CL-6B column. Buffer: (A) 15% (w/w) K₃PO₄; (B) 20% (w/v) (NH₄)₂SO₄; (C) 15% (w/v) Na₂SO₄; (D) 4 M NaCl in 10 mM phosphate (pH 7). Desorption with 10 mM phosphate buffer (pH 7). From Queiroz JA, Garcia FAP and Cabral JMS (1996) *Journal of Chromatography A* 734, 213–219, with permission.

from mixture on the matrix of the column. A specific ligand for a specific biological molecule is chosen and it is covalently bound to the matrix of the column. For example, a ligand such as adenosine will bind only enzyme adenosine deaminase and not any other molecules. When a mixture is applied to the affinity chromatography column then the molecule that has specific affinity for the ligand will stay in the column and all other unbound molecules will migrate through the column. The interaction between adsorbed molecule and ligand is reversible. Changing the pH or other conditions of the mobile phase can desorb the bound molecule. A molecule that has more affinity for the ligand than the bound molecule can be included in the mobile phase to elute the desired bound molecule. This chromatographic method is carried out under nondenaturing conditions during the separation of enzymes or proteins.

The type of ligand and its support, state of mobile phase at each stage of separation and flow rate determine the resolution in AC. Ligands can be specific for a molecule or a group of molecules. The desired ligand must be highly specific for enzyme molecule(s) to be separated, be stable under applied conditions, have reversible binding with applied sample and possess an appropriate functional group to couple with the support. Cross-linked agarose or other pressure-stable polymer is used as a support for the ligand.

Buffers at each step of separation must be non-denaturing to maintain specificity of ligand and eluting enzyme(s). Low pH buffers are employed in the desorption step to break the solute-ligand interaction. Specific desorbing agents, which compete with adsorbed solute molecule(s) for the same binding site, are sometimes also used. The flow rate of mobile phase also affects the retention time and peak shape.

Alhama *et al.* have applied AC technique for the purification of glutathione reductase and glucose-6-phosphate dehydrogenase from cell-free extract of baker's yeast, fish liver, and rabbit hemolysates with high recovery. They used an epoxy-activated silica column derivatized with the ligand 8-[(6-aminoethyl)amino]-2'-phosphoadenosine-5'-diphosphoribose. The bound ligand concentration was $11.4 \mu\text{mol g}^{-1}$ of dry silica and the loading capacity was 2–3 mg of glutathione reductase.

Hydroxyapatite High-Performance Liquid Chromatography

Hydroxyapatite, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, is a form of calcium phosphate which has been used, in particular, as a packing material for enzymes and proteins separations. The basis of separation is ionic interactions

Figure 5 Separation of a protein mixture: a = transferrin, b = myoglobin, c = lysozyme, and d = cytochrome *c*. Packing: Nucleosil 1000-5 DIOL CaP-HA 2.5% (100 × 6 mm). Linear gradient of sodium phosphate (pH 6.8), 1–350 mM (60 min); flow rate = 1 mL min^{-1} , temperature = 25°C . Reproduced from Bruno G, Gasparrini F, Misiti D, Arrigonimartelli E, and Bronzetti M (1990) *Journal of Chromatography A* 504, 319–333, with permission from Elsevier Science.

between amine groups of the enzymes and phosphate groups on the surface of the hydroxyapatite and, also, calcium coordination complex formation between calcium groups in the hydroxyapatite and carboxyl groups in enzymes. Low concentration phosphate buffers are used to elute acidic and neutral enzymes and high concentration buffers are used to elute basic enzymes.

A protein mixture containing transferrin, myoglobin, lysozyme, and cytochrome *c* was separated using hydroxyapatite as a support. Protein solution ($10\text{--}50 \mu\text{L}$; $1 \mu\text{g } \mu\text{L}^{-1}$ protein) was loaded onto the column and eluted with a linear gradient of sodium phosphate buffer (pH 6.8) (Figure 5).

Perfusion Chromatography

Perfusion chromatography is a new chromatographic technique, introduced by Afeyan and coworkers in 1989–1991, for reducing resistance to stagnant mobile phase mass transfer in liquid chromatography. It may be used for both rapid analysis and preparative chromatography of large molecules such as enzymes. A new chromatographic packing material (POROS, Perseptive Biosystems) which contains two sets of interconnecting bimodal pores has been employed in perfusion chromatography. The members of one pore set having a mean diameter in the range $6000\text{--}8000 \text{ \AA}$ are called throughpores. The high surface area needed for adequate sample capacity is achieved by the smaller diffusive pores ($d_{\text{pore}} \approx 1000 \text{ \AA}$). The mobile phase flows through the through-pores. In this manner, solutes enter the interior of the particles convectively by the through-pores and then diffuse into the diffusive pores.

Figure 6 Separations of hybridoma cell cultural supernatant on protein A POROS M. 0.5 mL injection; 30×2.1 mm column; 10 mM phosphate pH 7.4, 0.15 M NaCl; elution with 0.3 M acetic acid (2%, v/v), 0.3 M $MgCl_2$; 2 mL min^{-1} flow-rate. Reproduced from Afeyan NB, Fulton SP and Regnier FE (1991) *Journal of Chromatography A* 544, 267–279, with permission from Elsevier Science.

POROS-based chromatographic packing material can be used in any chromatographic mode such as ion exchange, reversed-phase, hydrophobic interaction, and affinity chromatography. These supports separate proteins rapidly compared with conventional HPLC using higher mobile phase velocities.

The separation of immunoglobulin G (IgG) from hybridoma cell culture supernatant has been completed in 80 s using a POROS protein A (aldehyde-coupled) column. The sample was loaded in a 0.1 M phosphate buffer pH 7.4 with 0.15 M NaCl and eluted with 0.3 M acetic acid (2%, v/v) with 0.3 M $MgCl_2$. The column was loaded with 0.5 mL of hybridoma cell culture supernatant with the flow rate of 2 mL min^{-1} (Figure 6).

Assay of Enzymatic Activity

An important aspect of the separation of enzymes by HPLC is the assay of enzyme activity. Enzyme-catalysed reactions can be monitored spectrophotometrically and many of the substrates or products absorb visible or UV light. It allows determination of the progress of a reaction by direct and continuous monitoring. While other methods of discontinuous assay focus on monitoring one of the compounds of the reaction, the HPLC technique offers the simultaneous determination of several substrates of the reaction. This method is probably the best as it offers a complete mass balance of the reaction being analysed.

Detectors for Enzyme Analysis

Ultraviolet-visible (UV-vis) detectors are the most commonly encountered detectors in enzyme analysis because enzymes are UV-active and UV detectors are

simple to use and relatively inexpensive. The analysis is also nondestructive and hence suitable for preparative work. Furthermore the solvents best suited for liquid chromatography are transparent to UV-vis. Refractive index detectors are nondestructive, concentration sensitive and universal in that they respond to virtually all compounds with the proper choice of mobile phase but are of low sensitivity. The specificity of analysis of enzymes by fluorescence detection arises because many parameters related to the fluorescence intensity can be exploited. However, this technique requires the use of very selective reagents that react with specific functional groups of the analyte to produce fluorescent derivatives.

Future Trends

HPLC will continue to be the important tool for separation of enzymes. The new capillary columns packed with nonporous support and microsporous support in perfusion chromatography will be helpful in fast analysis of enzymes or proteins. Separation is faster and more selective when HPLC is carried out at higher temperatures. A heat exchanger, which can bring the eluent rapidly to column temperature, will increase separation reliability at higher temperatures. Conventionally, HPLC is used for the analytical separation as well as for preparative separation of enzymes. Discontinuity of the HPLC process and the dilution of the products after elution are two major disadvantages. The simulated moving bed (SMB) technique can make HPLC a continuous process. A column packing material should be designed for a higher sample loading and for fast HPLC. Thus, a large-scale separation should be fully automated and continuously operating, loading samples, collecting fractions, regenerating the column and with various fail-safe devices to protect the column and product.

ESSENTIAL OILS

Distillation

E. Hernandez, Texas A&M University,
College Station, TX, USA

Copyright © 2000 Academic Press

Introduction

Essential oils are generally understood to be volatile compounds which are freely soluble in alcohol, ether and vegetable and mineral oils and are usually assumed to be the result of distillation or a steam-stripping process. The use and processing of essential oils began in the East more than 2500 years ago. The process of distillation, which is the technical basis of the essential oil industry, was also conceived and first employed in the Orient, especially in Egypt, Persia and India. Turpentine and camphor appear to be the first documented essential oils prepared by distillation in Greece by Herodotus (484–425 BC).

The use of essential oils in ancient times consisted of preparing ointments by mixing oils from flowers with fatty oils; this was done by placing flowers and roots with the oil in glass bottles which were then allowed to sit for periods of time. Sometimes the flowers or roots were macerated with wine before the fatty oil was added, and the product obtained by digestion filtered and boiled down to a thicker consistency.

Medieval alchemists laboured for many years to extract from materials found in nature what they called the *quinta essentia* or the fifth essence. They believed that a combination of earth, air, fire and water existed in some form or other from which quintessential materials could be extracted from some plants. These quintessential extracts derived from plants were believed to be remedies for a wide variety of diseases.

The production and use of essential oils did not become widespread until the second half of the 16th

century. In 1507, Hieronymus Brunschwig's book on distillation, *Liber De Arte Distillandi*, described distillation techniques for four essential oils, namely, turpentine (known since antiquity), juniper wood, rosemary and spike.

Before the ninth century it was still widely believed that most essential oils had strong curative properties. Therefore it was chiefly pharmacists who developed and improved methods of distillation for the recovery and purification of natural essential oils.

Eventually, with the development of the fields of medicine and pharmacology and the dispelling of some medicinal myths, the use of essential oils in pharmaceutical products lost importance and their use became restricted to perfumes, beverages and foodstuffs.

Applications of Essential Oils

Attractive aromas which leave a pleasant memory association are used as marketing devices to sell edible and cosmetic products, including unlikely materials such as detergents. The producer is counting on the consumer preferring a product that left a pleasant aromatic memory.

Current specific uses of essential oils are to add flavour to foodstuffs and beverages and to scent perfumes, lotions, soaps, detergents and household cleaners. For example, *d*-limonene from citrus peel is a very strong solvent and it is used in a wide variety of cleaning products. Essential oils are a major part of carbonated beverage flavourings; the most common flavours include lemon, lime, orange, cassia, cinnamon and nutmeg. Essential oils are also used to flavour many foods such as sweets and candies, cookies, snacks and chewing gum.

The field of aromatherapy constitutes a small part of the essential oils industry but it is a fast-growing area and requires a wide variety of essences. Not much scientific work has been done in this area to support any of the medicinal and psychosomatic

claims. Practitioners suggest that aromatherapy goes beyond the effect of simply imparting an agreeable sensation and psychological state of well-being. Some speculate that inhaling certain essential aromas can affect the limbic system, producing a measurable physiological response. More research is certainly needed to document the benefits of this application.

Other properties of essential oils with commercial potential include antimicrobial effects. The inhibition of 25 different bacteria using an essential oil of marjoram has been reported. Similar effects are noted for other volatiles and essences derived from plant materials. It was found that the short chain volatiles such as 5–8 carbon aldehydes and ketones resulting from the distillation of vegetable oils had antimicrobial properties against bacteria such as *Staphylococcus aureus* and *Escherichia coli*. In fact, this antimicrobial effect is believed to be a defence mechanism in plants against microbial pathogens. Another function of essential oils in plants is reported to be as an attractant of insects, enabling plants to use the insects as pollen carriers for plant reproduction.

The production of essential oils on a larger scale was started in the USA in the earlier 19th century. Three indigenous plants, sassafras, American wormseed, and wintergreen, as well as turpentine, were the first oils to be produced in the USA in large amounts for export worldwide.

Many aromatic plants for essential oils grow wild or are cultivated in small scale family-oriented businesses. Today only a few essential oils are produced by modern or centralized methods. An example of these is the cultivation and harvesting of aromatic flowers in the Grasse region of southern France, where essential oil distillation units are placed near the fields to extract and recover the essential oils on site. In the case of citrus oils, for example, much larger scale distillation systems are set in place at juice-processing plants. These aroma distillation units are set up next to the evaporators where the concentration of juices is taking place. These systems are common in the USA as well as in other large citrus-producing countries such as Brazil and China. It should be noted that these aroma distillation units are used not only in citrus-processing plants but in any plant that concentrates fruit juices by evaporation.

In addition to improving production and purification processes for the recovery of essential oils, the essential oil industry has been active in developing synthetic aromas. Essential oils are some of the most studied chemical compounds as regards their composition and physical and chemical properties. Advances in organic chemistry have allowed for the establishment of techniques to define the component

Table 1 Classification of components in essential oils

<i>Component</i>	<i>Examples</i>
Hydrocarbons	<i>d</i> -Limonene in lemon oil
Alcohols	Borneol in camphor
Esters	Methyl salicylate in oil of wintergreen
Aldehydes	Benzaldehyde, decanals
Ketones	Menthone in oil of peppermint
Lactones	Coumarin from Tonka beans

profiles of many aromas and fragrances which permit the establishment of composition standards for trade regulations and for the synthesis of aromas using less costly starting raw materials.

Essential oils are commonly grouped into six classes according to their chemical nature. **Tables 1** and **2** list some of the most commonly utilized essential oils worldwide.

The most common essential oil used as a food aroma and flavour is orange essence (Table 2). Over 50% of the commercial essential oils and natural extracts are obtained from cultivated plants. Examples of these include mint aroma and flower essences such as rose, geranium, mints, coriander, lavender and jasmine.

Citrus oils such as orange, lemon and grapefruit aromas are considered by-products of juice extraction and concentration. Orange oil, for example, is marketed both as a flavour and as a material for use in cleaning products. In this case the distinction has to be made that orange oil and citrus oils in general are recovered in two ways; one way is as *d*-limonene, in which the oil resulting from the peel of the fruit as the

Table 2 Main essential oils produced in the world

<i>Essential oil</i>	<i>Main components</i>
Orange	Limonene, terpeniols
Mint	Linalool, linalil acetate
Eucalyptus	Cineole, pinene, limonene
Citronella	Geraniol, citronellal, citronelol
Clove	Eugenol, caryophyllene
Lime	Limonene, terpeniols
Spearmint	Menthol, menthone, pulegone
Lavander	Pinene, lemonene, caphene, octanone
Marjoram	Tojuene, pinene, sabinene
Camphor	Bisabolol, cadinol cubenol
Coriander	Terpinene, <i>p</i> -cymen
Patchouli	Patchoulol, sesquiterpenes
Rose	Citronellol, geraniol, linalool
Cinnamon	Fenchene, cinnamaldehyde, pinene
Sandalwood	Santalene, curcumene
Lemongrass	Citral, linalool, geraniol
Jasmin	Benzyl acetate, linalool, benzyl benzoate
Ginger	Terpenio, neral, geraneal
Anis	<i>Trans</i> anethol, chavicol

juice is extracted. This has a lower value and is sold as flavouring and also as a cleaning agent. The true volatiles from citrus are what results from volatilization during the evaporation of the juice and this is a product that commands a higher value and has a wider range of aroma components such as aldehydes, ketones and terpenes. Other oils such as clove or pepper oil may come from spices, or as oils, oleoresins, extracts or flavours.

Other raw materials for essential oil production are harvested in the wild. Wild thyme and rosemary, for example, are common in Spain and grow back abundantly following harvest. Sumatran cinnamon trees are similarly self-rejuvenating. However, due to high demand, some countries have resorted to overharvesting plants for essential oil production from the wild. This has created local problems of forest destruction and the sustainability of the industry has become a serious concern for some underdeveloped countries. As a result, some countries, such as Brazil, have implemented harvest moratoriums or banned the harvesting of some species in order to avoid wiping out some species of aromatic plants. These conservation efforts and replanting programmes have meant that some oils are now available again commercially.

Recovery of Essential Oils

The aroma and fragrance industry has been estimated at approximately \$2 billion per year, with a growth rate of 3.5% per year. Orange oil is both the largest volume oil and, as a by-product of the orange juice industry, relatively inexpensive, ranging from \$0.75 to \$1.40 a pound. Although the US production of citrus oil is declining, with South America and China growing in importance as a major producer, the USA continues to be a major producer of mint and cedar oils. The mint oils as a group – peppermint, spearmint (both grown in the USA) and cornmint (produced in India and China and as a by-product of menthol production) – are the highest value oils, with peppermint selling for about \$12–15 a pound.

Distilled essential oils are generally recovered by three methods, classified according to the way heat is applied to materials: boiling water, steam distillation or a combination of both. Conditions of temperature, pressure or vacuum, and processing time will depend on the characteristics of the essential oil, particularly as regards susceptibility to oxidation and heat decomposition.

The basic process consists of macerating or comminuting the plant materials to rupture the oil sacs. This allows the essential oil to be exposed and carried by the steam or water used. Common materials used

in the recovery of essential oils are flowers, roots, seeds, leaves and twigs of aromatic plants.

Once the plant materials have been prepared, the method for removing the essential oil depends on the type of product being handled. For example, a combination of boiling water and steam injection is used with flower petals in order to avoid agglutination of the materials in the distillation unit. **Figure 1** illustrates this simple method of distilling essential oils. This type of distillation is commonly set up in the fields where the raw materials are being harvested in order to prevent spoilage and deterioration of aromas during transportation or storage.

A simple distillation apparatus consists of a retort or still, a condenser and a receiver. This system is commonly used in the fields for processing lavender. Typical conditions for this method are to heat a mixture of raw material with water to boiling point (100°C) while injecting steam. The resulting vapours are then condensed and recovered. This usually results in two phases: a heavy phase, mostly composed of water, and a light phase, which contains the essential oil.

A variation of this method is to apply vacuum (10–25 in Hg) to the system to allow boiling to take place at a lower temperature and thus prevent the thermal decomposition of the essential oil.

Some aroma systems involve the use of only steam in order to obtain a more concentrated essential oil in the condenser. This system is applicable where there is no agglomeration or agglutination of raw materials. When the raw material is liquid, such as fruit juice or macerated materials in water, the fresh liquid flows in countercurrent with vapour. Vapour–liquid-contacting devices such as a sieve plate column or a packed column are sometimes used. Under ideal conditions, it is advisable to have a rectification column next to the distillation unit in order to obtain a more concentrated and pure essential oil. This is the most efficient way from the standpoint of steam consumption as well. Such a scheme is illustrated in **Figure 2**, with distillation/rectification as the concentration step.

As mentioned above, essential aromas from citrus are recovered as a by-product from the production of citrus juice concentrates. These juices are usually concentrated by multiple effect evaporation. There are four or more effects where the first effect is usually heated by live steam and then subsequent effects are heated by the steam generated in the preceding effect. The vapours generated in the first effect are the richest in the essential oils and the essence is condensed and recovered in a distillation column. This is the most important source of essential oils with regard to volume, estimated worldwide at 25 000 metric tons and more than 60 million US dollars.

Figure 1 Aroma recovery unit by hydrodistillation.

There is another method of distillation used by very specialized flavour companies called molecular distillation. In this evaporation system the liquid introduced is spread on the walls of a heated vertical cylinder under high vacuum (less than 50 mmHg) by wiper blades forming a thin layer. This produces highly efficient mixing and heat transfer of the fluid, reducing the residence time to a minimum. Variable temperature allows for the fractionation of aroma components according to their molecular weight. Heat-sensitive aromas and specialized aromas such as dairy flavours are manufactured by the industry using this type of distillation system.

Other methods for recovering aromas and fragrances are solvent extraction (hexane, alcohols) and supercritical CO₂ extraction. Strictly speaking, the resulting oils from these extraction methods are not essential oils since no evaporation or distillation takes place. However, recovery of high priced aromas and fragrances by supercritical extraction is growing worldwide and extraction of some low price essential oils is also done using hexane or alcohol. Supercritical extraction has the advantage that it does not involve the application of high heat and addition of steam or water. Also, the extractability properties of CO₂, namely affinity for hydrophobic or hydrophilic com-

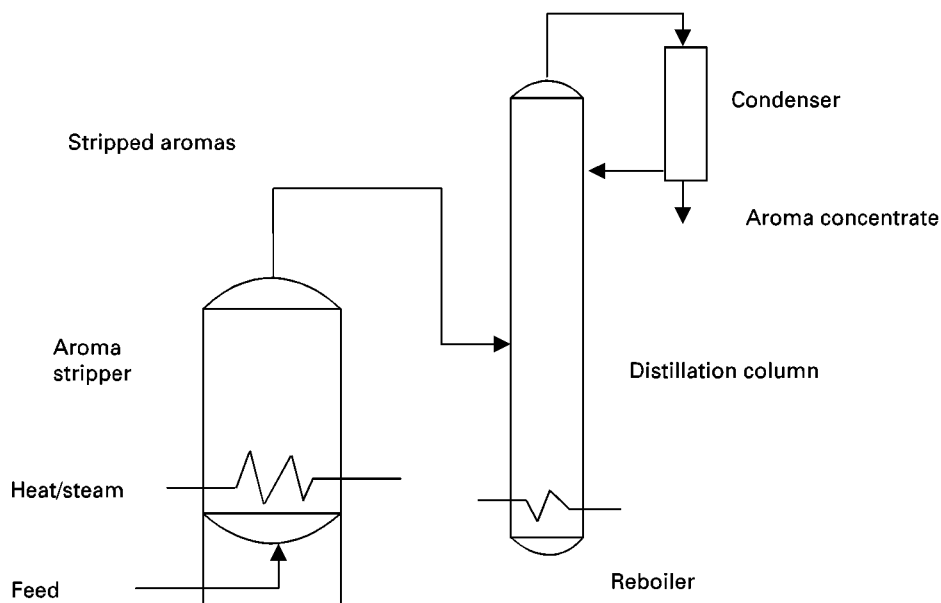

Figure 2 Aroma recovery unit with distillation column.

pounds, can be manipulated with pressure and temperature. Extraction methods by steam distillation, solvent extraction and supercritical CO₂ usually produce different results with regards to yield and composition profiles of the extracted materials. Steam distillation usually gives the lowest yield of recovered aroma but produces a concentrate that is a true essential oil. Solvent extraction with hexane or alcohols produces the highest yield but there is always the possibility that unwanted involatile materials might end up in the final product. Also, solvent extraction uses high temperatures. Supercritical CO₂ extraction produces a lower yield than conventional solvent extraction but higher than steam distillation and it also has the advantage of using little or no heat and no steam or moisture in the process. However, this method has the disadvantage of being expensive since it involves high pressure and sophisticated equipment and controls. In some cases the quality of the aroma extracts from CO₂ extraction is superior to aromas recovered by steam distillation.

Industry Standards and Trends

With the exception of large companies that have access to sophisticated analytical means, the assessment of quality of essential oils is difficult. However, the composition of many essential oils is well known and the industry can adopt standards that can be applied to essential oils. Oils used in medical applications, for example, camphor oil, must meet the standards set forth in the US pharmacopeia. Oils used in food products must meet the Food Chemical Codex standards and the Fragrance Manufacturers Association (formerly the Essential Oil Association, or EOA) is in the process of updating a specifications book.

It is common practice for large producers of essential oils to process their oils further following pressing or distillation, either to produce a standard product year after year, or to change the characteristics of the oil. For example, peppermint oil is commonly redistilled to remove some of the front-end components that give the oil an unwanted flavour or aroma note.

Another common practice is folding of oils, or concentrating them by removing certain components. It is common practice to redistil citrus essential oils, in some cases removing up to 90% of the original volume in order to remove most of the unwanted terpenes. This is known as terpeneless citrus oils, which carry a higher price in the essence markets. These folded oils are more stable, have a better fla-

avour, are more water-soluble and are easier to blend in beverages and foodstuffs.

Well-known profiles of components of essential oils are instrumental in setting standards for the assessment of quality and prevention of adulteration. Knowing the chemistry of essential oils has allowed the successful manufacture of synthetic essential oils; however, some essential oils are so complex that the odour and flavour characteristics just cannot be duplicated.

An essential oil is internationally defined as the product obtained by steam distillation, hydrodistillation or expression (for citrus fruits) of a plant or of a part of it. This definition is now less strictly applied, and the fractions resulting from several other techniques that sample the volatile fraction of a plant are now erroneously classified as essential oils. In general it would be more correct to call them volatile fractions of a vegetable matrix, and to use the term essential oil more specifically for samples obtained by distillation or expression. In addition to distillation or expression, the volatile fraction of a vegetable matrix can be obtained through static or dynamic headspace gas chromatography (HS-GC), solid-phase microextraction (SPME-GC), simultaneous distillation–extraction (SDE), solvent extraction or supercritical fluid extraction (SFE).

Components of an essential oil are generally medium-to-highly volatile with medium-to-low polarity, and as a consequence GC is the technique of choice for their analysis. Figure 1 shows the structure of some typical essential oil components. These characteristics also facilitate their identification, which in general can be achieved by combining chromatographic (retention indices) data with mass spectrometry (GC-MS) and Fourier transform infrared spectroscopy (GC-FTIR).

This article aims to cover the main aspects related to the analysis of essential oils, in particular with sample preparation techniques related to GC; GC

separation of enantiomers; multidimensional GC; identification of essential oil components through GC and/or combined techniques (GC-MS, GC-FTIR); GC-Isotope ratio mass spectrometry and authenticity of an essential oil; GC-sniffing for sensory evaluation; and statistical analysis applied to GC profiles.

Sample Preparation

Steam Distillation and Hydrodistillation

An essential oil is classically obtained by steam or hydrodistillation via equipment based on the circulatory distillation apparatus introduced by Clevenger in 1928. Apparatus and operation modes are now well established. Several pharmacopoeias give diagrams and instructions of how to obtain essential oils. Figure 2 is taken from the *European Pharmacopoeia*.

On the other hand, sampling techniques for the volatile material are under constant evolution. The most used techniques are static or dynamic HS-GC, SPME/GC, SDE and SFE.

Headspace Sampling (HS-GC)

Static HS-GC, dynamic HS-GC HS is a sampling technique applied to the determination of volatiles in the gaseous phase in equilibrium with the matrix to be sampled.

HS-GC sampling is generally classified as static or dynamic HS. In static HS-GC, the analyte is sampled from a hermetically sealed vial after the matrix has reached equilibrium with its vapour at a predetermined temperature. Figure 3A shows the static HS-GC pattern of a sage sample. The sample was

Figure 2 Apparatus for the determination of essential oils in vegetable drugs (*European Pharmacopoeia* (2000) 3rd edn, Copyright Council of Europe). Plant material suspended in water is heated to boiling; the resulting vapour, consisting of a homogeneous mixture of essential oil and steam, is then condensed in the refrigerator (F,G) and recovered in the collecting bubble (J); two layers are formed, the upper with the essential oil and the lower with the aqueous phase, the latter being continuously recirculated through the (M-B) tubing.

equilibrated for 1 h at 60°C and 1 mL of the gas phase in equilibrium with the vegetable matrix was automatically injected and analysed by GC.

In dynamic HS-GC, the sample is obtained by capturing the volatiles in a gaseous effluent passed through or over the matrix on to a suitable trapping system, such as cryotrap, solid adsorbents, liquid stationary phases or selective reagents for a given class (or classes) of compounds, coated on a solid support. The trapped volatiles are then recovered through heat or solvent elution either on-line or off-line to the gas chromatograph. **Figure 3B** shows the GC pattern of the same sage sample as in **Figure 3A**. The volatile fraction was transferred to a 50 mg Ten-

ax TA cartridge through a nitrogen flowstream of 30 mL min⁻¹ for 2 min.

Solid-phase microextraction SPME is a sampling technique based on absorption developed by Arthur and Pawliszyn. With SPME, the analytes are absorbed from the liquid or gaseous sample on to an absorbent coated fused silica fibre, which is part of the syringe needle, for a fixed time. The fibre is then inserted directly into a GC injection port for thermal desorption. SPME is a solvent-free technique which is sensitive because of the concentration factor achieved by the fibre, and selective because of the different coating materials which can be used. One of the advantages of SPME is the possibility to sample directly the vapour phase in equilibrium with the matrix (headspace (HS)-SPME), or the matrix extract or solution (liquid sampling-SPME) directly, provided that suitable fibres are used. **Figure 3C** shows the SPME-GC pattern of the same sage sample already analysed. The dried sage leaves are equilibrated as for static headspace sampling for 1 hour with a 100 µm polymethylsiloxane-coated fibre.

All these headspace techniques are easy to automate and to standardize. This is particularly true for static HS-GC and SPME-GC which can be used for fully automatic routine analysis. Static HS-GC is highly reliable for quantitative analysis, when associated with the multiple headspace extraction method developed by Kolb. Dynamic HS-GC is also quite easy to standardize, now that automatic purge-and-trap systems are commercially available. However, reproducible dynamic HS sampling is conditioned by a large number of parameters (volume to be sampled, volume of the headspace system, sampling time and speed, carrier flow rate, trapping material, including batch and producer, kinetics of component release in different matrices) that make it quite difficult to compare results from different laboratories.

The different HS sampling techniques are normally used for different applications: in general, static HS-GC is suitable for the analysis of highly volatile fractions, HS SPME-GC is suitable for the analysis of medium-volatile fractions, while dynamic HS-GC is used for trace analysis or for very diluted headspace.

Supercritical Fluid Extraction

The high selectivity of supercritical fluids, together with the low polarity and molecular weight of most of the volatile fraction components, permits low extraction pressure and temperature to be used, thus limiting the classes of the extracted components to those that characterize an essential oil (mono- and sesqui-terpenoids, phenylpropanoids and aliphatic oxygenated compounds). This often makes the com-

position of SFE extracts quite similar to that of the corresponding essential oil obtained through hydro- or steam distillation. In addition, several organoleptically important components that are water-soluble and which are generally lost in the water phase during the steam distillation are quantitatively recovered by SFE. Typical is the case of phenylethanol, which is the main component in a rose SFE extract, while it is a minor component in the corresponding essential oil.

GC Analysis

Classical GC Analysis

Essential oils are generally analysed by capillary GC. The most popular stationary phases used for essential oil analysis are methylpolysiloxanes (SE-30, OV-1, OV-101, DB-1, PS-347.5) and methylphenylpolysiloxanes (SE-52, SE-54, PS-086, DB-5) as apolar stationary phases; and polyethylene glycol

Figure 3 Continued

(Carbowax 20M) as a polar stationary phase. GC data are also very useful to identify most of the components in an essential oil: an effective approach is to combine the retention data from two different-polarity stationary phases (see below).

Enantiomer GC Analysis

One of the most important successes of the last 10 years has been enantioselective GC recognition of chiral essential oil components with cyclodextrin derivatives (CDs). The importance of enantiomer separation and of determining enantiomer excess is well known. Biosynthetic and geographical origins, as well as technological treatments and/or authenticity of most of the essential oils, can now also be evaluated through the enantiomeric composition of their underivatized optically active components. This is also important because optical isomers can have different sensory properties, such as the well-known cases of the different smells of both carvone and limonene enantiomers. The first GC separations of enantiomers through CDs were obtained by Koscielski and Sibilska in 1983; they separated α - and β -pinene, the corresponding pinanes and Δ -3-carene with a column packed with underivatized α -CDs. The first capillary column applications were in 1987 with the almost contemporary work of Juvancz and Schurig. CDs are generally carried in apolar to moderately polar polysiloxanes, as first proposed by Schurig. The chief reasons for this are the wider range of operating temperatures; the inertness and efficien-

cy of columns prepared by high temperature silylation; the possibilities of tuning column polarity by using different diluting phases; the small CD amounts necessary to prepare columns; shorter analysis times; and the possibility of measuring the thermodynamic parameters involved in enantiomer discrimination.

Almost all the essential oil components can now be separated on CD stationary phases without derivatization. This is particularly true for the so-called second-generation CDs, developed especially for GC, which show high enantioselectivity, and afford highly reliable column performance. The most successful CDs are symmetrically and asymmetrically alkylated CDs, acylated CDs and CDs asymmetrically substituted in position 6 with the groups *tert*-butyldimethylsilyl or hexyldimethylsilyl, and in positions 2 and 3 with methyl, ethyl or acetyl groups. In general, the most popular matrices for the CDs are polyphenylcyanopropylsiloxes (including various OV-1701 types), polyphenylsiloxanes (including SE-52 or PS-086) and methyl polysiloxanes (including SE-30, OV-1 and PS-347.5). The latest generation of CDs makes it possible to characterize an essential oil by determining the enantiomer abundances of several of its optically active components simultaneously, very often in a single GC run. Figure 4 shows the simultaneous enantiomer separation of optically active components characterizing lavender oil: linalyl oxides, linalol, linalyl acetate, camphor, borneol, bornyl acetate, α -terpineol and *cis*- and *trans*-nerolidols are successfully and simultaneously

separated with a 30% 2,3-diethyl-6-*t*-butyl-dimethylsilyl- β -CD in PS-086.

Koenig and Joulain have made a very important contribution to this field: they have identified and structurally characterized about 330 sesquiterpene hydrocarbons, including the enantiomer recognition of the optically active ones. **Figure 5** shows the enantioselective GC pattern of a group of sesquiterpene hydrocarbons (δ -elemene, α -copaene, *ar*-curcumene, β -bisabolene and (*E*)- α -bisabolene) separated on a 20% 2,6-di-*O*-methyl-3-*O*-pentyl- β -CD/OV-1701 column.

Multidimensional GC

Multidimensional GC (MDGC) is a very useful technique to analyse a complex mixture such as an essential oil. In MDGC, groups of components not separated on the first column can automatically be transferred on-line to a second column coated with a different stationary phase. The possibilities of MDGC are still not fully appreciated: it is true that early systems were difficult to tune, inflexible and above all very expensive; however, most of the present systems

Figure 5 Enantioselective GC pattern of a δ -elemene, α -copaene, *ar*-curcumene, β -bisabolene and (*E*)- α -bisabolene separated on a 20% 2,6-di-*O*-methyl-3-*O*-pentyl- β -CD/OV-1701 column. Analysis conditions: from 60°C (1 min) to 190°C (10 min) at 0.6°C min⁻¹. (Courtesy of Professor W. Koenig, University of Hamburg.)

are fully automatic and not too expensive. Above all, they consist of two independent GC units connected through a transfer interface, which can be used independently when MDGC is not necessary.

MDGC is particularly useful with enantiomer GC analysis, which may double the number of peaks of the optically active components, making the chromatogram resulting from the analysis of an essential oil even more complex, and increasing the probability of peak overlap, thus interfering with a correct determination of enantiomeric ratios. In these cases MDGC operates a sort of clean-up on the first column, so that only selected peaks are transferred to the chiral column.

Identification

Essential oil components are generally identified through GC or GC-MS or, better, through their combination. The safest way to identify an essential oil component, and in particular a sesquiterpene, is to combine dual-column GC data and mass spectrometry (MS) data with IR data, because of the high structure-related specificity of infrared spectroscopy (IR) signals. It is important to remember that identification and structure elucidation are totally different things: identification can only be by comparison with reference data. It is risky to propose a new structure or, worse, a new skeleton, from results obtained only by combined techniques (GC, GC-MS, GC-FTIR) without parallel isolation and spectroscopic investigation (in particular, nuclear magnetic resonance) of the new compound.

As in all fields of analytical chemistry, the introduction of data systems has revolutionized the approach to identification. Operators can now build their own personal libraries with retention indices and mass spectra obtained with their own instruments, and combine the GC and GC-MS data for crossed identification of essential oil components.

Identification through Chromatographic Data

Since essential oils are generally very complex mixtures, reliable GC location and identification of their components can only be through retention indices, calculated by the Kováts method or with the van den Dool algorithm; these make retention values independent of GC conditions. Identification through retention indices is in general only considered significant when two successful matches are obtained from different-polarity stationary phases. When a suitable reference database is available, the percentage of correct identifications obtained through retention data is generally around 65% with one column, 80% with two different-polarity columns, and above 90% with

three columns. The last two percentages are close to that obtainable with MS, which is generally around 90%. Since a GC system affording simultaneous injection into two columns is simple to assemble, and today's processing systems can easily handle two detector signals, a manual or automatic crossed-identification procedure is not difficult to set up. This is particularly true with the latest-generation instruments: the development of GC instruments with electronic pressure control of the mobile phase and of GC ovens in which the temperature is strictly controlled and evenly distributed, has overcome several problems with instrumentation. These give rigorous control of mobile-phase parameters (flow rate, pressure and average linear velocity) and of temperature parameters over the whole GC run. Thus the chromatographic process, and hence retention, becomes highly reproducible: as an example, under fixed conditions a retention index precision of 1 unit was maintained over 1 month for some of the most significant essential oil components of both *Matricaria chamomilla* (OV-1 column) and *Tagetes lucida* (CW-20M column; Table 1).

Retention indices are fundamental in making retention a reliable identification tool for GC, although many problems still exist; in particular, the variation of stationary-phase polarity and mobile-phase characteristics as a function of temperature in programmed analysis. As a consequence, a comparison of data from different laboratories can only be made with analyses run under carefully controlled operating conditions.

Identification by GC-MS

Mass spectral data are often – and perhaps to some extent erroneously – considered the key for component identification. Many people give too much priority to mass spectrometry (MS) data over chromatographic data, and seldom give due weight to the complementarity of GC and MS data. This is probably because many manufacturers and operators do not yet consider GC-MS as a technique in its own right, but a simple coupling between GC and MS.

Nowadays, identification is generally made through commercially available mass spectra libraries (NBS, NIST, Wiley, TNO); these are nonspecialized collections of spectra mainly taken from the literature. As a consequence, the identification of a component must be carefully confirmed, since the mass spectra are from different origins and have been recorded under different operative conditions. A classical example is the differences in the spectra produced by different mass analysers: ion trap, quadrupole or magnetic sector instruments. Most operators overcome this problem by building dedicated libraries

consisting of spectra recorded with their own GC-MS systems. Libraries dedicated to the essential oil field are also available, as is the case of Adams library for ion trap mass spectra, or the Joulain and Koenig collection of sesquiterpene hydrocarbon spectral data.

Chromatographic data used either actively or passively in a library search can play a fundamental role in the successful identification of essential oil components. Several compounds, in particular sesquiterpenoids, have low resolution mass spectra that are almost indistinguishable. In this case, mass spectra can mainly be used to locate the spectra in the total chromatogram; retention indices (better if from two

different polarity columns) are then used to identify each component. **Figure 6** shows retention indices and mass spectra of *cis* and *trans*- α -irones.

The use of retention indices, as a further active identification key in combination with mass spectra or within the classical library search procedure, can be extremely useful. The ideal procedure should include simultaneous and/or sequential searches with retention indices from two different stationary phases, and mass spectra in which flexible and selectable priorities can be actuated.

Unfortunately, identification by retention indices associated with mass spectra is not absolutely risk-

**Figure 6** Retention indices on OV-1 and CW-20M and mass spectra of *cis* and *trans*- α -irones.

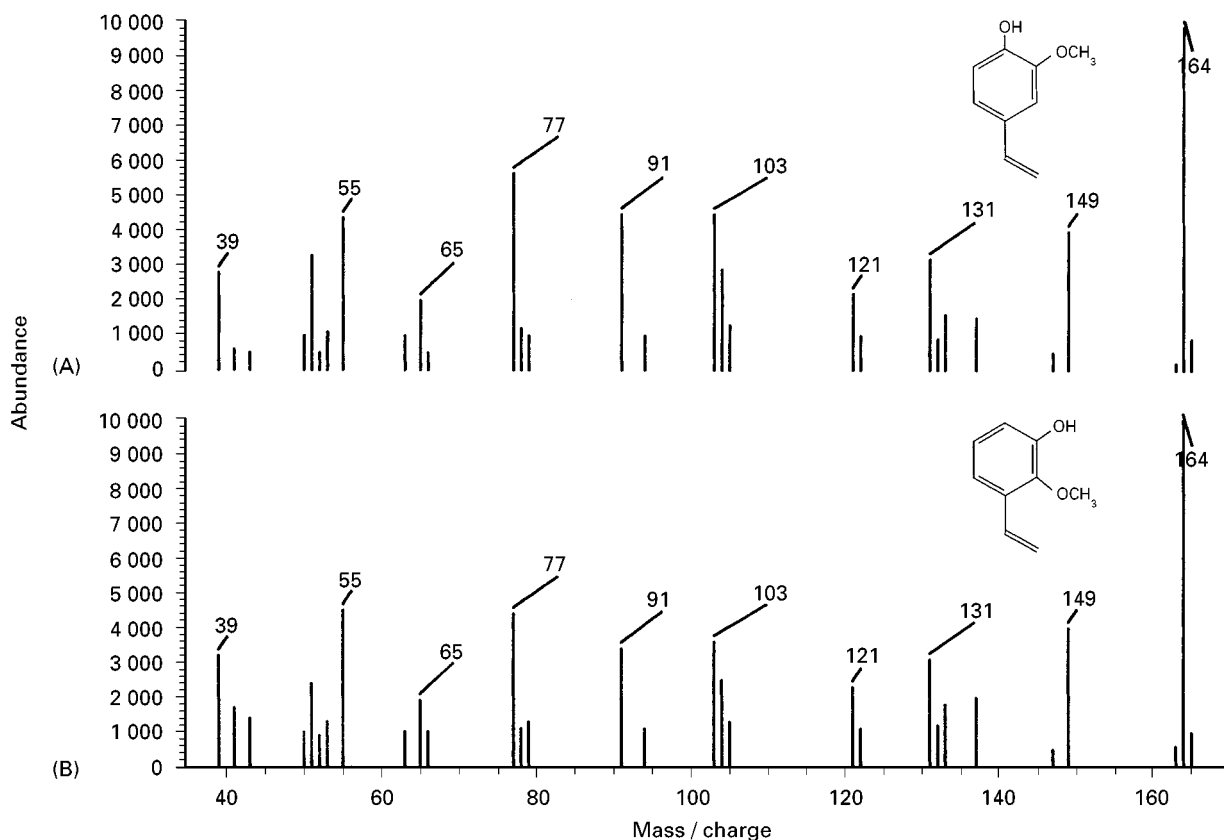

Figure 7 Retention indices on OV-101 and DB-Wax and mass spectra of (A) eugenol (RI(OV-101): 1323; RI(DB-Wax): 2158) and (B) 2-methoxy-3-hydroxy-allylbenzene (RI(OV-101): 1325; RI(DB-Wax): 2160). (Courtesy of Professor K.-H. Kubeczka, University of Hamburg.)

free: there are some rare exceptions in which pairs of compounds have almost identical mass spectra, and also have retention indices which fall within the instrumental and analytical limit on two different stationary phases. This is the case of mass spectra and retention indices of 2-methoxy-3-hydroxy-allylbenzene and eugenol on OV-101 and DB-Wax (Figure 7).

A last approach, no less important, is GC/single ion monitoring (SIM)-MS, which is very selective and as a consequence the most reliable procedure for quantitative analysis. In particular, GC-SIM-MS can be an alternative to MDGC for direct determination of enantiomeric ratios of optically active components in the essential oil. A suitable choice of specific diagnostic ions can overcome the interferences to a correct determination of enantiomeric ratio due to peaks coeluting with the two (or more) enantiomers.

Identification by GC-FTIR

Although MS is the preeminent technique to identify a component in a complex mixture analysed by GC, it has some drawbacks, e.g. in the differentiation of structural isomers giving identical mass spectra.

Fourier transform infrared spectroscopy (FTIR) combined with GC has emerged as a powerful technique and as the ideal complement to MS for component identification in complex mixtures, thanks to its ability to distinguish geometric and positional isomers and to characterize organic functions; moreover, the identification of a compound through its FTIR spectrum is very reliable. To exploit in full the complementarity between FTIR and MS data, systems combining online GC, FTIR and MS or FID have also been assembled. In spite of this, FTIR, as a detector for GC, is not as popular as MS, because of the lack of sensitivity for many compounds when compared to GC or GC-MS systems. Another reason is the lack of extensive libraries. The cheapest and most widely adopted GC-FTIR system is based on the so-called light-pipe interface, which produces vapour-phase spectra: this makes existing collections of spectra useless for automatic identification, because they are mainly recorded in the liquid or solid phase. Some relatively small collections of vapour-phase spectra of compounds in the essential oils and flavour fields are now commercially available.

GC-Isotope Ratio Mass Spectrometry

The stable isotope ratio is an important parameter in biochemistry, nutrition and drug research, and in origin assignment and authenticity control of essential oils. This ratio has gained in importance with the introduction of on-line coupled GC-isotope ratio MS systems, where the analytes eluting from the GC column are combusted to carbon dioxide in an oven and analysed in an isotope ratio mass spectrometer, adjusted for the simultaneous determination of mass 44 ($^{12}\text{C}^{16}\text{O}_2$), 45 ($^{13}\text{C}^{16}\text{O}_2$, $^{12}\text{C}^{16}\text{O}^{17}\text{O}$) and 46 ($^{12}\text{C}^{16}\text{O}^{18}\text{O}$) in the nmol range and with high precision ($\leq 0.3\%$). The actual ratio is obtained from the ratio of the areas of two isotope peaks; this value is then compared to a standard value by applying the following expression:

$$\delta = (R_{\text{sa}}/R_{\text{st}} - 1) \times 1000$$

where R_{sa} is the isotope ratio of the sample and R_{st} that of the standard; $\delta\text{-C}^{13}$ is given in parts per thousand.

The $\delta\text{-C}^{13}$ value is particularly effective when combined with enantiomeric recognition of the chiral component(s) characterizing an essential oil. Enantiomer GC analysis may fail in authenticity determination when recemates of natural origin are present, or when racemization occurs during processing or storage of natural products, and chiral essential oil components are blended with the corresponding synthetic chiral compounds.

Enantiomeric GC separation combined with isotope ratio MS is a very effective method of evaluating the authenticity of an essential oil since the mass spectrometer detects enantiomers of the same natural source which have identical $\delta\text{-C}^{13}$ values. As a consequence, identical $\delta\text{-C}^{13}$ ratios are expected for enantiomers from genuine compounds, even if the chiral molecules to be analysed are partially racemized: it seems improbable that racemic compounds would be synthesized through different biochemical pathways in the same organism. Enantiomer GC-isotope ratio MS or, even better, multidimensional GC-isotope ratio MS of enantiomers can therefore detect blends of optically pure chiral essential oil components with synthetic racemates.

Sensory Analysis (GC-Sniffing Detection)

The GC profile of an essential oil does not necessarily reflect the sensory properties of its components. Some of the components, present in large quantities, are not

relevant to the overall smell while others, present in trace amounts but with low detection thresholds, are not revealed by FID, nitrogen-phosphorous detector (NPD) or flame photometric detector (FPD) but are detected by GC-sniffing. Sensory methods are therefore needed to detect trace components responsible for the smell of an essential oil. A sniffing device is very simple and inexpensive to assemble. Several have been described: in a typical one, the flow of the gas eluting from the analytical column is split through a T piece on one side to an FID and on the other to the sniffing port, which consists of a shaped glass funnel. A stream of air (or nitrogen) saturated with water is sent coaxially with the mobile phase to the sniffing port to avoid dehydration of the nasal tissues. The results of olfactory measurements can be qualitative, giving a description of the odour of each peak corresponding to an odour-active component; on the basis of these qualitative results, a semiquantitative evaluation is also possible. Several approaches have been developed for semiquantitative sensory evaluation: the best known are Charm analysis developed by Accree and AEDA (aroma extract dilution analysis), developed by Grosch. Charm analysis is based on sniffing a series of decreasing dilutions of the components eluting in the GC odour-active zones characterized with a specific sensorial descriptor. The beginning and end of each particular odour perception are fixed. Charm values are calculated through the formula $c = d^{n-1}$, where n is the number of coincident responses and d is the dilution factor. AEDA is similar but it uses a dilution factor equal to the last dilution in which an odour-active component is detected.

GC Profile Analysis

Identification and quantitation of the characterizing components are not always sufficient to discriminate between essential oils from a single species, or to classify them, evaluate their quality or origin, or detect adulterations. On the other hand, although sensory analysis (sniffing) is of prime importance in overall evaluation, it is also sometimes insufficient and, above all, it is generally considered insufficiently objective. This is particularly true when series of samples of different origins have to be evaluated at the same time. In these cases, the overall GC profiles of the essential oils under investigation (or the profile of the volatile fraction obtained through related sampling techniques) can be a successful marker to characterize and/or discriminate between them objectively. However, essential oil profiles are so complex that multivariate statistics is needed to obtain an exhaustive evaluation. Several statistical approaches have

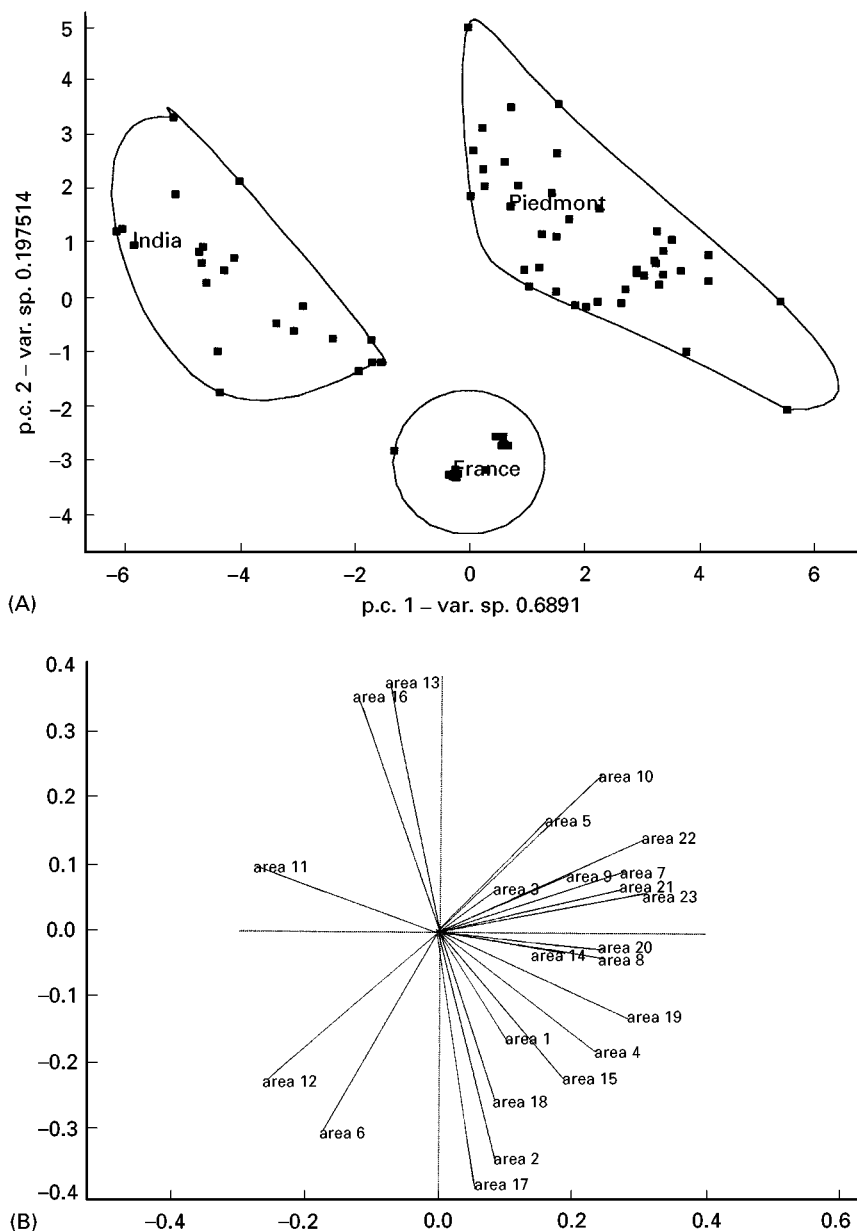

Figure 8 (A) Scatterplot of principal components and (B) distribution of the loadings considered for PCA of a set of peppermint essential oils of different origins (Piedmont (Italy), France and India.)

been proposed (cluster analysis, fuzzy clustering, linear discrimination analysis, neural network, principal component analysis (PCA), and principal component similarity analysis). PCA is successful in analysing multivariate data, since it can investigate relationships between large numbers of variables, and it is useful for reducing the numbers of variables in a data set by finding linear combinations of those variables that explain most of the variability. These characteristics make PCA successful in comparing and discriminating groups of essential oils, for instance versus a series of reference samples,

in particular for routine purposes. The success of PCA is strictly related to a correct selection of variables (the peak areas corresponding to specific essential oil components, generally chosen among those whose peak areas are detectable and reproducibly measurable in all samples under investigation). **Figure 8** shows the distribution of the loadings considered for PCA and the scatterplot of principal components of a set of peppermint essential oils of different origins (Piedmont (Italy), France and India): PCA clearly distinguishes the origins of the samples.

Conclusions

Although essential oil analysis is now a well-established field, further work is needed, not only to improve sample preparation and analysis techniques, but also to deal with one of the main aims of this research field: to isolate and elucidate the structure of new odorous compounds. These studies evolve along two main lines. The first and classical one combines isolation and spectroscopic techniques and mainly concerns new mono- and sesquiterpenoids. The second mainly involves the so-called supervolatile fraction and perfumed trace compounds, two fractions that play a fundamental role in odour impact. For the supervolatile fraction, some topics requiring further study are HS combined with effective cryotrapping techniques, systems for direct GC injection of large volumes of gas samples and GC columns with a high retention capacity. For compounds present in the essential oil at the p.p.m. level (e.g. pyridine derivatives in peppermint and orange oils), a number of points would benefit from further investigation. These include increased selectivity of sample preparation techniques and increased sensitivity and selectivity of analysis techniques.

Introduction

Essential oils are mixtures of mainly volatile components belonging to different chemical classes. They

are characterized by a pleasant smell and are generally obtained by steam distillation of aromatic plants, with the exception of citrus peel essential oils, which are produced by cold-pressing the peel of the fruits. This process involves the abrasion of peel and the removal of the oil in an aqueous emulsion that is subsequently separated in a centrifuge. Other methods may be water distillation or extraction with sub- or supercritical fluids. Essential oils are not soluble in water, but are quite soluble in alcohol.

Resins can be either natural or prepared: natural resins are exudations from trees or plants, and are formed in nature by the oxidation of terpenes; prepared resins are oleoresins from which the essential oils have been removed. Resins are mixtures of many components; they are solid, amorphous, more or less coloured, nonvolatile, with a characteristic smell, insoluble in water, but soluble in alcohol or other organic solvents.

Balsams are natural raw materials exuded from a tree or a plant; they have a high content of benzoic acid, benzoates or cinnamates.

The main constituents of essential oils, balsams and resins are terpene or aromatic hydrocarbons, and their oxygenated derivatives (alcohols, aldehydes, esters, ketones, oxides, etc.).

The physiological role of oils and resins in plants and trees is not well understood. It is likely that they play a role as lures for insects. They may also serve to protect plants from parasites, increase the rate of transpiration and act as a seal for wounds. They are largely used in perfumery, food or pharmaceutical industries, as flavouring agents or because of their different pharmacological actions.

Characterization of Essential Oils, Balsams and Resins

Essential oils may be characterized by the determination of physicochemical properties such as boiling point, freezing point, solubility, density, optical rotation, refractive index, etc. These parameters can also help in the detection of adulteration. For the study of the qualitative and quantitative composition of essential oils and resins, chromatographic methods are the techniques of choice. Since the main part of the oil consists of volatile components, gas chromatography (GC) equipped with FID (flame ionization) or MS (mass spectrometer) detectors is the most used technique.

High performance liquid chromatography (HPLC) is also widely used for separation of semi-volatile or nonvolatile components, for preparative purposes, or for the analysis of thermally labile components. The limitation of HPLC is detection, because many com-

ponents of essential oils do not absorb in the UV-visible region, and UV detectors are the most popular in HPLC. Thin-layer chromatography (TLC) is a very widely used chromatographic technique, and modern HPTLC can be advantageously used instead of HPLC or GC in many analytical situations.

Some of the advantages of TLC are its simplicity, economy in materials, simultaneous analysis of a large number of samples and the use of complementary post-chromatographic universal and selective detection methods. Some disadvantages of TLC, such as the long times required for development or the difficulties in controlling the speed of solvent migration, may be overcome by OPLC (overpressured layer chromatography). OPLC, developed by Tyihak and co-workers at the end of the 1970s, is a planar liquid chromatographic technique with advantages over classical TLC and HPLC: the stationary phase is covered completely by a flexible membrane under external pressure and, because the eluent is introduced to the layer by means of a pump, the solvent flow rate may be controlled. Improved separation efficiency, shorter time requirement, better resolution, and lower solvent consumption than classical TLC or HPLC can thus be obtained. Moreover, OPLC can be used for analytical or preparative purposes and maintains all the advantages already mentioned for classical TLC.

Another advance in the development of TLC is chromatography on permanent rod-shaped layers (Chromarods), whose mechanical and chemical properties permit detection of the separated components in an ionization detector; this technique was developed in the late 1960s and can be successfully used for quantitative separations of substances that cannot be analysed by GC because of their low volatility.

There are many papers on planar chromatography that well illustrate the most recent developments of this technique: the use of multidimensional development, the coupling with particular detectors such as MS or FT-IR detectors, or the use of fully computerized image processing instruments. All these developments are accompanied by improvements in the performance and in the reproducibility of pre-coated layers for planar chromatography.

The literature reports some applications of planar chromatography to the analysis of essential oils, balsams and resins, to obtain different information. Methods have been developed that use both conventional TLC, HPTLC and OPLC for analytical and/or preparative separations. Only a few papers have been published on the separation of terpenes and related substances on Chromarods. One of the reasons for this is probably the volatility of terpenes of low

relative molecules mass, leading to low, irreproducible FID response. Resins have been separated from arnica (benzene/chloroform, 67:33) and Tolu balsam (benzene/chloroform/formic acid, 69:29:2), but the results obtained were not satisfactory. The number of applications is limited, if compared with the applications of GC or HPLC to the analysis of essential oils and plant extracts. However, often TLC is essential as a simple analytical and preparative technique. A recent review summarized the chromatographic methods reported by the *European Pharmacopoeia* (2nd edn) for the analysis of products from medicinal plants, including essential oils, balsams and resins. Over half of the methods reported for medicinal plant products are chromatographic methods, of which TLC represents 82%.

Preparative TLC

Essential oils and resins are complex mixtures containing numerous components that belong to different chemical classes present in different concentration. Often it is necessary to fractionate the mixture into single chemical classes or to isolate single components, particularly useful for the determination of properties such as authenticity, geographical origin or pharmacological activity.

This fractionation can be carried out by preparative TLC. For example, for detecting illegal adulteration of pharmacognostic mint (*Mentha arvensis*) or peppermint (*M. piperita*) oils with racemic menthyl acetate, samples were separated by TLC (polygram SIL G/UV plates, CH₂Cl₂ as mobile phase) and the zone of menthyl acetate extracted from the plate and analysed by chiral capillary GC. Since natural mint oils contain 100% of the (–)-isomer of menthyl acetate, the presence of the (+)-isomer can be used to quantify this kind of adulteration. In this case, pre-separation is necessary to obtain a reliable stereodifferentiation without problems of peak overlap in a direct GC analysis.

TLC has been used as preparative tool to obtain pure components to be used for further characterization. For example, components of the sesquiterpene fraction of camomile oil were separated by semipreparative TLC. The components so obtained – *trans*-farnesene, chamazulene, *cis*-en-in-dicycloether, *trans*-en-in-dicycloether, (–)- α -bisabolol, (–)- α -bisabolol oxide A, and (–)- α -bisabolol oxide B – were analysed by GC-MS, and the MS spectra were used to build a database since mass spectra of these components are not included in some commercial MS libraries. **Figure 1** shows the TLC separation obtained using silica gel TLC plates. **Table 1** reports the R_F values and identification of components.

Figure 1 TLC chromatograms of tetraploid camomile (CFH) essential oil obtained by steam distillation (A), compounds isolated from CFH oil (B) and separation of *trans*-farnesene and chamazulene (C). Mobile phase: (A) and (B) dichloromethane/toluene/ethyl acetate (70:28:2, v/v/v); (C) cyclohexane. Detection by spraying the plates with 1% vanillin solution. (Reproduced with permission from Zekovic Z, Pekii B, Lepojevic Z and Petrovic L (1994) *Chromatographia*, 39: 587–590.)

Preparative separations have also been carried out by OPLC to isolate antifungal compounds of the essential oil obtained by water distillation of the fresh bark of *Ocotea usambarensis* from Rwanda. The strategy followed for characterization of essential oil constituents is illustrated in **Figure 2**. This scheme shows how a combination of chromatographic techniques, including TLC, can be useful to characterize bioactive constituents of medicinal plants.

Quantitative Analysis by TLC

Some methods have been developed for the quantitative analysis of the main volatile components of essential oils by TLC as a rapid and easy alternative to other chromatographic determinations, in particular GC and HPLC which are more expensive and time-consuming.

It is difficult to find applications of TLC densitometry to problems in the field of essential oils, e.g. for the quantification of individual components, probably because of the volatility of the various components. One example is the quantitative determination of linalool, linalyl acetate and terpinen-4-ol in lavender oil. The first two compounds are the main components of the oil.

Table 1 hR_F values of camomile oil components separated in Figure 1

N	Compounds	hR_F (%)		Colour
		A, B	C	
1	<i>Trans</i> -farnesene	93.22	64.61	Dark green
2	Chamazulene		46.15	Dark red
3	<i>Cis</i> -en-in-dicycloether	63.13	–	Light brown
4	<i>Trans</i> -en-in-dicycloether		–	
5	(–)- α -Bisabolol	41.53	–	Violet
6	(–)- α -Bisabolol oxide A	20.76	–	Yellow
7	(–)- α -Bisabolol oxide B	16.94	–	Yellow

A,B, mobile phase dichloromethane/toluol/ethyl acetate (70 : 28 : 2, v/v/v). C, mobile phase cyclohexane. (Reproduced with permission from (1994) *Chromatographia*, 39: 587–590.)

Figure 3 shows the TLC and GC analysis of a lavender oil. The quantitative results obtained with the two techniques are comparable. This result shows that TLC densitometry is a good technique for both

qualitative and quantitative analysis of the main components of essential oils. It can be useful in the identification of an oil, and can simultaneously also detect less volatile components.

Other examples are the quantitative determination of citral in citrus oils and 1,8-cineole in eucalyptus oils. The determination of citral (a mixture of two terpene aldehydes, neral and geranial) is of particular importance for citrus oils, mainly for lemon oils. TLC determination of citral has been carried out on silica gel plates, developed with hexane/chloroform (70 : 30) and measured at 250 nm with a TLC scanner. The results were compared with those obtained by GC, and the ratio between TLC and GC values was constant at 0.8.

Eucalyptus essential oil contains a high amount of 1,8-cineole, an oxygenated monoterpene. In recent years, interest in developing new uses for cineole-rich eucalyptus oils has been renewed. The determination of 1,8-cineole by TLC has been carried out using silica gel plates and a mixture of light petroleum/chloroform (70 : 30) as mobile phase. Visualization is with 4-dimethylaminobenzaldehyde-S reagent (4-DMAB) and quantitation is with a scanner. Quantitative results compared with GC-MS data were found to be essentially identical.

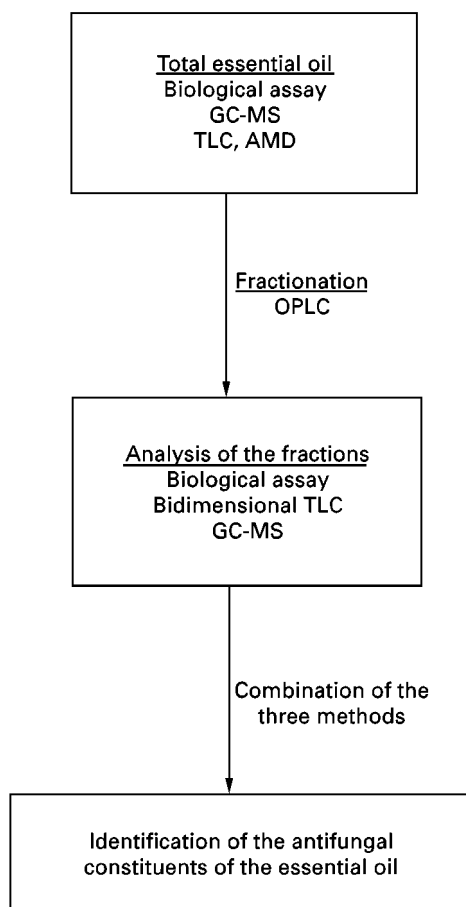

Figure 2 Strategy for the characterization of essential oil constituents from the bark of *Ocotea usambarensis* (Laureaceae). (Reproduced with permission from Hostettmann K., Terreaux, C, Marston, A and Petterat O, (1997) *Journal of Planar Chromatography*, 10: 251–257.

TLC for Detection of Authenticity and Botanical Origin

TLC can be used for screening samples to establish their authenticity and botanical origin. An example is the determination of the quality of cinnamon by TLC densitometry. Cinnamon is one of the oldest known spices; the cinnamons of commerce are derived from the dried inner bark of several species of *Cinnamomum*. Cinnamon oil derived from the inner bark of *Cinnamomum zeylanicum* Nees is generally

Figure 3 TLC (middle), densitometry (upper) and GC (lower) of lavender oil. TLC conditions: 20 × 20 cm plates, coated with 0.25 mm silica gel 60. Mobile phase: dichloromethane/methanol, 10 : 1.

Detection: anisaldehyde/sulfuric acid ($\lambda = 680$ nm); copper-acetate/phosphoric acid (white light); copper-sulfate/phosphoric acid followed by sulfuric acid spray (white light).

Sample volume: 15 mL of a 5% dichloromethane solution of oil or pure standard components. GC conditions: 25 m × 0.32 mm i.d. HP-5 fused silica capillary column (0.17 μ m film thickness); carrier gas: H₂; detector (FID) and injector (split) at 250°C. Temperature program: 60–240°C, 6°C min⁻¹. (Reproduced from (1989) *Mikrochim. Acta (Wien)*, 3: 1–6, with permission from Springer-Verlag, Wien.)

considered to have a better flavour, and commands the highest price.

This oil can be adulterated with cinnamon leaf or root bark oils, that have a different composition from inner bark oil and are less valuable. Moreover, some countries consider oil obtained from *C. cassia* Blume as cassia oil, and it is unlawful to present cassia as cinnamon, or to prepare mixtures of the two and present the result as cinnamon.

Figure 4 shows the TLC densitometry separation of polar aromatic semivolatile compounds of cinna-

mon and cassia. As can be seen, cinnamon and cassia oils can be easily distinguished because of the presence of higher amount of coumarin and the absence of eugenol in cassia oil.

Another example is the method developed to discover the poisonous Japanese star anise or shikimi fruits (*Illicium anisatum*), when they are mixed with those of the Chinese anise or star anise (*I. verum*). Miristicin only occurs in the essential oil of shikimi, albeit in small amounts, but it is absent in star anise. TLC allows the detection of an admixture of only 5% shikimi, as shown in Figure 5.

Figure 4 Separation of cinnamon and cassia oils by silica gel HPTLC plates. (A) Authentic sample of essential oil from the inner bark of *Cinnamomum zeylanicum* Nees; (B) cinnamon oil adulterated with leaf oil; (C) authentic sample of cassia oil from *C. cassia* Blume. Peaks: 1, cinnamyl alcohol; 2, coumarin; 3, eugenol; 4, 2-methoxy-cinnamaldehyde; 5, *trans*-cinnamaldehyde; 6, cinnamyl acetate. TLC conditions: TLC plates predeveloped in hexane/triethylamine (46 + 4, v/v) and separation in unsaturated chamber with hexane/chloroform/triethylamine (90 + 6 + 4, v/v/v). The separation was scanned at $\lambda = 255$ nm. (Reproduced with permission from Poole SK, Kiridena W, Miller KG and Poole CF (1995) *Journal of Planar Chromatography*, 8: 257–268.

Determination of the Antioxidant Activity of Essential Oils

The versatility of TLC is also illustrated in the following example, where the composition and the antioxidant activity of essential oils from oregano plants

Figure 5 TLC chromatogram of (1) mixture of shikimi fruit and star anise fruit oils; (2) mixture of standard compounds; and (3) reference mixture. Key: A, anethole; F, foeniculin; M, myristicin; S, safrol; r, red; b, blue. (Reproduced from (1990) *Deutsche Apotheker Zeitung*, 130: 1194–1201, with permission from Deutscher Apotheker, Verlag.)

grown wild in Greece is studied. The composition has been studied by GC-MS (ITD) and carvacrol found to be the main components. A variety of oregano, *O. vulgare* subsp. *hirtum*, has a high thymol content, while the other plant species contain less than 1% of thymol. The antioxidant activity of essential oils, pure carvacrol, thymol and butylated hydroxytoluene (BHT) was tested on silica gel TLC plates. The plates were sprayed with a solution of β -carotene and linoleic acid and then exposed to daylight until the background colour disappeared. Spots of components having antioxidant activity remained yellow for a longer period.

TLC for the Analysis of Phenolic Compounds

TLC has been used to analyse less volatile components such as flavonoids, phenolic acids or coumarins. These classes of components are very important for the characterization of plant materials, and can have specific pharmacological activities. For example, the spasmolytic activity of camomile is mainly due to the presence of flavonoids apigenin, apigenin-7-*O*- β -glucoside and its acetylated derivatives. **Figure 6** show the HPTLC chromatogram of camomile flavonoids. HPTLC is the fastest chromatographic method for qualitative identification of apigenin and its glucosides in camomile. Quantitative

Figure 6 TLC chromatogram of camomile flavonoids. Key: C, dry extract of camomile ligulata flowers (CLF); AC, dry extract of autofermented CLF; A, apigenin; L, luteolin; ADG + AMG, mixture of apigenin-7-*O*- β -diacetylglucoside and apigenin-7-*O*- β -monoacetylglucoside; AG, apigenin-7-*O*- β -glucoside. Experimental details: silica gel 60 F254 HPTLC plates precoated with concentrating zone; eluent: benzol/ethylmethylketone/methanol (5 : 5.3 : 1.5); detection, $\lambda = 254$ nm. Yellow spots of separated flavonoids appear after spraying the plate with 96% sulfuric acid and heating briefly to 120°C. (Reproduced with permission from (1994) *Chromatography*, 39: 587–590.

Figure 7 Densitogram of a camomile sample. Peaks: 1, apigenin-7-*O*-glucoside; 2, caffeic acid; 3, apigenin; 4, umbelliferone; 5, ferulic acid; 6, herniarin. (Reproduced from Menziani E, Tosi, B, Bonora A, Reschiglian, P and Lodi G (1990) *Journal of Chromatography*, 511: 396–401, with permission from Elsevier Science.)

determination is possible using appropriate instruments.

With the development of the automated multiple development (AMD) technique, planar chromatography may be applied successfully to the analysis of complex matrices. AMD-HPTLC gives the opportunity to carry out separation processes using a gradient development mode. An optimized AMD-HPTLC procedure has been applied to the separation of phenolic compounds (flavonoids, coumarin, phenylcarboxylic acids) of *Chamomilla recutita* flower extracts. **Figure 7** shows the densitogram obtained under optimized conditions: HPTLC plates and stepwise gradient development in an enclosed chamber. Fifteen steps were used, with drying times 6 min for the first four steps, then 4 min for the next 13 steps, and 10 min for the last step. As preconditioning, nitrogen was bubbled through water; the preconditioning time was 15 s for each step.

Cold-pressed citrus essential oils contain about 90–99% of volatile components, with a nonvolatile residue that ranges from approximately 1 to 10% in the different oils and consists, in large part, of many oxygen containing heterocyclic compounds, mainly the coumarins, psoralens and polymethoxylated flavones. The qualitative and quantitative composition of the nonvolatile residue characterizes the different citrus oils, and play an important role in identification, quality control and authenticity. The literature reports numerous TLC methods for the analysis or preparative isolation of oxygen heterocyclic

compounds in citrus oils. An OPLC method has been developed to separate these components in seven citrus oils: sweet orange, bitter orange, mandarin, grapefruit, lemon, bergamot and Mexican lime. The OPLC separation is fast (10 min) and allows the differentiation of the various oils and the determination of possible contamination or sophistication of the oils.

In particular, many methods for the determination of bergapten (5-methoxypsoralen) have been reported, because of the problems linked with its phototoxicity. The *European Pharmacopoeia* (3rd edn) reports a TLC method to detect the presence of bergapten in bitter orange flower oil. Bergapten shows a greenish-yellow fluorescence at 365 nm. The presence of this psoralen may be an indication of the presence of bitter orange peel oil.

Conclusion

The examples described above show that both analytical and preparative, planar chromatography can be used successfully in a very wide range of applications to essential oils, balsams and resins. Thin-layer chromatography has the ability to separate mixtures of substances of similar structure and the flexibility of a variety of methods of detection. It also has the advantages of being cheap and easy to perform. As recently stated by J. Sherma in a review that appeared in *Analytical Chemistry* in 1996, 'fully instrumental planar chromatography, performed properly is the most economic, powerful, and accurate quantitative analytical method for mixtures of soluble substances of low vapour pressure'.

Introduction

Although some explosives are thermally labile and others are not volatile enough, gas chromatography (GC), with a variety of detectors, has been found to be a good method for separation and analysis of a certain number of organic explosives. This can be achieved when using the GC under controlled experimental conditions, such as the temperature of the column, injector and detector, type and length of the column, special injection techniques and the use of selective detectors.

In this article we will describe some of the GC methods used for the analysis of explosives – the preferred columns, the injection techniques and the preferred detectors. In order to be able to evaluate GC as a method for the analysis of explosives, it is necessary to present a short overview of the main organic explosives (Figure 1). These explosives can be divided into the three following groups:

1. Nitroaromatic compounds
2. Nitrate esters
3. Nitramines

The most widely used nitroaromatic explosive is 2,4,6-trinitrotoluene (TNT). Nitrate esters include ethylene glycol dinitrate (EGDN), glycerol trinitrate (nitroglycerin, NG) and pentaerythritol tetranitrate (PETN). Nitramine explosives include 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX), 1,3,5,7-tetranitro-1,3,5,7-tetrazacyclooctane (HMX) and 2,4,6-*N*-tetra-nitro-*N*-methylaniline (tetryl).

Additional nitroaromatic compounds encountered are 2-, 3- and 4-nitrotoluene, 2,4- and 2,6-dinitrotoluene (DNT) and degradation products of TNT such as 2-amino-4,6-dinitrotoluene and 4-amino-2,6-dinitrotoluene.

Extraction Procedures

Various extraction procedures can be used. Several of them are described as follows.

Extraction of Explosives from Water

1. Liquid-liquid extraction is carried out with a separation funnel using 1 L of water (containing TNT and other nitroaromatic compounds) and shaking three times with 30 mL of methylene chloride. The combined organic phases are dried over anhydrous sodium sulfate and reduced in volume to 1 mL in a rotary evaporator at 40°C, after the exchange of the methylene chloride with methanol. Other solvents can be used, such as benzene or toluene for nitroaromatic compounds, or isoamyl acetate for nitramines. Extraction can also be carried out using 100 mL of water. In that case only about 6 mL solvent are required.
2. Solid-phase extraction is carried out using Amberlite XAD-2, XAD-4, XAD-8 resins (1 : 1 : 1), C18 phases, phenyl phases and cyano phases, 2.5 g of XAD resin is placed in a 15 × 1 cm i.d. glass column plugged with silanized glass wool and flushed with methanol and water. 1 L of water, containing the explosives, is forced through the column at a flow rate of 30 mL min⁻¹, using nitrogen pressure. The column is then dried with a stream of nitrogen and eluted twice with 15 mL of methylene chloride. Drying, concentration and solvent exchange are carried out as in the liquid-liquid extraction method. Recovery for TNT is 95%.

Extraction of Explosives from Soil

1. 10 g of undried, homogenized soil is extracted with 25 mL acetone in an ultrasonic bath for 30 min. The extract, after passing through filter paper, is ready for analysis. Recovery for RDX is 95%.
2. Supercritical fluid extraction (SFE) can be used for the extraction of explosives from soil. Extraction is made with supercritical CO₂ at 5000 psi and 50°C. The dynamic SFE mode is being used, where fresh supercritical fluid is flushed continuously through the sample matrix and then passes through a trap in which the analytes of interest are collected. This mode of operation gives a better recovery than the static mode.

Capillary Columns

Low polarity columns are used, because the polar interaction of the nitro groups can produce irreversible adsorption on the stationary phase or decomposition of the explosives at higher temperatures.

Figure 1 Structure of commonly used explosives (see text for abbreviations used).

Columns commonly used for the separation and analysis of explosives include DB-1 (BP-1 or CP-Sil 5CB) (100% dimethylpolysiloxane) and DB-5 (5% phenylmethylpolysiloxane). Other columns, such as DB-17 (50% phenylmethylpolysiloxane) and OV-225 (50% cyanopropylphenylmethylpolysiloxane) have also been used, but only for separation of nitroaromatic compounds.

Another important factor is the column length. Compounds which evaporate at higher temperatures, such as RDX and PETN, should be eluted from the column as fast as possible in order to minimize their decomposition. This can be done by either increasing the flow rate of the carrier gas or decreasing the length of the column. Columns as short as 1.5 m have been used although short columns will, of course, have a poorer separation capability.

Table 1 shows a summary of GC columns and conditions which have been used for the separation of a variety of explosives.

Injectors

Injectors used include split-splitless injectors at temperatures ranging from 170°C to 250°C, a flash vaporizing injector at 270°C and a temperature-programmable injector (cooled with liquid CO₂),

programmed from -5°C to 250°C at a rate of 200°C min⁻¹. A temperature-programmed injector is much better suited for GC analysis of thermally labile compounds, as it will minimize decomposition in the injector.

Detectors

Electron-Capture Detector (ECD)

An electron-capture detector is an ionization chamber in which electrons are produced from a radioactive source (usually tritium or nickel-63). These electrons are injected into a stream of inert carrier gas (helium or nitrogen), where they reach thermal energy equilibrium through collisions with the carrier gas. The thermal electrons are collected at an anode, thus producing a standing current. When an electron-capturing compound (the sample), such as a halogen- or a nitro-containing compound, is introduced into the carrier gas, the standing current is reduced. The reduction in current is proportional to the concentration of the sample. Electron-capture detectors have a fast response and are highly sensitive for most electron-capturing compounds. However, their specificity for explosives is low. Detection limits are in the 5–50 pg range for the various explosives.

An example is presented in Figure 2, which shows the GC-ECD chromatogram of a soil sample taken from a former explosives storage bunker. The column used was a 30 m, DB-5 capillary column, held at 180°C isothermal. The dinitrotoluenes were by-products of TNT, while the aminodinitrotoluenes were microbial degradation products of TNT.

Thermal Energy Analyser (TEA) Detector

The TEA detector, also known as a chemiluminescence detector, is a nitrogen-specific detector. In the TEA detector, nitro compounds are pyrolysed to form NO radicals, which pass into a reaction chamber where they are oxidized by ozone to form electronically excited nitrogen dioxide (NO₂^{*}). The excited nitrogen dioxide decays back to its ground state with emission of chemiluminescent light in the near-infrared region ($\lambda \cong 0.6\text{--}2.8 \mu\text{m}$). The intensity of the emitted light is proportional to the NO concentration and hence to the nitro compound concentration. The TEA detector, although more specific for explosives than the ECD, is less sensitive by one to two orders of magnitude. An example is presented in Figure 3, which shows the GC-TEA chromatograms of pure PETN and of a sample taken from the debris of a bombing, containing traces of PETN.

Table 1 GC columns used for separation of explosives

Column type	Column dimensions	Temperature programme	Carrier gas	Detector/s used	Explosives analysed
DB-1	30 m × 0.32 mm i.d. 0.25 µm film	70–250°C at 3°C min ⁻¹	He	MS	DNT, TNT
DB-1	5 m × 0.20 mm i.d. 0.33 µm film	75–225°C at 20°C min ⁻¹	He	ECD, MS	Semtex ^a , PETN, RDX
DB-1	15 × 0.25 mm i.d. 0.25 µm film	80–250°C at 25°C min ⁻¹	He	MS	TNT, Tetryl, RDX, HMX, PETN
BP-1	12.5 m × 0.22 mm i.d. 0.25 µm film	60–240°C at 40°C min ⁻¹	He	TEA	NG, TNT, RDX
BP-1	12 m × 0.25 mm i.d. 0.25 µm film	60–250°C at 40°C min ⁻¹	He	ECD	EGDN, NG, PETN, DNT, TNT, RDX
DB-5	10 m × 0.32 mm i.d. 0.25 µm film	50–250°C at 10°C min ⁻¹	He	TEA	EGDN, NG, PETN, DNT, TNT
DB-5	15 m × 0.25 mm i.d. 0.25 µm film	50–260°C at 25°C min ⁻¹	He	MS	DNT isomers
DB-5	1.5 m × 0.25 mm i.d. 0.25 µm film	60–220°C at 20°C min ⁻¹	He	MS	NG, PETN
CP-Sil 5CB	20 m × 0.25 mm i.d. 0.25 µm film	50–90°C at 5°C min ⁻¹ 90–250°C at 3.5°C min ⁻¹	H ₂	ECD	DNT, TNT
DB-17	30 m × 0.32 mm i.d. 0.25 µm film	70–250°C at 3°C min ⁻¹	He	ECD, TEA	DNT, TNT
OV-225	30 m × 0.32 mm i.d. 0.25 µm film	70–250°C at 3°C min ⁻¹	He	ECD, TEA	DNT, TNT
OV-101	25 m × 0.25 mm i.d. 0.1 µm film	50–240°C at 40°C min ⁻¹	He	ECD	EGDN, NG, PETN, DNT, TNT, RDX, HMX, Tetryl
DB-1301	4.5 m wide bore 1.0 µm film	128–225°C at 30°C min ⁻¹	He or H ₂	ECD	DNT, TNT, RDX, HMX

^aSemtex is a plastic explosive containing RDX and PETN.

The chromatograms were recorded at two different injection temperatures: 170°C and 250°C. At 250°C PETN decomposes, therefore a decomposition peak appears in the chromatogram. The column used was a 10 m, DB-5 capillary. Injections at 170°C and

250°C were done with a split–splitless injector, in the splitless mode.

Gas Chromatography–Mass Spectrometry (GC-MS)

The good separation capability of capillary column GC, together with the high sensitivity and identification capability of the mass spectrometer, have made GC-MS a powerful method in analytical chemistry. The use of GC-MS for the analysis of explosives is limited by the thermal decomposition characteristics of some of the explosives. Precautions to be taken when analysing explosives by GC-MS are similar to those taken when using GC with any other detector.

GC-MS for the analysis of explosives has been used in three different ionization modes: electron ionization (EI), chemical ionization (CI) and negative-ion chemical ionization (NCI). The produced ions are mass separated by a mass analyser (magnetic sector, quadrupole or ion trap), detected by an electron multiplier, recorded by a data system and stored in the computer as a mass spectrum. There are different ways to display the results: (i) as a total ion

Figure 2 GC-ECD chromatogram of a sample taken from a former explosives storage bunker. Peak identity: 4: 2,6-dinitrotoluene; 5: 2,4-dinitrotoluene; 6: TNT; 7: 4-amino-2,6-dinitrotoluene; 8: 2-amino-4,6-dinitrotoluene; 9: RDX. Figure 3 GC-TEA chromatograms. (A) Pure PETN. (B) A sample from a bombing scene, containing PETN. Chromatograms were run at injection temperatures of 170°C and 250°C. Peak d is a decomposition product of PETN. (Reproduced from Kolla P (1994) *Journal of Chromatography A* 674: 309–318, by permission of Elsevier Science Publishers.)

chromatogram (TIC) or reconstructed ion chromatogram (RIC), which is equivalent to a GC chromatogram – a mass spectrum of each one of the GC peaks can be displayed; (ii) as mass chromatograms, which are GC chromatograms including only preselected masses. Each one of the GC separated compounds can be represented by one or several masses which are characteristic of the full mass spectrum.

Electron Ionization (EI)

The basic form of ionization in mass spectrometry is electron ionization (EI), where an electron beam, usually at an energy of 70 eV, collides with the molecules of the sample to transform them into positively charged ions. In addition, extensive fragmentation of the ions occurs, resulting in a mass spectrum which

Figure 4 GC-MS EI mass chromatograms of a mixture of explosives (10 ppb each), extracted from water by liquid-liquid extraction. (Reproduced from Yinon J (1996) *Journal of Chromatography A* 742: 205–209, by permission of Elsevier Science Publishers.)

does not always contain a molecular ion. The fragmentation patterns thus obtained can be correlated with specific functional groups, enabling recognition of many structural features in the analysed molecule. An EI mass spectrum of a molecule can, therefore, be considered a ‘fingerprint’ of that molecule and can be used as an identification tool.

An example is presented in **Figure 4** which shows the GC-MS EI mass chromatograms of a mixture of explosives (10 ppb each), extracted from water by liquid-liquid extraction with methylene chloride. Each of the explosives could be identified by at least one characteristic ion (in most compounds a fragment ion). The column used was a 15 m \times 0.255 mm i.d. DB-1 capillary column. Column temperature programme was 80°C to 250°C at 25°C min⁻¹. Injector temperature was programmed from -5°C to 250°C at 200°C min⁻¹. The mass spectrometer was an ion trap operated in the EI mode.

Chemical Ionization (CI)

In chemical ionization (CI) ions are formed by reaction of the sample molecules with a known pre-selected set of reagent ions. These reagent ions are produced by ion-molecule reactions in a reagent gas introduced in the ion source of the mass spectrometer at a pressure of 0.1 to 1.0 Torr. Common reagent gases are methane and isobutane.

CI mass spectra contain usually an MH⁺ ion and little fragment ions. It is, therefore, suitable for molecular weight identification. In many cases, in the CI mass spectrum of an explosive an MH⁺ ion might be observed, while in the EI mass spectrum of the same compound there is no molecular ion. For example, the EI mass spectra of NG and PETN are similar,

containing abundant ions at m/z 30 (NO⁺), m/z 46 (NO₂⁺) and m/z 76 (CH₂ONO₂⁺). However, they have different GC retention times, but this means that their identification is based on chromatographic properties. In the CI mass spectra of NG and PETN, MH⁺ ions are observed, at m/z 228 and m/z 317, respectively.

Negative-ion Chemical Ionization (NCI)

In negative-ion chemical ionization (NCI) a reagent gas at 0.1 to 1.0 Torr is introduced in the ion source of the mass spectrometer. This reagent gas acts primarily as a moderator in producing high concentrations of low energy electrons. Negative ions are formed in the analysed sample by electron capture. These ions are either molecular ions or (M-H)⁻ ions. Fragment ions are also formed by dissociation of part of the molecular ions. Special reagents can be introduced into the ion source causing ion-molecule reactions, thus forming characteristic adduct ions. For example, the NCI mass spectrum of TNT will contain abundant anions at m/z 227, M⁻, m/z 210, (M-OH)⁻, m/z 197, (M-NO)⁻ and m/z 181, (M-NO₂)⁻. The detection limit of explosives in the NCI mode is, in general, lower by one order of magnitude than in the positive CI mode.

Conclusions

While GC is a chromatographic method and needs comparison of retention times with standards, mass spectrometry is an identification method and provides a ‘fingerprint’ of the investigated compound. The combination of GC with MS incorporates both

separation and identification capabilities, and is therefore superior to GC alone.

Both GC and GC-MS, although being suitable techniques for the separation and analysis of explosives, have a limitation in that the injector and column have to be heated. This fact necessitates taking special precautions when dealing with the more thermally labile compounds. Liquid chromatography–mass spectrometry (LC-MS), where the injector and column are at room temperature, does not have these limitations, and is therefore a better choice when analysing the more thermally labile explosives. However, GC-MS is readily available in most analytical laboratories, while LC-MS is not. This situation is expected to change in the next 5 to 10 years, which will place LC-MS as the method of choice for the separation and analysis of explosives.

In both GC-MS and LC-MS, the addition of tandem mass spectrometry (MS-MS) provides an extra dimension for improved selectivity and therefore improved identification.

Introduction

Explosive analysis is important in different areas: explosive manufacture (quality and wastewater control),

forensic science and toxicology (investigation of explosions or of criminal actions) and environmental monitoring (water and soil analysis at sites intensively used for military purposes). **Figure 1** shows some of the more common explosives.

In the literature various methods and procedures have been described for analysing these compounds. In the last few years, the investigation of explosives in the water and soil around former ammunition plants,

Figure 1 Structures of common explosives.

munition depots or dumps dating back to World War II has become increasingly important. In these samples there are not only explosives but also their by-products and metabolites. For example, water samples from around the former ammunition plant at Elsnig (Saxony, Germany) contained many explosive-related compounds of various classes (Table 1).

These constituents, which range in concentrations from ng L^{-1} to mg L^{-1} , make it difficult to analyse such samples. However, to assess the toxic potential, reliable analysis of all the compounds down to the trace amounts (about $0.1 \mu\text{g L}^{-1}$) is necessary, as some are highly toxic, carcinogenic or mutagenic.

Capillary gas chromatography offers advantages of separation efficiency and favourable detection limits; however, because of the thermal instability and high polarity of some compounds, high performance liquid chromatography (HPLC) determination is often the method of choice. This requires thorough optimization of HPLC conditions (stationary and mobile-phase) as well as selective and sensitive detection systems and, in some cases, selective sample preparation or pre-separation of the sample into different fractions.

The aim of this article is to provide an overview of the possibilities given by HPLC methods to determine

explosive-related compounds in complex samples, including separation, detection and sample preparation, focusing in particular on compounds occurring in samples around former ammunition plants (Table 1).

Sample Preparation

Water Samples

Brown glass bottles should be filled up to the brim with water samples and the bottles made gas-tight, for example, using Teflon packings, and stored at 4°C . To prevent adsorption losses or degradation at the glass surfaces, the addition of methanol or acetonitrile or the use of silanized glass vessels is recommended. To prevent bacterial degradation, sodium azide (about 0.5g L^{-1}) can be added to the samples.

In principle, for extraction and enrichment, various methods such as liquid-liquid extraction (LLE), solid-phase extraction (SPE) or solid-phase microextraction (SPME) can be used.

Neutral compounds An effective and reproducible liquid-liquid extraction of neutral explosive compounds such as the nitroaromatics can take place with various solvents such as dichloromethane, ethyl

Table 1 Compounds in water samples in the neighbourhood of the former ammunition plant in Els nig

Compounds	Abbreviations
<i>Nitroaromatics and nitramines</i>	
2,4,6-Trinitrotoluene	2,4,6-TNT
Hexahydro-1,3,5-trinitro-1,3,5-triazine	RDX/Hexogen
2,2',4,4',6,6'-Hexanitrodiphenylamine	Hexyl
1,3-Dinitrobenzene	1,3,-DNB
2,4-Dinitrotoluene	2,4-DNT
2,6-Dinitrotoluene	2,6-DNT
3,4-Dinitrotoluene	3,4-DNT
Nitrobenzene	NB
2-Nitrotoluene	2-NT
3-Nitrotoluene	3-NT
4-Nitrotoluene	4-NT
Octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine	Octogen/HMX
1,3,5-Trinitrobenzene	1,3,5-TNB
<i>Chloroaromatics</i>	
Chlorobenzene	CIB
1-Chloro-2,4-dinitrobenzene	1-CI-2,4-DNB
1-Chloro-4-nitrobenzene	1-CI-4-NB
1,2-Dichlorobenzene	1,2-DCIB
1,4-Dichlorobenzene	1,4-DCIB
2,3-Dichloronitrobenzene	2,3-DCINB
2,5-Dichloronitrobenzene	2,5-DCINB
1,2,4-Trichlorobenzene	1,2,4-TCIB
<i>Amino- and aminonitroaromatics</i>	
2-Amino-4,6-dinitrotoluene	2-A-4,6-DNT
4-Amino-2,6-dinitrotoluene	4-A-2,6-DNT
2-Amino-4-nitrotoluene	2-A-4-NT
2-Amino-6-nitrotoluene	2-A-6-NT
4-Amino-2-nitrotoluene	4-A-2-NT
2,6-Diamino-4-nitrotoluene	2,6-DA-4-NT
2,3-Diaminotoluene	2,3-DAT
2,4-Diaminotoluene	2,4-DAT
2,6-Diaminotoluene	2,6-DAT
3,5-Dinitroaniline	3,5-DNA
<i>Nitrophenols</i>	
2,4-Dinitrophenol	2,4-DNP
3,4-Dinitrophenol	3,4-DNP
3,5-Dinitrophenol	3,5-DNP
2-Methyl-4,6-dinitrophenol	2-M-4,6-DNP
4-Methyl-2,6-dinitrophenol	4-M-2,6-DNP
3-Methyl-2-nitrophenol	3-M-2-NP
3-Methyl-4-nitrophenol	3-M-4-NP
4-Methyl-2-nitrophenol	4-M-2-NP
5-Methyl-2-nitrophenol	5-M-2-NP
3-Nitrophenol	3-NP
4-Nitrophenol	4-NP
2,4,6-Trinitrophenol	Picric acid/PA
<i>Nitrobenzoic acids</i>	
2-Amino-4-nitrobenzoic acid	2-A-4-NBA
2,4-Dinitrobenzoic acid	2,4-DNBA
2-Nitrobenzoic acid	2-NBA
3-Nitrobenzoic acid	3-NBA
4-Nitrobenzoic acid	4-NBA

acetate, methyl isobutylketone and methyl tert-butyl ether at different pH values. As a rule, recovery of >70% can be achieved with triple extraction

(stirring or shaking in an Erlenmeyer flask). In order to obtain good recovery for the relatively highly volatile mononitrated aromatics and chloroaromatics, great care should be taken when concentrating or redissolving extracts. To extract polar compounds like hexogen, octogen or nitroguanidine, continuous LLE in rotary perforators is more effective (Figure 2).

Good results are also obtained with SPE. For neutral nitroaromatics recoveries of between 70 and 100% are reached with octadecylsiloxane-bonded silica materials (RP-18). Increasingly, the highly porous (specific surface >1200 m² g⁻¹) and high purity adsorbents based on styrene-divinylbenzene (SDVB) copolymer are used and these are particularly suitable for the more water soluble compounds such as nitramines.

The US Environmental Protection Agency (EPA) method makes use of salting-out-effects in the extraction. This enables nitramines, nitroaromatics and nitrate esters to be extracted with solvents freely miscible with water, such as acetonitrile. Here, good recoveries are obtained, but reproducibility is not as good as with the methods mentioned above.

Acidic compounds The extraction of acidic compounds such as nitrophenols and nitrobenzoic acids should take place at low pH in order to ensure the presence of these compounds in their nondissociated form. For this purpose a pH value of 2 has proved successful.

Also, continuous extraction in a rotary extractor leads to a higher yield than is the case in discontinuous extraction (Figure 3). Suitable solvents are dichloromethane and ethyl acetate.

In general, lower recoveries will be obtained for the volatile ortho-substituted nitrophenols if a concentration step is necessary after the extraction.

High recoveries are obtained on SDVB copolymers. In SPE with RP-18 materials, recoveries >70% for the mononitrophenols are only reached if large amounts of salt (300 g NaCl L⁻¹) are added.

An efficient enrichment of acidic compounds is also possible after ion pair formation with tetrabutylammonium chloride in a neutral to basic medium or by extractive derivatization by means of acetic anhydride or pentafluorobenzoyl chloride in the presence of a phase transfer catalyst with dichloromethane as solvent.

Basic compounds An efficient enrichment of aminoaromatics and especially of diaminoaromatics can be reached at pH 12 with continuous LLE with dichloromethane or SPE on SDVB copolymer materials (Figure 4). Discontinuous extraction with

Figure 2 Comparison of various extraction techniques for neutral compounds. Samples of 0.5 L (water spiked with $2 \mu\text{g L}^{-1}$ for each component and adjusted to pH 9 with 0.1 mol L^{-1} sodium hydroxide) were enriched as follows: (A) discontinuous LLE (open columns): stirring three times with 25 mL dichloromethane for 30 min in an Erlenmeyer flask; (B) continuous LLE (hatched columns): 0.5 L extraction with 150 mL dichloromethane in a heavy-phase rotary perforator (Normag); (C) SPE-RP-18 (dotted columns): enriched on 2 g PolarPlus (Baker), conditioned with 3 mL acetone, methanol and water, and eluted with 6 mL methanol; (D) SPE-SDVB (filled columns): enriched on 200 mg LiChrolut EN (Merck), conditioned with 3 mL acetonitrile, methanol and 9 mL water, and eluted with 2 mL methanol acetonitrile mixture (1 : 1).

dichloromethane is not effective. The use of RP-18 materials or ethyl acetate as a solvent is out of the question because of the high pH.

Fractionation Where there are very complex samples, for example, the water samples from Elsnig, precise qualitative and quantitative analysis is only possible after pre-separation of the components. A suitable method is class fractionation based on LLE (Figure 5) at various pH values.

Here, by means of the discontinuous dichloromethane extraction at pH 9, the nitro and mono-aminoaromatics – which in most cases are the main contaminants – can be almost completely separated from the acidic and basic compounds. Only the more polar nitramines are not completely extracted and are partially included in the other two fractions. Using a more efficient extraction technique in the first extraction step (for example, continuous extraction or SPE on SDVB), selective pre-separation is not possible since acidic and basic compounds would also be partially extracted.

Soil Samples

The basic condition for reliable analysis of soil samples is representative sampling and good homogenization of the samples.

The method most frequently used to prepare the soil samples to analyse explosives is extraction in an ultrasonic bath. Compared with Soxhlet extraction it has several advantages: careful treatment of thermolabile compounds, easy handling, minimum apparatus expenditure and low consumption of solvents.

Suitable solvents are, in principle, acetone, methanol and acetonitrile. However, with a view to the subsequent HPLC determination, methanol and acetonitrile should rank first.

Nitroaromatics are quantitatively extracted by both solvents. But for the more polar compounds like octogen, hexogen and hexyl, acetonitrile is preferred (Table 2).

Ultrasonic extraction is described in detail in US-EPA-8330. In this case, 2 g of soil is extracted

Figure 3 Optimization of extraction for acidic compounds. Samples of 0.5 L (water spiked with $2 \mu\text{g L}^{-1}$ for each component and adjusted to pH 2 with 0.1 mol L^{-1} hydrochloric acid) were extracted with 150 mL dichloromethane in a heavy-phase rotary perforator or with 200 mL ethyl acetate in a light-phase rotary perforator, respectively. Open columns, MeCl 3 \times 30 min; hatched columns, MeCl 4 h; dotted columns, MeCl 10 h; filled columns, Etac 4 h.

with 10 mL acetonitrile over 18 h at room temperature.

A new efficient method for extraction of soil samples is accelerated solvent extraction (ASE), which has proved suitable for nitroaromatics.

HPLC Separation Systems

In general, RP-18 materials are used to separate explosive-related compounds. According to sample composition and detector selection, the composition of the mobile phase (type and amount of organic modifier, buffer additives) varies considerably. The most common mobile phases are buffered or unbuffered methanol–water and acetonitrile–water mixtures in isocratic or gradient operation.

Ethanol, *n*-propanol and dioxane as modifiers or ternary solvent mixtures such as water–methanol–acetonitrile or water–methanol–tetrahydrofuran are of little practical importance and result in too small a selectivity change compared with binary mobile phases.

Because of the generally limited separation performance of HPLC, complete separation of all explosive-related compounds cannot be achieved on any one column in one chromatographic run, not even under

carefully optimized separation conditions. Therefore, before separation in the case of complex samples, pre-separation of the components into different fractions by HPLC is useful.

Neutral Compounds

RP-18 phases are very suitable for separation of complex mixtures of nitro- and nitroaminoaromatics, nitramines and nitrate esters with methanol–water or methanol–buffer mobile phases.

In general, at a methanol–water ratio of about 1:1, the retention of compounds on RP-18 phases will increase as follows: nitroguanidine < octogen < hexogen < EGDN < DEGN < 1,3-DNB < 2,4,6-TNT < 4-A-2,6-DNT < 2-A-4,6-DNT < 2,6-DNT < 2,4-DNT < 2-NT < 4-NT < 3-NT < PETN < diphenylamine (Figure 6).

For some compounds, however, various RP-18 columns show different selectivities, which result in co-elution and retention reversal of various pairs of substances, as shown in Table 3. Two columns of complementary selectivity can be used to verify the separation results or to reduce peak overlapping.

If chlorinated aromatics additionally occur in real samples (Table 1) these can be determined under the same conditions as the nitroaromatics. However, for

Figure 4 Extraction of basic compounds. Samples of 0.5 L (water spiked with $2 \mu\text{g L}^{-1}$ for each component and adjusted to pH 12 with 1 mol L^{-1} sodium hydroxide) enriched (A) by continuous LLE with 150 mL dichloromethane and (B) by SPE on 500 mg LiChrolut EN (Merck), conditioned with 3 mL acetonitrile, methanol and 9 mL water, and eluted with a 2 mL methanol/acetonitrile mixture (1:1). Open columns, LLE 4 h; hatched columns, LLE 10 h; filled columns, SPE-SVDB.

Table 2 Extraction of spiked soil samples with different solvents

Compound	Acetonitrile		Methanol	
	Recovery (%)	RSD (%)	Recovery (%)	RSD (%)
Hexogen	97	2.5	82	2.4
Hexyl	86	2.2	73	1.5
Octogen	95	3.4	69	4.3
2,4,6-TNT	98	2.1	98	2.1

2 g soil spiked with 10 mg kg⁻¹ for each component, extracted with 10 ml solvent for 15 min in an ultrasonic bath. RSD, relative standard deviation ($n = 3$).

the more retained dichloro compounds, gradient elution is recommended.

To clarify peak overlapping, other phases in addition to RP-18 phases have proven their value. US-EPA, for example, recommends a cyanopropyl column as a second column showing a clearly different selectivity: nitroguanidine < NB < toluol < 2-NT < 4-N....T < 3-NT < EGDN < 1,3-DNB < 2,6-DNT < 2,4-DNT < TNT < 4-A-2,6-DNT < 2-A-4,6-DNT < hexogen < tetryl < diphenylamine < octogen < PETN.

Similar retention orders are also observed under normal-phase conditions on silica gel, cyanopropyl-

siloxane and aminopropylsiloxane-bonded silica sorbents. As the normal-phase mode has considerable disadvantages (disturbance by traces of water, no gradient elution), these separation systems are used only rarely and in most cases only with detectors which are incompatible with aqueous mobile phases, such as the thermal energy analyser (TEA) and the electron-capture detector (ECD).

Large selectivity differences in RP-18 phases are also obtained on nitrophenyl-modified silica gel and on porous graphitic carbon (PGC) (Table 4).

Thus, retention on these phases will increase with the growing number of nitro groups. Furthermore, in contrast to the RP-18 columns, large retention differences are observed for the isomeric dinitro and aminodinitro compounds. In addition, the PGC phase, due to its high hydrophobicity, shows generally higher retentions, which require a higher methanol content (> 85%) and the separation performance is not satisfactory, due to the low efficiency of such columns.

In addition to the commercially obtainable columns, special materials such as the charge transfer phases like arylpropylether, *N*-propylaniline and safrol phases or a two-dimensional coupling of RP-18 phases with these columns for increasing the selectivity have been tested but offer no great advantage over the common materials.

Figure 6 Chromatogram of a standard mixture of explosive-related compounds. 51% methanol–49% water (v/v); Spherisorb ODS 2 column, 5 μ m, 250 \times 4 mm (HP); 1 mL min⁻¹; 25°C; UV 254 nm.

Acidic Compounds

The separation of the acidic explosives hexyl and picric acid and the metabolites nitrophenols and nitrobenzoic acids is, in principle, possible on RP-materials under the following conditions: at acidic pH value; with the addition of ion pair reagents like hexadecyltrimethylammonium chloride at neutral or basic pH values; and after methylation.

The separation of the underivatized compounds at acidic pH between approximately pH 2 and 4 is relatively simple. For acidification of the mobile phase, many acids and buffers can be used. For example, to separate nitrophenols, in addition to octogen and hexogen, a 0.01 mol L⁻¹ sodium dihydrogen phosphate/phosphoric acid buffer (pH 3) on RP-18-columns is suitable (Table 5).

4-M-2-NP	16	8.37	16	7.79
5-M-2-NP	16	8.37	16	7.79

Dimension of both columns: 250 × 4 mm; 5 μm; ^ahold-up time 1.73 min; ^bhold-up time 1.59 min. 51% methanol–49% 0.01 mol L⁻¹ sodium dihydrogen phosphate–phosphoric acid. buffer pH 3(v/v); 1 mL min⁻¹; 27°C; 10 μg mL⁻¹ per component.

To separate nitrobenzoic acids a further decrease in pH is necessary. Good separation of these compounds in the presence of nitrophenols and nitramines can be obtained at pH 2 (addition of 0.005 mol L⁻¹ sulfuric acid) and a methanol content of 47% (Figure 7).

Under these conditions for the determination of hexyl a gradient after 20 min to 85% methanol within 20 min is used.

Basic Compounds

The RP-18 phases based on silica are, in principle, also suitable for the determination of the metabolites diaminotoluenes, diaminonitrotoluenes and nitroanilines. For this, however, particularly inert materials with a low silanol group activity are necessary because otherwise the peaks show marked tailing and large peak widths. For example, a Eurosphere column showed good properties in this respect (Figure 8).

We have not been able to observe an increase in separation performance with falling pH improving peak shapes, as is often described in the literature. On the other hand there is, as expected a reduction in the retention under these conditions. An increase in retention by restraining the protonation of the basic compounds at pH values > 10 is not to be recommended because of the instability of the phases used.

Alternatives to the separation of the diamino compounds, which on RP-18 phases are insignificantly

retained or only poorly separated should be separated on porous polymer or PGC phases, because these phases have relatively homogeneous nonpolar surfaces and high stability over the full pH range.

Even using various mobile phases and buffer systems, these columns do not show any satisfactory separation of the compounds of interest; this is due to the low efficiency of commercial columns.

Detection

UV Detection

To detect explosive-related compounds, UV is mainly used. Aromatic nitrocompounds are UV-absorbing and can, as a rule, be sensitively detected at 254 nm (Figure 9). At this wavelength it is also possible to detect nitramines and aminoaromatics. In addition to sensitive detection, selectivity against matrix components and eluent impurities is reached at this wavelength, as most interferents absorb at lower wavelengths.

As a rule, nitrate esters and chlorobenzenes do not show a maximum at wavelengths higher than 200 nm. Therefore, these compounds should be detected at the lowest possible wavelength. For methanol-containing eluents the minimum practicable wavelength is around 210 nm.

The UV detector shows a high linearity for the explosive-related compounds in the concentration range of about 0.01 to 100 μg mL⁻¹.

For aromatic nitro-compounds, limits of detection (LODs) reach 5–50 ng mL⁻¹ (0.1–1 ng absolutely for an injection volume of 20 μL) in the sample solution. For nitrate esters and nonnitrated chlorobenzenes the LODs are around 100–250 ng mL⁻¹ (or 2–5 ng absolutely).

Using variable wavelength detectors, multichannel wavelength detectors or photodiode array detectors, it is possible to optimize the selectivities and LODs for certain purposes, by measuring at the absorption maximum or at several wavelengths in one chromatographic run. For example, hexyl can be selectively detected at high and sensitively at 420 nm.

Additionally, the photodiode array detector enables compounds to be identified with marked absorption maxima and minima (e.g. nitrophenols, nitrobenzoic acids and nitroaromatics) by means of the simultaneously recordable spectra.

Electrochemical Detection

In principle, all the nitrocompounds can be determined by means of the electrochemical detector in the reduction mode. Phenols and amino compounds can be detected in the oxidation mode.

Figure 7 Chromatogram of a standard mixture of nitrophenols, nitro benzoic acids, nitramines and hexyl. Eurospher 100 RP 18 column, 5 μm , 250 \times 4 mm; 47% methanol–53% 0.01 mol L⁻¹ sulfuric acid (pH 2) (v/v), after 20 min linear gradient to 85% methanol within 20 min, 1.0 mL min⁻¹, 27°C; UV 254 nm. (Reproduced with permission from Lewin U *et al.* (1997) *Chromatographia* 45: 91.)

Figure 8 Chromatogram of a standard mixture of amino and diaminoaromatics Eurospher 100 RP 18 column, 5 μm , 250 \times 4 mm (Knauer); 40% methanol–60% 0.01 mol L⁻¹ water (v/v), 1.0 mL min⁻¹, 27°C; UV 254 nm.

The method mainly used in HPLC for electrochemical detection is amperometry: a constant optimized potential difference (working potential) is applied between the working and reference electrode, which has previously been determined from cyclic voltammograms or hydrodynamic voltammograms.

In commercially available electrochemical detectors, solid electrodes are used as they are easier to handle, although nitroaromatics can be detected sensitively with liquid mercury electrodes and in particular with the hanging mercury drop electrode.

To determine explosive-related compounds, the standard electrode material, glassy carbon, has proved its value, because it can be used over a wide potential range of about -1.3 to about $+1.3$ V. In addition, amalgamated gold electrodes or mercury film electrodes have been used for reductive detection.

The selectivity of detection can be influenced by the choice of working potential. In general, substances

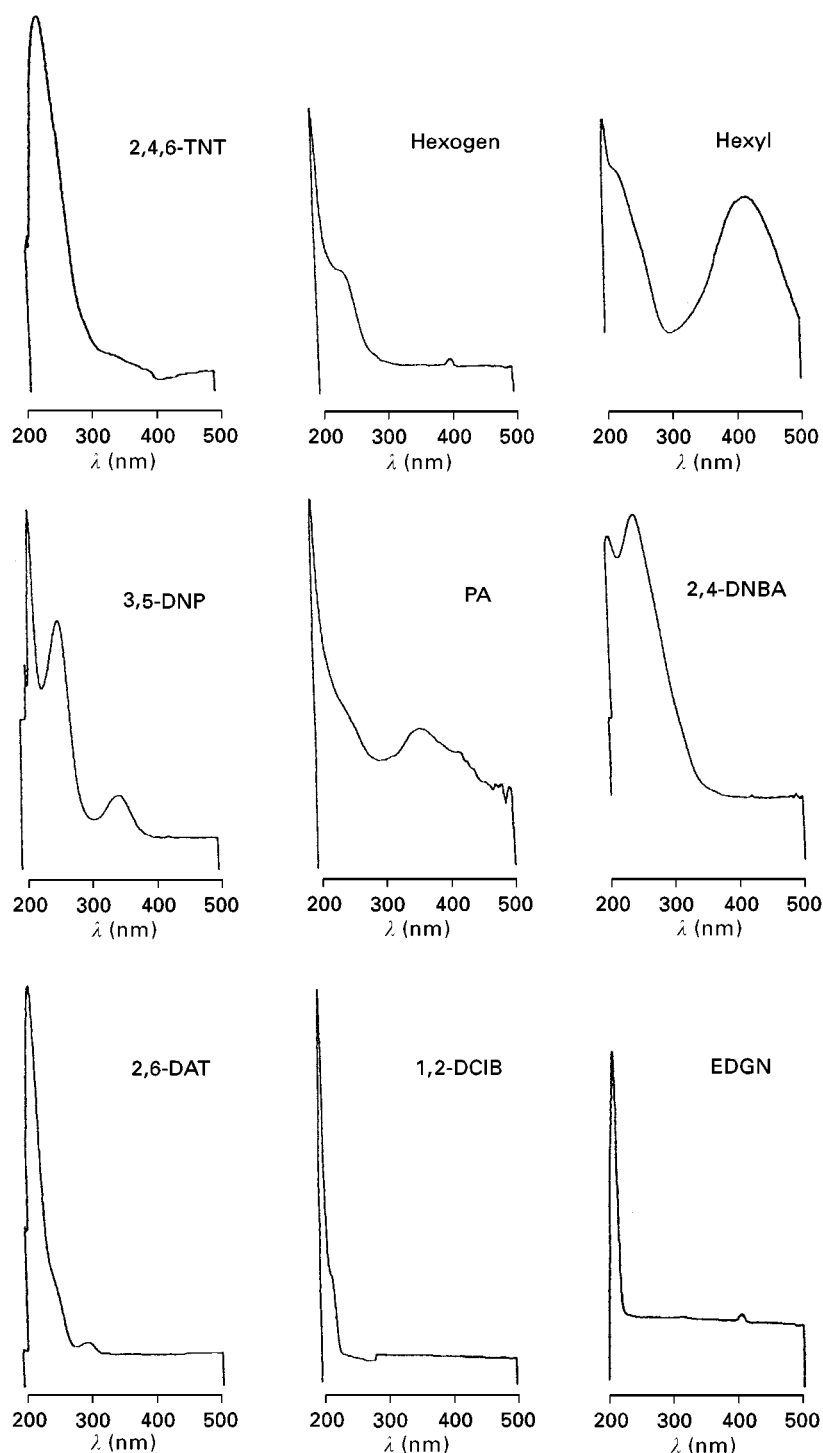

Figure 9 Spectra of explosive-related compounds. Detected with HP 1050 variable wavelength detector in the scanning mode with 51% methanol–49% water or 0.01 mol L⁻¹ phosphate buffer (pH 3) (v/v) for the acidic compounds, respectively.

whose half-wave potential is at least 150 mV larger than the working potential are not detected.

Dual cells or electrode arrays may result in an increase in the informational content of a chromatographic run or in a reduction in the limit of detection

by measuring simultaneously at various potentials or at each optimal potential of the compounds.

Reduction mode Nitro compounds have very different half-wave potentials. They depend on the type,

Figure 10 Electrochemical detector chromatograms of the neutral fraction of a groundwater sample from Elsnig at different potentials. Eurospher 100 RP 18 column, 5 μm , 250 \times 4 mm (Knauer); 51% methanol–49% 0.01 mol L⁻¹ phosphate buffer (pH 3) (v/v). (Reproduced from Lewin U *et al.* (1996) *Journal of Chromatography A* 730: 161, with permission from Elsevier Science.)

number and position of the substituents and rise, for example in the following way:

In this way a limited selective detection of certain compounds is possible (Figure 10). The optimum potential for the detection of all components is in perchlorate eluent (pH 5.5) at around -1.2 V.

General problems in reductive detection are caused by the difficulty of complete removal of oxygen dissolved in the mobile phase or in the sample, which is reduced at potentials of about -0.5 V and leads to greater disturbances by system peaks and high residual currents. In most cases it is not possible to reach much lower LODs than with UV detection.

Oxidation mode A great advantage of oxidative detection is that, unlike the reductive mode, oxygen has no negative influence on the detection. Like reductive

detection, the aminoaromatics and nitrophenols have very different half-wave potentials, depending on the type, number and position of the substituents (Table 6).

For example, nitro groups will increase half-wave potentials, whereas they are reduced by amino and methyl groups, which can be utilized for selective detection.

However, the greatest selectivity advantages of anodic detection in analysing explosive-related compounds is that aminoaromatics become selective in the presence of nitroaromatics and nitramines (Figure 11).

Likewise, phenols and hexyl can be detected selectively, in addition to nitrobenzoic acids and nitramines (Figure 12).

In this way, the electrochemical detector, especially coupled with the UV detector, which is almost universal for explosive-related compounds, leads to a valuable gain in information in real samples.

Furthermore, for most nitrophenols and aminoaromatics, lower LODs are reached by anodic detection compared with UV detection. In particular, the detection limits for diamino compounds are lower by a factor of up to 100 (up to 0.05 ng mL⁻¹ or 1 pg absolute) without enrichment.

Figure 11 Chromatograms of the basic fraction of a groundwater sample from Els nig (upper level). (A) UV (254 nm); (B) electrochemical detector (+ 0.7 V). Eurospher 100 RP 18 column, 5 μm , 250 \times 4 mm; 40% methanol–60% 0.01 mol L⁻¹ sodium perchlorate solution (v/v), 1.0 mL min⁻¹, 27°C. (Reproduced with permission from Lewin U *et al.* (1997) *Chromatographia* 45: 91.)

The electrochemical detector shows high linearity over a concentration range of 10⁴ but, compared with UV detection, reproducibility is somewhat lower. Furthermore, there is often a decrease in the response over a long measuring period: this can be attributed to passivation of the electrode surface and requires its regeneration.

Determination of the nitroaromatics in the easier oxidation mode takes place after photolysis in a post-column reactor via the nitrite produced, which is

oxidized on a glassy carbon electrode. For this, LODs of 120–250 pg have been found. The expense of the apparatus, however, is relatively high and the yield of the photolysis is very different for the various compounds.

Mass Spectrometric Detection

In the last few years the development of mass selective detectors for coupling with HPLC has made good progress. In addition to thermospray ionization (TSI),

Figure 12 Chromatograms of the acidic fraction of a groundwater sample from Els nig (lower level). (A) UV (254 nm); (B) electrochemical detector (+ 1.2 V). Eurospher 100 RP 18 column, 5 μm , 250 \times 4 mm (Knauer, Berlin); 51% methanol–49% 0.01 mol L⁻¹ phosphate buffer (pH 3) (v/v), after 20 min linear gradient to 80% methanol within 20 min, 1.0 mL min⁻¹ (Reproduced with permission from Lewin U *et al.* (1997) *Chromatographia* 45: 91.)

the atmospheric pressure ionization (API) techniques, electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI) are increasingly gaining in importance.

Explosives can be detected with TSI as negative ions (mostly $[M + \text{CH}_3\text{COO}]^-$ or $[M - \text{H}]^-$). Nitramines and amino compounds can be registered as positive ions (mostly $[M + \text{NH}_4]^+$). With negative ionization in the full-scan mode, LODs are in the ng mL^{-1} range. With selected ion monitoring in the filament-on negative ion mode, the LODs are a factor of 100 lower.

As a result of the electron-withdrawing effect of the nitro groups, nitroaromatics can be detected with API as negative ions $[M - \text{H}]^-$ (Figure 13).

The sensitivity of detection depends on the type, number and position of the substituents. It increases with the number of nitro groups and is considerably higher for nitrophenols and nitrobenzoic acids than for the corresponding neutral nitrobenzenes and nitrotoluenes.

Furthermore, sensitivity depends on the composition of the mobile phase such as the type and quantity of the organic modifier, buffer additives and pH value.

As with TSI, hexogen and octogen form clusters with acetate ions $[M + \text{CH}_3\text{COO}]^-$. A cluster formation of these compounds with ammonium ions $[M + \text{NH}_4]^+$ should, in principle, also be possible in the positive mode.

In addition to the molecular ions and molecular cluster ions, fragment ions are also formed, and elimination of oxygen or reductions and rearrangements of the nitro group are observed. Nitrophenols fragment with the loss of the hydroxyl and the nitro group. This can be used to obtain structural information. However, the assignment of position isomers is difficult, so that to investigate complex samples, carefully optimized HPLC conditions are needed and the additional use of a UV detector is an advantage.

The LODs largely depend on the particular compound and are between 0.1 and $10 \mu\text{g mL}^{-1}$ for the neutral nitroaromatics and nitramines and around $10\text{--}100 \text{ ng mL}^{-1}$ for the nitrophenols. Reproducibility is acceptable (about 2–5%).

Nuclear Magnetic Resonance Spectroscopy

Proton nuclear magnetic resonance spectroscopy ($^1\text{H-NMR}$) is well suited for the determination of explosives because these analytes are small aromatic molecules which offer good manageable spectra; their aromatic protons appear over a relatively wide frequency range (approximately 3 ppm) because of the various substituents (nitro, carboxyl, methyl, hy-

droxyl and amino groups). Thus, reliable identification in very complex samples is possible by the HPLC-NMR coupling which has been developed over the last few years.

In the continuous flow mode at low flow rates ($< 0.02 \text{ mL min}^{-1}$) and large injection volumes (approximately $400 \mu\text{L}$), determination of explosives in the lower microgram range is possible. The reproducibility of about 2% in the upper microgram range is acceptable.

Further Detection Techniques

Fluorescence detection is not suitable for the determination of nitro compounds, as nitro groups will diminish fluorescence intensity. However amino compounds can be determined very selectively and sensitively.

As nitro compounds form nitrogen monoxide by pyrolysis, they can also be detected by a thermal energy analyser. The sensitivity depends on the substance class and is lower for nitroaromatics than for nitramines and nitrate esters. An advantage of the detector is its specificity for compounds carrying oxygen-nitrogen functional groups. Because of the complex apparatus and the restriction to the normal-phase separation mode, the detector has not achieved wide usage.

Occasionally, reports have been published on further pre-column and post-column derivatization techniques. For example, for the amino compounds the diazotization and coupling with *N*-(1-naphthyl)-ethylenediammonium chloride into azo dyes is suitable. This reaction is also suitable for the determination of nitroaromatics after conversion with titanium(III) chloride into the amines or after photolysis and diazotization of the nitrite formed with sulfanilamide.

The electron-capture detector, widely used in gas chromatography, was not successful in practice because of incompatibility with polar mobile phases.

Conclusions

To determine the thermally unstable explosive-related compounds, the method of choice is HPLC. However, because of the limited separation performance, where there are very complex samples, HPLC determination is only possible after optimization of the method and pre-separation of the samples into different fractions.

RP-18 phases have proved their value as standard columns. In special separation problems the use of a second column is useful.

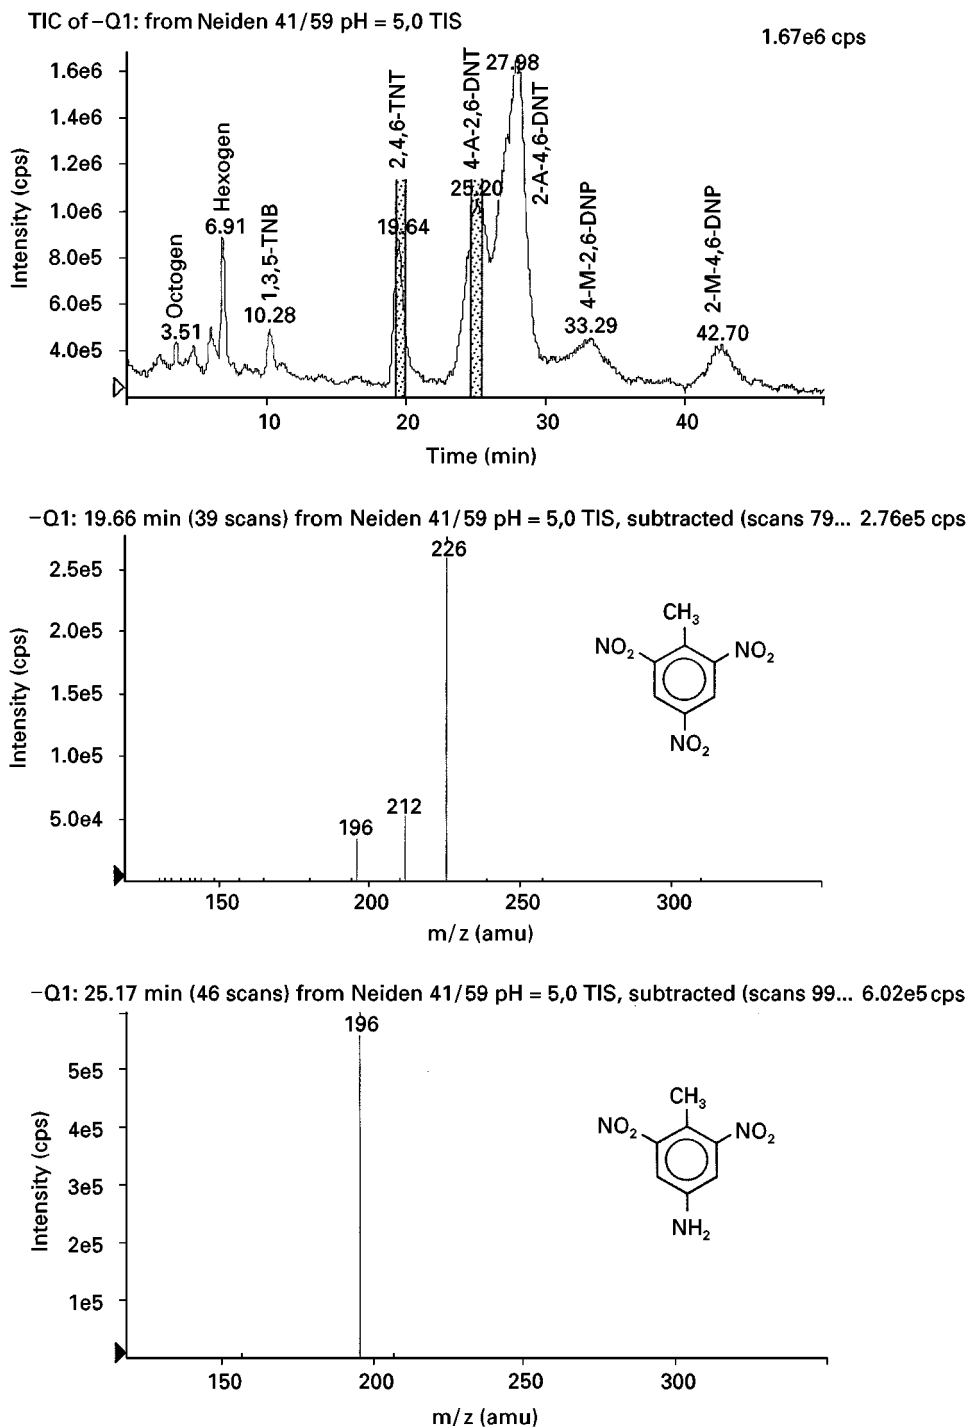

Figure 13 TIC and several mass spectra of an extract of drainage water from contaminated soil. PE-SCIEX API 100 LC/MS-System; Heated Nebulizer™ (PE), Ultrasep ES RP 18 column, 5 μ m, 250 \times 4 mm (Sepsev, Berlin); 41% methanol-59% water (v/v) adjusted to pH 5.0 by means of acetic acid, 20°C.

In most cases, UV detection, which is almost universal for explosive-related compounds, is used. Because of the complexity of samples, to clarify signal overlapping, and last but not least for identification, the use of selective detectors such as the electrochemical and mass spectrometric detector as well as HPLC-

NMR coupling, which has been recently commercialized, are of great advantage.

In general, the available techniques (including sample preparation) enable explosives, their by-products and metabolites to be determined down to a range of 0.1 μ g L⁻¹.

Introduction

The term explosive has two meanings. It is used for individual chemical compounds among which trinitrotoluene (TNT), 1,3,4-trinitro-1,3,5-triazacyclohexane (hexogen-RDX), 1,3,5,7-tetranitro-1,3,5,7-tetrazacyclooctane (octagen-HMX), pentaerythriol tetranitrate (pentrik-PETN) nitroglycerine (NG) and nitrocellulose (NC) are commonly known. This term is also used for mixtures of the above individual compounds and their mixtures with other, non-explosive substances; the type and amount of components in a mixture determines its properties (brisance, melting, plasticity and the like). Explosives have been classified in many ways according to different criteria. Most important is the kind of addition, the NO₂ group and type, and the velocity of the reaction involved. The first are divided into the following groups; nitro compounds containing the C-NO₂ group, nitrate esters with C-O-NO₂ group and nitramines with C-N-NO₂ group. The second criterion divides explosives into high and low explosives (HEs and LEs respectively).

The identification and quantification of the HEs or LEs are very valid and also present difficult analytical problems. These problems become evident especially

during: (i) testing of environmental pollutants, (ii) forensic investigations, and (iii) checking technological processes and service conditions of munitions manufacture. From an analytical point of view, at least three groups of TLC applications in explosive investigations can be distinguished. The first of them, most often represented in the research literature, concerns qualitative (including screening methods) and quantitative analysis of explosives. The second is where TLC is applied as a clean-up technique. In this case analysis is completed by other analytical techniques. The last group of applications mainly covers the evaluation of LE stability.

Although, recently, more sophisticated methods such as thermal analyses and gas or liquid chromatography are commonly used in many laboratories, TLC is still in use. Starting from paper chromatography and improved over many years, TLC has become very effective in the analysis of explosives. Apart from high performance adsorbents, and the ability to perform separations in both normal and reversed-phase systems, the real advances are due to the development of densitometry and the spray-on technique of sampling.

Analyses of Explosives

Early TLC analysis was performed on homemade chromatographic plates and involved the separation of classical HEs such as TNT, RDX,

Analytes	Chromatographic system		Type of elution
	Stationary phase	Moblie phase	
TNT, RDX, PETN, tetryl, NC, NG	Silica gel	Trichloroethylene–acetone (4 : 1)	One-dimensional, isocratic
TNT, RDX, HMX, PETN, tetryl	Silica gel HPTLC F ₂₅₄	Carbon tetrachloride–aceto- nitrile (8 : 1)	One-dimensional, isocratic
HMX, RDX, 2,4-DNT, TNT, NG, PETN, tetryl	Silica gel HPTLC F ₂₅₄	I petrol ether – acetone (3 : 1) II petrol ether – ethyl acetate (8 : 1)	Two-dimensional, isocratic
Trinitrobenzene, 2,4-DNT, TNT tetryl, NG, PETN, RDX	Silica gel HPTLC F ₂₅₄	Benzene - petrol ether– methanol (8 : 6 : 1)	One-dimensional, isocratic
TNT m-dinitrobenzene, trinitro- benzene, tetryl, 2,4-dinitrochloro- benzene, picramide, heksyl	Silica gel G-magnesium silicate (1 : 1)	Xylene	One-dimensional, isocratic
2,3,4-TNT, 2,4,6-TNT: 1,2-DNB: RDX	Silica gel HF ₂₅₄	Benzene–hexane–pentane (5 : 4 : 1)	One-dimensional, isocratic
RDX, HMX, tetryl, PETN, TNT, 2,4-DNT, 2,6-DNT	Silica gel with chemical bonded octadecyl, RP-C-18		AMD, gradient elution
Hexyl, picric acid, RDX, HMX, 2,4,6-N-tetranitro-N-methyl- aniline, 2,4- and 2,6-dinitro- toluenes, TNT, 1,3-dinitrobenzene, 2-amino-4,6-dinitrotoluene, 4-amino- 2,6-dinitrotoluene	Silica gel HPTLC		AMD, gradient elution

HMX and PETN (see Yinon and Zitrin in Further Reading).

One-dimensional ascending or horizontal techniques have usually been applied for the development of chromatograms in a closed chamber (Table 1). Multiple and two-dimensional development techniques have seldom been used but automated multiple development (AMD) and gradient development are becoming more frequently used.

In TLC much attention is paid to the methods of analyte visualization, especially to search for specific reactions which can confirm the presence of an analyte in a spot or band. Confirmation of the identity of an analyte is thus based on at least two criteria,

R_F and colour reaction. The majority of more or less specific explosive visualization schemes have been worked out long ago (Table 2). Exhaustive reviews of those methods can be found in the publication by Yinon and Zitrin, mentioned above, and in York *et al.* (see Further Reading).

Most investigations on the analysis of explosives by TLC have been confined to environmental protection. In such research, classical TLC has been applied mainly as a screening method and has served to provide essentially qualitative analysis; instrumental TLC provides both qualitative (screening) and quantitative determination. Environmental analysis of explosives is justified by the fact that nitrotoluenes and

especially trinitrotoluenes are highly toxic compounds. The aromatic amines formed by their biodegradation are suspected to be carcinogenic. Due to careless handling during the manufacture, loading, and packing etc., of explosives, groundwater, surface water and soil may be contaminated with these compounds. Occasional plant accidents, and residues from World War II are also sources of pollution.

Screening methods, which most often use colorimetric visualization reactions, serve to lower the cost and are less time-consuming for the analysis of a large number of samples. An excellent example which illustrates the advantages of TLC for such applications is provided by Haas and Stork. The most interesting information in this work lies in the method of sample preparation (liquid-liquid extraction) and the technique of separation of large numbers of analytes. Water samples taken from waste-heaps, containing post-production residues of TNT, were extracted with isopropyl ether under a range of pHs. At pH 4 aromatic amines were retained in the aqueous phase and phenols and nitro compounds were extracted into the organic phase (ether extract A). To enable extraction of amines into the organic phase, the pH was adjusted to 8 (ether extract B). Phenols were isolated from extract A by treating with 1M NaOH (nitrotoluenes remained in the extract). The aqueous phase, of extract A was then re-adjusted to pH 4 and re-extracted to transfer phenols to the organic phase (extract C). After drying and concentration, the three extracts are analysed by normal phase chromatography using two-dimensional isocratic elution. Analytes are identified by the quenching of fluorescence or by colour reactions. In extract A (nitrotoluenes) 25 compounds were found and 2,4-, 2,6-dinitrotoluene and TNT were identified. In extract B (nitroamines) 26 compounds were found. In extract C, containing phenols, 28 compounds were found and 2,4-dinitro-6-methylphenol and 2,6-dinitro-4-methylphenol were identified. Confirmation of TLC results and quantification were performed using spectrophotometry and gas chromatography.

On-site TLC screening methods for explosives in soil have been reviewed by Nam who suggested that the results obtained using two colorimetric-based methods (TNT and RDX-methods), commonly used for on-site analysis of explosives in the USA, are not perfect. The first of the methods, is based on the reaction of an acetone soil extract of TNT with base, to produce reddish coloured Jankowsky ions. For the RDX method, the soil extract is first acidified and reacted with zinc to reduce the RDX to nitrous acid; the solution obtained is reacted with Griess reagent to produce a reddish coloured azo dye. Unfortunately,

these are not specific reactions and require other techniques for confirmation. The work describes the separation techniques for nitroaromatics, nitroamines and nitrate esters, classical, colour visualization methods and also the costs of analysis. Laboratory analytical methods for the most commonly found components of explosives, and environmental transformation of these substances in a soil matrix, have been developed in the work of Jenkins *et al.*

More recently gradient automated multiple development (AMD) HP TLC using a normal phase system has been applied to the determination of explosives and their biodegradation products in contaminated soil and water. The subjects of examination were hexyl, picric acid, RDX, HMX, 2,4,6-N-tetranitro-N-methylaniline, 2,4- and 2,6-dinitrotoluenes, TNT, and other by-products such as 1,3-dinitrobenzene, 2-amino-4,6-dinitrotoluene, and 4-amino-2,6-dinitrotoluene found in former ammunition site waste in Germany. The use of optimized gradient elution and an AMD system allowed the separation of analytes from environmental samples and quantification at the 5–20 ng level; humic substances presented in water samples do not interfere. In the case of samples of soil with a high concentration of humic substances, a clean-up technique is necessary. The superiority of TLC is displayed by the fact that similar analyses using GC or HPLC require (even for water samples) very careful sample clean-up or the application of size exclusion chromatography.

Modern TLC equipment has also been applied to the quantitative determination of HE residues in soil and water using a reversed-phase system with automated multiple development gradient elution after liquid-liquid and solid-phase extraction. Quantification was carried out by UV or visible absorption light measurement *in situ*. The work demonstrated that the application of AMD was effective for the isolation and separation of relative complex HE mixtures in one analytical process (Figure 1). Most of the examined HEs absorb UV light, which allows their quantification by densitometry (Table 3).

During the measurement of PETN, Wurster's salts were applied (organic nitrate esters oxidize Wurster's salts yielding the so-called 'Wurster's cations' which are intensely coloured). It has been proved that this reaction can also be used for quantitative analysis. The extraction of HEs from water samples, using solid-phase extraction (SPE) cartridges filled with SDB-1 phase (recoveries $\approx 90\%$), was shown to be more effective than liquid-liquid extraction. Slightly lower values of recoveries during extraction from soil (77.0–84.4%) were obtained but these result from the more complex procedure for their preparation for analysis (necessity of purification).

Figure 1 Chromatogram of high explosives: 1 = octagen, 2 = hexogen, 3 = tetryl, 4 = pentrit, 5 = trotyl, 6 = 2,4-DNT, 7 = 2,6-DNT: (A) scanning at wavelength 220 nm, (B) pentrit, scanning at 600 nm. The proposed technique for the elimination of the majority of non-polar impurities from soil extracts using SPE is very effective for the identification and quantification of the analytes examined (Figure 2).

Post-blast analyses, or identification of explosive residues in forensic investigations, are directly associated with combat, and criminal or terrorist activity. Results of such analyses may give information about the type, and sometimes also about the source of

Table 3 Parameters of quantification

explosives or about possible contact with explosives. From an analytical point of view, these methods are similar to investigations of explosives in environmental matrices; the difference concerns isolation from the matrix (debris, bodies and surfaces). These matrices are usually extracted in two ways: by water and by organic solvent. The water extract is then analysed for inorganic ions and the organic extract for the explosives. Yinon and Zitrin have described the complexity of such analysis (see Further Reading).

TLC as a Clean-up Method

Forensic and environmental analyses are usually performed in several stages, one of the most important being sample preparation. This stage covers the isolation, concentration, and purification of analytes for further analysis. Three basic methods of purification of analytes may be distinguished: liquid-liquid extraction, solid-phase extraction and preparative thin layer chromatography. For preparative TLC, the analytes are spotted as a long band on the start line. After developing chromatograms the plates are dried, and cut, if plastic or aluminium, or scored, if glass, so that they contain the standard lanes and part of the sample. Classic, preparative TLC has been rarely used for the purification of explosives. Easy access and a variety of stationary phases for SPE make it more useful than preparative TLC in this application.

Table 4 Examples of TLC separation and visualization of stabilizers

Stabilizer	Chromatographic system		Type of elution	Visualization

TLC in Research

This work mainly concerns LEs (propellants). Nitrate ester-based propellant compositions decompose under normal storage conditions producing nitrogen dioxide as a primary decomposition product. This NO_2 is the source of further, autocatalytic decomposition of propellants, limiting their safe storage life. In order to reduce the rate of deterioration of propellants, stabilizers (usually diphenylamine - DPA) or centralite I-(N,N'-diethyl-N,N'-diphenylurea) -EC, which react with the primary decomposition products, are usually incorporated, to inhibit degradation. The amount of stabilizers added varies, but is typically less than 1% (in the case of DPA) and 3% (in the case of centralite). The stabilizers react with nitrogen oxides forming different degradation products and whilst some of these products also act as stabi-

lizers others contribute to stabilizer depletion. Examples of the application of TLC to stabilizer measurement are presented in **Table 4**.

One example of the application of TLC for propellant stability research uses three chromatographic systems for the isolation of stabilizers (**Figure 3**) from single-base, free emulsion double base and emulsion propellants (**Table 5**). Samples are divided into 2 parts. One is heated for 1 h at 120°C in an open vessel and the other left unheated. All samples are then dissolved in acetone (this procedure is more effective than the extraction of stabilizers) and analysed to observe the differences between the state of chemical change of the stabilizer and its reaction products before and after ageing. Analyses are performed using a liquid-crystal detector, and confirmation was done using densitometry.

Figure 3 Fragments of propellant chromatograms: (A) single-base, (B) double base, (C) emulsion propellant. Abscissa - absorbance, ordinate - range of the spots in mm. Peaks notation: 1 = 4-nitrodiphenylamine, 2 = N-NO-diphenylamine, 3 = 2-nitrodiphenylamine, 4 = diphenylamine, 5 = 4-nitro centralite, 6 = centralite, 7 = 2,4-dinitrotoluene, 8 = dibutylphthalate, (c) 9 = centralite, 10 = 2,4-dinitrotoluene, 11 = diphenylamine. In three lots of single-base propellants, stored for 48, 47 and 41 years consumption of DPA in the range 75–100% was determined (before heating). The main products of chemical change are N-NO-DPA, 4-NO₂-DPA, 2-NO₂-DPA and also traces of dinitro-DPA. The most often observed differences in the concentrations of DPA before and after heating were in the range 0.2–0.6% (m/m). In most stable double-base propellants during storage of up to 50 years, a small decrease of 5–10% EC content was observed. Rarely, traces of 4-NO₂-EC were found. This work also found that in some unstable double-base propellants (stored for 40 years) and mortar propellants (stored for 38 and 23 years), 90–100% of the EC had changed into its reaction products mostly into mono-nitro-EC. Studying chemical changes of EC stable propellants before and after heating, there were determined differences in EC concentrations in the range 0.2–0.8% (m/m). As in single-base propellants, the dynamics of stabilizer changes in double-base propellants, both under natural and accelerated ageing varies up to ten times under the same conditions of ageing. It means, that the quality, especially of basic components of the propellants, has greater influence on their decomposition than the 'age'. The use of TLC methods to determine the stabilizers and their reaction products in the propellants seems to be suitable and reliable.

Conclusions

There are a large set of analytical needs connected with the analysis of explosives. The importance of this problem can be appreciated by looking at the statistics on recent bombings in the world. Besides the tasks mentioned above, there is a need for vehicles or mail screening, bomb search, protection of special infrastructure features, and so on. Of course, not all analysis can be performed using TLC.

In the history of TLC for analysis of explosives the 1960s and 1970s was a time of very intensive use. The development of modern analytical methods has caused a decrease in interest in TLC. An increase of interest in TLC, as applied to the analysis of explosives,

can be observed in the 1990s and is connected with the intensive development of the method.

TLC, like all other chromatographic techniques, is a comparative method. It is impossible to obtain information about the structure or identification of unknown compounds or mixtures. In such cases there exists the possibility of combining TLC with other, mainly spectroscopic, analytical techniques (e.g. TLC-MS). Such combinations will probably start widening the application of TLC in the analysis of explosives.

FATS

Crystallization

K. Sato, Hiroshima University, Higashi-Hiroshima, Japan

Copyright © 2000 Academic Press

Introduction

Fats, as mostly represented by triacylglycerols, are employed in foods, cosmetics, pharmaceuticals, etc. as the main bodies of end products, or as the matrices in which fine chemicals are dispersed. The crystallization behaviour of fats has two major industrial implications: (a) processing of the end products made of fat crystals, such as chocolate, margarine and shortening, whipping cream, etc. and (b) separation of specific fats and lipids materials from natural resources, mostly from vegetable or animal fats and oils, which contain various molecular species having different chemical and physical properties. As for the separation technology of crude fat resources, such as palm oil, milk fats, hydrogenated vegetable oils, etc. it may be worth noting that current market demands raise a great necessity to develop the fractionation of high-melting and low-melting fats and lipids through dry fractionation. The main causes for this are the replacement of hydrogenation by dry fractionation, a new regulation of usage of fat materials for confectionery fats, better functionality of physically refined

vegetable oils compared to conventional materials, etc. This review highlights the basic information on recent research on the crystallization of fats, with a specific emphasis on the separation phenomena.

The specific characteristics of the crystallization of fats are, on the one hand, polymorphism, and molecular interactions on the other. No long-chain compound without polymorphic modifications is present, and this property is more enhanced in triacylglycerol (TAG) crystals. The molecular interactions in TAG crystals are operative mostly through van der Waals forces between hydrophobic aliphatic chains, in which geometrical and steric hindrance is critical between the glycerol groups.

Polymorphism in Fats

Polymorphism is defined as the ability for a chemical compound to form different crystalline or mesophase (liquid crystalline) structures. The melting and crystallization behaviour differs from one polymorph to others, since the different crystal structures correspond to different Gibbs energies.

Polymorphic crystallization is primarily determined by the rate of nucleation, as determined by thermodynamic and kinetic factors. If the first crystallizing form is less stable, it converts to more stable polymorphs through the solid matrix or liquid mediation. As a consequence, morphology of fat crystals is a function of the crystal structure itself, and the thermal processes of the crystallization and sub-

Figure 1 Relationship of molecular properties of fat crystals and macroscopic physical properties of fats.

sequent transformation. The interrelationships among fat molecule structures, polymorphic crystal-line structures, phase behaviour of the mixing of different fats and other ingredients, melting and solidification, and transformation and crystal morphology are illustrated in Figure 1.

Molecule Structures and Polymorphism of Fats

This section briefly describes the molecular structural properties of fat polymorphs.

Typically, three polymorphs, α , β' and β , are usually observed in TAG crystals. However, two or even three more forms are present in TAGs if their fatty acid structures are rather complicated, in the sense that the three fatty acid moieties (R_1 , R_2 and R_3 in Figure 1) differ in their chemical structures (length, saturated/unsaturated, even-chain or odd-chain, etc.). The three forms are basically characterized by the lateral chain packing mode, expressed in subcell structures: hexagonal (H) packing for α , orthorhombic perpendicular (O_{\perp}) packing for β' , and triclinic parallel (T_{\parallel}) packing for β . Since the lateral packing mostly determines the crystalline density, it follows that α is the least dense packing, β' intermediate and β the densest packing. As for the chain length structure, the double chain length is revealed in the TAGs containing similar types of three fatty acid moieties, and, by contrast, the triple chain length structures are revealed in the TAGs where one or two of the fatty acid moieties are largely different in their shapes from the others.

Polymorphism and Macroscopic Physical Properties

The microscopic properties of the fat polymorphs eventually result in complex macroscopic physical properties of mixing, melting/crystallization and the structure/morphology of the crystallized materials. In particular, the rate of crystallization and the crystal morphology are directly influenced by polymorphism.

Mixing of fats The mixing properties of different TAG materials, is highly relevant in fat materials, because many fats present in real systems are multi-component in two ways: (a) a fat phase containing many different types of TAGs and (b) each TAG molecule involving different types of fatty acid moieties, namely mixed-acid TAGs. Three typical phases occur in binary solid mixtures, when the two components are miscible in all proportions in a liquid state: solid solution phase, eutectic phase, and compound formation. The general tendency in the relationship between the molecular interactions and the phase behaviour may be summarized as follows: structural affinity results in solid solutions, poor interactions form eutectic phases and specific interactions give rise to molecular compounds.

In addition, polymorphism makes the mixing behaviour more complicated. For example, in the mixture of mono-saturated acid TAGs, a eutectic phase with a limited region of solid solution is the stable form when the chain length difference is no larger than two carbon atoms. However, metastable forms of α and β' exhibit solid solution phases. Furthermore, the chain length structure also affects the mixing behaviour, even if the polymorphic properties are similar between the component TAGs: for example, the double chain length and triple chain length structures are not miscible with each other.

As for the formation of compound systems, compound formation occurs in particular sets of TAG mixtures, in such mixtures as SOS/SSO (1,2-distearoyl-3-oleoylglycerol) and POP/OPO (P = palmitoyl), where the compound is formed at a concentration ratio around 1 : 1. The mixing behaviour and the crystallization properties in binary fat mixtures will be discussed in a later section.

Melting behaviour The melting behaviour in relation to fatty acid composition of TAGs is straightforward: the longer the fatty acid chain, the higher the melting point, and saturated-acid TAGs have higher melting points than unsaturated fatty acid TAGs. The next concern is the effects of polymorphism of fats (which are mostly of a monotropic nature) on the melting and crystallization behaviour. As an example, we take three polymorphic forms of

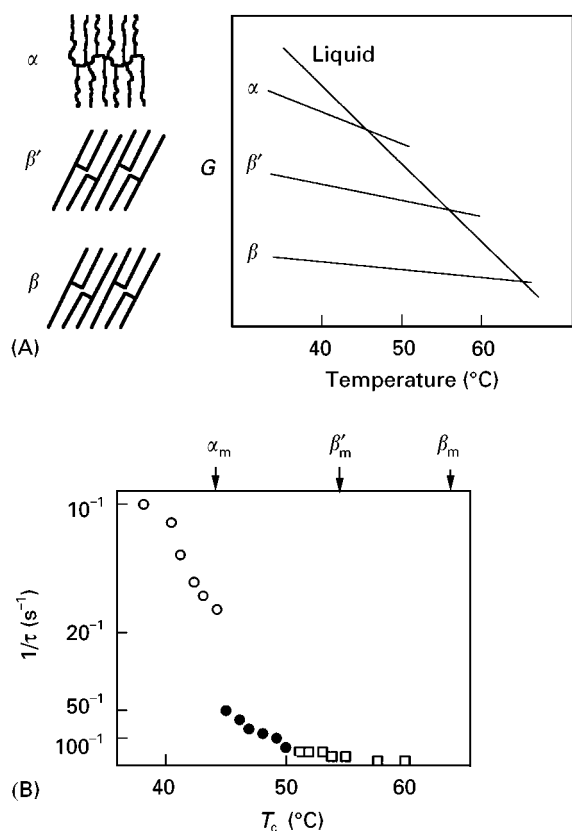

Figure 2 (A) Structure models and Gibbs energy (G)-temperature (T) relationship of three polymorphs of PPP, and (B) rate of nucleation of PPP polymorphs. \circ , α form; \bullet , β' form; \square , β form. T_c , crystallization temperature.

tripalmitoylglycerol (PPP), whose structural and crystallization properties have been well elucidated, as illustrated in Figure 2.

Figure 2(A) shows α , β' and β forms of PPP. Molecular structures of the three forms are briefly specified by the following: disordered conformation in α , intermediate packing in β' and most dense packing in β . Therefore, the Gibbs free energy (G) values are highest in α , intermediate in β' and lowest in β , resulting in the lowest melting temperature for α , etc. As a result of the combined effects of the molecular structures and the rate of crystallization, the crystal morphology is of amorphous irregularity for α , tiny bulky shape for β' and needle shape for β .

The polymorphic properties of PPP are basically common to those in the other fats. However, more complexity is revealed when the fatty acid compositions of the three moieties become heterogeneous, in particular for TAGs involving saturated and unsaturated fatty acid moieties as present in many vegetable fats.

Structure and morphology The crystal structures are determined by X-ray analysis using single crystals, are

unique for the specific polymorph of a specific TAG. The morphology of crystals, however, is a result of combined interactions of the crystal structure itself, and rate of crystal growth of the specific crystalline faces which are influenced by the growth conditions. For simplicity, however, it may safely be referred to the polymorph-dependent crystal morphology; α reveals irregular shaped tiny crystals, β' bulky-shaped tiny crystals, and β lozenge-shaped needle crystals.

Polymorphic Crystallization

Polymorphic crystallization is primarily determined by the rate of nucleation, being governed by thermodynamic and kinetic factors. A primary concern is the polymorphic nucleation, in which the so-called Ostwald step rule is of great interest. This predicts that a phase change may occur step by step by way of successively more stable phases. Thus, the metastable forms nucleate first, prior to the most stable form, when nucleation is induced under large kinetic factors, e.g. supercooling or supersaturation. When the kinetic factors are minimized, the step rule is broken, and the more stable forms are nucleated at very reduced rates.

This tendency was confirmed in the crystallization of three forms of PPP. For PPP, induction time (τ), the time until the occurrence of the first-appearing crystals are detectable, is shortest for α , intermediate for β' and longest for β as shown in Figure 2(B) for the case of simple cooling of the liquid. However, when the temperature of cooling fluctuates around the melting points of α or β' , the nucleation of more stable forms is markedly accelerated, because of melt-mediated crystallization.

Melt-mediated nucleation is ascribed to the monotropic nature of polymorphism, as revealed in the following processes: (a) melting of the less stable form, (b) nucleation and growth of more stable forms, and (c) mass transfer in the liquid formed by melting of the less stable form. It often occurs that the rate of melt-mediated transformation is considerably higher than the rates of crystallization of the stable polymorph without passage through metastable forms. Dynamic X-ray diffraction studied using synchrotron radiation (SR-XRD) has enabled *in situ* observation of the melt-mediated transformation over a time scale of tens of seconds.

In regard to the SR-XRD studies, deeper insights of the polymorphic crystallization have been unveiled by the time-resolved analyses of the crystallization from neat liquid. The result has shown that: (a) the formation of lamella ordering, both for double or triple chain length structures occurs more rapidly

than that of the subcell packing; (b) the rate of the α - β' melt-mediated transformation is remarkably high when the lamella structures of the pre-existing form (α) remains. So-called 'melt-memory effect', meaning the effect of solid structures present in the liquid phase, may be clarified by the time-resolved SR-XRD under temperature variation.

The control of the polymorphic crystallization may be affected by the addition of crystal seeding and the application of shear stresses. As to the former effect, it was found that specific molecular interactions between the crystal seed materials and the polymorphic forms of specific fats are a prerequisite for the seeding effect, in polymorphic correspondence, structural similarity and thermal stability. As a typical demonstration, a quite interesting seeding effect has been observed in cocoa butter crystallization, which has been applied to solidification control of chocolate production processes.

Cocoa butter has six polymorphs of form I through to VI, in which form V is the most desirable. For optimally obtaining form V in the solidification process, a tempering process is applied using the following temperature profile: first cooling the molten chocolate to 26–27°C, reheating to around 30°C, and subsequent cooling for bulk solidification. During the first cooling process, rapid crystallization causes the formation of unstable polymorphic forms of cocoa butter crystals due to Ostwald's Law of stages. The occurrence of the unstable forms are not favourable, because they cause poor moulding and induce fat bloom. Therefore, the first-cooled chocolate is heated to around 30°C, so that the unstable forms melt and quickly change to form V by the melt-mediated transition. After the tempering, chocolate is poured into a mould, and cooled for complete solidification.

The seed crystallization technique aims at achieving two major advantages, compared to the tempering technique: (a) it accelerates the crystallization of form V of cocoa butter, and (b) it does not use the cooling/heating process of tempering. For this purpose, a technique using BOB (1,3-dibehenoyl-2-*sn*-oleoylglycerol) β_2 polymorph has been developed.

Figure 3 shows the relative crystallization time (t_r) of seeded dark chocolate examined at 30°C. The crystallization time was measured with a rotational viscometer and t_r is defined as the ratio of the crystallization times with and without seeding. Figure 3 clearly shows that the stable form β_1 of SOS, which is a major component TAG in cocoa butter, is most effective, stable form β_2 of BOB is in-between and β of SSS is least effective. From this result, one may argue that there are three factors in the crystal seeding effect: (a) similarity in the crystal structure between the seed crystal and form V of cocoa butter, (b)

Figure 3 Relative crystallization time (t_r) of cocoa butter with the addition of three crystal seeding materials (SSS, tristearoylglycerol).

thermodynamic stability of the seed crystal, which is related to its solubility in the molten cocoa butter, and (c) the relationship of the acyl chain length of TAG between the seed material and cocoa butter. As to (a), it was shown that the β_2 of BOB or SOS and form V show identical structural properties to each other. However, the melting point of SOS β form, around 43°C, is too low for it to be put into molten cocoa butter at 30°C, and thereby no effect of crystal seeding is operative. As to the β form of SSS (tristearoyl-glycerol), its melting point, 70°C, is optimal as far as the thermodynamic stability is concerned. However, the molecular structural affinity between the β of SSS and β_2 of BOB is poorest, because of the difference in the chain length structure: double chain length for β of SSS and triple chain length for β_2 of BOB. Therefore, a final solution of the finest seeding material is the β_2 of BOB.

As to the shear effect, the newest finding of the shear stress application on cocoa butter crystallization indicates a by-passing effect to crystallize β -type polymorph (form V), which otherwise does not crystallize directly from the quenched liquid. A time-resolved SR-XRD spectra revealed the transformation from β' -type to β -type polymorphs during the initial stages of crystallization under shear stresses. The molecular mechanism for this conversion is not fully understood.

Phase Behaviour and Crystallization Kinetics in Binary Fat Mixtures

Fats present in natural sources are mixtures of different types of TAGs. Therefore, the complicated behaviour of melting, crystallization and transformation, morphology, etc. of real fat systems is partly due to the physical properties of the component TAGs, and partly or more importantly due to the phase behaviour of the mixtures. To resolve these complexities in mixed systems, a fundamental study has been made on binary and ternary mixtures of specific TAG components. Recent studies carried out on the phase behaviour and crystallization kinetics of the binary mixtures of principal TAGs, are given below.

In general, three typical phases may occur in binary solid mixtures, when the two components are miscible in all proportions in a liquid state: a solid solution phase, a eutectic phase and compound formation. For TAG mixtures, two factors are concurrently dominating: polymorphism and chain-chain interactions.

The polymorphic influence is clearly seen for the PPP-SSS mixture system, where the carbon numbers (n_c) of the fatty acid moieties of the two TAGs differ by two. Solid solutions are formed in the α and β' forms, yet the eutectic phase was formed in the most stable β form. This contrast is ascribed to the less condensed molecular packing in α and β' and to the most dense packing for β . It is reported, however, that the formation of the solid solution in the metastable forms is hindered when the difference in n_c between the component TAGs exceeds four, and that eutectic phases become predominant.

It has recently been found that the phenomena observed in the PPP-SSS mixture above does not simply apply to the mixtures of saturated-unsaturated mixed-acid TAGs such as POP-OPO, POP-PPO and many other similar mixtures, where O is oleic acid moiety, and PPO, for example, is a stereoisomer of POP where the fatty acids are connected to different glycerol carbon atoms. Despite the quite diversified phase behaviour exhibited in these combinations, one may make two important points: (a) steric hindrance between the saturated acid and oleic acid moieties induces the formation of eutectic phases for the α , β' and β polymorphs for the mixture of POP-PPP, and (b) attractive interactions through the saturated and oleic acid moieties cause the formation of molecular compound at a 50 : 50 concentration ratio of the two components. Quite interestingly, the chain length structure of the molecular compound is largely deformed from those of the component molecules, e.g. a triple chain length structure in POP and PPO, but a double chain length structure in the molecular compound of POP-PPO.

Therefore, the eutectic phase is revealed in the component and compound materials.

The formation of the molecular compound has two implications for the fat separation problems: firstly, no easy separation is possible by dry fractionation for the molecular-compound mixtures, and secondly polymorphic transformation is affected by the presence of the molecular compounds. More interestingly, the rate of nucleation of the molecular compound is much higher than those of the component TAGs.

The diverse properties in fat mixing behaviour, as illustrated above for a typical model substance, might also be revealed in natural fats having high melting fractions, such as palm oil, shea fats, etc. Therefore, for the purpose of the separation of the high-melting and low-melting fractions, it is pertinent to examine physical analyses of the mixing behaviour of the principal TAG components, as basic research on the one hand, and to extend the main results to more multi-component systems tightly mimicking real systems.

Extraction by Solvent Based Methods

Along with proteins and carbohydrates, fats and oils make up the major classes of food components. Edible fat and oil usage falls into four major product categories: cooking and salad oils, shortenings, margarines and specialty products. Tissues from animals liberate oils on being boiled and oils can be pressed from fruits, vegetables and seeds, such as olives, soybean and sesame. Solvent extraction is a viable alternative to pressing and can recover nearly all the oil from the seeds. Figures for world production of fats and oils have only been kept since 1942 and, although growth in the use of fats and oils since then has outstripped population increases, there has been a significant shift from animal to vegetable fats. **Table 1** shows the relative changes in world production figures for selected major fats and oils since 1935.

Traditional methods employing liquid extraction rely on the use of simple processing equipment and low pressure applications. They fall into two main categories of water flotation and traditional pestle and mortar extraction procedures. The water flotation method involves heating in water followed by size reduction (pestle and mortar-type equipment) and skimming off of the oil followed by heating to remove the moisture. Coconut and palm oil extraction efficiencies range from 40 to 60%, though free fatty acid contents are high. The Ghani mill (typically powered by animals) has been used in India for 3000 years and at the beginning of this century approximately 97% of oilseeds were processed this way, utilizing over half a millionghanis. This figure has dropped to 4% in modern times, owing to the introduction of screw and hydraulic presses, and solvent extraction.

The hydraulic press was invented by Joseph Bramah in 1795 and continued to be used in the American oilseed crushing industry until the 1940s. By then, new options were replacing the labour-intensive batch-processing presses, with expellers (continuous screw presses) and direct solvent extraction with the two unit operations often occurring together as a two-stage process. Mechanical expression can only reduce oilseed oil content to 2–3% whereas solvent extraction will reduce this figure to about 0.5%. Low temperatures during solvent extraction can produce a higher quality oil than higher temperature screw pressing but may also extract nontriglyceride material, making the oil inferior to pressed oil.

Solvent extraction of fats and oils from seeds became possible from the middle of the 19th century. In 1948 the first commercial solvent extraction plant was built. Since then, over 200 extractors have been supplied worldwide for capacities up to 6000 tons per day. Solvent processes found favour in the vegetable oilseed refining industry, with continuous miscella (solvent plus pressed cake) refining and continuous solvent fractionation (e.g. winterization) becoming commercial reality in the early 1950s.

Solvent Extraction Methodology

Extraction Theory

Solvent extraction is usually used to recover a component from either a solid or liquid. The sample is contacted with a solvent that will dissolve the solutes of interest. Solvent extraction is of major commercial importance to the chemical and biochemical industries, as it is often the most efficient method of separation of valuable products from complex feedstocks or reaction products. Some extraction techniques involve partition between two immiscible liquids; others involve either continuous extractions or batch extraction of solid. Because of environmental concerns, many common liquid–liquid processes have been modified either to utilize benign solvents, or replaced by processes such as solid-phase extraction. The solvent can be a vapour, supercritical fluid or liquid, and the sample can be a gas, liquid or solid.

Table 1 World production of commercially important edible fats and oils

Fat/oil source	World production (MMT)			
	1935	1955	1975	1995
Soybean	0.5	2	8.5	16
Palm	0.5	1	2	14.5
Rapeseed (canola)	1.3	1.5	2	9.5
Butter	4	3.5	5.3	8
Sunflower	0.4	1.5	3.5	7.5
Tallow	1.7	3	5.5	7
Lard	3	3.5	4.2	5.5
Cottonseed	1.5	1.8	2.8	4.8
Peanut	1.8	2	3.2	3.9
Coconut	1.7	2	2.5	3.3
Sesame	0.8	1	1.7	1.9
Fish	0.5	0.5	1.2	1.5
Olive	0.6	0.6	0.7	0.8
Total	18.3	23.9	43.1	84.2

MMT, million metric tons.

Fats and oils are hydrophobic and hence insoluble in polar solvents. Use is made of their affinity for nonpolar media in oil extraction, separation of oil from bleaching earths and oil-refining technology. Fatty acids accompanying oil extraction are also soluble in polar solvents and use can be made of this in refining methods to separate the two groups. However, difficulty is experienced in that fatty acids and other liquids may be more soluble in the oils themselves than in the selected separation solvent. Solubility covers a wide range and is influenced by a rise in temperature (which increases solubility) and an increase in chain length (lower solubility) of fatty acids making up the triglycerides.

Choice of Solvent

The ideal solvent for oil extraction must possess several features that are impossible to find in any one solvent. These properties include the ability to solubilize the oil at low temperatures, selectivity towards triglycerides, chemical inertness, immiscibility with water, nonflammable, low viscosity and surface tension, nonexplosive, noncaustic, low boiling point, nonirritant and nonpoisonous.

Hexane is the almost exclusively chosen solvent due to its solvent power, volatility, low and nontoxic residue levels and immiscibility with water. However, care in handling is required due to high flammability. Before hexane, carbon disulfide and trichloroethylene were used; however, the former has since been banned and the latter declared undesirable for preparing animal feeds. The greater solvency and nonflammability of trichloromethane renders it of use for extraction of tallow from meat and bone but, due to desolventizing problems, it is not used with oilseeds. Replacement with dichloromethane is an option but not favoured due to the risk of hydrochloric acid formation and the use of ethanol, either as a solvent or as an azeotrope with hexane, has been studied but not commercialized.

Recovery of solvent from the extraction of fats is a major consideration in solvent choice. The acceptable recovery standard is 99.92%, which can be represented by a loss of 1.135 litres of hexane per processed tonne of soya. Losses may occur from desolventizing the meal, from stripping the final oil product and from air and water discharges to waste. In the US the Environmental Protection Agency is charged with controlling emission levels with respect to hexane, although required levels are still to be set under the Federal Clean Air Act. A likely example for soybean processing is 0.2–0.25 kg for every 100 kg of beans processed. To date, the industry relies on self-regulation, required because of the high cost of lost solvent.

Supercritical fluids have been investigated since the last century, with the strongest commercial interest initially focusing on the use of supercritical toluene in petroleum and shale oil refining during the 1970s and latterly supercritical carbon dioxide for fats and oils. Carbon dioxide cannot be used as a simple substitute for organic solvents, however. Phosphatides (e.g. lecithin) are selected against compared with hexane when extracting vegetable and fish oils, for example. As a solvent, dense carbon dioxide tends to be selective for lower molecular weight lipophilic compounds. This can be utilized for partial fractionation of free fatty acids from triglycerides, decreasing cholesterol levels and increasing β -carotene content by selective control of solvent temperature and pressure to exploit differences in solubility, vapour pressure and molecular weight.

General Processes

The main disadvantage of solvent extraction is the high equipment cost and plants tend to be large, processing hundreds to thousands of tons per day. The extracted miscella (solution of solvent plus oil) contains fines, which need to be separated and well washed. Solvent and oil will also be held up in the solids (marc).

Pretreatment Before oil can be extracted from fruits and vegetables, the seeds must be prepared. Seed preparation for extraction involves cleaning, dehulling, cooking to denature proteins, adjusting moisture content to the right level and then crushing or rolling into particles or flakes of uniform size and thickness.

For solvent extraction, the optimum moisture level allows flaking of the seeds whilst minimizing crumbling. Ready penetration of the solvent is enhanced without blocking the extractor so that the miscella which forms can be easily separated from the cake.

Improving pretreatment of press-cakes allows a reduction in solvent-to-solids ratios and a reduction in solvent hold-up in the desolventization process. The French Enhanser Press is an extruder used to pelletize oil-bearing seeds or pre-press cake to provide an ideal medium for solvent extraction. As pellets discharge from the die plate of the Enhanser Press, they expand and flash off moisture. This creates dense pellets with a vast matrix of open-structured, internal solvent passages. These pellets yield much better extraction results than flakes or pre-press cake. This results in savings in distillation energy (steam required).

Extraction The extraction operation typically follows a countercurrent flow process where the solids move in the opposite direction to the solvent–oil

miscella, which meets the oil-rich flakes at high oil concentration. The flakes are sequentially extracted with solvent of lesser oil content through the different stages until the almost entirely extracted meal is finally met with pure solvent to complete the extraction efficiently. The first miscella wash leaves the system for distillation and oil recovery while the final extracted flakes go to a desolventizing process.

Batch extractors. The process involves sequential washing of oil-bearing material with progressively leaner miscellas until the final wash is with solvent alone. The vessels are loaded one at a time and are no longer used for any other than specialty runs.

Total immersion extractors. The material to be processed travels through a pool of solvent. These are early designs (1930–1950s) and suffered from excess fines carried along in the solvent.

Percolation extractors. These may be either batch or continuous and differ from the immersion extractor in that the solvent passes through the solids, dissolving out the oil. Five main types are in use: basket, rotary, perforated belt, sliding-bed and rectangular loop extractors.

Combined plants. Percolation and immersion extraction may be combined sequentially to advantage (e.g. C.M.B. Percolimm). Flaked seed, which has been percolation-extracted, is immersion-extracted and then desolventized. The immersion miscella is used as a solvent in the percolation extractor for the original seed flakes. The extractors are of two main types: deep- or shallow-bed. The deep-bed-type (or rotary extractor) is semi-continuous with a number of baskets supported on a drainage screen, designed to allow the miscella to pass. The screens can be rotating or fixed, as can the baskets and washing manifolds. The extractor moves slowly and miscella drains through the screen until the basket reaches the final position when the solids are released, the screen reclosed and a fresh load of solids deposited. The shallow-bed-type

works similarly for drainage of miscella and operates in continuous mode where the flakes meet solvent in a countercurrent direction in different zones of the extractor. The percolation extractor employs solvent being pumped over and percolating down through a bed of flakes or a cake and leaving via a perforated plate at the bottom. Immersion extractors are claimed to allow better extraction from fine cake particles, which may block the bed of a percolation extractor. Examples of immersion and percolation extractors are shown in Figures 1 and 2.

Desolventizing The extracted flake material may contain 25–35% residual solvent. In the desolventizer/toaster, steam is used to evaporate the volatile solvent countercurrently. The vapour phase is condensed and collected. The meal is toasted in steam-jacketed trays, then dried and cooled. For edible flour, the process may be replaced with a flash desolventizing system.

Solvent stripping of the extracted oil is carried out by evaporation. Removal of flavour components is likely at this stage also. The miscella is normally separated into oil and vapour through a series of falling film evaporators and stills with the miscella on the tube side and the vapours on the shell side. The first-effect evaporator uses steam and solvent vapour from the desolventizer/toaster to concentrate the miscella to about 80% oil content. The second stage operates atmospherically or under vacuum to bring the concentration up to 95–98% oil, and the remaining volatiles are stripped in the still operating under vacuum. Refinements to the process are used depending on the oil being extracted. For cottonseed oil, caustic may be added during the first- and second-effect evaporators and the mix centrifuged to remove colour bodies before they set during distillation.

Recovery of the solvent from immersion extractors traditionally took place in a series of interconnected cylindrical vessels where the marc progressed by dropping from one vessel to the next in a zigzag fashion. These early models were often named schneckens (winding staircase) desolventizers. With

Figure 1 Oil solvent extraction apparatus (immersion type). Courtesy of Europa Crown Ltd., Hessele, UK.

Figure 2 Oil solvent extraction apparatus (percolation type). Courtesy of Europa Crown Ltd., Hessele, UK.

the advent of percolation extractors, the desolventizer/toaster appeared in the 1950s. This consists of an upright cylinder divided into horizontal sections or trays. Material is agitated via a sweep arm which also opens a door, allowing product to fall to the tray below. Heat is supplied to vaporize the solvent, which is flashed off the topmost trays with sparge steam, which also partially cooks (toasts) the solids. The sparge steam can be absorbed by the solids on condensing, which prevents carry-over of dust to the condenser. A variation to the basic models allows flash desolventizing, where recirculating steam under high velocity strips the solvent at low temperature to avoid denaturing the protein. Another variation is countercurrent desolventizer/toasters, where the steam is introduced at the bottom and travels through to the top to a steam-jacketed desolventizing tray, where indirect steam flashes off surface solvent. Flash desolventizers are used to prepare high nitrogen soy protein for meat analogues and the desolventizer/toasters recover solids as animal feed. In the solvent extraction industry, the term DTDC stands for desolventizing–toasting–drying–cooling. These four operations can be performed in a single DTDC machine, or split between two separate DT and DC machines. Both types of configurations have specific advantages which may make one or the other preferable in certain applications. **Figure 3** shows a DTDC system.

Solvent refining of fats and oils Fractionation using solvents involves forming a miscella of oil in the solvent, which is then cooled to produce crystallization. Filtration of the stearin fraction follows and both fractions are then heated to recover the solvent. The Bernardini process uses hexane as solvent and produces two stearin and one olein fractions. Acetone and 2-nitropropane have also been utilized as solvents. The process for palm oil involves cooling an equal mixture of oil and hexane to 30–33°C and pumping to the chiller where the mixture is held at 20°C, when crystallization begins. The cooled mass is

passed to a second vessel and the temperature reduced to 10°C. Filtration using rotary drums separates out the first stearin fraction and the oil plus solvent is carried through a further series of cooling steps at 7°C, 4°C and 2°C respectively. The second stearin fraction is then removed through drum filters. All three fractions are freed from solvent by distillation.

Beef tallow and hydrogenated vegetable oils can also be similarly doubly fractionated. The first stearin fraction can be used for shortenings, the second for confectionery butters and the third (or olein fraction) as a frying oil which is liquid at room temperature. Without solvent, the conventional dry fractionation yields a stearin fraction which contains too much entrained oil to be of use as a confectioner's hard butter.

Winterization is beneficial for rice bran oil where the oil is frequently cloudy at room temperature. Solvent winterization separates the high and low melting triglycerides. Solvents used include hexane, acetone and isopropyl acetate. Although fractional crystallization from miscella has had limited acceptance, it is potentially less labour-intensive than the conventional batch winterizing process with faster throughput and yields greater quantities of winterized oil. In addition, manufacturers could produce modified fats without the formation of *trans* isomers by fractionally crystallizing mixtures of vegetable and animal oils from miscella. Other options involve adaptation of the technology for continuous miscella hydrogenation and miscella bleaching employing silica gel to remove colour.

Solvent extraction of oils from used bleaching earths is a logical method of recovery but only for large volumes to make it economical. Enclosed filters allow hexane to extract the oil from the earth in several stages before recovery of oil by evaporation of the miscella. Chlorinated solvents are also effective solvents depending on the end use of the recovered oil. Supercritical fluids are being researched as a cheaper alternative.

Selected Applications in the Fats and Oils Processing Industry

Table 2 shows a range of applications arising from patents during the 1970s. Other examples include separation of fat-free protein and oil from peanuts, rice bran and soybean (hexane), cottonseed (hexane plus acetic acid), starch plus oil from corn grits, germ, hulls and gluten (hexane or isopropyl alcohol) and separation of beef tallow into five fractions with distinctive thermal characteristics by multistep crystallization. Direct solvent extraction is used for low content (<20%) oilseeds such as soya, rice bran and milled corn germ. Pre-pressing followed by solvent extraction is utilized with high oil content seeds, although some manufacturers claim high efficiency with direct methods.

Using water as a solvent for oil extraction has commercial applications for palm, olive and coconut oils but not for oilseeds due to high residual oil in the extracted meal and extra energy needed in the separation and drying steps. Adding enzymes to the aqueous medium to digest cell walls can be advantageous,

as in the development of processes to extract olive, canola and coconut oils. Hexane may also be added to aid the separation.

Isopropanol and ethanol were used to extract cottonseed oil since the combination made it possible to extract the gossypol and render the solids more suitable as animal feed. However the oil needs more refining due to phosphatides and carbohydrates which are also extracted.

Two-phase extraction employing polar and non-polar solvents has been successfully used in rapemeal processing. An extraction with methanol followed by washing with hexane and phase separation lowers the glucosinate content.

Soybeans

Soybean oil had very rapid growth to become the dominant edible oil in the world, partly due to the versatility of the oil which enables it to be used in a wide variety of products and applications.

Solvent extraction is the preferential method for soybeans, the others being hydraulic pressing and expeller pressing. Soybeans form stable flakes,

Table 2 Patents issued for solvent extraction applications from 1973 to 1977

<i>Solvent system</i>	<i>Oil source</i>	<i>Equipment</i>	<i>Patent</i>
Hexane-ethanol (2-30%)	Soybean, cottonseed, safflower, sunflower, peanut, sesame	Countercurrent extraction, centrifugation, steam stripping	AE Staley
2-Propanol-H ₂ O ₂ (0.1-1.0%)	Oats	Soxhlet, centrifugation, evaporation	Du Pont
Hexane	Yeast powder	Continuous solvent extraction (Rotocel)	Simon-Rosedowns
Water (1 part) plus 2 parts acetone or ethyl alcohol-ethyl acetate-acetone (1 : 1 : 1) or ethyl alcohol-ethyl acetate-isopropyl ether (4 : 2 : 1)	Palm fruit, olives	Multistage countercurrent disintegrator-extractor basket centrifuge Buchner filter vacuum stripping	RA Gouche

unlike cottonseed, peanut and other high oil-bearing seeds, where meals need to be processed through slotted wall extruders before being solvent-extracted.

Palm

For extraction of palm oil it is common practice to use screw presses and not employ wet methods. Similarly, solvent fractionation processes are available for fractionation but the comparative operational cost of miscella crystallization and filtration restricts the process to production of 2-oleodipalmitin-rich fractions for use in cocoa butter substitutes. Yield of olein from the miscella is about 80%.

Canola (Rapeseed) and Sunflower

Canola and sunflower are high oil content seeds and are generally processed by a pre-press solvent extraction. This removes the oil from the seed in two steps, which maximizes oil yields while minimizing residual oil in the meal. The canola presscake, which yields approximately 60% oil, may be mechanically extruded to improve the solvent extraction process. The industry increasingly relies on DTDC equipment for desolventizing.

Animal Fats

Screw presses are the method of choice for most renderers, although some animal fats are solvent-extracted. Use of solvents such as acetone to remove unwanted components such as cholesterol from milk fat has proven effective. The potential for solvent residues in the product does not meet with regulatory or consumer approval, however, hence the solvent

extraction process is only applied for technical purposes.

Using an immersion system (e.g. Kurd), raw material from animal processing is first heated and broken into small pieces before being mixed with the solvent (usually perchlorethylene) in an autoclave. The miscella is drained and may be used again for a second extraction, when the solvent is evaporated and the solids returned to the extractor for desolventizing with steam. The solids, free of solvent, contain 40-60% water and are then dried and milled for meal. Continuous percolation plants may also be utilized (De Smet extractors). The raw material is broken up in a cooking step and excess tallow drips through a perforated plate, leaving the residue with 30-35% fat. This is ground and extracted (usually with hexane) in a similar fashion to the system described for immersion extractors earlier and the solvent separated from the miscella by evaporation. The solids are toasted to desolventize them.

Solvent extraction may be combined with press extraction, either by using solvent techniques for further oil recovery after pressing or by pressing miscella out of the solid residue rather than recovery by decantation. These options reduce the amount of solvent that has to be removed, lowering cost and saving energy.

Fish Oils

Conventional fish oil extraction requires relatively high temperatures and solvent extraction can provide a low temperature alternative, but solvent choice is limited to food grade-approved cases. The use of alcohol, an approved solvent, has proven uneconomical due to poor extraction efficiencies. Supercritical

carbon dioxide extraction is considered safe but, although the product is of good quality, possible removal of antioxidants, such as tocopherols and phospholipids, and the retention of residual trace components is of concern.

Cottonseed

Cottonseeds contain about 30% oil. Screw pressing is commonly used for cottonseed oil pressing, but direct solvent (hexane) extraction yields 11.5% more oil, leaving less than 1% in the meal. Pre-pressing followed by solvent extraction is the most economical alternative due to the cost of solvent. Refining is necessary to remove the gossypol and related pigments.

Safflower

Oil extraction in the safflower industry has shifted from a largely screw press expeller base to less costly expander-extruders which are capable of extracting two-thirds of the oil and preparing collets ideal for solvent extraction. Solvent is able to move naturally through the fibre channels and the bed acts as a natural filter medium.

Coconut

Copra is processed using a dry process comprising crushing or expelling and optional further solvent extraction to recover the residual oil. This contrasts with the wet method for the fresh kernel which separates oil from the coconut milk by centrifugation.

Olives

Solvent recovery of oil from olives is limited to pomace processing. Superior olive oil is produced by pressing. The solvent extracts minor components at higher levels than physical methods and requires refining before use.

Cocoa Butter

Cocoa beans possess a chocolate aroma which develops during roasting of the beans. However, this aroma is lost if solvent extraction is employed during processing. The yield of cocoa butter is higher but the value may be less if the odour is desired.

The major triglyceride found in cocoa butter is 2-oleopalmitostearin. Cocoa butter substitutes can be manufactured using solvent systems based on methanol and hexane to prepare this triglyceride via isolation of saturated 1,3-diglycerides from the reaction of palm oil (hydrogenated soybean or cottonseed oils have also been employed) and glycerine using sodium methoxide catalysts. The isolated diglycerides are

then reacted with oleic anhydride to give the 2-oleo-disaturated product.

Recent Developments

Advances in solvent extraction technology have involved the areas of energy conservation, influences of increasing size of extraction plants, adaptation of conventional extraction plants to produce edible meals, percolation versus immersion extractors and direct solvent extraction versus pre-pressing followed by solvent extraction.

Commercial developments are attractive for alternative or specialty oils compared with traditional oil products and for overcoming the costs and constraints of traditional solvent extraction systems for minimizing industrial wastes. Utilization of vapour contactors to conserve heat during processing and dual-stage stripping columns in removing the last traces of solvent from the oil also contribute to efficiency.

The biggest interest in the last decade has been the applications of supercritical carbon dioxide, because it has a near-ambient critical temperature (31°C), thus biological materials can be processed at temperatures around 35°C. The density of the supercritical CO₂ at around 200 bar pressure is close to that of hexane, and the solvation characteristics are also similar to hexane, thus it acts as a nonpolar solvent. Around the supercritical region, CO₂ can dissolve triglycerides at concentrations up to 1% mass. The major advantage is that a small reduction in temperature, or a slightly larger reduction in pressure, will result in almost all of the solute precipitating out as the supercritical conditions are changed or made subcritical. Supercritical fluids can produce a product with no solvent residues. A wide range of fats and oils have been extracted employing supercritical fluid extraction from sources including fish, vegetable oils, nuts, cereals, citrus peel, egg yolk, wormwood and yeast extract. Examples of pilot and production-scale products include decaffeinated coffee, cholesterol-free butter, low fat meat, evening primrose oil and squalene from shark liver oil.

Processes for the selective extraction of fats and oils employing propane and a mixture of propane with up to 50% carbon dioxide in the subcritical state have been described (European patents 0-591-981, 1993 and 0-721-980, 1995) for the extraction of fats and oils from vegetable, animal and microbial materials. The low pressures involved allow milder extraction conditions than conventional processing, providing a good yield of high grade products.

FLAME IONIZATION DETECTION: THIN-LAYER (PLANAR) CHROMATOGRAPHY

The Iatroscan is a British invention brought to fruition in Japan by Iatron Laboratories of Tokyo, which is basically a hospital equipment company. It has become unexpectedly popular in such diverse analytical areas as marine lipids and heavy petroleum fractions. The combination of the resolving power of thin-layer chromatography (TLC), itself only somewhat more than 40 years old, with the simplicity and sensitivity of the hydrogen flame ionization detector (FID), developed about that time as a superb detector for gas-liquid chromatography (GC), was a happy marriage, usually summarized as TLC-FID. The basic separation technology of the Chromarod-SIII is conducted on a quartz rod 0.9 mm in diameter and 152 mm in length, coated with 75 μm thickness of

silica gel (10 μm particles) held in place by a soft glass frit. Ten Chromarods are conveniently held in a stainless steel rack for application of samples and subsequent development in a covered solvent tank, exactly as for planar TLC. The removal of solvent takes only a few minutes and the rack can then be dropped into a holding frame in the Iatroscan proper for scanning. This process can be controlled for maximum sensitivity but usually takes less than 10 min.

A virtue of the 10 Chromarods is that 10 different samples can be quickly compared or any combination can be replicated or compared to calibration standards run at the same time. The basic mechanism for passing the rod through the flame is fully automated. In the popular Mark III Iatroscan, the frame holding the development rack of up to 10 Chromarods was inclined. This has been replaced in the Mark V unit (Figure 1) with a horizontal frame. In the Mark IV Iatroscan the TLC-FID principles remained the same

Figure 1 Top view of Mark V Iatroscan with horizontal rack holding 10 Chromarods in position for automatic scanning in the FID. The flame jet on the right is visible below the ion collector. The Chromarods pass between the two FID parts as the frame holding the development rack cycles for scanning. After each scan the frame moves sideways and returns between the Chromarods, bypassing the FID and moving sideways to start the next Chromarod. The right-hand rod is reflected in part of the ion collector.

but some improvements in quantitation of lipids were found in a new detector design, and that development led to an improved FID arrangement installed in the Mark V. It has not yet been rigorously evaluated for quantitation, for example in conjunction with hydrogenation of complex lipid extracts, but should be an improvement over the robust Mark III as regards quantitation.

General Considerations

GC and high performance liquid chromatography may frequently require an hour for each analysis. With several sets of Chromarods at hand, an analyst can conduct several types or sets of analyses per hour, since the development times (40–50 min) and scan times (~10 min) can overlap. Tanks with different solvent systems can be ready to participate in this

process. Generally, the Iatroscan has not found wide application in the food industry. The response of carbohydrates in the FID is low because of the high oxygen content of the molecules.

The first problem in taking up TLC-FID is that those familiar with planar TLC often think in mg, and must adapt to μg – usually not more than 20 μg total per Chromarod. The second is that the application of a few micrograms of nonvolatile material in 1 μl of solvent can be automated or manual, but always results in some band spreading at the point of application. Solvent focusing has been found to overcome this usually minor problem and to narrow the sample band mixtures prior to actual development. Usually the choice is of a poor solvent for the materials in question, and for focusing, a development of the solvent front of less than 1 cm is adequate. An example is presented in **Figure 2**.

It is rare to find any unburnt organic material after analysis but it is good practice to clean the silica gel Chromarods regularly overnight in strong sulfuric acid, rinsing thoroughly in water, and passing through the scan cycle prior to use. If the previous samples generate any residue problems, such as from the calcium, magnesium and zinc of phytic acid, it will show up in this conditioning scan.

Early Chromarods showed variations in thickness and polarity that were mostly overcome with the introduction of the machine-produced silica gel Chromarods S-III. Alumina rods are also available but the literature does not indicate their wide use. Although there is a tendency to regard many solids and liquids as nonvolatile, this can be a tricky subject. Polar groups such as those of fatty acids and esters

Figure 2 (A) Caffeine deposited on a Chromarod S-III from an aqueous solution and then developed and scanned. (B) Benefit of solvent focusing with methanol prior to development. (Reproduced with permission from Ackman RG and Heras H (1997) Recent applications of Iatroscan TLC-FID methodology. adhere to the silica gel quite well. Sterols are polar (R-OH) molecules of reasonably high molecular weight (387 for cholesterol), but the planar molecule may make hydrogen bonding difficult, and erratic calibration factors have been reported. It is assumed that the radiant heating of the approaching flame can sometimes vaporize part of the sterol band before it can be combusted to form ions. Squalene (molecular weight 411) had practically no binding capability and can lose half its apparent mass for similar reasons, but we have found that it is easily made less volatile and gives a full response if the Chromarod is exposed to iodine vapour for a few minutes prior to scanning.

The Chromarod-Iatroscan technology for analysis of nonvolatile materials is especially useful for high-molecular-weight polymeric oxygenated materials such as are found in oxidized oils. These are usually not easy to move along the Chromarod with developing solvents, whereas simple dimeric and trimeric triacylglycerols can be resolved by development. With the use of a nitrogen-specific attachment, the FID has greatly augmented sensitivity in the N-sensitive mode. This thermionic detector mode has long been available in GC, and is notoriously temperamental. It can extend TLC-FID into the selective analysis of many shellfish toxins, many of which contain a few atoms of nitrogen in very large molecules (e.g. mol. wt 301, $7 \times N$, for saxitoxin).

For brevity this review will focus on two materials, marine lipids and heavy hydrocarbon fractions, but the possibilities for analysing reasonably large molecules are almost unlimited.

Marine Lipids

The first installation of an Iatroscan in North America was in 1976 in a marine lipids laboratory. The resulting publications on analyses of various complex materials attracted much attention among lipid chemists and biochemists, leading to a special issue of the journal *Lipids* in August 1985. Lipids of individual small marine organisms could be analysed for the first time and the sensitivity enabled extraction of water-soluble lipids to be modified to collect and extract less sample, and thus conserve on solvent use. The Iatroscan was quickly adopted in many countries with marine research programmes.

It is not often recognized that many human body lipids, especially those of muscle, liver and the blood, have fatty acid compositions spanning the same range as are found in fish oils and lipids. The latter include all varieties of lipids found in ourselves and other animals, and can be good materials to train with. Some will be featured in the few following examples of separations as demonstrations. In fish muscle lipids the fatty acid extremes in all lipid classes are the relatively short chain myristic acid (14:0) and palmitic acid (16:0) on the one hand, and the long chain, highly unsaturated eicosapentaenoic acid (20:5n-3) and docosahexaenoic acid (22:6n-3) on the other hand. A superefficient separation is shown in **Figure 3**. In the A and B chromatograms the free fatty acids and sterol esters are split into two respective subclasses, one with 14:0 and 16:0 as the principal fatty acids and the other with 20:5 + 22:6 as the dominant fatty acids. After hydrogenation,

Figure 4 Iatroscan TLC-FID showing the effect of the degree of unsaturation on the separation of C_{22} free fatty acid standards on Chromarods-SII. Experimental conditions are development in hexane:diethyl ether:formic acid (97:3:1, v:v:v) for 40 min. O, Origin; SF, solvent front. Shorthand gives chain length and number of methylene interrupted ethylenic bonds.

chromatogram C shows that the pairs have collapsed into single peaks as the Chromarod behaviours of the resulting 14:0, 16:0, 20:0 and 22:0 are not very different. This is shown by the behaviours of selected sets of fatty acids and triacylglycerols (Figures 4 and 5).

Hydrogenation is not possible with many classes of organic compounds: it is not only feasible in analyses of lipid classes, but it has a unique advantage. The hydrogenated lipid fatty acids, unlike the natural highly unsaturated fatty acids, are stable to oxidation and can be studied and analysed at leisure, or with different solvent systems. Peaks are also sharper, improving sensitivity limits slightly.

For most simple lipid classes such as are found in vegetable oil products and mixtures, separation by lipid classes is facilitated by the fact that the common fatty acids are palmitic (16:0), stearic (18:0), oleic (18:1), linoleic (18:2n-6) and α -linolenic (18:3n-6). Except for palmitic acid, these are all identical in chain length (C_{18}), and the unsaturated acids differ

only in having the 1, 2 or 3 ethylenic bonds. Chromarods dipped in silver nitrate can resolve such mixtures as well as handle some types of *cis-trans* separations, but these simple vegetable lipid cases are usually best handled by GC.

It is possible to develop one or more classes of lipids along the Chromarod, while 'parking' the rest at or near the point of application, scanning partway down the Chromarod to determine the most mobile class, then redeveloping the balance of the material applied to whatever extent is desired into the clean space thus presented by the first scan. This means that multiple scans are always of the same original sample and conducted on the same Chromarod.

A good example of multiple development is provided by a lipid class analysis of the total lipids of the muscle of the fish silver hake (Figure 6). The actual separation of the lipid classes was conducted with a development sequence of three different solvent systems. The extracted lipids were dissolved in

Figure 5 Iatroscan TLC-FID showing the effect of the degree of unsaturation and chain length on the separation of triacylglycerol standards on Chromarods-SII. Experimental conditions and abbreviations are the same as in Figure 4. TAG-16:0, tripalmitin; TAG-12:0, trilaurin; TAG-18:0, tristearin; TAG-18:3, trilinolenin. chloroform at an appropriate concentration, and this solution was then spotted on to Chromarods-SIII in 1 μ L volumes from glass Microcap 1 μ L disposable pipettes. The Chromarods were then conditioned in a constant humidity chamber for 5 min. The first development was carried out for 55 min in hexane:chloroform:propan-2-ol:formic acid; 80:14:1:0.2, by vol. The Chromarods were then dried at 100°C for 1.5 min and partially scanned from the top to a point just below the diacylglycerol peak (Figure 6I). The Chromarods were then redeveloped in acetone for 15 min, dried at 100°C for 1.5 min and partially scanned to below the acetone-mobile polar lipid position (Figure 6II). Finally, the Chromarods were again developed in chloroform:methanol:water (70:30:3, by volume) for 60 min, dried at 100°C for 3 min and completely scanned to reveal different phospholipids (Figure 6III).

In this example the free fatty acids are clearly separated from triacylglycerols. This is sometimes difficult to achieve in a single development of a mixture of animal lipids with one of the common lipid class solvent systems such as hexane:diethyl ether:formic acid 85:9:1 (by volume). The problem can be clarified by considering the free fatty acids as having a key position on the silica gel of the Chromarod, and adjusting the solvent polarity to

achieve relative movement of the rest of the neutral lipids, which usually develop in the order wax/sterol esters, triacylglycerols, cholesterol, and di- and monoacylglycerols, to positions where there is no conflict with the free fatty acids.

Solving such problems with TLC-FID may be compared with GC with only one column, and changes in temperature programming may be the only variable possible. With the Chromarod an unlimited choice of solvent systems is available and, when combined with scan and redevelopment, almost any lipid class separation is possible.

Figure 7 is of a commercial animal lipid mixture. The A chromatogram appears to show that the dominant triacylglycerol is accompanied by two peaks matching exactly 1,3-diacylglycerols and 1,2-diacylglycerols. This was considered to be an unusual composition. To verify it, hydrogenation of 10 mg of the sample (a simple process carried out by stirring in methanol:hexane : : 3:2 under hydrogen for 1 h, with a few mg of PtO₂), gave the materials of the B chromatogram. The triacylglycerol peak is sharper and the supposed 1,2-diacylglycerol is now added to the original 1,3-diacylglycerol peak. Clearly, the supposed 1,2-diacylglycerol component consisted of two highly unsaturated fatty acids, probably a mixture of arachidonic acid (20:4n-6) and docosahexaenoic acid

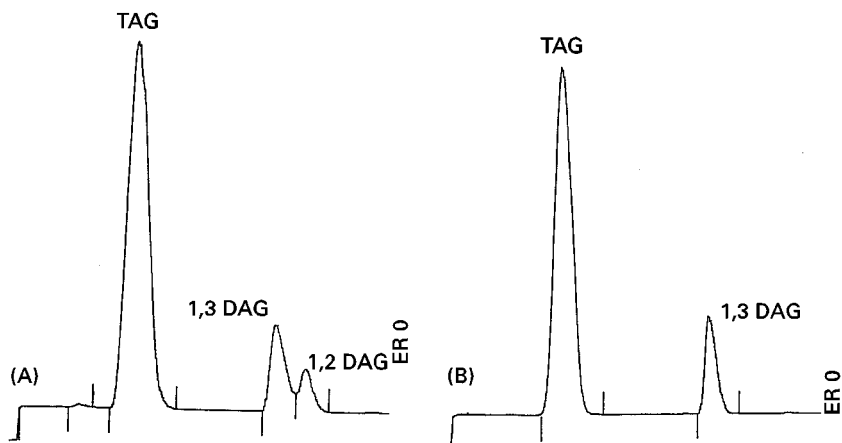

Figure 7 A commercial lipid product developed (A) in a solvent mixture of hexane:ethyl acetate:formic acid; 94:6:1 (v:v:v) hydrogenated, and (B) reanalysed. The smaller peaks, ostensibly 1,3-diacylglycerols (1,3 DAG) and 1,2-diacylglycerols (1,2 DAG), were shown to be two types of 1,3-diacylglycerol. TAG, Triacylglycerol.

(22:6n-3), materials currently of interest in infant nutrition.

Heavy Hydrocarbon Fractions

At one time coal provided a variety of liquid and semisolid materials, the latter usually referred to as pitch. The high-molecular-weight materials consisted of polycyclic aromatic hydrocarbons that could be individually defined with some difficulty, and more complex materials that were defined, mostly by solubility, as maltenes, asphaltenes and pre-asphaltenes. The use of TLC-FID in their analysis has been investigated for more than a decade and it promises to reduce solvent use and speed up analysis time enormously. The trend to coal liquification to produce fuel fractions competing with petroleum fractions makes new analytical technology even more useful to that industry, and at the same time the petroleum industry is turning to heavy crude oils and raw materials recovered from tar sands.

The products recovered from crude petroleum range all the way from hydrocarbon gases to alkanes of chain lengths up to C_{100} , polycyclic aromatics ranging from naphthalene upward, and other very complex high-molecular-weight materials, often incorporating nitrogen or sulfur. In the petroleum industry, standard methods tend to be time-consuming and complex. To make the life of the petroleum analyst even more difficult, 'cracking' to produce more valuable volatile fractions leaves residues of heavy materials such as asphaltenes. The application of TLC-FID to the latter has shown superiority to conventional methods, and has gradually been accepted, as shown by numerous publications.

The problem in crude petroleum analyses was basically the lack of natural standards, so that the quantitation of the FID response would reflect the mass of the particular complex fraction and pure chemicals representative of a fraction were unsatisfactory reference materials. For North Sea crude oils this difficulty has been overcome by preparation of appropriate standard fractions from typical crude oils, so that TLC-FID can provide data reliable for interlaboratory comparisons. In the petroleum laboratory particular difficulty is found with methods for heavy aromatic fractions and the more polar classes of materials. The latter often contain sulfur and nitrogen molecules and this makes some reporting technologies of little use, but the impact on TLC-FID response is not very significant.

One reason for industry laboratory problems is the obsolescence of standard methods, a problem not limited to the petroleum industry alone. When very large volumes of commodities are bought and sold there must be standards (and applicable methods) agreed on by all parties. Many have been around for decades with no changes. Meanwhile the internal combustion engine has been progressively fine-tuned to conserve energy, and even the robust diesel engine needs higher standards for volatile distillates. Complex refining and cracking steps produce even more heavy residues which must be investigated and utilized. The TLC-FID, introduced in about 1976, was immediately seized on by the petroleum industry and offers distinct advantages. The example given in **Figure 8** is taken from a recent paper on the subject. The Chromarod scans illustrate the weaknesses of the ASTM method D2007-91, based on rather lengthy and cumbersome open column chromatography on clay and silica gel columns in series.

Figure 8 Superiority of Iatroscan TLC-FID over ASTM D2007 method in hydrocarbon analyses as exemplified with an aromatic petroleum extract and its fractions from the ASTM method. Chromatograms are for (A) TLC-FID of aromatic extract; (B) saturates by ASTM D2007, (C) aromatics by ASTM D2007, (D) polars by ASTM D2007; (E) residual polars from clay. Two-step Chromarod development of *n*-heptane for 30 min, followed by development with toluene for 5 min. (Reproduced with permission from Barman BN (1996) Hydrocarbon-type analysis of base oils and other heavy distillates by thin-layer chromatography with flame ionization detection and by the clay-gel method. *Journal of Chromatography Science* 34: 219–225.)

Conclusion

A recent paper on supercritical fluid chromatography suggested that often attempts to replace older and proven GC and HPLC methods with novel technology can be disappointing. That the TLC-FID system has been popular in only a few analytical fields may be due to the need for close interaction between the analyst and the method – almost a lost art in the face of contemporary automated equipment.

One exception to this is the TLC-FID of the Chromarod-Iatroscan combination, mostly used in research laboratories. As long as researchers have relatively nonvolatile organic materials to analyse, their resolution and determination by TLC is often a challenge for which the flexibility of the Iatroscan is ideally suited. Their chemical nature may have been

defined by decades of patient work by others, but the adaptation to rapid analysis by thin-layer silica gel chromatography on a microgram scale may require a combination of imagination, knowledge and perseverance. The TLC-FID is a system that offers the challenge that makes science enjoyable!

FLASH CHROMATOGRAPHY

C. F. Poole, Wayne State University, Detroit, MI, USA

Copyright © 2000 Academic Press

Flash chromatography and related techniques are widely used for laboratory-scale fractionation of mixtures from organic synthesis or for analysis when only a modest increase in resolution over conventional column liquid chromatography is required. These techniques employ short columns packed with particles of an intermediate size (typically 40–60 μm) combined with accelerated solvent flow achieved through modest pressure or suction. Compared to conventional column liquid chromatography, separations are obtained in less time; isolated compounds are often purer because resolution between bands is increased and band tailing is reduced; and compounds that are degraded or altered during chromatography are recovered in higher purity because of the shorter contact time with the chromatographic system.

The main applications of flash chromatography are purification of synthetic products, isolation of target compounds from natural products, the simplification of mixtures prior to high resolution preparative (usually) liquid chromatography and the fractionation of

complex mixtures into simpler groups for analysis. Its primary virtue is low cost, since virtually no special equipment is required, and the stationary and mobile phases are inexpensive enough to be discarded after a single use, or can be recycled. Resolution is less than that obtained by medium and high pressure liquid chromatography but the operational costs and equipment needs are greater for these techniques. Flash chromatography is often employed as a pre-separation technique to remove particulate matter and sample components that are either weakly or strongly retained on the separation column in medium and high pressure liquid chromatography. This allows higher sample loads to be separated under more selective separation conditions and avoids column contamination and regeneration problems. The production costs of the isolated products are thus rendered more favourable.

Dry-column Chromatography

Dry-column chromatography (Figure 1) is a variant of preparative thin-layer chromatography with similar resolution but a higher sample loading capacity. A glass column or nylon tube is packed with thin-layer chromatographic grade sorbent, usually silica gel, to a height of 10–15 cm. Sample is added as

Figure 1 Apparatus for dry-column chromatography.

a concentrated solution or preadsorbed on to a small amount of sorbent. Separation is achieved by developing with a suitable volume of solvent to reach the lower end of the bed. Suction at the bottom of the column and/or slight overpressure at the top may be required to supplement capillary forces in moving the mobile phase down the column. Separated bands are removed by extrusion, slicing (if a nylon column is used) or by digging out, and the products freed from the sorbent by solvent extraction. The separation is fast, requires very little solvent and provides higher resolution than classical column techniques due to the use of sorbents with a smaller average particle size. It is suitable for the recovery of small quantities of material since the loading capacity is only about 0.2–1.0% w/w of the sorbent used, depending on the difficulty of separating the bands of interest.

Thin-layer chromatography provides a suitable technique for method development in most cases, although significant differences in separations can arise for mixed solvents, particularly when the solvent components differ in polarity and/or volatility. These differences result from the absence of pre-equilibrium with a vapour phase in the dry-column technique. Nylon columns can be more difficult to pack than glass columns, particularly when longer lengths are used, but nylon columns are easier to section and allow colourless bands to be observed with a UV lamp. Glass columns built up of segments connected by ground-glass joints can be useful for simplifying the extrusion process.

Dry-column chromatography is not a widely used technique. Preparative thin-layer chromatography or flash chromatography has generally been preferred. Although separations are fast, the recovery of separated zones is slow and labour-intensive compared to elution methods.

Vacuum Chromatography

Vacuum chromatography can be taken to mean the operation of a short column under suction to accelerate solvent migration. Either a short column or a Büchner filter funnel fitted with a glass frit is dry-packed with sorbent. The sorbent bed is consolidated initially by tapping the side of the column during filling and pressing the top layer of the sorbent bed with a flat object, such as a stopper, while suction is applied at the other end. Consolidation is completed by releasing the vacuum and pouring a solvent of low polarity over the surface of the sorbent bed followed by restitution of the vacuum. If the column is packed correctly the solvent front will descend the column in a horizontal line; otherwise the column should be sucked dry, repacked and tested again. When all the solvent has passed through the column, residual solvent trapped between particles is removed by suction. A solution of the sample in a suitable (weak) solvent or preadsorbed on to a small amount of sorbent or inert material, such as Celite, is applied to the top of the column (Figure 2). The sample solvent, if used, is sucked gently into the column packing. A piece of filter paper with the same diameter as the inside diameter of the column or funnel is placed on top of the sorbent bed to prevent disruption of the bed during addition of solvent. The column is then eluted with appropriate solvent mixtures of gradually increasing solvent strength. Between solvent applications the column is sucked dry and the eluent collected in test tubes or round-bottom flasks. Using a multiport manifold (similar to a pig adapter for distillation) or a separatory funnel allows sequential fraction collection without having to disassemble the apparatus after each fraction is collected.

Vacuum chromatography is simple, rapid and convenient. Optimum sample loads are similar to flash chromatography. However, it is not unusual to use sample overload conditions to separate simple mixtures by stepwise gradient elution or to simplify mixtures for further separation. Under these conditions the sample loads may reach 10% (w/w), or even higher, of the bed mass. Compared to flash chromatography, solvent changes are easy because the head of the column is at atmospheric pressure.

Figure 2 Apparatus for vacuum chromatography. (Reproduced from Pelletier SW, Chokshi HP and Desai HK (1986) Separation of diterpenoid alkaloid mixtures using vacuum liquid chromatography. *Journal of Natural Products* 49: 892, with permission from the American Chemical Society.)

Flash Chromatography

A glass column of a suitable length containing a small glass-wool plug and a layer of acid-washed sand or glass frit at its base is partially filled with sorbent using the dry-packing or slurry-packing technique. Incremental addition of the sorbent followed by tapping of the column with a hard object generally gives better results for dry packing than bulk filling of the column. After packing, the column is freed from trapped air and further consolidated by forcing several column volumes of a weak solvent through the sorbent bed until no further air bubbles are seen exiting the column and the bed is stable. It is difficult to pack wide-diameter columns (> 5 cm) by dry-packing procedures and in this case slurry packing is nearly always used. In this case, the column is partially filled with a small volume of weak solvent and a dilute suspension of the sorbent in the same solvent is added slowly in increments, with excess solvent intermittently drained away. Periodic pressurization of the sorbent bed is used to aid consolidation. Tapping the sides of the column is not normally employed. The sample is added to the column in a small volume of solvent or adsorbed to a small amount of packing material.

Finally, a thin layer of glass beads, acid-washed sand or other inert material is added to the top of the column to prevent disturbance of the column bed by solvent added for elution. The amount of free space above the sorbent bed must be sufficient to hold the volume of solvent equivalent to the fraction size collected, or a solvent reservoir must be inserted between the column and the pressure regulation valve. The flow rate is adjusted to about 5 cm min^{-1} by application of gas pressure and controlled by the regulation

valve. Pressures employed are typically less than 1–2 atm, with the various parts of the apparatus (**Figure 3**) held in place by springs, clamps or screw-thread connectors. It is a wise precaution to use plastic-coated glass columns or a safety shield to minimize the possibility of accidents. The column should not be allowed to run dry during the elution sequence.

Flash chromatography is simple to perform and is widely used in many laboratories. The main disadvantage is that the apparatus requires constant disassembly and reassembly of the air pressure inlet adapter in order to introduce new solvent into the column. Potter described an apparatus with a lateral solvent reservoir to overcome this problem. The essential feature of this apparatus is that a solvent reservoir with tap at the reservoir-to-column inlet is attached to the side of the column with the inlet situated above the height of the sorbent bed. A second tap at the top of the column allows air pressures to be equalized for rapid solvent addition to the column, without having to disassemble the apparatus. Radial compression columns have also been used with some commercial flash chromatography apparatus.

Stationary Phases

Silica, and to a lesser extent alumina, are the most common stationary phases used for the separation of low molecular weight organic compounds. Chemically bonded silica sorbents are used for the separation of polar organic compounds in the normal and reversed-phase modes. Wide-pore, chemically bonded phases are used for the separation of biopolymers. There is no technical reason why any

Figure 3 Apparatus for flash chromatography.

moderately rigid chromatographic sorbent, stable to solvent changes and available in the required particle size range, could not be used. In practice, the cost of the sorbent has to be set against the value of the product isolated, since the sorbent is often used for a single sample application and regeneration may be impossible, or tedious, costly and uncertain. Chemically bonded phases are more expensive than silica, or have to be synthesized from silica prior to use, and for this reason are less popular. For low molecular weight neutral organic compounds, small-pore silicas with a high surface area and high loading capacity are preferred, in particle size ranges of 20–40 or 40–63 μm . The smaller particle size materials provide higher resolution per unit length but generate greater back-pressure. Since longer columns can be used for the larger particle size sorbent, differences in resolution are often not great. Because of the limited operating pressure, columns are rarely longer than 30 cm, and 10–15 cm is recommended, unless longer columns are required to provide additional resolution. The optimum mobile-phase velocity for these particle

sizes is about 5 cm min^{-1} . At this velocity well-packed columns are expected to provide about 5–20 theoretical plates per centimetre of bed height, depending on the column packing density and the quality of the sorbent material.

Some separations demand specially prepared stationary phases. A method has been described for impregnating silica with silver nitrate for the isolation of compounds with unsaturated groups capable of forming charge transfer complexes with silver. Silica was impregnated with phosphoric acid and the calcium salt of ethylenediaminetetraacetic acid to isolate microtoxins that were either unstable or produced tailing bands on normal silica gel. Thin-layer chromatography is generally a suitable technique to identify suitable additives for improving chromatographic properties in flash chromatography. Silica and chemically bonded phases coated with cellulose *tris*(3,5-dimethylphenyl carbamate) were used to isolate 10–100 mg amounts of pure enantiomers from racemic mixtures. The selection of mobile phases for this application is conveniently optimized using high pressure liquid chromatography.

Sample Loading

The sample is usually added to the column in a small volume of a weak solvent and the solution forced into the sorbent bed, forming a narrow sample application zone. For samples of low solubility in weak solvents, the sample is taken up in a strong solvent and added to a small amount of column packing material or other inert support. The solvent is then stripped from the slurry under vacuum to produce a dry free-flowing powder that can be added to the top of the column. Sorbent (1–2 g) may be required for each gram of sample. It is important that the sample is completely dry (high vacuum is used to remove the last traces of solvent) and free of lumps to obtain symmetrical separated zones. If the sample layer is relatively long compared to the column bed length, then a stepwise solvent gradient must be used for elution to minimize zone broadening.

There are no simple relationships between the sample amount that can be separated, the dimensions of the sorbent bed and the volume and number of collected fractions. The loading capacity depends on the ease of separation of neighbouring zones, the sorption capacity of the sorbent and the method of sample elution. It can be increased by using wider columns and sorbents with a larger specific surface area. A rough empirical guide is presented in **Table 1**. For stepwise gradient elution it has been assumed that the sample can be separated into fractions of different polarity when estimating the typical sample load.

Even for difficult samples it is often more productive to use column overload conditions, combining fractions containing pure materials, and recycle those containing mixtures. Flash chromatography may lack the resolving power needed to separate the components of interest. In this case a higher resolution technique, such as medium or high pressure liquid chromatography, would be a better choice, perhaps using flash chromatography to isolate fractions containing the components of interest from other sample components.

Method Development

Thin-layer chromatography is widely used to optimize the separation conditions for silica gel flash chromatography. For isocratic separations a mobile phase which provides an R_F of about 0.35 for the zone of interest is chosen. If several zones are to be separated, then the solvent strength is adjusted such that the centre zone has an R_F of 0.35. If all zones of interest are well separated from each other and from impurities ($\Delta R_F \geq 0.2$), then the solvent strength can be adjusted so that the most retained zone of interest has a $R_F \approx 0.35$. For fractionation and large sample loads it is critical that the most selective solvent composition for the separation is used. This can be quickly identified using the PRISMA model, a guided trial-and-error procedure using thin-layer chromatography and parallel separations with different solvents. The same process can be used to identify the composition of solvents suitable for the recovery of individual sample zones in order of increasing polarity by stepwise gradient elution.

For samples of wide polarity a useful gradient is to start from a weak solvent, such as hexane, and add to this various volume increments of a strong dipolar solvent (such as ethyl acetate, dichloromethane, chloroform or acetone), terminating with the strong dipolar solvent. Then continue adding volume increments of a strong hydrogen-bond solvent (methanol, ethanol, 2-propanol) to the strong dipolar solvent, terminating with the strong hydrogen-bond solvent. Monitoring the separation by thin-layer chromatography allows the solvent gradient to be trimmed and optimized to suit the requirements for individual separations. Predicting the number of fractions required at each step remains quite arbitrary and is best conducted by monitoring the composition of each fraction as it is collected. When adding a strong solvent in a binary mobile phase for a silica gel sorbent, it is important to note that the solvent strength for the mixture has a steep curved profile. For compositions containing low volume fractions of strong solvent, the volume fraction of strong solvent should be incremented by small changes, resulting in relatively large changes in retention, for example, 1%, 3%, 5%, 10% (v/v). At higher volume fractions of strong solvent, the changes in volume fraction should be larger to produce a significant change in retention, for example, 30%, 40%, 60%, 80%, 100% (v/v).

Silica gel (or alumina) is the most suitable sorbent for the separation of low molecular weight organic compounds soluble in organic solvents and for separations of geometric isomers and diastereomers. For compounds at the extreme end of the general adsorption scale (Figure 4), separations are difficult because

Table 1 Approximate sample-loading conditions for flash chromatography (density of silica $\approx 0.45 \text{ g mL}^{-1}$)

Column diameter (cm)	Amount of silica gel (g)	Sample loading for a particular TLC resolution (g)		Sample loading (g)	Typical fraction volume (ml)
		$\Delta R_F \geq 0.2$	$\Delta R_F \geq 0.1$		
Isocratic elution (bed height=15 cm)					
1	5	0.1	0.04		5

of inadequate selectivity. Water-soluble compounds, including biopolymers and easily ionized compounds, are generally better handled by reversed-phase chromatography. Compounds of low polarity that are weakly retained on silica gel with hexane as a solvent can be separated on chemically bonded phases in the normal or reversed-phase modes. For reversed-phase separations, chemically bonded phases with water as the weak solvent are used, and the solvent strength and selectivity of the eluting solvent changed by adding different volumes of water-miscible organic solvents, such as acetone, methanol, acetonitrile, tetrahydrofuran, etc. Optimization of solvent composition by thin-layer chromatography is possible but predictions may be unreliable due to differences in sorption properties between the column and layers. A better solution is to pack a short (10 cm) metal column with the sorbent for flash chromatography and use high pressure liquid chromatography to optimize separation conditions. Ideally, for isocratic elution a solvent composition should be chosen that provides a retention factor of 2–3 for the component of interest or those components of a mixture that are the most difficult to separate. For mixtures of wide polarity, stepwise solvent gradients are easily constructed and optimized by the same approach.

Detection

Monitoring separations by flash chromatography can be online and continuous using standard liquid chromatographic detectors (e.g. UV-visible, refractive index, or evaporative light scattering) but is more commonly done offline by collecting fractions that are subsequently combined, based on the similarity of their composition. Suitable monitoring techniques are thin-layer, gas or liquid chromatography, electrophoresis, bioassays, immunoassays and spectroscopy (e.g. infrared and nuclear magnetic resonance).

For neutral organic compounds, thin-layer chromatography is widely used. Microscope slide-sized plates are suitable to screen individual fractions as they are obtained and larger plates for the grouping of multiple fractions. A wide range of selective and universal visualizing reagents are available to meet most detection requirements. Compounds with UV absorption can be visualized by fluorescence diminution using layers containing an inorganic fluorescent indicator. But most of all, thin-layer chromatography is used because it is quick, portable, inexpensive and generally adequate for the task.

Future Developments

Flash chromatography and related laboratory-scale techniques are already widely used for preparative chromatography when only modest resolution is required. The virtues of these techniques are favourable cost considerations and minimal instrumentation requirements. They are not a substitute for high resolution, preparative-scale techniques but a complement to them. Consequently, radical changes in how flash chromatography is carried out are not expected. The most likely future development is the wider use of sorbents other than silica gel in generally optimized separation schemes, made possible by the declining cost of chemically modified and other selective sorbents.

FLAVOURS: GAS CHROMATOGRAPHY

F. P. Scanlan, Quest International, Naarden, The Netherlands

Copyright © 2000 Academic Press

Flavours are composed from a wide variety of materials such as essential oils, extracts of natural products, individual aroma chemicals and many other materials having an organoleptic impact producing a desired effect. Flavour analysis by gas chromatography (GC) is only associated with volatile and semi-volatile compounds. From an early stage in the development of GC, the analysis of flavours has played an important part. Up until the 1980s, the emphasis was on using GC to identify individual flavour molecules at trace levels (parts per million (ppm) to parts per trillion (ppt) range and sometimes less). This is still an important part of the job for flavour analysts, although today there is a greater tendency to correlate molecular structures with sensory attributes. GC methods that have been developed for flavour analysis include temperature-programmed capillary GC and GC combined with mass spectrometry (MS). Likewise, a technique such as GC-Olfactometry (GC-O), which was once the realm of the flavour and fragrance industry, is currently enjoying applications in the food and beverage, cosmetics, packaging, plastics, and pharmaceuticals industries.

This article provides a comprehensive review of the most important GC applications in flavour analysis. The Further Reading section lists some important literature sources that provide a useful overview of GC as applied to flavour analysis. In addition there is the Food Science & Technology Series from Elsevier Science Ltd. This series contains the proceedings from the International Flavor Conferences and the

Weurman Flavour Research Symposia. Many GC methods have been used for a variety of purposes, including flavour and raw material quality control, flavour stability, identification of off-flavours and taints, studies of flavour biogenesis and metabolic pathways of plant volatiles, identification of new flavour molecules, consumer product development, and process optimization. The flavour analysis techniques covered here are: headspace GC including solid-phase microextraction (SPME) combined with GC thermal desorption techniques, pyrolysis-GC-MS, multidimensional GC, GC-MS and GC with selective detectors, chiral separations, GC-O and the recently developed fast GC process. Of course the quality of an analysis depends on the extraction techniques and sample preparation procedures. These areas are covered in other chapters in this encyclopedia. Headspace analysis and pyrolysis are also considered to be sampling techniques, but they are included here as they can be used in a coupled mode.

Headspace Gas Chromatography and Thermal Desorption Techniques

Since the early application of headspace GC analysis to flavours the technique has undergone a considerable degree of automation. Now it is possible to perform high throughput analysis, and reduce variability by automating the sampling and injection process. Basically there are two forms of headspace analysis: static and dynamic. In both forms volatiles that could be a source of interferences for the GC separation are removed from a complex sample matrix. It is important to note that the headspace contains the part of the flavour that one perceives first. Static

headspace analysis is performed in a closed vessel in which the volatiles reach an equilibrium between two phases. The results depend on the partition coefficients of the individual molecules between these phases. In dynamic systems an inert carrier gas is swept over the sample and the volatiles are trapped onto a support. Static headspace analysis has been automated in combination with cryofocusing devices. Dynamic headspace analysis can handle higher sample throughputs using automated thermal desorption devices in combination with cryofocusing to treat a series of sampling tubes containing the trapped volatiles. A variety of adsorbent phases are used for trapping volatiles according to their polarity. In recent years the solid phase micro-extraction (SPME) technique has been developed for sampling volatiles. It is based on the principle of using a stationary phase coated onto a fibre that traps the volatiles in contact with the surface. The fibre can be placed in the headspace above the sample or indeed can be plunged into a liquid sample. After a predetermined time, the fibre is removed and inserted directly into the GC injection port. Commonly used phases are polydimethylsiloxane (PDMS) and polyacrylate (PA) as well as the more conventional octadecylsilyl C18. The simplicity and cost effectiveness of this technique has led to its widespread application for flavour analysis. It is also possible to use this technique with some GC autosamplers. The GC chromatograms in Figures 1 and 2 allow a comparison of results obtained from solvent extraction and SPME, respectively. The sample was a lemon flavour. For SPME extraction, a PDMS fibre was placed over the sample in a closed conical flask

for 15 min at room temperature. A 50 : 50 v/v (100 mL) mixture of pentane and ether was used for the solvent extraction. To obtain a representative extract, a combination of polar and apolar solvents is often used in flavour analysis. GC analysis was run on a 50 m \times 0.32 mm i.d. \times 1 μ m HP-5 apolar phase column. The first observation to be made is that the solvent peaks at the beginning of Figure 1 are absent on Figure 2. Also absent in Figure 2 is the very broad peak at 39–45 min. This peak is benzoic acid, which unfortunately also creates interferences with other compounds eluting over the same time period. As expected, solvent extraction also shows some smaller broad peaks belonging to the polar acids eluting before 24 min. The absence of these peaks with SPME is expected as PDMS is an apolar material. This absence can also be an advantage in that interferences can be reduced. Relative concentrations of extracted compounds can be lower with SPME as compared with solvent extraction. This is because of the limited surface area available for adsorption on the SPME fibre. Quantitative results are difficult to compare, but qualitatively both techniques reveal nearly all the same apolar flavour compounds. The most abundant apolar compound after just 31 min is limonene. Another difference between the two techniques is the molecular weight range extracted. Solvent extraction allows the largest molecular weight range to be extracted. While there are limitations to SPME, this can be advantageous for some applications in which it is necessary to avoid interfering compounds and produce a 'cleaner' extract. Thermal desorption techniques involve the extraction of volatiles from

Figure 1 GC trace obtained after solvent extraction of a lemon flavour.

Figure 2 GC trace obtained after SPME of a lemon flavour for 15 min.

a sample contained in a glass tube, or as mentioned previously from a trapping material, directly into a GC injection port. A form of cryofocusing or cooled injection is required for reliable quantitative analysis.

Multidimensional Gas Chromatography (MDGC)

Flavours and especially natural flavour extracts can be extremely complex, containing hundreds of compounds that are not always completely resolved. The problems of separating overlapping peaks can be overcome by the use of very high resolution columns and also by using two columns instead of one to improve the peak capacity. The use of a switching mechanism between the columns makes it possible to select a segment of the chromatogram obtained with the first column and transfer it to a second column for further separation (heart-cutting). The second column may be of another polarity or performance or indeed may be a chiral column. Such a system can also be used in connection with a collection device to recover the isolated component. The collection device may be a cryogenic system or glass tubes filled with a suitable trapping materials. An elegant possibility exists whereby the glass collection tubes fit into the injection port of a GC column fitted with a septumless cooled injection system, facilitating the transfer of the isolated volatiles into a GC-MS or GC-O usually fitted with a pre-column. Equally, using a simple accessory the isolated volatiles can be transferred to a suitable support for nuclear magnetic resonance

(NMR) or infrared (IR) analysis. Another variation on the single oven is the dual-oven system. This has the advantage of controlling the temperature of both columns. Multidimensional systems can be used for performing semipreparative GC isolations. They have also been used with a isotope ratio mass spectrometer for authenticity analysis. Multidimensional systems are very flexible and are extremely useful in the flavour laboratory for ultratrace analysis.

Gas Chromatography–Mass Spectrometry and Gas Chromatography–Selective Detection

Gas Chromatography–Mass Spectrometry (GC-MS)

GC analysis benefited from the advances in more stable and higher resolution columns and became more powerful when used with a mass spectrometer. Without underestimating other analytical techniques, GC-MS is probably by far the technique that has contributed the most to the analysis of flavours over the last 30 years. The literature is plentiful on GC-MS applications to flavour analysis. The combination of the separation power of the gas chromatograph with the selectivity of the mass spectrometer has been the major analytical tool for revealing components of essential oils and natural products as well as all volatile flavouring materials. GC-MS applications enabled the VCF (volatile compounds in food) list of known flavour molecules to grow from about 500 in the early 1960s to nearly 7000 today.

Gas Chromatography–Atomic Emission Detection (GC-AED)

The atomic emission detector is a multi-elemental detector based on the principle of scanning the atomic emission bands of several elements as compounds elute from the GC and enter a microwave plasma. For the selected element, AED is generally more sensitive than the flame ionization detector (FID) (at low parts per million (ppm) levels) and there is the possibility of acquiring data for several elemental wavelengths simultaneously. AED can be used as a low-level screening tool for organohalogens, organosulfur, organometallics and also some isotopes useful for isotopic labelling studies. With respect to essential oils and flavours, this technique has been used for the detection of trace contaminants such as pesticides. One of the advantages of AED is that complex matrices such as a citrus oil may be injected neat or as a simple dilute solution to avoid the need for tedious extraction techniques. GC-AED is a useful complementary technique to benchtop GC-MS.

Gas Chromatography–Sulfur Detection

It was only in the 1980s that attention was given to the relevance of sulfur volatiles and semi-volatiles to the character of flavours. Previously, sulfur molecules were not considered very important and were more often associated with off-odours and contaminations. Studies carried out on products such as cheese, truffles and fresh strawberries have revealed the importance and flavour impact of sulfur compounds. Both sulfur chemiluminescence detection (SCD) and flame photometric detection (FPD) are used for selective sulfur detection. These techniques have also been used in combination with sniffing port detection and headspace analyses. Generally, the identification of sulfur compounds has been difficult because their olfactory detection threshold is extremely low. Thus, they may be detected by the nose but the analyst must carry out several extractions and concentrations of the product to obtain a sample large enough to cause a peak to appear on the chromatogram.

Gas Chromatography–Nitrogen Detection

Nitrogen–phosphorus detection (NPD) has been applied to the analysis of nitrogenous compounds in cheese, meat and yeast extracts for flavouring specialities. Amino compounds and breakdown products of proteins are often associated with bitterness and are important when considering the taste of a flavouring.

Gas Chromatography–Electron-Capture Detection (GC-ECD)

The analysis of some classes of flavour compounds, such as the highly volatile aldehydes or volatile fatty acids, is facilitated by employing derivatization techniques using halogen-containing reagents, e.g. pentafluorobenzylhydroxylamine (PFBOA). The high sensitivity of the ECD technique is therefore advantageous for detecting trace-level derivatized carbonyl compounds. This approach has also been applied in flavour studies of lipid oxidation compounds.

Chiral Separations

Many flavour molecules have one or more chiral carbons and can exist as enantiomers. The separation of enantiomers by GC can be used as a method for studying their individual odours or for the purposes of authenticity analysis. Most natural biosynthetic pathways produce flavour molecules with one predominant enantiomer. This can be exploited for the control of food and beverage adulteration. The chiral GC chromatograms shown in Figures 3 and 4 are analyses of flavour extracts made from strawberry fruit preparations. The chiral column was 25 m long and contained a diacetyl tert-butyltrimethylsilyl β -cyclodextrin stationary phase. Figure 3 shows the separation of both the (*R*)- and (*S*)-enantiomers of ethyl-2-methylbutyrate at 9 min while only the (*S*)-enantiomer is present in Figure 4. Both enantiomers in Figure 3 are present in almost equal abundance which is indicative of the addition of a ‘nature identical’ ester. The development of chiral stationary phases (mainly modified β -cyclodextrin phases) has allowed the resolution of many enantiomers. When enantiomer separations have been combined with CG-O to differentiate the odour of each enantiomer they have revealed three main classes of enantiomers: enantiomers of equal odour; enantiomers having the same odour but different intensities or secondary notes; and enantiomers with quite different odours. Examples of enantiomers with different odours are (+)-nootkatone, which has the aroma of grape-fruit peel, and (–)-nootkatone, which has stronger woody, spicy notes and only minor grapefruit peel character. Also, (+)-(*S*)-carvone has a typical caraway oil smell while (–)-(*R*)-carvone has a minty odour. An interesting compound is 5 α -androst-16-en-3-one, where the (–) enantiomer is odourless and the (+) enantiomer is characterized as either musk-like or urine-like. Human genetics throws in a further complication with this molecule, in that a third of the population perceive it as odour-

Figure 3 Separation of (*R*)- and (*S*)-enantiomers of ethyl-2-methylbutyrate at 9 min.

less, another third as musk-like and the remaining third as urine-like.

Gas Chromatography–Olfactometry (GC-O)

The most valuable detector in flavour analysis is the human nose. GC-O is the technique in the flavour

analyst's arsenal that correlates analytical and sensory data. The use of a sniffing port as well as a physical detector to sniff GC effluents dates back to the early 1960s. The technique has since improved, because of technological advances in GC instrumentation, sniffing port design and the use of computer tools for data processing. The strength of GC-O lies in the fact that the odorous compounds in a product's

Figure 4 Separation of the (*S*)-enantiomer of ethyl-2-methylbutyrate.

extract can be detected from among all the other non-odorous compounds in the sample. GC-O involves measuring the perceived odour and its retention time. The odour of a molecule can be described in terms of its aromatic quality, intensity and potency. Intensity pertains to the perception one has at a given concentration, whereas potency refers to a comparison of concentration amounts with respect to other molecules at the same intensity level. As for all GC analysis, identification is helped by using compilations and databases of relative retention times. There are a few variations of the GC-O technique: Charm (combined hedonistic response method), AEDA (aroma extract dilution analysis) and OSME (Greek for smell). Charm and AEDA are techniques for measuring potency and OSME quantifies intensity. In its simplest form the nose sniffs effluents from the GC column and the retention times of interesting compounds can be noted along with an odour descriptor. A sniffing port can be mounted on top of the GC or in the GC oven door, or can be connected via a heated transfer line as is the case with the recently commercialized flexible sniffing port. By making it possible to use an electronic push-button device or joystick an electronic signal can be generated that represents the nose response, see **Figure 5**. Overlaying the signals for the nose and for a physical GC detector (often an FID device) results in a chromatogram displaying the retention times of the odorous molecules on top of the normal FID peaks of the mixture. This result can be termed an 'aromagram' and an example is displayed by **Figure 6**. This is an example of head-

space analysis carried out on a commercial American roast coffee purchased in a supermarket. Coffee aroma is very complex, containing over 800 volatile compounds. To facilitate explanation, the example shown is the 30–39 min segment of the chromatogram. The FID signal is in blue and the electronic push-button signal generated while sniffing is overlaid in red. Flavour descriptors as stated by the observer are shown. The retention indices for the odorous peaks are indicated at the baseline of the red signal. It is interesting to note that many peaks do not necessarily have an odour and many odorous molecules are too low in concentration to have a detector response. Sulfur-containing molecules (e.g. the peak at retention index 1236) often have extremely low odour thresholds and never show up on a chromatogram unless the sample has undergone some pretreatment. In these cases, GC-O in combination with a retention index database can be very useful. As the nose is generally more sensitive than any physical detector, the retention times of odorous molecules often correspond with the absence of any chromatographic peak. To resolve this, more sample work-up, column liquid chromatography and/or MDGC are possible solutions. There are some limitations to the technique. Unfortunately, human noses are not standardized and some suffer from anosmia, the inability to perceive a certain odour, and also sensitivities are different. Some people are more sensitive to particular odours than others. Another difficulty is in attributing a meaningful and consistent flavour descriptor. To overcome this, subjects can be tested for anosmia and

Figure 5 GC-O instrumentation.

trained in flavour language. Also, it is known that some molecules exert a synergistic effect when in the flavour but do not show this when eluted separately on the column. Thus, the odour impact can be different. Finally, a subject must be very experienced to be able to relate the sniffing of individual compounds back to the organoleptic impact of the entire flavour mixture. What is important is that the subject's perception is reproducible. The most potent odour molecules contributing to a flavour can be determined by performing GC-O with successive dilutions of the injected sample. GC-O can be made more powerful for routine flavour analysis by combining it directly with MS detection. Thus retention indices, mass spectra and flavour descriptors can be obtained. The combination of retention indices with mass spectra are especially useful when identifying some terpenes that have very similar mass spectra.

Pyrolysis–Gas Chromatography–Mass Spectrometry

Pyrolysis-GC-MS has found some limited applications in flavour analysis, primarily in the study of process or reaction flavours. In fact, the very first use of a glass capillary column was on the pyrolysis products of tobacco, to study cigarette aroma and filtration. The area of most interest has been the study of flavour volatiles formed from Maillard reactions between amino acids and reducing sugars. The Maillard reaction is responsible for the brown colour and the taste of bread crusts and meat and is essential in most savoury flavour systems. The applications studied by pyrolysis generally involve a great variety

of flavour compounds, and the use of a pyrolysis probe mounted on a GC column that is coupled to a mass spectrometer is a pre-requisite for their identification. For Maillard studies, the pyrolysis chamber is used as a reactor. A limiting parameter of commercial pyrolysis devices is the small sample capacity (generally milligrams). Thus the concentrations of volatiles generated are equally low and can limit the analysis to the study of the major compounds formed. However, this may yield useful information. Another way to exploit this technique is by using model mixtures of flavour components to investigate the reactions that control or favour the development of flavours from their thermal precursors.

Fast Gas Chromatography

Recent advances in GC instrumentation, notably in electronic pressure control of column and split flows, faster ovens and the use of narrow bore columns, have made it possible to increase the speed of analysis without loss of resolution. Generally, GC runs of more than 2–3 h are common for determining the quality of an essential oil. It has recently been shown that analyses of nutmeg and lemon essential oils that once took 80 min can now be achieved in less than 20 min. Fast GC has reduced run times considerably and is consequently very advantageous for routine quality control laboratories under pressure to achieve a greater sample throughput per shift. Figures 7 and 8 illustrate the fast GC analysis of a lemon oil. The 80 min chromatogram (Figure 7) was obtained on a standard 60 m × 0.32 mm i.d. × 1.2 μm RSL-200 column (apolar phase). The 8 min chromatogram

Figure 6 An example of an aromagram of an American toast coffee.

Figure 7 Fast GC analysis of a lemon oil (80 min chromatogram).

(Figure 8) was obtained with a column of the same phase but with the dimensions $15\text{ m} \times 0.1\text{ mm i.d.} \times 0.25\text{ }\mu\text{m}$. The analyses were performed in constant pressure mode. The hydrogen carrier gas velocity was changed from 27 cm s^{-1} to 46 cm s^{-1} . Pressures were 48 kPa and 227 kPa respectively. Likewise the split ratio was modified from 1/25 to 1/1000. In both cases the injection volume was $1\text{ }\mu\text{L}$. The oven temperature programme was also modified

to obtain similar resolutions. As shown, peak elution order was not changed and relative abundances are satisfactory in spite of a ten-fold reduction in analysis time.

Future Developments

Advances in GC instrumentation, column technology and application of computer tools will have positive

Figure 8 Fast GC analysis of a lemon oil (8 min chromatogram).

consequences for flavour analysis. There will most likely be a development of larger capacity sampling devices using adsorbant tubes and SPME fibres for headspace analysis. The desire to analyse unstable volatiles will lead the analyst to develop derivatization techniques. GC-O will become better known and will not be used only for flavour and fragrance analysis. The evolution of this technique may see the development of expert systems, such as voice recognition software to automatically annotate aromagrams and software to help with interpretation against known chemical data and correlation with sensory data. The development of flavour databases that combine chromatographic and spectroscopic data will continue. Increasing the speed of analysis will see fast GC develop for flavour quality control analysis. An interesting development in the task of comparing data from different instruments with different detectors is retention-time (RT) locking. This has already been successfully applied and will be aided by the development of specific RT lock flavour and fragrance libraries.

Introduction

Foam separation methods have long been used for the separation of various samples ranging from metal ions to mineral particles. The separation is based on a unique parameter of foaming capacity or foam

affinity of samples in aqueous solution and it has a great potential for application to biological samples. However, the use of this method in research laboratories has been extremely limited, mainly due to a lack of efficient instruments. Foam separation instruments generally consist of a single tubular column where the foam is generated by introducing the gas phase at the bottom of the column (Figure 1). Under the gravitational field, the foam moves upwards towards the top of the column to collect foam-active materials. Although various mixing devices such as baffles, solid beads and rotary mixers are used to improve contact, the use of a short column under

Figure 1 Conventional foam separation column.

a gravitational field limits the efficiency of these systems and consequently, the separation is inefficient.

In 1976, foam countercurrent chromatography (CCC) was developed to improve the foam separation technology. In this foam CCC method, foam and liquid undergo countercurrent movement through a long, fine, Teflon tube (10 m \times 2.6 mm i.d.) under a strong centrifugal force field as illustrated in Figure 2. This article describes the foam CCC technology and its application to a variety of samples.

Apparatus of Foam CCC

Figure 3 illustrates the design of the foam countercurrent chromatograph. The motor drives the rotary

frame around the central axis of the centrifuge. The rotary frame holds a coiled separation column and a counterweight symmetrically at a distance of 20 cm from the central axis of the centrifuge. A set of gears and pulleys produces synchronous planetary motion of the coiled column. This planetary motion induces a countercurrent movement between foam and the mother liquid through a long, narrow, coiled tube. Introduction of a sample mixture into the coil results in the separation of sample components. Foam-active components are quickly carried with the foaming stream and are collected from one end of the coil while the rest move with the liquid stream in the opposite direction and are collected from the other end of the coil (Figure 2).

The column design for foam CCC is shown in Figure 4. The coil consists of a 10 m long, 2.6 mm i.d. Teflon tube with a 50 mL capacity. The column is equipped with five flow channels. The liquid is fed from the liquid feed line at the tail and collected from the liquid collection line at the head. Nitrogen gas is fed from the gas feed line at the head and discharged through the foam collection line at the tail while the sample solution is introduced through the sample feed line at the middle of the coil. The head-tail relationship of the rotating coil is conventionally defined by an Archimedean screw force where all objects of different density are driven towards the head. Liquid feed rate and sample injection rate are each separately regulated using needle valves while the foam collection line is left open to the air.

Application

Foam CCC can be applied to a variety of samples having foam affinity. Foam affinity can be classified into two categories: (i) the affinity to the foam-producing carrier; and (ii) the direct affinity to the gas-liquid interface. Samples which lack direct affinity to the gas-liquid interface can be indirectly absorbed to the foam if they have an affinity to the foam-producing agents such as a surfactant. Samples, such as detergents and other foam-producing substances, can be separated without special treatment because they have affinity to the gas-liquid interface.

Foam Separation Using Surfactants

This technique is applied to the sample having affinity to the foam-producing carrier. Sodium dodecyl sulfate (SDS) and cetyl pyridinium chloride (CPC) were used as carriers to study the effects of electric charges on the foam affinity of various compounds. Figure 5

Figure 2 Foam CCC scheme.

illustrates two sets of foam chromatograms obtained from a mixture of methylene blue and DNP-leucine mixture using SDS (top) and CPC (bottom) as carrier reagents. In each chromatogram, the ordinate indicates absorbance values measured at two wavelengths, 430 nm for DNP-leucine and 620 nm

for methylene blue. When the sample mixture was introduced with the anionic SDS surfactant, the positively charged methylene blue was adsorbed on to the foam and quickly eluted through the foam collection line (top, right) while the negatively charged DNP-leucine was carried with the liquid stream in

Figure 3 Design of foam CCC centrifuge. (Reproduced from Ito (1985) with permission from Marcel Dekker Inc.)

Figure 4 Column design for foam CCC.

the opposite direction and eluted through the liquid collection line (top, left). Similarly, when the same sample mixture was eluted with the cationic CPC surfactant, the negatively charged DNP-leucine

was totally eluted through the foam collection line (bottom, right) and positively charged methylene blue through the liquid collection line (bottom, left).

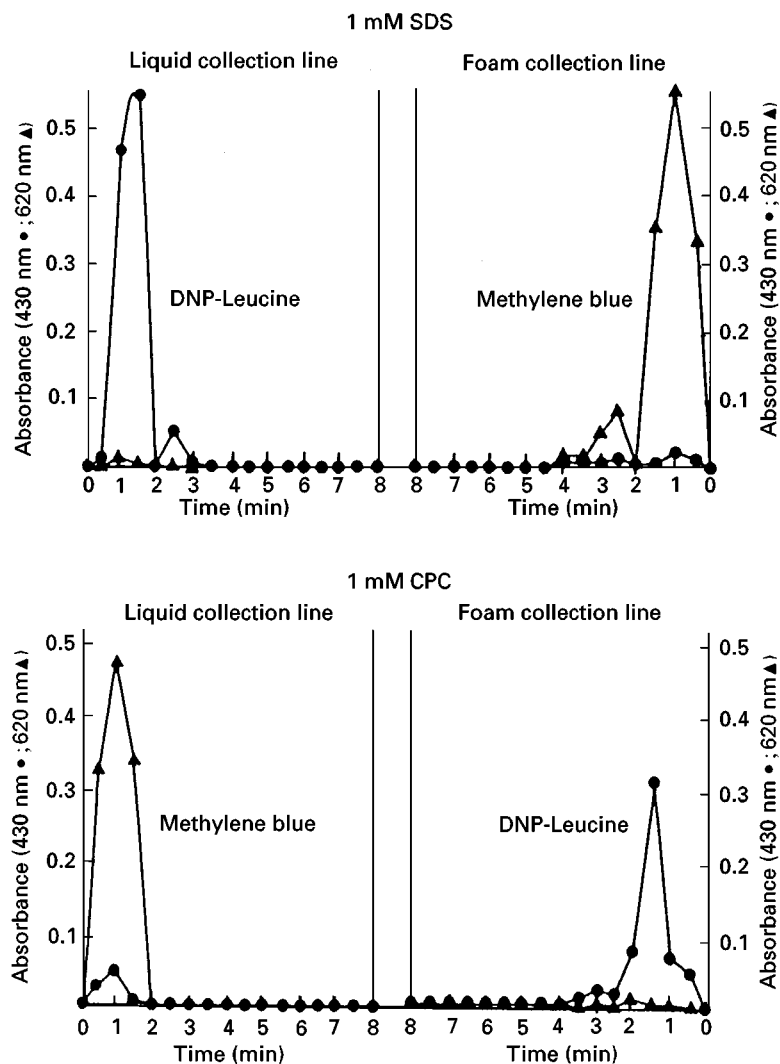

Figure 5 Separation of methylene blue and DNP-leucine by foam CCC. (Reproduced from Bhatnagar and Ito (1988) with permission from Marcel Dekker Inc.)

Foam Separation Without Surfactants

Using ionic surfactant as carriers, the samples which lack direct affinity to the gas-liquid phase interface can be separated if they have opposite electric charges. However, in this case complicated procedures are required to remove the surfactants after fractionation. On the other hand, many natural products have foaming capacity, and therefore foam CCC may be performed without such surfactants.

In order to demonstrate this possibility, bacitracin complex (BC) was selected as a test sample, because it has a strong foaming capacity. Foam CCC for separation and enrichment of BC components has been conducted using nitrogen gas and distilled water entirely free of surfactant or other additives. The following sections describe chromatographic fractionation of BC with batch sample loading and enrichment of foam-active compounds from a bulk liquid on continuous sample feeding.

Batch sample loading BC is a basic cyclic peptide antibiotic commonly used as a feed additive for livestock worldwide. It consists of more than 20 components, but chemical structures of these components are still unknown except for BCs-A and -F.

Foam separation of BC components was initiated by simultaneous introduction of distilled water from the tail and nitrogen gas from the head into the rotating column while the needle valve at the liquid collection line was fully opened. After a steady-state hydrodynamic equilibrium was reached, the pump was stopped and the sample solution was injected through the sample port. After the desired standing time, the needle valve opening was adjusted to the desired level and pumping was started again. Effluents from both outlets were collected at 15 second intervals.

Figure 6 shows the elution curve of BC components from the foam outlet. The vertical axis indicates the absorbance at 234 nm and the horizontal line, the fraction number. This elution curve shows three major peaks as indicated by arrows. The fractions corresponding to these peaks were subjected to HPLC analysis.

HPLC chromatograms of BC components in the foam fractions are shown in Figure 7. Under reversed-phase HPLC conditions, BC was separated into more than fifteen peaks. Generally, hydrophilic compounds elute earlier than hydrophobic compounds under these conditions. In this study, the HPLC elution time is used to indicate the polarity of the BC components. Thus, BC-A which elutes earlier in HPLC is more hydrophilic than BC-F. The most hydrophobic compounds (peaks 14 and 15) with the

Figure 6 Elution curve of bacitracin components from foam line. Foam CCC conditions: liquid flow rate, 3.2 mL min⁻¹; needle valve, 0.8 turn open; standing time after sample injection, 5 min; N₂ gas pressure, 80 psi; revolution speed, 500 rpm; sample size, 5 mg per 0.5 mL in H₂O; fractionation, 15 s per tube.

longest retention time in HPLC analysis were collected in the first foam fraction with a small amount of less hydrophobic compounds (peaks 11 and 13). Peak 15 is hardly visible in the HPLC chromatogram of the original sample due to its low concentration, but the same peak is clearly observed in the chromatogram of the first foam fraction. BC-A was almost completely isolated in peak 11 from other components eluted in the tenth fraction. In the twentieth fraction, peak 7 appeared in the HPLC chromatogram. Components with lower hydrophobicity than peak 7 did not appear in the foam fractions. These results clearly indicate that the bacitracin components are separated in the order of hydrophobicity of the molecule in the foam fractions with the most hydrophobic compounds being eluted first.

As described above, BC components were separated according to their hydrophobicity using foam CCC without surfactant. This method can also be applied to continuous sample feeding as described below.

Continuous sample feeding On the basis of the preliminary experimental results, the following foam CCC conditions were chosen for large scale sample feeding. The conditions were as follows: needle valve, 2.0 turns open; sample concentration, 50 p.p.m.; sample size, 2.5 L; sample feed rate, 1.5 mL min⁻¹ at 40 psi; ni-

Figure 7 High performance liquid chromatographic analyses of bacitracin components in foam fractions. HPLC conditions: column, Capcell Pak C18 (5 μm , 150 \times 4.6 mm, i.d.); mobile phase, $\text{CH}_3\text{OH}/0.04 \text{ M Na}_2\text{HPO}_4$ (62/38); flow rate: 1 mL min^{-1} ; detection, 234 nm.

trogen gas feed pressure, 80 psi; liquid flow rate, 0; sample collection, pooling the foam and the liquid effluents separately; and revolution speed, 500 rpm.

Figure 8 shows the results of HPLC analyses of bacitracin in the foam and liquid fractions obtained by large scale continuous foam CCC. The concentration in the foam fraction increases with the hydrophobicity of the components. Peak 3 was enriched 22 times; peak 7, 31 times; peak 11, 1400 times; peak 12, 1070 times; peak 13, 1380 times; and peak 14, 2260 times. In the liquid fraction, peaks 3 and 7 were barely detected. Thus, continuous enrichment and concentration in foam CCC is quite effective for the detection and isolation of a small amount of natural product with a foaming capacity.

Estimation of applicability of the sample to foam CCC In order to apply the foam CCC technique to various natural products, it is necessary to establish a set of physicochemical parameters which reliably indicate their suitability for foam CCC. In foam CCC the sample solution is introduced from the sample inlet at the middle of the coiled column where it is

immediately mixed with the N_2 stream and the generated foam moves towards the foam outlet at the tail. Since the coiled column consists of a 10-m-long tube, the foam must travel through a 5-m-long narrow coiled path before it reaches the foam outlet. As the foam travels through the decreasing pressure gradient along the coil, every bubble is expanded while the excess fluid is removed by the centrifugal force. Therefore, we assume that the foam must be subjected to a repetitive process of coalescence, eruption and regeneration before reaching the foam outlet at the tail. Consequently, successful foam CCC using nitrogen gas and distilled water free of surfactant requires strong foam-producing capability and foam stability of analytes. A lack of either property would result in its failure.

For this purpose, two parameters were selected, i.e. 'foaming power' and 'foam stability', which can be determined by one simple test. In each test, the sample solution (20 mL) is delivered into a 100 mL graduated cylinder with a ground stopper and the cylinder vigorously shaken for 10 s. The foaming power is expressed by the volume ratio of the result-

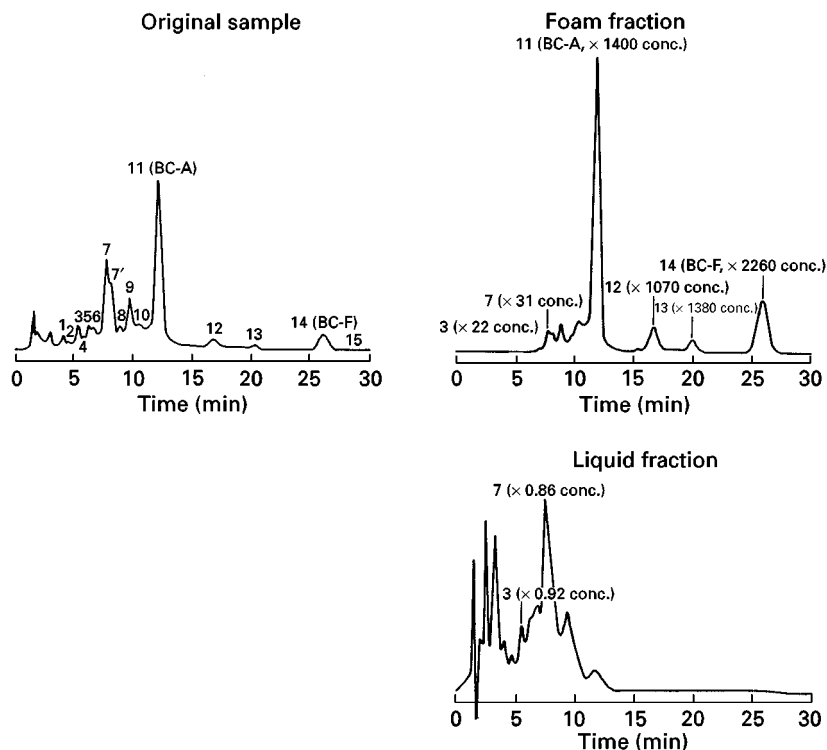

Figure 8 High performance liquid chromatographic analyses of bacitracin components in foam and liquid fractions. HPLC conditions: column, Capcell Pak C18 (5 μ m, 150 \times 4.6 mm, i.d.); mobile phase, CH₃OH/0.04 M Na₂HPO₄ (62/38); flow rate, 1 mL min⁻¹; detection, 234 nm.

ing foam to the remaining solution, and the foam stability by the duration of the foam.

In order to correlate the foaming parameters measured by this simple test method to the productivity in foam CCC, the following five samples were selected because of their strong foaming capacities: bacitracin, gardenia yellow, rose bengal, phloxine B, and senega methanol extract. The results of our studies indicated that a sample having a foaming power greater than 1.0 and a foam stability over 250 min could be effectively

enriched by foam CCC. These minimum requirements of foaming parameters tentatively determined by the bacitracin experiment were found to be consistent with those obtained from the other four samples.

The above simple test has been applied to enrichment of microcystins, hepatotoxic cyclic peptides produced by cyanobacteria. Microcystins was extracted from the bloom sample 917S with distilled water to obtain two extracts with different foaming capacities. The first extract had foaming power of 1.88 and

Figure 9 High performance liquid chromatographic analyses of bloom sample 917S extract that satisfies the foaming parameters: A, original sample; B, foam fraction; C, liquid fraction.

foam stability of 93 min which satisfied only the former requirement. The second extract had a foaming power of 1.32 and the foam stability of 720 min which satisfied both requirements for foam CCC. Then, both samples were subjected to foam CCC.

Figure 9A shows a typical HPLC chromatogram of an extract from cyanobacteria bloom sample 917S containing microcystins. As indicated in the chromatogram, peaks 1 (microcystin RR), 2 (microcystin YR), 3 (microcystin LR), and 4 (microcystin LR-s) were chosen to evaluate their foam enrichment. In the first extract, the enriched concentrations of the components are only 3–4 times and polar components with retention times shorter than that of microcystin RR were still present in the foam fraction. The HPLC analysis of foam fraction and liquid fraction of the second extract is shown in Figures 9B and C. The enrichment reached 10–30 times and polar components are eliminated from the foam fraction indicating that the target compounds are selectively enriched. The HPLC analysis of liquid fraction of both extracts showed similar profiles. These results indicate that these foaming parameters can be effectively applied to a crude mixture containing a large amount of impurities.

Conclusions

Foam CCC can be successfully applied to a variety of samples having foam affinity with or without surfactants. The present method offers important advantages over the conventional foam separation methods by allowing efficient chromatographic separation of sample in both batch loading and continuous feeding. We believe that the foam CCC technique has a great potential in enrichment, stripping and isolation of foam-active components from various natural and synthetic products in both research laboratories and industrial plants.

Introduction

Food is a complex heterogeneous mixture of a wide range of chemical constituents such as moisture, carbohydrates, proteins, fibres, vitamins, etc. Besides these, processed foods contain a wide array of additives and contaminants. Analysis of product composition is a prerequisite for ascertaining product quality,

implementing regulatory enforcements, checking compliance with national and international food standards, contracting specifications and nutrient labelling requirements and providing quality assurance for use of the product for the supplementation of other foods.

Food preservatives form an important class of food additives. They are primarily used to prevent microbial growth, to improve or maintain the nutritional value of food, to maintain palatability and wholesomeness and to enhance flavour and colour. Other food additives used include colours, colour modifiers, flavours, flavour enhancers, humectants, non-nutritive sweeteners, pH control agents, thickeners, stabilizers and emulsifiers. Food additives are regulated and specified by law in most countries to ensure safety for the consumer and prevent deception and fraudulent practices. Labelling regulations require that information be provided on the kind of food, its processing and the additives contained in it.

The complex heterogeneous nature of foods demands effective separation techniques such as High Performance Liquid Chromatography (HPLC) with its wide array of column materials, and detectors. Food additives are usually present in small quantities in processed food items. Their separation from food constituents therefore requires a thorough understanding of the chemistry and physics of the food constituents and additives in order to select the best analytical procedures. Increased automation has gained universal acceptance for the effective separation and analysis of nearly all food components and food additives.

Typical HPLC Analytical Systems

In HPLC analysis of food additives, a single solvent (or solvent mixture) is often not sufficient to carry out the separation under isocratic conditions. Hence, solvent systems of varying proportions are generally used for gradient elution. Abundant literature is available on convenient, versatile and precise liquid chromatography (LC) separations of complex food constituents and additives. Problem areas such as band tailing, trace analysis, preparative separations and so on have received considerable attention and these particular problems can now be tackled in relatively systematic and simple ways.

LC is ideally suited for the separation of macromolecules and ionic species, heat-labile natural products and high molecular weight or less stable compounds such as proteins, nucleic acids, amino acids, dyes, synthetic polymers and food additives.

HPLC is well suited for the quantitative determination of food additives in one step and it has largely replaced other analytical methods.

On account of the wide range of different classes of chemical compounds and matrices encountered, it is not possible to give a universally applicable analytical scheme for food additives. Figure 1 illustrates the various steps involved in the analysis of antioxidants in potato chips by HPLC as a typical example.

Preservatives

Preservatives are chemicals added to food products to prevent or inhibit the growth of microbes. Benzoic acid, sorbic acid, propionic acid and methyl-, ethyl- and propyl-esters of *p*-hydroxybenzoic acid (parabens) are the most commonly used preservatives.

Preliminary extraction from the food matrix before analysis is required. Steam distillation, solvent and solid phase extractions are the most commonly used methods. Hild and Gertz have reviewed the analytical methods available for the quantitative determination of preservatives in food.

For the HPLC determination of benzoates and sorbates, many methods have been reported using either isocratic or gradient techniques with RP-columns and UV detection at ambient temperatures. LC has been used to separate the homologous esters of *p*-hydroxybenzoic acid (parabens) including methyl- and propyl-hydroxybenzoates. This is of specific importance as the homologous esters of *p*-hydroxybenzoic acid (parabens) are a group of similar compounds having closely related properties. The method described can efficiently determine parabens along with BHA, TBHQ, PG, NDGA and Ionox-100 on reverse phase systems with electrochemical detection. The typical linear range extends from 10^{-11} to 10^{-6} mole of injected analyte. Recovery of parabens is about 80%. Detector potential for parabens is +1.10 V and the electrochemical detector provides low limits of detectability.

Normal as well as reversed phase methods have been used to determine the esters of *p*-hydroxybenzoic acid by extraction with acetonitrile. For normal phase HPLC, the use of LiChrosorb Si 60 columns with a mobile phase of iso-octane + diethyl ether + acetonitrile (500 + 35 + 0.3) and for RP HPLC, RP-18 columns with methanol-water (80 : 20) and UV detection have been suggested. Recoveries are 95–104% with 1–2% RSD. A method for the analysis of parabens in meat products has been developed in which the samples are extracted with acetonitrile, filtered and analysed on a C18 column. The peaks are detected and quantitated using UV detector at 254 nm. Average recoveries are 92% for methyl paraben and 94% for propyl paraben.

HPLC has been used to determine sorbic acid, benzoic acid and *p*-hydroxybenzoic acid (PHB) esters

Figure 1 Stages of typical HPLC analysis of antioxidants in potato chips.

in foods. A mixture of acetonitrile, 2-propanol, ethanol and oxalic acid was used for extraction. After refrigerating and separating the interfering materials by centrifugation, the extract was analysed without further cleanup, using Spherisorb ODS II (3 μm) and methanol–water–phosphoric acid–tetrahydrofuran as eluant and detection at 230 nm and 245 nm. The detection limits were 0.5 mg/kg, 2 mg/kg and 10 ng/kg for sorbic acid, benzoic acid and esters of p-hydroxybenzoic acid, respectively.

Using C-18 silica with methanol and phosphate buffer (1:9, v/v) a lower limit of detections ranging from 5 mg/kg to 1 mg/kg can be obtained for benzoic and sorbic esters of PHB.

The sorbate content of commercial yoghurt sample following ion-pair extraction of sorbic acid and benzoic acid in tri-n-octylamine has been reported. It uses a RP-18 column with methanol–phosphate buffer (40:60, pH 4.5, ionic strength 0.1). Mean recoveries are 70–88% with a precision of 1.1 to 3.3% RSD. Isocratic HPLC is suitable for the determination of the benzoic and sorbic acid in beer. Steam distillation and direct extraction as sample pretreatment methods for analysis of benzoic acid and sorbic acids in salad dressing mayonnaise have been compared. Benzoic acid in chilli sauce can be determined by using RP-HPLC with detection at 254 nm.

Gradient elution methods have been compared for the simultaneous determination of benzoic acid, sorbic acid and parabens in ground beef, non-meat products and pork sausages. These preservatives were extracted with 70% ethanol and analysed on a Novapak C-18 column with a linear gradient mobile phase consisting of 10–70% methanol in 1.5% aqueous ammonium acetate and 1.5% aqueous acetic acid over 10 minutes, with 10 minute hold. Recoveries of benzoic acid, sorbic acid, methyl-, ethyl-, and propyl parabens range from 99–103%. Seven preservatives have been simultaneously measured in 28 food samples. Better selectivity and sensitivity for HPLC compared to other procedures have been reported.

A method applicable to many liquid and solid foods has been described. A C-18 column is used with methanol–phosphate buffer (5:95, v/v) as a mobile phase. This work was carried out to check the specificity of the isocratic-LC method for common food additives such as L-ascorbic acid, caffeine, artificial sweeteners, antioxidants and synthetic colours. The method is applicable for determining benzoic acid and sorbic acid in a wide variety of foods such as beverages, fruits, seafoods, vegetables, sauces, dairy products, bakery products and confectionery products. 4-Hydroxyacetanilide is used as internal standard and detection is at 227 nm. Mean recoveries of

90–105% with a precision of 1–6% and detection limit of 20 mg/kg have been achieved. RP-HPLC for quantitative and simultaneous determination of benzoic acid, sorbic acid, PHB, salicylic acid, 5-nitro-furylacrylic acid, *p*-chlorobenzoic acid and PHB esters in wines and beverages has also been reported.

Sulfites and sulfiting agents permitted in the food industry include sodium sulfite, sodium hydrogen sulfite, sodium metabisulfite, potassium metabisulfite, calcium sulfite and potassium hydrogen sulfite. In the 1980s, an ion-pair method was introduced for the determination of sulfites in fruit juices, dried bread, salad dressing, ground beef, liquid caramel, fruit cake, apple pie, raisin, apple juice, apple sauce, dried onions and white wine using high pressure ion-exchange (I-E) polystyrene with $-\text{NH}_3^+$ and $-\text{NR}_3^+$ groups as stationary phase and 0.0024 M Na_2CO_3 and 0.003 M Na_2HCO_3 as mobile phase with conductivity detector. It has a very good detection limit of 1 ppm and an analysis time of 25 minutes. The results were not affected by the presence of volatile acids or even organic sulfur compounds. Average recoveries of 98.3% with standard deviation of 1.88 were reported with a detection limit of 1 p.p.m.

Electrochemical detectors are now preferred for sulfite analysis due to their better sensitivity. Sulfites have been analysed in lemon juice, beer, mashed potato and white wines using anion exchange

stationary phase and 6 mM H_2SO_4 as mobile phase with electrochemical detectors. Average recoveries were 81–103% with standard deviation of 4.6%. Other food products analysed by different workers by this method include apple, avocado mix, broccoli, cabbage, ketchup, grape juice, mushrooms, onions and raisins.

Table 1 gives details of some methods for the analysis of preservatives in foods and food products.

Antioxidants

During storage, oils and fats undergo various reactions that reduce their nutritive value and also produce volatile compounds, to give unpleasant smells and tastes; the phenomenon is referred to as rancidity. In many cases the presence of antioxidants can inhibit the onset of rancidity.

Synthetic antioxidants permitted to be added to food are:

BHA – 1(or 3)-(t-butyl)-4-hydroxy anisole

PG – Propyl gallate

TBHQ – t-Butyl hydroquinone

NDGA – Nor dihydroguaiaretic acid

OG – Octyl gallate

DG – Dodecyl gallate

(BHT – Butylated hydroxytoluene is allowed in a few countries)

Table 1 Details of some methods for the analysis of preservatives in food and food products

Food Products	Preservative analysed	Analytical details		
		Stationary phase/ column	Mobile phase	Detection system
Meat samples	Parabens	μ -Bondapak C-18	45% acetonitrile in water	UV at 254 nm
Yoghurt	Sorbic acid, benzoic acid	RP-18	Methanol-phosphate buffer (pH 4.5, ionic strength 0.1) (40 : 60)	UV at 254 nm
Fruit ready to serve, beverages, jams, jellies, meat products	Benzoic acid, sorbic acid, parabens	Novapak C-18	Gradient elution of 10–79% methanol in 1.5% aqueous ammonium acetate and 1.5% aqueous acetic acid over 10 min	UV at 254 nm
Beverages, fruits, seafoods, vegetables, sauces, dairy, bakery and confectionery products	Benzoic acid, sorbic acid	C-18	Methanol : phosphate buffer (0.03 M, pH 6.5) (5 + 95)	UV at 227 nm
Salad dressing, caramel, fruit cake, apple pie, raisins, onions, sauce, white wine, fruit cocktail	Sulfites (free and total)	I-E polystyrene column	0.003 M NaHO_3 , 0.024 M, Na_2CO_3 , in pure water	Dionex conductivity detector

Satisfactory and complete extraction of antioxidants from a food matrix into various organic solvents is not always easy because of co-extraction of interfering substances. Antioxidants such as BHA, BHT, TBHQ and Ionox-100 are susceptible to losses due to evaporation and utmost care needs to be exercised during concentration under vacuum. NDGA, PG, OG and DG are relatively polar nonvolatile compounds and their recovery is usually satisfactory. HPLC produces good separation between chemically similar compounds in mixtures to be analysed and enables the determination of up to 15 different antioxidants in one single run.

The general analysis protocols for antioxidants in foods comprise extraction in solvents and determination by reversed phase HPLC. The best solvents for extracting antioxidants from fats are acetonitrile and water-alcohol mixtures. The fat is usually dissolved in hexane or petroleum ether and the antioxidant is then extracted into the polar solvent. The literature indicates the use of a variety of chromatographic procedures with UV detection at 280 nm as most commonly used. Mobile phases are acetonitrile, acetic acid, methanol and water.

A HPLC method for the simultaneous determination of phenolic antioxidants in vegetable oils, lard and shortening has been reported. It was concluded that nine antioxidants, viz, BHA, TBHQ, IONOX-100 and THBP, PG, OG, DH and NDGA in vegetable oils, lards and shortening could be separated by gradient elution with water-acetonitrile plus 5% acetic acid as mobile phase. The recoveries ranged from 96 to 103%. A rapid and specific HPLC method for analysis of TBHQ in vegetable oils is also documented. A HPLC method was investigated with amperometric detection to analyse BHA, BHT and TBHQ in edible oils. The antioxidants were well separated, identified and quantified with high sensitivity. Recoveries ranged from 98 to 101%.

The use of RP-HPLC to quantitatively determine five antioxidants—BHA, BHT, PG, OG and DG—in fats has been described. HPLC enables the determination of the full range of antioxidants from polar compounds to the non-polar substances in a single chromatogram using gradient elution. Sensitive detection wavelengths are at 280 nm for UV and at 315 nm for fluorescence emission measurements.

Amperometric detection, which is both sensitive and specific has been used. Determination of BHA and BHT in chewing gums after extraction in hexane and with a second extraction into dimethyl sulfoxide has been reported. The resulting extract was acidified with hydrochloric acid and separated on a μ -Bon-

dapak C-18 column with a mobile phase of acetonitrile-water (55:45, v/v). Antioxidants and antimicrobials (Parabens) have been analysed in a variety of commercial products, such as cereals, snacks and shortenings using amperometric detection. The typical linear range is from 10^{-11} to 10^{-6} mole of injected analyte.

Seven antioxidants have been determined using a linear gradient from 30% solution B (acetonitrile-acetic acid 95:5, v/v) in solution A (water-acetic acid 95:5, v/v) to 100% solution B over 10 minutes with detection at 280 nm. Fifteen antioxidants have been measured in dried foods as well as fats and oils. The antioxidants were separated by isocratic elution with fluorescence and UV detection. Recoveries ranged from 80–106.7%.

The antioxidants diphenylamine and ethoxyquin were estimated using methanol–0.01 M ammonium acetate (60:30, v/v) with fluorescence and UV detection. This method has been used successfully for the separation of fungicide residues and antioxidants in fresh fruits. BHA, BHT, PG, OG, DG and TBHQ in corn oil, cottonseed oil and beef fat have been determined. A procedure for the determination of antioxidants in vegetable oils without prior extraction did not resolve BHT from neutral lipids and suffered from interference due to co-eluting materials. PG, trihydroxybutyphenone, TBHQ, BHA, BHT, NDGA and 3,5-di-tert-butyl-4-hydroxy-methylphenol have been determined in fats, oils and dry foods. Antioxidants in dried foods such as potato flakes, dry coffee, whiteners and dessert topping mixes were isolated after rehydration and extraction in acetonitrile and subsequent separation on a C-18 column. The overall recoveries ranged from 64.3 to 103.6%. The method is highly accurate and hence was adopted as an official method (AOAC).

Tocopherols in vegetable oils have been separated by both reversed-phase and normal-phase LC. A method using a Radial PAK cartridge has been used for analysing individual tocopherols in eleven samples of lupine oil. The results showed the presence of γ -tocopherol (42–69 mg/100 g oil), and δ -tocopherol in traces (0.1–0.7 mg/100 g oil). This method is superior to GC in which up to 30% tocopherol losses occur during pretreatment of the sample. The simultaneous determination of α -tocopheryl acetate, tocopherols and tocotrienols in food involving extraction in hexane, separation on Lichrosorb Si-60 with hexane-di-isopropyl ether (93:3) as mobile phase and fluorescence detection at 290 nm, 330 nm, has been reported. Recoveries are 95–100% with a detection limit of ≤ 20 ng.

Most methods for the analysis of antioxidants use C₁₈ columns with detection at 280 nm. However,

electrochemical or fluorimetric detection or simultaneous detection by two or more techniques has also been used. Mobile phases are usually composed of aqueous acid (acetic/phosphoric acid), buffers or salts together with methanol or acetonitrile. In many cases results are improved by gradient elution.

A method using a C-18 column for α -tocopheryl acetate and tocopherols has been described which allows separation of nine synthetic phenolic antioxidants along with natural antioxidants. Gradient elution is with water-acetonitrile-methanol-isopropanol. This method not only allows simultaneous detection of antioxidants and triglycerides but is also useful in studying inhibition effects of antioxidants in oil.

BHA, BHT, TBHQ, NDGA and gallates have been resolved and quantitatively determined on a Lichrosorb RP-18 column with gradient elution using acetonitrile-water-phosphoric acid and detection at 280 nm. Fluorimetric detection can also be used. The analysis of BHA, BHT, TBHQ and gallates in carrot juice, powdered milk, appetizers and cake using electrochemical detection has also been reported. It was suggested that as many as twelve antioxidants could be detected by a single isocratic HPLC analysis. The quantitation of BHA, BHT, TBHQ, NDGA, gallates and other antioxidants in foods using Supelcosil LC-

18 column with acetic acid-water-acetonitrile as mobile phase and UV detector at 280 nm has also been documented.

Murakita (1992) and Klein & Leubolt (1993) have reviewed the analysis of various antioxidants by HPLC.

Table 2 shows details of major liquid chromatographic methods for the analysis of antioxidants in foods and food products.

Non-Nutritive Sweeteners

Saccharin, cyclamates, aspartame, acesulfame-K are some of the widely used non-nutritive sweeteners.

Soft drinks containing saccharin are readily analysed with minimal sample treatment. For juice, sweets, jams or desserts, an additional extraction step has to be performed. A method for the separation and detection of saccharin, sodium benzoate and caffeine has been reported involving the use of 5% acetic acid as mobile phase and UV detection at 254 nm. The resolution factor was > 2.0 between saccharin and sodium benzoate and between benzoate and caffeine. The detection limits were 0.14, 0.05 and 0.024 μg for saccharin, benzoate and caffeine respectively. Analysis of non-artificially sweetened soft drinks gave no interfering peaks with these additives. This method has been adopted by the AOAC because of its accu-

Table 2 Liquid chromatographic methods for the analysis of antioxidants in foods and food products

Food products	Antioxidant analysed	Analytical details		
		Stationary phase/ column	Mobile phase	Detection system
Potato flakes	BHA, BHT	C-18	Reversed phase gradient elution by acetonitrile with 5% acetic acid and 5% acetic acid in water	UV, 280 nm
Coffee whiteners	TBHQ, BHA	C-18	Reversed phase gradient elution by acetonitrile with 5% acetic acid and 5% acetic acid in water	UV, 280 nm
Dessert topping PG, DG, OG mixes		C-18	Reversed phase gradient elution by acetonitrile with 5% acetic acid and 5% acetic acid in water	UV, 280 nm
Cheese, snacks, cake mix	BHA, BHT, TBHQ, PG, OD, DG	C-18	Reversed phase gradient elution by acetonitrile with 5% acetic acid and 5% acetic acid in water	UV, 280 nm
Oils, lards, shortenings	BHA, BHT, TBHQ, THBP, Ionox-100, NDGA	C-18	Reversed phase gradient elution. Water-acetonitrile with 5% acetic acid	UV, 280 nm
Instant cereals, snacks, gelatin desserts, hydrogenated fats	BHA, TBHQ, PG, NDGA and Parabens	μ -Bondapak C-18	Methanol-0.1 M ammonium acetate (or 0.01 M phosphate) buffer (1 : 1, v/v)	Amperometric detection

racy. An isocratic HPLC method using a cation exchange column, a 0.1 M ammonium dihydrogenphosphate mobile phase and UV detection at 214 nm has been reported for the detection of saccharin, aspartame, benzoic acid and caffeine in soft drinks. Base-line separations of these four additives were achieved. Changing the wavelength of detection from 254 nm to 214 nm led to an increase in the detection response of aspartame. At all levels of addition the recovery for aspartame was 100%. Analysis time could be reduced by increasing the flow rates without sacrificing resolution.

A gradient method for the separation of saccharin, aspartame, benzoic acid and some colours in soft drinks using a detection wavelength of 214 nm has been reported. The mobile phase was methanol (10% increasing to 60%) with 50 mM phosphate buffer at pH 3.6. For aspartame, either isocratic or gradient elution was used. A method for the determination of aspartame, cyclamate, dulcin and saccharin using an ion-pair separation with indirect photometric detection has also been reported. A method for determining acesulfame-K using UV detection at 237 nm and a mobile phase of water-methanol (9 : 1, v/v) containing 10 mM tetrabutylammonium hydrogensulfate has been reported. The absence of appreciable absorption above 200 nm by cyclamate has led to the advent of special methods for its detection. Post-column ion-pairing of cyclamate with either methyl violet or crystal violet renders it easily detectable. Pre-column derivatization agents used are sodium hypochlorite or *o*-phthalaldehyde. An ion pair HPLC method with indirect photometric detection of cyclamate has been used for thick yoghurt samples and solid foods such as biscuits.

A method has been described for the detection of acesulfame-K, saccharin, dulcin, benzoic acid, caffeine and vanillin in ready-to-serve beverages, dry beverage mix samples and other food products. The separation was carried out on a μ -Bondapak C-18 column using methanol-acetic acid-water (35 : 5 : 60, v/v/v) as mobile phase and with UV detection at 254 nm. This method is advantageous because all the additives can be detected in a single step, which renders it useful in routine food analysis. Biemer analysed acesulfame-K in candy gum using an anion exchange column, sodium carbonate (300 mg/L) as mobile phase and conductometric detection.

A method for the determination of aspartame, saccharin, benzoic acid, sorbic acid and caffeine in cola drinks, table-top sweeteners, soft drinks and complex foods on a LiChrosorb C-18, column using acetonitrile-0.1 M sodium dihydrogenphosphate (15 : 85, v/v) at pH 4.5 and UV detection at 215 nm has been

reported. Analysis of acesulfame-K, alitame, aspartame, caffeine, sorbic acid, theobromine, theophylline and vanillin in table-top sweeteners, candy, liquid beverages and other foods using a μ -Bondapak C-18, column and a mobile phase of acetonitrile-0.0125 M potassium dihydrogen phosphate (10 : 90, v/v) at pH 3.5 and UV detection at 220 nm has been advocated. This method allows for the simultaneous determination of theobromine, theophylline, caffeine, vanillin, dulcin, sorbic acid, saccharin, alitame, aspartame and their degradation products in a single run of 60 min duration. Table-top sweetener, candy, soft drink, fruit juice, fruit nectar, yoghurt, cream, custard, chocolate and biscuits have been analysed by simple extraction or by just dilution using this method.

Some of the simpler LC methods for sweetener analysis are given in Table 3.

Food Colours

Colour is a prime sensory quality by which foods are judged and food quality and flavour are closely associated with colour. Consumers are conditioned to expect foods of certain colours and to reject any deviation from these expectations. Colourants also play a significant role in enhancing the aesthetic appeal of food. Colourants are very important ingredients in many convenience foods such as confectionery products, desserts, snacks and beverages.

The regulatory status of colourants used in different countries throughout the world is in a constant state of flux due to the toxicological considerations. An extensive review of genotoxicity of food, drug and cosmetic colours and other azo triphenylmethane and xanthan dyes has been published by Combes and Haveland-Smith (1982).

Synthetic colours can be classified by their chemical structure as azo (mono, di and tris), indol, triphenylmethane and methin dyes. They are mostly acidic or anionic and acidic groups like sulfuric acid, carboxylic acid or hydroxy groups form a negatively charged coloured ion. Basic or cationic dyes contain substituted amino groups.

The dyes have to be first extracted from the complex food matrix; adsorbents like wool fibres, powdered polyamide, cellulose ion exchange resins or RP cartridges (Sep-Pak C18) are frequently used. Ion-pair chromatography has been used for the quantitative analysis of twelve primary food colours in grape beverages with a mobile phase of 45 : 55 methanol-water, the useful detection wavelengths were 610 nm for blues and greens and 480 nm for reds, oranges

Table 3 Simpler methods for the analysis of food products for non-nutritive sweeteners

Food products	Sweetener analysed	Analytical details		
		Stationary phase/ column	Mobile phase	Detection system
Coffee, carbonated cola, lemon beverages	Sucralose	RadialPak C-18	Water-methanol 70 : 30	RI
Fruit drinks, cherry nectar, mayonnaise, chocolate	Cyclamate	Nucleosil C-18	Methanol-water 80 : 20	UV, 313 nm
Fruit juice, yoghurt, Cola	Acesulfam-K	Lichrosorb RP-18	Methanol-water 9 : 1 with 1 mM tetra butyl ammonium hydrogen sulfate	UV, 237 nm
Cola, pudding, chocolate	Saccharin, cyclamate, Alitame	μ Bondapak C-18 or Supelcosil LC-18	Phosphate buffer 20 mM (pH 3.5) : acetonitrile 97 : 3	RI, UV 200 nm
Ready-to-drink and dry mixes of beverages, tomato sauce	Saccharin, Acesulfam-K	μ Bondapak C-18	Methanol-acetic acid-water, 35 : 5 : 60	UV, 254 nm
Candy, chewing gum	Saccharin, Acesulfam-K	AS4A, anion exchange resin	Sodium carbonate (140 mg/L)	Conductivity
Candy, beverages, pickles, soy sauce	Rebausides A and C, Stevioside	Lichrosorb NH ₂	Acetonitrile-water	UV, 210 nm
Diet cola	Saccharin, Acesulfam-K	Hypersil ODS	Phosphate buffer (pH 3.5)-acetonitrile 85 : 15	UV, 216 nm
Soft drinks, candy, pickle	Rebausides A, Stevioside	Finepak SIL NH ₂	Acetonitrile-water 80 : 18 with tetrabutyl-ammonium phosphate	UV, 210 nm
Fruit yoghurts	Aspartame	μ Bondapak C-18	Phosphate buffer 125 mM (pH 3.5)-acetonitrile 90 : 10	UV, array 400
Soft drinks, table-top sweeteners	Acesulfam-K, Sucralose, Saccharin, cyclamate	Supelcosil LC-18	Acetonitrile (20 mM) : phosphate buffer (pH 3.5)-gradient of 97 : 3 to 85 : 15	Vis 585 nM (after post column ion-pairing)
Candy, soft drinks, yoghurt, custard, fruit juice, nectar, biscuit, chocolate	Aspartame and its decomposition products, Saccharin, Alitame, Acesulfam-K	μ Bondapak C-18	Phosphate buffer 125 mM (pH 3.5)-acetonitrile 90 : 10, 85 : 15, 98 : 2	UV, 220 nm
Table-top sweeteners	Acesulfam-K	Lichrosorb RP-18	Potassium phosphate buffer	UV, 227 nm
Shrimp	Saccharin	IonPac AS-5	Sodium carbonate (7.7 mM) acetonitrile, sodium hydroxide (33 mM) Cyanophenol	Conductivity

and yellow. Ponceau, Fast red-E, Benzyl violet 4B, erythrosine and some non-permitted synthetic colours were separated. The procedure has been reported to be a viable and quicker alternative to TLC-spectrophotometric techniques. A method for the determination of L-orange, Sunset Yellow FCF and Ponceau 4R by means of ion-pair chromatography has also been described. It has been used for analysis of food dyes E 110, E 111 and E 12 in fish samples

using Nucleosil, C-18 or Lichrosorb RP-8 columns and detection at 505 nm. The mobile phase consisted of water-acetone mixtures (80 : 20) with tetrabutylammonium chloride added as ion-pair agent (0.2 g/L).

Carotenoids in red bell peppers were separated without saponification using a C₁₈ column and methanol-ethyl acetate as mobile phase with detection at 475 nm.

Table 4 Simpler methods for the analysis of colours in food and food products

Food products	Colour analysed	Analytical details		
		Stationary phase/ column	Mobile phase	Detection system
Fruit juices, grape beverages, confectionery	Ponceau, Fastred E, benzyl violet 4B, erythrosine	Ion-pair HPLC	Methanol–water	480 nm, 610 nm
Fish, bakery, meat products, miscellaneous products	E-110-orange II E-III-orange I and E-124 Ponceau 4R	Lichrosorb RP-8	Water – acetonitrile (80 : 20)	505 nm
Olive oil	Chlorophylls, carotenoids	C-18	Methanol – acetone	410 nm
Red bell pepper	Carotenoids	ODS	Methanol – ethylacetates (1 : 1)	410 nm
Strawberry	Anthocyanins	ODS	10–30% aq. acetonitrile with 0.5% TFA	Photodiode array detector

A rapid method has been reported for quantitation of chlorophylls and carotenoids in virgin olive oil, by solid phase extraction on a C-18 column. The fat free pigments were separated and concentrated. A total of 17 pigments were separated and quantitated with a C-18 column and gradient elution of water–ionic pairing reagent–methanol and methanol–acetone (1 : 1). Detection was at 410 nm and 430 nm. β -Carotene and other hydrocarbon carotenoids have been determined in red grape fruit cultivars with non-aqueous eluents using a C-18 column and isocratic mobile phase consisting of acetonitrile, methylene chloride and methanol (65 : 25 : 1, v/v/v).

Anthocyanins have been extracted from cultured cells of strawberry plants using a 35% solution of acetic acid–acetonitrile–water (20 : 25 : 55), containing 0.1% trifluoroacetic acid; using a C-18 column, and using 10 to 30% aqueous acetonitrile containing 0.5% of trifluoroacetic acid as eluent in 30 min at 40°C with photodiode array detection. The method yielded higher concentration of anthocyanin than other methods.

Table 4 gives details of methods for the analysis of colours in foods and food products.

Emulsifiers and Wetting Agents

Food emulsifiers assist the stabilization and formation of emulsions by reducing surface tension at the oil–water interface. Common food emulsifiers used are:

- lecithin and lecithin derivatives
- glycerol fatty acid esters
- hydroxycarboxylic acid and fatty acid esters
- lactylate fatty acid esters
- polyglycerol fatty acid esters

- ethylene or propylene glycol fatty acid esters
- ethoxylated derivatives of monoglycerides.

Quantitative analysis of emulsifiers is difficult as most of them are similar in structure, their commercial sources are quite heterogeneous and their extraction from starchy foods is very difficult. A key problem is the quantitative extraction of emulsifiers and the exclusion of interfering substances. This problem is further complicated by the presence of food ingredients such as proteins, and the innate heterogeneity of most of the emulsifiers as well as the wide variation in their composition. The schemes of analysis for lecithin, monoglycerides, TEMS, acetylated monoglycerides, partial polyglycerol esters, propylene glycol esters, polysorbates, lactic acid esters, ethoxylated monoglycerides and sugar esters have been discussed. Baur has recommended solvents for extraction of emulsifiers.

A method for the separation of monoglyceride (E 471), sodium stearoyllactylate (E 481), calcium stearoyllactylate (E 482), diacetyltartaric acid esters of mono- and diglycerides (E 472e) and mixed acetic and tartaric acid esters of mono- and diglycerides (E 472f) on a semi-preparative column has been described. Various emulsifiers were identified by off-line high resolution mass spectrometer. Analysis of sodium or calcium stearoyllactylate showed that the major components were 2-stearoyl and 2-palmitoyl lactic acid and their salts.

Sodium dioctylsulfosuccinate, a wetting agent, has been permitted in a variety of food products including dry beverage bases. A post-column ion-pair extraction method was employed using methylene blue as counterion. Then the compound was extracted into chloroform from the aqueous phase

For analysis, a CN column was used with acetone–0.01 M KH_2PO_4 (1 : 5, v/v) as a mobile phase.

Thin-Layer (Planar) Chromatography

M. Vega, Faculty of Pharmacy, University of Concepción, Concepción, Chile

Copyright © 2000 Academic Press

Introduction

Thin-layer chromatography (TLC) is a relatively old technique among the other chromatographic separation methods. In food additive analysis, this simple technique is the tool of choice, mainly because the high throughput of samples that it can manage in parallel and the wide range of compounds that can be analysed simultaneously.

Food Additives

Anything added to food is not necessarily a food additive. Generally, a food additive is a substance or a mixture of substances different to the bulk of the food and present as a result of any aspect of production, processing or packing. This definition does not include hazardous contaminants.

The Codex Alimentarius Commission for Food Additives defines these as follows:

Food additive means any substance not normally consumed as a food by itself and normally used as a typical ingredient of the food, whether or not it has nutritive value, the intentional addition of which to food for a technological (including

organoleptic) purpose in the manufacture, processing, preparation, treatment, packing, packaging, transport or holding of such foods, results or may reasonably expect to result (directly or indirectly), in it or its by-products becoming a component of or otherwise affecting the characteristics of such foods. The term does not include 'contaminant' or substances added to the food for maintaining or improving nutritional qualities.

Others definitions include:

Substance with non-nutritive properties, known chemical composition, intentionally added to food; generally in small amounts, with the aim of improving presentation (appearance, flavour, texture) and conservation properties of foods.

In other countries, such as Spain, additives are all substances that can be added intentionally to food and drink, without the purpose of changing the nutritive value, to modify processing and conservation characteristics, as well as to improve their adaptation to the use for which it is produced.

Classification of Food Additives

Many methods have been used to classify food additives. The majority imply functional grouping.

Chemical-type grouping is convenient because it puts together moieties of similar structures and chemical properties in comparative categories. Toxicological and metabolic studies can also be correlated with chemical grouping. However, compounds belonging to the same chemical family have different functions in the food industry. In spite of the fact that a compound can have two or more different functional groups, this classification is more practical in the food industry. **Table 1** shows a typical classification of food additives.

Table 1 shows the diversity of compounds included in the different classes generated. Grouping by functional group type can include chemical substances both naturally and structurally quite different. This is an additional problem for the analysis of substances considered, classified or included in lists of food additives.

In modern quality control, analysis is required at every step and not just in the final product. This is to prevent possible defects directly at the critical points but it produces a significant increase in the number of samples and the number of analyses to be carried out.

On the other hand, it is important to consider that additives can be applied exclusively to those foods where regulation points out specifically that they must be used and normally they must be declared on labels attached to the food.

In spite of tolerance limits for some additives, the amount added should not exceed the amount adequate to attain the objective, using the appropriate manufacturing procedure. This justifies the necessity to detect and quantify food additives. Today there are many analytical procedures applied to these substances. Obviously the method used will depend on the analytes, and their characteristic and/or physico-chemical properties.

Table 1 Permitted classes of food additives in Australia

<i>Class of additive</i>	<i>Property of food influenced</i>
Preservatives	Shelf-life
Colourings	Appearance
Flavouring and flavour enhancers	Flavour
Antioxidants	Shelf-life
Artificial sweetening substances	Flavour, energy value
Vitamins and minerals	Nutritive value
Modifying agents	
Vegetable gums	Texture, appearance
Mineral salts	Texture, appearance
Food acids	Shelf-life, flavour, texture
Emulsifiers	Texture, appearance
Humectants	Texture, shelf-life
Thickeners	Texture

It is necessary to extract the additive compound from the food matrix and to apply additional purification procedures where necessary. Chromatographic methods, which involve a separation process, allow the isolation of the compound(s) to be analysed. High performance liquid chromatography (HPLC), gas chromatography (GC) and TLC have all been used extensively for the final analysis.

For large numbers of samples, the comparative advantage of TLC is that it is a completely instrumental technique that can deal with many samples simultaneously, and with samples of a diverse nature.

In the past few years, many reviews have been published with the aim of featuring the relevant characteristics of instrumental planar chromatography, or high performance thin-layer chromatography (HPTLC).

In the first place, it is necessary to describe the advances obtained in the preparation of sorbents for stationary phases.

Silica still represents the most frequently used material for the stationary phase. Approximately 90% of separations by TLC are still carried out using silica. Modern sorbents are characterized by smaller and more uniform particle size, implying a reduction of equivalent plate height. This results in a higher number of theoretical plates for a given run length compared with traditional phases and, in turn, this allows separations in shorter distances with corresponding time savings and reduction of diffusion problems that appear when the mobile phase is retarded excessively.

Stationary phases of polarity from intermediate to reversed phase, have been developed. Most of them are obtained by chemical modification of silica gel (**Table 2**).

Recently, sorbents with spherical particles such as Lichrospher Si 60 F254s have appeared. They offer shorter analysis times, improved separation

Table 2 HPTLC stationary phases used in food additives analysis

<i>Stationary phase</i>	<i>Food additives</i>
3-Aminopropyl	Sugars, carboxylic acids, preservatives
Reversed-phase, C18	Preservatives, antioxidants
Aluminium oxide	Lipophilic food dyes
Silica normal	Antioxidants, sweeteners, surfactants, dyes
Cellulose	Artificial sweeteners, carboxylic acids
Cellulose MN 300	Food dyes

efficiency, more compact spots, higher spot capacity and lower detection limits. All these new plates are applicable to the analysis of many analytes including those used as food additives.

Advances in instrumentation in the whole chromatographic process, ranging from application devices through automatic developing chambers, and automated multiple development (AMD) chambers with computer control, all deserve special consideration. Computer-controlled AMD using polarity gradients increases efficiency in separation to limits comparable to HPLC, and retains the high throughput of samples to be analysed in the same chromatographic run.

Major developments in densitometers have meant improvements in the quantitative analytical ability of planar chromatography. These, coupled to software, allow quantitative analysis of substances at very low concentrations thanks to the high sensitivity of detectors that allow measurements over the whole UV-visible spectrum as well as fluorescence.

Another important aspect of HPTLC in food additive analysis, is that there are some compounds with difficult detection characteristics. The variety of reagents available, overcomes this difficulty and they can be used as pre- or postchromatographic derivatizing agents.

Finally, video scanning not only allows information to be saved digitally but also gives quantitative results from image integration.

Unlike HPLC, TLC needs very little sample purification and can be used with raw or dirty materials, thereby saving time and additional expense.

Applications of HPTLC in Food Additive Analysis

TLC has been used for many years in the analysis of food additives, such as food dyes, preservatives (Table 3), antioxidants and sweeteners.

Food colourants are in many cases fundamental food additives because consumers judge product quality by its colour. On the other hand, before a dye (natural or synthetic) is permitted for use on food it has to be shown that it is nontoxic and noncarcinogenic. The current list in western European countries comprises about 30 natural or artificial substances permitted as food dyes, and is very small compared to the vast number of known dyes. This makes it necessary to have easy and fast methods to detect forbidden or unapproved food dyes (Table 4).

Because the importance of colourings in foods, a variety of separation procedures are still being examined with the aim of improving performance.

Table 3 Analysis of preservatives by HPTLC

Preservatives	Layer	Eluent	Detection	Reference
p-Hydroxybenzoates n-propyl, ethyl, methyl	Silanized silica C18	Methanol-water (7 + 3, 6 + 4, 5 + 5, 4 + 6 v/v)	UV $\lambda = 270$ nm	Volkman D (1980) <i>HRC and CC</i> , 3: 189
8 different preservatives	Mixed layers of silica and cellulose, F254	Petroleum ether-CCl ₄ - CHCl ₃ -formic acid- glacial acetic acid (50 + 40 + 20 + 8 + 2 v/v)	UV $\lambda = 254$ nm	Gosselé JAW (1971) <i>Journal of Chromatography</i> 63: 433

The use of surfactants, (hexadecyltrimethylammonium bromide) incorporated in the mobile phase for the separation of acids and alkaline food colourings, new polymer coatings for plates and new adsorbents such as Scolecite (corresponding to a natural zeolite) are recent approaches. Some colourants such as indigo carmine, cochineal red, acid amaranth and tartrazine G, have been separated on thin magnesium oxide layers with mixtures of 15% sodium citrate and methanol. Reversed-phase plates, obtained by impregnation of silica plates with 10% liquid paraffin in petrol ether are used for separation of different food dyes with advantage.

For food preservatives like benzoic and sorbic acid, the use of methods such as solid phase extraction (SPE) allow a better separation of these food additives from natural ingredients present in beverages.

Overpressured thin layer chromatography (OPTLC) has been shown to be a good tool for the separation

of a variety of food additives, like antioxidants, natural food colourings, preservatives and water-soluble vitamins with silica plates. In this field, AMD has also been successful in the separation, identification and quantification of a diverse range of antioxidants.

Other food additives that requires adequate control are artificial sweeteners and antioxidants, because of the carcinogenic properties attributed to some of them. Analysis of these is frequently carried out by HPLC, but, HPTLC shows the comparative advantages formerly mentioned. **Table 5** summarizes some HPTLC systems for analysis of these food additives.

FOOD MICROORGANISMS: BUOYANT DENSITY CENTRIFUGATION

R. Lindqvist, National Food Administration,
Uppsala, Sweden

Copyright © 2000 Academic Press

Introduction

Density gradient centrifugation is an established technique for the separation and purification of eukaryotic and prokaryotic cells, viruses and subcellular components such as plasmids, mitochondria and nucleic acids. Using this technique, components may be separated based on their differences in density or size during centrifugation in a gradient medium. Gradient media that have been used include caesium chloride, sodium metrizoate, sucrose, Ficoll, Ludox[®], Percoll[®] and BactXtractor[™]. One of the limitations with this technique has often been the properties of the gradient medium used. For instance, it is crucial that the gradient medium is at physiological ionic strength to avoid cell lysis or dehydration effects. Further, the gradient medium should be nontoxic and not affect the viability of the cells.

Density gradient centrifugation using different gradient media has been used to separate a wide range of microorganisms from various types of samples. For example, bacteria have been recovered from soil using sucrose gradients and different types of protozoa have been separated from river water, faeces, etc., using various gradient media. Further, gradient centrifugation in Percoll[®] has been used to distinguish subpopulations of pathogenic bacteria and to separate live from dead eukaryotic cells.

To some extent this technique has also been used to separate microorganisms from food, e.g. in the separation of bacteria from milk and natural yoghurt. The main benefits of using density centrifugation is its simplicity and speed in separating and concentrating intact organisms from foods while at the same time removing compounds that might interfere with or inhibit the detection method. The ability to remove inhibiting or interfering material present in food has been evaluated by subsequent detection of prepared microorganisms through methods of varying sensitivity such as traditional plate count procedures, the polymerase chain reaction (PCR), nucleic acid sequence based amplification (NASBA), and ATP measurements.

The present work describes how to use buoyant density centrifugation and gives an example of how

to design a procedure for the separation of microorganisms from a specific food. This approach has been successful for several food/microorganism combinations and it has been possible to separate and concentrate bacteria from food and to remove inhibitors sufficiently to allow detection of bacteria by both PCR and NASBA. However, in some cases, especially when the food contains denser components, there can be limitations which may be overcome by use of a two-layer technique also described here. The protocols presented are based on work described in Lindqvist *et al.* (1997), Lindqvist (1997) and Anonymous (1995) (see Further Reading).

General Theory and Methodology

Principles of Centrifugation

Equation [1] describes the sedimentation of a sphere in a centrifugal field:

$$v = [d^2(\rho - \rho_1)/18\eta] \times g \quad [1]$$

where v = sedimentation rate, d = diameter of the particle (hydrodynamically equivalent sphere), ρ = particle density, ρ_1 = liquid density, η = viscosity of the medium and g = centrifugal force.

From this relationship it can be seen that the sedimentation rate of a particle is proportional to its size and to the density difference between the particle and the medium. Also, the sedimentation rate is zero when the density of the particle is equal to the density of the surrounding medium. Further, the sedimentation rate decreases with increasing viscosity of the medium and increases with increasing centrifugal force applied. From this it also follows that separation depending on the conditions chosen may be carried out based on either the size (rate zonal centrifugation) or the density differences (isopycnic centrifugation) between particles. In the latter case, each particle will sediment to an equilibrium position in the gradient where the gradient density is equal to the density of the particle. In the present work, the isopycnic technique is discussed.

The specific cell density, i.e. cell weight/cell volume when measured by buoyancy in a given medium capable of forming density gradients, is referred to as the buoyant density. Consequently, anything that affects the size of the microorganism, e.g. osmotic

conditions and growth phase, may also affect their buoyant densities and, thus, separation. This stresses the importance of the properties of the gradient medium and of using standardized conditions when developing and using the separation protocol.

Gradient Media

Two gradient media with favourable properties for work with microorganisms are Percoll® and BactXtractor™. The composition and properties of these gradient media are similar (see below). The most important difference is that BactXtractor may be autoclaved after NaCl and peptone have been added to prepare a standard isotonic medium (SIM). Percoll and BactXtractor are nontoxic, have a low osmotic pressure and viscosity. These media consist of colloidal silica particles of 15–30 nm diameter coated with polyvinylpyrrolidone (PVP). They can form self-generated gradients in the range of 1.0–1.3 g mL⁻¹, which correspond to the cell densities of many microorganisms. When a solution of Percoll® (or BactXtractor™) is centrifuged at > 10 000 × *g* in an angle-head rotor, the coated and hydrated silica particles will sediment resulting in an uneven distribution of particles and the formation of a self-generated density gradient. The gradient is formed isometrically around the initial density of the gradient medium and becomes steeper with centrifugation time. The shape of the gradient can be visualized by the use of coloured density marker beads and is related approxim-

ately linearly to the *g* force and time of the centrifugation. Rotor geometry and the size of the tubes also have a marked effect on gradient shape. In contrast to the self-generated continuous gradient, for some applications a uniform density centrifugation using one (cushion) or several layers (step gradient) of the gradient medium is preferred. The latter approaches are discussed here for the separation of bacteria from food.

Overview of Methodology

When designing a separation protocol, the same procedure may be followed independent of the subsequent detection method. This procedure includes the following steps (Figure 1): (1) determination of the buoyant density of the microorganism; (2) determination of the buoyant density of the food; (3) selection of the concentration of the gradient medium to be used in the separation of the microorganism from food; (4) evaluation of the separation protocol with the desired detection method; and (5) optimization of the protocol if necessary.

Preparation of the Gradient Medium

The gradient media, Percoll® (Pharmacia Biotech, Sweden) or BactXtractor™ (QRAB, Uppsala, Sweden) have a density of around 1.130 g mL⁻¹. Before use, the medium is made isotonic with physiological saline by aseptically adding 8.5 g L⁻¹ NaCl, and

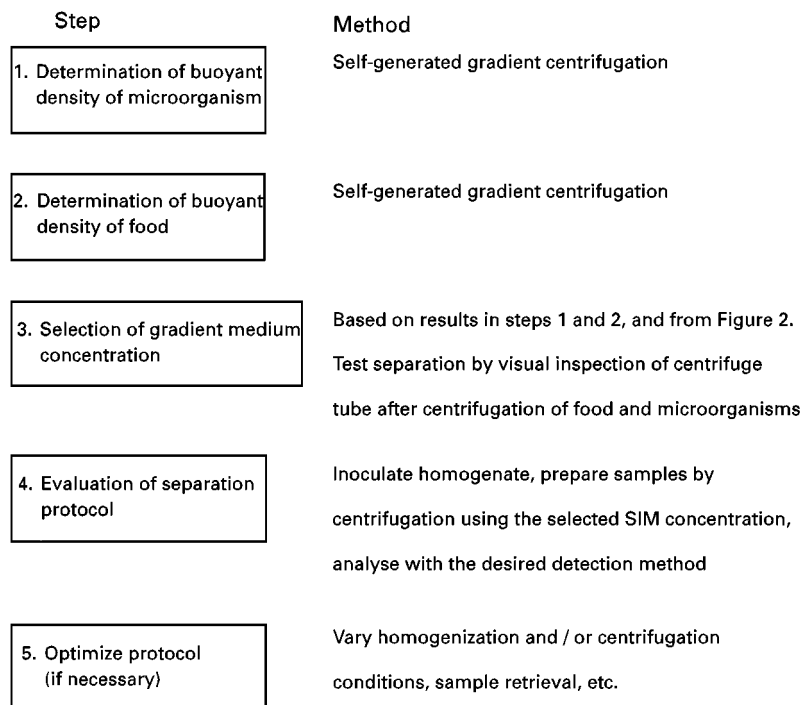

Figure 1 Schematic overview of the sequential steps involved in designing a protocol for separation of microorganisms from food.

its suitability for maintaining microorganisms is improved by addition of 1.0 g L⁻¹ peptone. This stock solution is termed 100% standard isotonic medium (100% SIM) and may be autoclaved if prepared with BactXtractor™. The solution of 100% SIM is diluted to the required concentration with the appropriate volume of peptone-water (8.5 g NaCl and 1.0 g peptone in 1 litre of Millipore water).

The density of the 100% SIM solution described above is calculated by the following formula:

$$\rho_s = [V_g \times \rho_g + m_{NaCl} + m_p] / V_g$$

$$= [100 \times 1.130 + 0.85 + 0.1] / 100 = 1.1395 \quad [2]$$

where ρ_s = the density of 100% SIM (g mL⁻¹), V_g = the volume of gradient medium to be prepared (mL), assumed here to be 100 mL (the volume change by addition of solutes is negligible), ρ_g = the actual density of the gradient medium, assumed here to be 1.130 g mL⁻¹, m_{NaCl} = the amount of NaCl added (g), assumed here to be 0.85 g and m_p = the amount of peptone added (g), assumed here to be 0.1 g.

By using eqn [2], the density of 100% SIM was calculated to be 1.1395 g mL⁻¹, assuming that 100 mL of gradient medium with a density of 1.130 g mL⁻¹ was mixed with NaCl and peptone. The relationship between density and concentration of SIM can be determined by plotting the calculated density of a 100% solution and the density of a 0% solution, i.e. the density of the diluent, as a function of percent SIM concentration and then determining the equation for the straight line between these two

points:

$$\rho_{sy} = [(\rho_g - \rho_p) / (100)] \times C_s + \rho_p$$

$$= [(1.1395 - 1.0095) / 100] C_s + 1.0095$$

$$= 0.0013 \times C_s + 1.0095 \quad [3]$$

where ρ_{sy} = the density of SIM of concentration C_s (g mL⁻¹), ρ_p = density of peptone water, estimated here to be 1.0095 g mL⁻¹, C_s = concentration of SIM (%) and ρ_g = the actual density of the gradient medium, assumed here to be 1.130 g mL⁻¹.

The line described by eqn [3] and shown in Figure 2 is valid only for the properties of the gradient medium and diluent assumed in this work but similar graphs can easily be constructed for other experimental conditions. The graph can then be used to determine what concentration of SIM is required to produce a gradient medium of a particular density.

Determination of the Buoyant Densities of Microorganisms

Since the buoyant densities of microorganisms may be affected by a number of factors, it is important that they are handled and separated from food under standardized conditions. For instance, the buoyant densities of bacteria in Percoll® gradients have been shown to vary with growth rate and during the cell cycle for some bacteria but not for others. Further, efforts to inactivate bacteria by, for instance, boiling, heating, and low pH treatment have shown that,

Figure 2 The relationship between density and concentration of the standard isotonic medium (SIM). The relationship described by this line is only an example and was calculated based on the conditions described in this work. The exact relationship must be calculated based on the density of the gradient medium and the diluent used.

depending on the treatment and the strain used, this may or may not affect their buoyant densities. Some variation in buoyant densities of a given strain may be expected depending on the culture media used, storage time after growth, etc., but ideally this is in a density range where separation is not affected. However, the presence of different subpopulations in the sample, e.g. log-phase and stationary cells, may result in a wide continuous distribution, or even separate bands, of microorganisms within the centrifuge tube.

Preparation of Microorganisms

A sufficient number of strains are cultured and treated under relevant conditions to collect data on the buoyant density of the microorganism and its variation. The number of cells loaded on to the gradient must be large enough to form a visible band in the centrifuge tube after centrifugation. In most cases a solution containing 10^8 – 10^9 cfu mL⁻¹ is sufficient. The solution is prepared by centrifuging an appropriate volume of culture, washing, and resuspending in physiological saline or peptone-water. The washing and resuspension of cells in fresh physiological saline solution serves to suppress variations in osmotic pressure introduced by the presence of metabolites, etc.

Sampling Loading

The appropriate volume of the microorganism suspension or solution containing the density marker beads is carefully layered on the standard isotonic medium. There are no definite rules on how much sample it is possible to load on to the gradient and

this must be tested empirically. The best SIM concentration to use depends of course on the microorganisms. In our work, concentrations between 50% and 80% and between 40% and 70% have been used with microorganisms and food, respectively. However, in addition to buoyant density, specific requirements on the amount of sample and the shape of the gradient may influence the scale of the experiment, i.e. rotor geometry and size of the tubes. **Figure 3** shows examples of a large scale and a small scale protocol.

Generation and Reading of the Gradient

The gradient is generated by centrifugation and is visualized by substituting the sample volume with a solution of colour-coded density marker beads (Pharmacia Biotech, Sweden) on top of the gradient medium. A volume of marker solution equivalent to the sample volume is prepared by adding approximately 5–10 μ L of each marker bead to a physiological saline solution. During centrifugation, the density beads equilibrate at positions in the gradient corresponding to their densities. The distance of the differently coloured density beads from the bottom of the tube is recorded and the densities of the beads are plotted versus the position to generate a calibration curve (**Figure 4**). Similarly, the position of the microorganisms in the centrifuge tube is recorded and the corresponding buoyant density is read from the calibration curves. The best resolution is obtained in the steep part of the curves where a large distance in the centrifuge tubes corresponds to a small difference in density (**Figure 4**). By comparing the shapes and locations of the three gradients in **Figure 4** it can be seen that the resolution in the 60% SIM gradient is

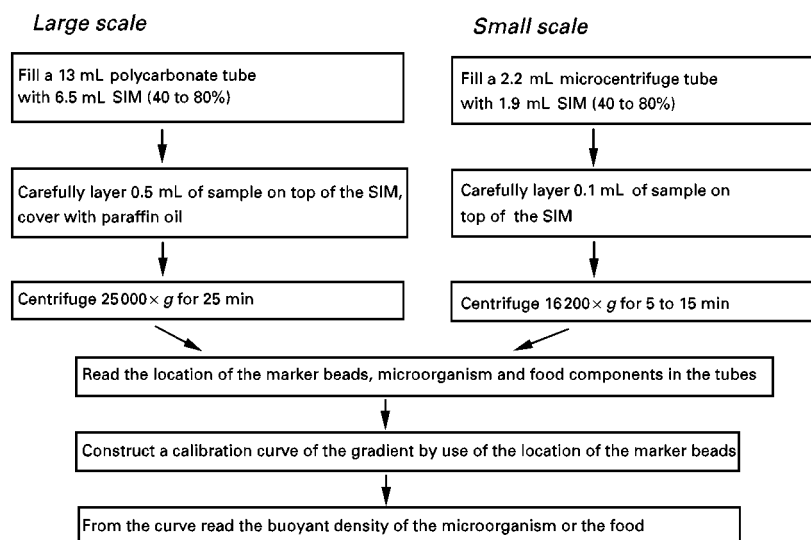

Figure 3 Example of two protocols for the determination of the buoyant density of microorganisms and food.

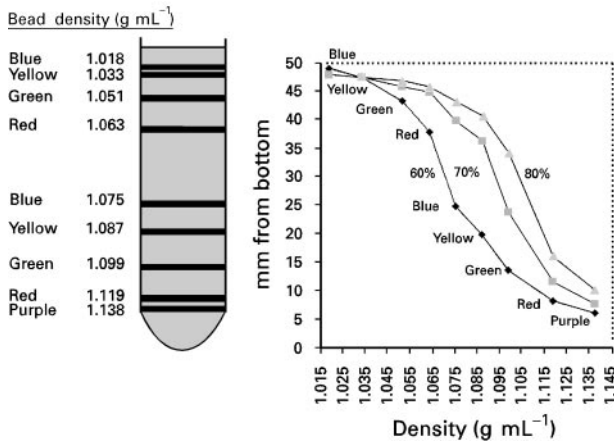

Figure 4 Illustration of how to construct calibration curves for the determination of the buoyant densities of microorganisms and food. The gradients were generated by layering 0.5 mL of density marker beads on 6.5 mL of 60%, 70% or 80% SIM and centrifuging at $25\,000 \times g$ for 25 min. Left: the positions of the different bands of colour-coded density marker beads in 60% SIM. Right: the curves were constructed by plotting the position and the density of the density marker beads in the diagram. The best resolution is obtained in the steep part of the curves, i.e. large difference in position corresponds to a small difference in density.

better at lower densities and vice versa for the 80% SIM. However, in addition to the selection of the SIM concentration, it is sometimes useful to vary the centrifugation time and speed when optimizing the gradient for a specific microorganism or food. In a given gradient, the width of the more or less well-defined band of microorganisms following centrifugation depends on the number of microorganisms and the range of buoyant densities present in the population under study.

Determination of the Buoyant Densities of Food

The food homogenate to be loaded on the gradient medium must be sufficiently concentrated to be visible in the centrifuge tube. Thus, a more concentrated homogenate is often used for this step than will be used in the final separation protocol. Typically a 1 : 1 to 1 : 10 (w/v) homogenate is suitable. The determination of the buoyant density of food is then carried out by centrifugation in a self-generated density gradient as described above for the microorganism.

Selecting the Concentration of the Gradient Medium

The simplest technique to separate microorganisms from food is to centrifuge the sample on a single layer

of gradient medium of a uniform density (cushion centrifugation). During the previous steps the buoyant densities of the microorganism and of the food have been determined under the relevant conditions which will indicate if separation is possible, i.e. if there is a difference in buoyant densities that may be exploited. The food is generally less dense than the microorganisms and the density of the gradient medium is chosen so that it lies between the densities of the food and the microorganism. Thus, the microorganisms will be found in the bottom of the tube after centrifugation. The optimum concentration of SIM to use to obtain the cutoff density between food and microorganisms can be determined from the relationship between density and SIM concentration described in eqn [3] and Figure 2.

Separation by a Uniform Density Centrifugation

A quick way to test if the correct concentration of SIM has been selected is to run a uniform density centrifugation (see below) of a cell suspension and food homogenate, respectively. After centrifugation, food should remain on top of the gradient medium and cells should be visible in the lower part of the tube. Based on the exact position of microorganisms, the volume of sample that needs to be retrieved is determined. The sample volume is the amount of medium contained in the centrifuge tube from the upper band limit to the bottom of the tube.

In order to run a uniform density centrifugation, gradient formation during centrifugation should be avoided. This may be achieved either by centrifugation in a swing-out rotor or, if using an angle-head rotor, by centrifuging under conditions where gradient formation is negligible (e.g. low g forces or short centrifugation times).

Evaluation of Protocol

To evaluate the separation procedure, inoculated food homogenates are analysed with the desired method of detection, e.g. plate counts or PCR. The size of the centrifuge tubes to use depends on the amount of sample needed for detection as well as the number of samples to be analysed in a given time.

In Figure 5, examples of a large scale (larger sample capacity) and a small scale (larger sample throughput) protocol for separation of microorganisms from food are offered to assist in the selection of which centrifugation conditions to be used. Similar, or identical, protocols have been used to separate microorganisms, e.g. *Shigella* spp., *E. coli* O157:H7, *Yersinia enterocolitica*, *Campylobacter* spp. and

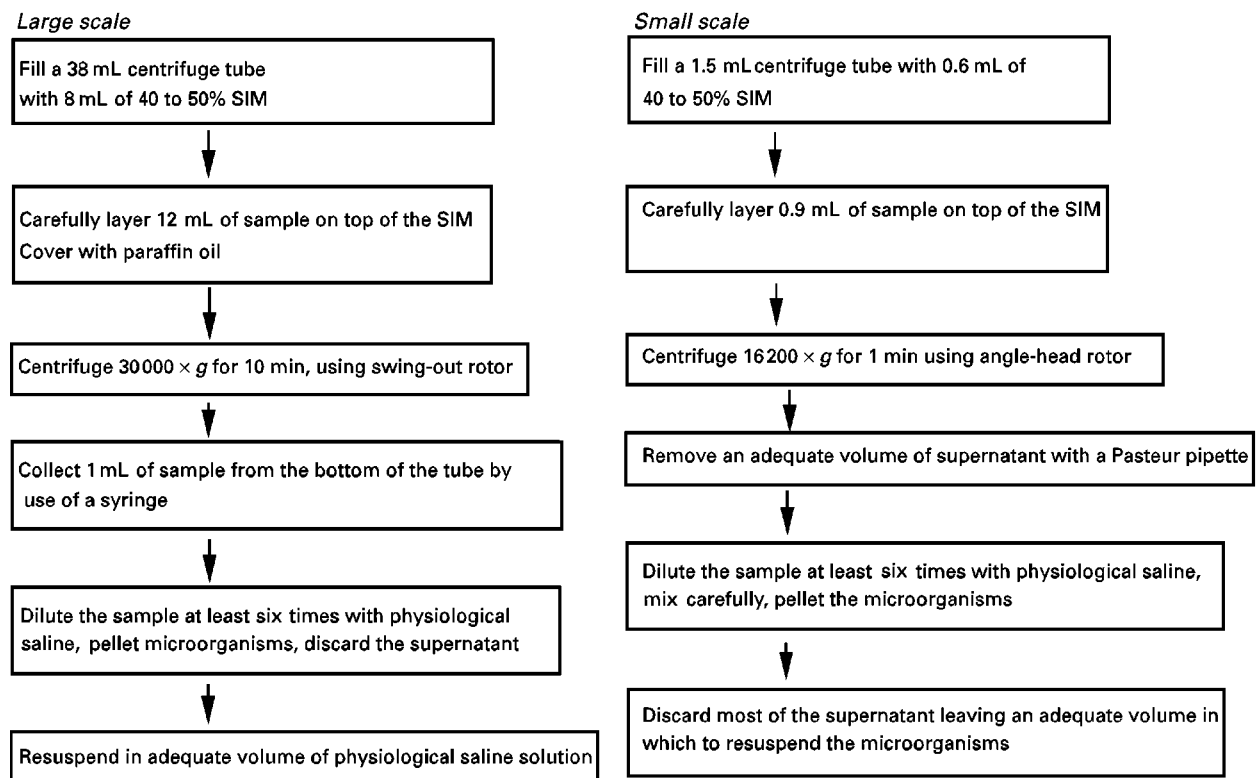

Figure 5 Example of two protocols for the separation of microorganisms from food by a uniform density centrifugation.

Zygosaccharomyces rouxii from different foods, e.g. raw beef, ground beef, different vegetables, shrimps, chicken, blackcurrant syrup, and milk, prior to detection by methods such as PCR, NASBA and plate count procedures.

Optimization of Protocol

If, due to incomplete separation, the detection limit is not satisfactory there are some key separation parameters that can be changed. Initially it can be helpful to add density marker beads corresponding to densities similar to those of the microorganisms during the uniform density centrifugation. The location of the beads will indicate where in the tube the microorganisms will be found and if the optimal SIM concentration has been used. The beads may also indicate if a gradient has formed during centrifugation.

Instead of sampling from above, as suggested in Figure 5, microorganisms can be retrieved by insertion of a syringe through the bottom of the centrifuge tube to avoid the mixing of inhibitory compounds or particles from the supernatant during cell removal.

If particles from the food end up in the treated sample, one can try to decrease the particle content in the sample volume prior to centrifugation by diluting

the homogenate and/or preparing the homogenate in a stomacher bag with a filter bag. If this does not help, or if the food contains particles denser than the microorganism, it is possible to use two layers of gradient medium of different but uniform concentrations (step gradient). The density of the second layer is chosen to lie between that of the microorganisms of interest and the denser components of the food. This technique has been used to separate pathogenic bacteria in a blue cheese from the lighter cheese particles and from denser fungal mycelia. The sample is retrieved at the interface between the gradient layers and this position can be identified by centrifugation of an identical tube where the sample is replaced with density marker beads.

Another possibility, if the exact buoyant density of the microorganism is known such as in a well-defined and constant experimental system, is to perform the separation step using a continuous gradient centrifugation.

Future Developments

Buoyant density centrifugation is a general method which recovers nonattached microorganisms over a specific buoyant density. This suggests two possible areas for development and improvement. The first

would be to increase the fraction of nonattached cells by optimization of the homogenization or stomaching process. The second area is the exciting possibility of developing a separation protocol specific for single types of microorganisms, or a systematic or metabolic group of microorganisms. This may be achieved by manipulating the buoyant density of an organism through a selective uptake of a specific compound. Further, since it is possible to perform the separation on a micro scale, it may be feasible to design automated systems for sample preparation and analysis with a high sample capacity.

FOOD TECHNOLOGY

Membrane Separations

M. Cheryan, University of Illinois, Urbana, Illinois, USA
Copyright © 2000 Academic Press

One of the earliest successful industrial applications of membrane technology was in the food industry. In 1972, a dairy plant in New York began processing cheese whey by reverse osmosis. Membrane separations are now ubiquitous in the food industry, as shown in Table 1. The main use of reverse osmosis is the concentration of liquid foods, to complement or replace evaporation. Nanofiltration is used for desalting and de-acidification with partial concentration, while ultrafiltration is used for fractionation, concentration and purification of food streams. Microfiltration is used for clarification and removal of suspended matter to replace centrifuges and filter presses. It is also used for pasteurizing and sterilizing liquids instead of using heat. Electrodialysis is finding use for demineralization and de-acidification, as a possible

partial replacement for ion exchange. To date, pervaporation applications are few in the food industry, although it could be used for purification of volatile aroma compounds partially to replace distillation. This article focuses on selected food products with varying physical properties and chemical composition and will illustrate the general applicability of membrane technology in the food industry.

Dairy Industry

Milk

The dairy industry probably accounts for the largest share of installed membrane capacity among food-processing applications. Figure 1 is a general schematic of possible applications of membranes in the processing of milk. Reverse osmosis (RO) is mostly used to pre-concentrate milk prior to evaporation (although there are RO techniques that could concentrate skim milk up to 45% solids, as with the Fresh-note process, described later). This not only saves sufficient energy to justify the technology, but it also

RO, reverse osmosis; NF, nanofiltration; UF, ultrafiltration; MF, microfiltration; ED, electrodialysis; CMR, continuous membrane reactor; PV, pervaporation.

exposes milk to less heat during the concentration process, which minimizes protein denaturation and development of the 'cooked' flavour and other heat-damaging effects on the constituents of milk.

Perhaps the greatest potential for RO and/or ultrafiltration (UF) in the dairy industry is in bulk milk transport, especially in those countries which have large distances between producing and consumption areas. Considering that milk is more than 85% water, preconcentration of the milk prior to shipment to central dairies should result in considerable savings in transportation costs, as well as reducing chilling and storage costs. RO milk products, when reconstituted with good-quality water, are indistinguishable from unconcentrated milks in flavour and other quality attributes. On-farm ultrafiltration of milk is technically feasible for large dairy herds if the concentrated milk is used for the manufacture of cheese. Stability of ultrafiltered milk is satisfactory with proper pretreatment such as thermalization at 65–70°C for 10–20 s to minimize lipase activity, and if health and safety requirements are met on the farm.

Ultrafiltration of milk RO milk could be used in the manufacture of several other products, such as cultured milk products and cheese. However, UF seems

to be the preferred technique in these applications. UF allows the passage of the lactose and soluble salts while retaining the protein and fat and some of the insoluble or bound salts. There is considerable potential in the manufacture of specialty milk-based beverages such as lactose-reduced and calcium-enhanced fluid milk products. Total milk protein isolates are usually manufactured by co-precipitation using a combination of heat, acid and/or calcium salts. This generally results in low protein solubility, which restricts its use as a functional food ingredient. UF of milk in combination with diafiltration can produce 90% protein isolates from milk with lactose concentrations of less than 0.1%.

The principal use of milk UF in the dairy industry today is the manufacture of cheese. From a membrane technologist's point of view, cheese can be defined as a fractionation process whereby protein (casein) and fat are concentrated in the curd, while lactose, soluble proteins, minerals and other minor components are lost in the whey. In the UF cheese-making process, milk is first concentrated to a 'pre-cheese' which will have the same protein, fat and/or solid levels normally found in cheese. This pre-cheese is then converted to cheese by conventional or modified cheese-making methods. Some of the benefits of

Figure 1 Membrane processing of milk. (Reprinted with permission from Cheryan and Alvarez (1995).)

using UF in cheese-making are:

- There is an increase in yield of 10–30% with soft and semi-soft cheeses due to the inclusion of the whey proteins
- The amount of enzyme (rennet) required is sometimes lower
- There is a reduced volume of milk to handle
- Fewer cheese-making vats are required
- Plant space is used better
- There is little or no whey production because most of the water and lactose has already been removed

Considerable research has been conducted with a variety of cheeses such as feta, quarg, white cheeses from Turkey, Egypt (domiati, kariesh), Greece (teleme) and South America (queso fresco), goat's milk cheese, Camembert, ricotta, mozzarella, cheddar and processed cheese.

Microfiltration of milk The main applications of microfiltration (MF) in milk processing are fat separation and bacterial removal. This concept has been put into commercial practice as the uniform transmembrane pressure (UTP) or co-current permeate flow (CPF) process. Tubular ceramic membranes with 1.4 μm pores are operated in a double-loop constant-pressure operation. Because of the uniform and low pressure profiles in the membrane module, fouling is low and flux is very high (700–1000 $\text{L m}^{-2} \text{h}^{-1}$ at 10-fold concentration of skim milk). Bacterial retention is 99% and the microbial load usually found in milk and fat is also substantially rejected. On the

other hand, there is no significant change in the concentration of other components, so the permeate is essentially bacteria-free skim milk.

This process became commercial in 1989 to produce more stable pasteurized and refrigerated milk products. It could also be useful in subtropical and tropical countries, where inadequate refrigeration and transportation facilities result in high microbial loads in the milk coming into dairy plants. Such a membrane system in the bulk-milk holding station or on the receiving dock of the milk-processing plant could lower the microbial load significantly and improve the quality of milk products in these countries.

Enriched casein fractions (i.e. separated from whey proteins and other soluble milk components without isoelectric precipitation) can be produced using MF membranes. In addition, β -casein can be isolated from casein micelles if the temperature is lowered to less than 5°C, which causes β -casein to dissociate from the micelle and be removed in the permeate (a loose UF membrane of 100 000 (molecular weight cut-off) can also be used to isolate β -casein from milk). This protein has biological activity potential in pharmaceutical applications.

Cheese Whey

Whey is a by-product of the cheese industry. During the manufacture of cheese, most of the milk protein (the casein) and fat is concentrated in the curd, which eventually becomes the cheese, while other constituents go into the water phase and become the whey. Every 100 kg of milk will give about 10–20 kg of

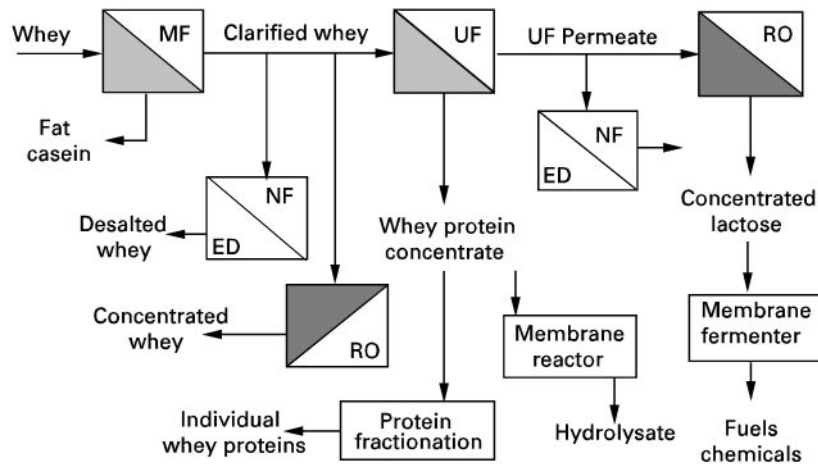

Figure 2 Membrane processing of cheese whey. (Reprinted with permission from Cheryan (1998).)

cheese depending on the variety, and about 80–90 kg of liquid whey. The disposal of whey is a problem: its biological oxygen demand (BOD) is 32 000–60 000 p.p.m. It has low solid content and a very unfavourable ratio of lactose to protein, which makes it difficult to utilize in food products without changing its composition. Prior to membrane technology, as much as 60–70% of the whey produced was disposed as sewage, with the rest being used primarily for animal feed or human food. World production in 1996 was estimated at 80–130 million tons per year: the USA produced about 30 million tons per year.

Membrane technology, and UF in particular, has provided a valuable means of upgrading cheese whey and increasing its utilization as a human food. The appropriate membrane can simultaneously fractionate, purify and concentrate whey components (Figure 2), enhancing their market value and reducing the pollution problem. Today, whey protein concentrates (WPC) produced by UF are well established in the food and dairy industries. Owing to the relatively mild process conditions of temperature and pH, the functionality of the whey proteins remains good, giving rise to a wide range of applications. The initial protein content of 10–12% (dry basis) can be increased by UF, to result in 35, 50 or 80% protein products, with a concomitant decrease in lactose and some salts. WPC can be further fractionated into β -lactoglobulin and α -lactalbumin fractions as shown, or be used for the manufacture of caseinomacropptide, a compound which may have a pharmaceutical value.

Fruit Juices

Next to the dairy industry, fruit and vegetable juices have benefited the most from membrane technology.

There are three primary areas where membranes can be applied in this application: firstly, clarification, e.g. in the production of sparkling clear beverages using microfiltration or ultrafiltration; secondly, concentration, e.g. using reverse osmosis to produce fruit juice concentrates of greater than 42° Brix (a measure of sugar concentration); and thirdly, de-acidification, e.g. electro dialysis or nanofiltration to reduce the acidity in citrus juices.

Clarification of Fruit Juice

Fruit juices are prepared by extraction followed by a series of filtration and clarification steps to yield clear single-strength juices (Figure 3). These operations are usually labour- and time-consuming. Membrane filtration can replace the holding, filtration and decantation steps. The properties of the membrane, especially its pore size distribution, affect flux and capacity, as well as juice properties such as clarity, browning compounds and total phenolics in the finished product.

Membrane filtration has several advantages over traditional methods. It eliminates fining agents (bentonite, gelatin, etc.), most enzymes (pectinase, amylase), centrifugation and diatomaceous earth filtration. Process times are reduced from 12–36 to 2–4 h. Juice yields are higher, by 2–15%, and product quality is better. The largest application is apple juice, but the following have also received considerable attention: apricot, carrot, cherry, cranberry (which was one of the earliest applications of ceramic membranes), blackcurrant, grape, guava, kiwi, lemon, lime, maple sap, melon, orange, passion fruit, peach, pear, pineapple, plum, raspberry, strawberry and tomato.

Citrus juices (grapefruit, orange, lemon, lime) are being upgraded by combining UF and adsorbent resin

Figure 3 Processing fruit juices by conventional and membrane technology. (Reprinted with permission from Cheryan (1998).)

technology to remove bitter compounds such as limonin, naringin, hesperidin, polyphenols and many other off-flavour compounds. These compounds are in the aqueous phase of the juice. Fresh or reconstituted citrus juice which has been de-oiled and pasteurized is first ultrafiltered to separate the pulp. The clarified permeate containing the sugars and bitter compounds enters the absorption column which contains an adsorbent resin specifically designed to remove these compounds. The debittered juice is then recombined with the pulp (the UF retentate) to give a product with less than 5 p.p.m. limonin, which is its apparent taste threshold (400–500 p.p.m. for naringin).

In recent years, several fruit juice installations have incorporated ceramic membranes. The higher cost has been justified by the higher flux, much longer life and their resistance to aggressive processing and cleaning conditions. The ability to backflush to unblock feed channels and back-pulsing during operation are other advantages.

Concentration of Fruit Juice

Orange and other citrus juice concentrates are mostly produced by conventional multi-stage evaporation. RO with the appropriate polyamide composite membrane can concentrate juice without a significant loss of aroma, sugar or acids. The low temperatures avoid thermal damage of delicate aroma components.

However, conventional RO is limited by osmotic pressure and viscosity considerations to less than 30° Brix. Therefore, RO can be used as a preconcentration step, with thermal evaporation completing the required concentration to 42–45° Brix. Adding RO ahead of the evaporators can increase evaporator capacity and reduce thermal treatment.

A significant development in the 1980s was the development of the FreshNote process by Du Pont and FMC. It allowed the production of highly concentrated (42–70° Brix) fruit juices using a combination of high and low retention RO membranes. UF is first used to separate the pulpy solids from the serum. The UF retentate, about 1/10th–1/20th the feed volume, is subjected to a pasteurization treatment that destroys spoilage microorganisms and improves stability of the finished product when blended back with the concentrated UF permeate. The serum (UF permeate), which amounts to about 90–95% of the feed volume, is concentrated by RO using hollow fine fibres made of aromatic polyamide. Pressures are typically 1000–2000 psi. A multistage system is used with high rejection membranes in the early stages and low rejection membranes in later stages. Permeates with significant sugar or flavour compounds are returned to stages containing high rejection membranes. Fruit juice concentrates of 45–55° Brix have been obtained commercially, and up to 70° Brix has been obtained in pilot trials. Careful control of

operating conditions is necessary. For example, the freshly extracted juice is blanketed with nitrogen and its temperature is controlled below 10°C throughout the remainder of the process. The flavour compounds in the serum are not subjected to any heat during processing, which also explains the high flavour scores for this product. Flavour and cost comparisons indicate very good market potential for this process. Commercial installations to date include tangerine juice and apple juice concentrates.

Concentration of tomato juice presents a difficult problem, because it has a high pulp content (25% fibre) and a high viscosity (which behaves in a non-Newtonian manner). Because of this, tubular modules are probably best. The colour of the final tomato concentrate is very good, and shows none of the browning normally associated with evaporation.

The interest in RO of maple syrup grew in the 1970s in response to increasing energy prices. RO is able to remove about 60% of water from the maple sap, resulting in a decrease of 33% in the processing cost compared to the all-thermal process. The concentrate is then boiled in a conventional open-pan evaporator to develop the characteristic colour and flavour.

Sugar Refining

The most appropriate application of membranes in this industry is for clarification and purification of the extraction juices. If UF or MF were used at the mill to remove the colloidal and macromolecular impurities, a clear decolorized thin juice would be obtained with little or no need for addition of lime, carbon dioxide or sulfite. If ion exchange is done immediately after UF, lime could be eliminated completely. An added benefit of membrane technology is that, with no macromolecules and reduced lime levels, fouling and scaling of the evaporator is reduced, which in turn reduces down time and cleaning costs. Higher yield of sugar and better crystallization are also possible: near-white sugar could be made in a single crystalliza-

tion step. The MF or UF pretreatment is well suited for subsequent ion exchange softening and chromatographic purification. Another advantage is that a high quality soft cane molasses is obtained and this can go directly to chromatographic separation to recover sucrose and fructose, or to MF to remove some of the monovalent salts.

Another place in the sugar industry for UF or MF is to clarify thick juice (after evaporation), reducing bacterial counts and storage losses. Treating thick juice has the advantage of handling lower volumes, but this is partially compensated for by higher viscosity and lower flux.

Vegetable Proteins

Most of the work in this area has been done with soya beans. Once the oil has been removed from soya beans, the resulting meal is mostly used for animal feed, with perhaps only about 3–5% being used directly as human food. UF has been successfully used to upgrade the quality of the soy protein by selectively removing undesirable components such as oligosaccharides (implicated in gastrointestinal stress when consuming soya beans) and phytic acid (which forms insoluble chelates with minerals and can form complexes with proteins that reduce their bioavailability). To produce soy protein concentrates, the raw material is defatted soy flour which is extracted with dilute alkali. The extract is then ultrafiltered. The final composition will approximate to a soy protein concentrate of 70% protein, dry basis. To produce isolates (90% protein), the fibre and insoluble carbohydrate are removed by centrifugation or filtration prior to UF. The UF technique usually results in higher yields because of the inclusion of soy whey proteins that are normally lost in conventional manufacturing methods. These whey proteins could also be contributing to the superior functional properties of the UF soy products, in addition to the benefits of the nonthermal and nonchemical nature of the UF process.

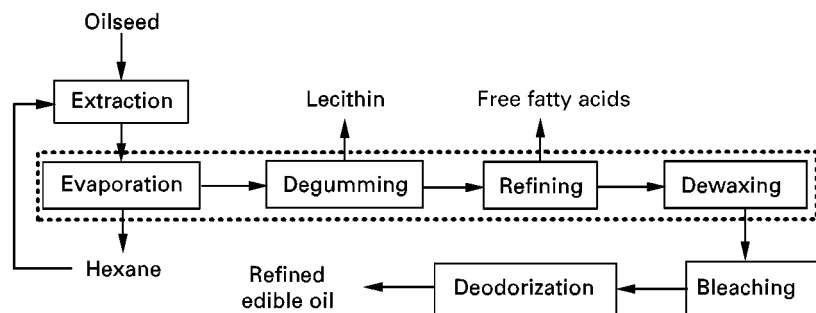

Figure 4 Edible oil processing. Membrane technology can be used in the four unit operations within the enclosed box.

Vegetable Oils

The basic unit operations in vegetable oil processing are shown in Figure 4. Oil is extracted from plant material (oilseeds) using a solvent, usually hexane. Published research indicates that about 50–70% of the hexane can be recovered and recycled using nanofiltration membranes instead of the evaporators used today, thus reducing energy consumption substantially. The extracted crude oil is mostly triglycerides, but it also contains small amounts of free fatty acids, phosphatides (lecithins/gums) and waxes, among other impurities. In place of physical or chemical refining, it is possible to use UF membranes for the degumming step, thereby producing a substantially oil-free lecithin.

In membrane refining, the crude oil is treated with a solvent such as methanol to extract the free fatty acids. After phase separation, the methanol layer is subjected to nanofiltration to recycle the methanol while producing a free fatty acid concentrate. This avoids the traditional alkali-refining process which results in soapstock formation and oil losses. Dewaxing with microfiltration membranes can also be done. In this process, the oil is cooled to a temperature below the wax crystallization temperature before being microfiltered to produce a stable edible oil. The application of membrane technology in the edible oil industry is expected to reduce energy consumption, reduce losses of oil, reduce the usage of chemicals and water and reduce the discharge of contaminated effluents.

Conclusions

The food industry is one of the largest users of membrane technology. With new developments in low-fouling membranes and modules, and membranes

stable in organic solvents, the applicability of this technology will widen considerably in the industry, especially in the production of 'neutraceuticals' (minor compounds in plants that are thought to have considerable health benefits) and grain processing (e.g., corn, soyabeans, wheat).

Supercritical Fluid Chromatography

J. W. King, National Center for Agricultural Utilization Research, Agricultural Research Service/USDA, Peoria, IL, USA

The role of supercritical fluid chromatography (SFC) in the analysis of foods and agriculturally derived products has been somewhat moderated by uncertainties in the availability of required instrumentation for the past 15 years. In addition, SFC competes for the same analytical opportunities as gas (GC) and

high performance liquid chromatography (HPLC) and hence is often ignored or relegated to a minor role by food analysts. Despite these difficulties, SFC has been applied to a variety of applications for the detection and quantification of analytes, that are at least soluble to even a minor extent in supercritical carbon dioxide (SC-CO₂) – by far the most popular mobile phase utilized in the technique.

The application of SFC to food matrices came naturally due in part to the early application of SC-CO₂ extraction in the food industry, i.e. for the

extraction of coffee, hops and similar food items used routinely by the consuming public. SFC is particularly applicable to the analysis of lipid-containing materials, due to relative high solubilities exhibited by these solutes (analytes) in SC-CO₂. Analysis and detection of ultra-trace components in foodstuffs, e.g. pesticides or drugs, has not been generally successful because of the problems in routinely interfacing and using sensitive detectors, such as the electron-capture detector (ECD) with SFC, due to the change in mobile-phase characteristics with respect to time during the analysis. However, the ability routinely to use the flame ionization detector (FID) with SFC has provided the analyst with a useful technique to detect an array of components, or a specific moiety, in complex food matrices.

With respect to the chromatographic technique utilized, it is capillary SFC which has been cited more often than packed-column SFC in the analysis of foods. This is somewhat unfortunate since the packed-column mode also offers interesting possibilities, particularly when interfaced with a ultraviolet (UV) detector or evaporative light-scattering detector (ELSD). The recent use of this technique for the analysis of chiral compounds may also create some opportunities in food analysis, where the knowledge of the chirality of certain compounds (e.g. flavour esters) is of importance. In general, the coupling of analytical supercritical fluid extraction (SFE) with SFC has not been adopted to any considerable extent

by food analysts, due to the lack of an interface that permits routine coupling and use of the SFE/SFC mode. However, preparative and even production scale SFC has been utilized for specialized applications in the food production industries, and probably will see increased application due to the current interest in producing high value nutraceutical components, in a natural and environmentally benign manner.

Since SFC is perceived as a niche technique in the food industry, it is important to recognize when and where it can be used to advantage relative to what can be achieved using GC and HPLC. Some of these opportunities are as follows:

1. Reduction of the use of organic solvents relative to HPLC;
2. Direct analysis of samples avoiding sample preparation steps;
3. Deformulation of commercial food products;
4. Detection of product adulteration or deterioration;
5. Support of food engineering extraction/reaction process development.

With respect to nonpolar solutes, pressure- or density-programmed SFC provides the capability to analyse compounds having molecular weights approaching 1200 amu in one chromatographic analysis. Separation of these compounds is a function of their

Figure 1 Supercritical fluid chromatography analysis of deodorizer distillate with an SB-octyl-50 column using flame ionization detection (FID).

solubility in the mobile phase, their respective vapour pressures and miscibility of the solute in the fluid phase. For example, in Figure 1, a number of components have been separated using a capillary SFC method that traditionally would have required the use of both GC and HPLC, and derivatization of some of the analytes. Utilizing SFC allows the analyst to avoid the above approaches, and to analyse directly the sample, obtaining a snapshot of the entire molecular composition. These characteristic elution patterns produced by SFC can be used to identify the presence or absence of a particular molecular constituent in a food sample, thereby providing valuable information for the food product formulator, to match or alter in developing new and competitive products.

Increasing concerns about minimizing or eliminating the use of hazardous organic solvents in the laboratory also bodes well for the application of SFC. Incorporating SFC for the separation and detection of food-related solutes, eliminates not only most of the traditional solvent needs associated with HPLC, but any solvents utilized in the extraction or sample work-up steps prior to analysis. In this regard, SFC is an excellent tool for monitoring the end-result of an extraction or reaction of a food component using supercritical fluid media. Also, by using SFC, food-related analytes that are thermally labile or susceptible to degradation via oxidation are not exposed to the harsh conditions that often accompany their analysis by GC or HPLC. This advantage can be attributed to the protective action of CO₂ which excludes oxygen, and the low temperatures used when separating components via SFC.

Selecting and Optimizing Separation Conditions for Food Components

For the SFC analysis of food-related samples, the analyst will undoubtedly want to start with a general fluid-programming sequence to interrogate the sample matrix as to its components. These programmes are executed for an extended time to ensure optimum resolution and detection of the unknown or target analyte(s). Run times of 90 min in length are not unusual in this initial stage of method development. After the target analytes have been identified by retention time-matching with standards, or via an independent method such as mass spectrometry (MS), the original programme can be modified to reduce the analysis time or improve the resolution within the chromatogram. However, changes in the mobile-phase programme will usually be done to hasten the elution of early or late eluting components that are of no importance in the analysis. In the

analysis of food components, both changes in the rate of increase of the fluid pressure or density with respect to time, or in some cases changeover to an exponentially-based fluid programme, will suffice to optimize the SFC run.

Because of the molecular complexity exhibited by many food ingredients and compositions, it is not unusual to have a temperature gradient with respect to time superimposed on the mobile-phase pressure programme during the SFC run. For example, separation of the like-carbon number triglycerides in soybean oil is not possible by pressure or density programming alone, but by superimposing a temperature gradient during the analysis, these oil components can be well separated. SFC analysis under isobaric conditions is limited in application when analysing foods; however, it should not be overlooked since it can often yield the most precise and accurate results.

The FID is the most commonly used detector for SFC. FID sensitivity to food components is lower than that obtained with GC since expansion of the mobile phase dilutes the detector signal substantially. However, the FID signal can be amplified to permit analysis down to the p.p.m. level, provided any shift in the baseline can be compensated for. Analytes with chromaphoric properties are amenable to UV detection in conjunction with SFC. The absorption maxima of components shift as a function of fluid density or pressure, but most detector units constructed for operation at these elevated pressures allows for stop flow or *in situ*, on-the-fly scanning of peaks to determine absorbance maxima shifts. For example, bathochromic shifts of 15–20 nm have been recorded for carotenoids over a 250 atm pressure interval in SC-CO₂. The mating of the ELSD detector with SFC has been reported by several investigators; however, day-to-day stability is inferior to that experienced with HPLC-ELSD couplings when applied to food analysis. Hetero-element-specific detectors, such as ECD or flame photometric detector, have mostly been utilized in research studies using SFC and have not seen serious adoption for routine analysis. Again, detector sensitivity and stability under SFC conditions limit their sensitivity at best to parts per million range. The use of SFC with mass spectroscopy has remained mainly an academic art, and commercial instrumentation development has been limited to date.

Most of the promising applications of capillary SFC have utilized nonpolar bonded phases such as methyl, octyl, phenyl and biphenyl silicas. The weak elutropic strength of neat SC-CO₂ has favoured the use of short chain length; monomeric silane-modified columns have C₁, C₄, C₁₈, phenyl, amino and diol

phases for packed-column SFC. The choice of these phases is not so much related to their selective interaction with food-related solutes, but to their surface-modifying properties which reduce peak tailing and solute interaction with the silica matrix. Resin columns have also been utilized, but they are susceptible to voiding unless specifically packed for use under supercritical fluid conditions.

Types of Food Components Analysed by SFC

A myriad of food-related components and matrices have been analysed by SFC, as indicated by the partial listing in Table 1. These include naturally occurring ingredients such as fats/oils, spices, etc.; minor unwanted constituents like pesticides, antibiotic drugs and mycotoxins; and specific food components, including nutraceuticals and flavouring aids. Inspection of Table 1 indicates a preponderance of applications in the lipid analysis area. Indeed, SFC is tailor-made for lipid analysis, although somewhat lacking in the high resolution capabilities demonstrated by high temperature GC. The retention pattern for lipid solutes in SFC, as shown in Figure 1, follows a distinct pattern governed approximately by the solute's molecular weight/volatility characteristics. Elution of the following classes of lipids is in the order: fatty acid methyl esters, free fatty acids, hydrocarbons, vitamins, sterols, wax esters, mono- followed by diglycerides, and then triglycerides/steryl esters. Although there is some overlap between individual classes of the above solutes, due to the overlapping molecular weights ranges (e.g. triglycerides and steryl esters), this separation pattern has proven very useful in tracking conversion of lipid species undergoing

reaction as well as in the quality control of food raw products and ingredients.

Triglyceride-based oils/fats are also readily amenable to analysis by SFC. Separation of the individual components is once again governed by molecular weight considerations, thereby allowing SFC to facilitate the separation of the major triglyceride species, i.e. T₅₀, T₅₂, T₅₄, etc. For some oils, such as coconut oil, well-resolved chromatograms result, while for other oils, e.g. soybean oil, there is overlap between the saturated and unsaturated triglyceride species, making superimposition of temperature gradient along with the pressure gradient programme for the mobile phase necessary to achieve adequate resolution. However, even without ideal resolution, the rapid analysis afforded by SFC can be used to considerable advantage for quality control, where speed, rather than optimal separation, is often desired.

Detection of minor components in foods is limited by the detector stability problems noted previously; however, those components which can be detected by using FID, UV or ELSD are often analysed more rapidly by SFC, due to the time savings afforded by avoiding elaborate preparation of the sample prior to analysis. SFC analysis provides a more detailed profile of the entire sample in addition to detecting the target analyte. This allows a more accurate assessment of the total contribution of the minor constituent to the entire ingredient profile, e.g. the presence of sterol esters in sawtooth palmetto berry extracts, where fatty acids and triglycerides are the major constituents.

Other food sample types that are readily analysed by SFC are the fat-soluble vitamins, essential and flavour oil ingredients, spice materials, hop compo-

Table 1 Food components separated and analysed by SFC

Carbohydrates	Derivatized corn syrups, mannose glycans
Chiral compounds	Monoterpenes, pyrazines, clenbuterol
Drugs/antibiotics	Caffeine, erythromycin, polycyclic ether antibiotics, sulfonamides, assorted steroids
Hydrocarbons	Sesquiterpenes, squalene, waxes and wax esters
Lipids	Fatty acids, fatty acid esters, monoglycerides, diglycerides, triglycerides, sterol esters, sterols (cholesterol), fat-soluble vitamins, tocopherols, phospholipids (lecithin), lipid hydroperoxides, glycolipids
Nutraceuticals	Valeriana, ginkgolides, sawtooth palmetto berry
Oils/fats	Celery oil, coconut, fish, soybean, wheat germ, palm oil, rice oil, milk/cheese triglycerides
Packaging/film components	Polypropylene oligomers, polyvinyl chloride, phenolic antioxidants, low molecular weight polystyrene
Pesticides	Halogenated, organophosphorus, carbamate, pyrethrins, acidic phenoxy herbicides, sulfonyl ureas
Pigments	Carotenoids, xanthophylls
Speciality ingredients	Hops components
Spices/flavours	Capsicum, cardoman, coumarin, curry, garlic components, majoran, rosemary, vanillin
Terpenes/essential and fruit oils	Grapefruit oil, limonenes, mint, lemon
Other toxicants	Mycotoxins, nitrosamines, polycyclic aromatic hydrocarbons

nents and nutraceutical formulations. Some SFC-based separations require the use of a co-solvent (usually 5–20 vol%) in addition to the SC-CO₂ for the mobile phase. For example, phospholipids are only sparingly soluble in neat SC-CO₂, but these polar lipid compounds can be chromatographed successfully on packed silica columns by incorporating ethanol and/or water as a modifier into the mobile phase. Likewise, carbohydrate moieties, which exhibit limited or no solubility in SC-CO₂ or SC-CO₂/co-solvent mobile phases, can be derivatized to allow their analysis by SFC.

Selected Applications of SFC in Food Analysis

In this section, several brief examples will be given to illustrate the utility and potential of SFC in food analysis. **Figure 2** illustrates the SFC separation and detection of α -tocopherol and cholesterol in a fish oil capsule. This was achieved on a capillary SB-methyl column at 120°C using the density programme noted on the horizontal axis. Although this analysis took over 90 min to perform, it illustrates some of the benefits that can be achieved using SFC. For example, the chromatogram in **Figure 2** was achieved with no sample preparation other than to dilute the oil in a small quantity of solvent and to inject it into the chromatograph. In addition, no derivatization of the sample was required and adequate resolution be-

tween the α -tocopherol and cholesterol was achieved using the lengthy density programme. However, it is perhaps more important that, by adjusting the elution conditions, the background components (fish oil triglycerides) that were of no interest in this analysis can be programmed off the column without resorting to a pre-fractionation of the sample prior to SFC analysis or derivatization of the sample matrix.

Not all applications of SFC require the above conditions for high resolution separations. For example, packed-column SFC (5 μ m, C₈ Deltabond) has been used to clean up samples prior to other types of chromatographic analysis (GC). In this case, organochlorine and organophosphorus pesticides were extracted by SFE with SC-CO₂ from a meat sample, and the pesticides separated from the co-extracted fat moieties using the packed SFC column. Hence, by 'heart-cutting' the appropriate elution fraction, a lipid-free, pesticide-containing fraction was provided for GC residue analysis.

SFC is an excellent technique to monitor reaction chemistry between lipid species, since it avoids the need to employ more than one analytical technique or sample derivatization. Further, it permits the successful chromatography of all of the relevant reactants and products in one chromatographic analysis. Examples where SFC has been applied are in the esterification or transesterification of lipids, glycerolysis reactions and randomization of fats/oils. **Table 2** shows the analysis of the glyceride content of

Figure 2 Determination of cholesterol and α -tocopherol in a fish oil capsule by capillary SFC.

Table 2 Analysis of glycerides in a randomized fat sample

Methods of analysis	MG	DG	TG	Time of analysis

a randomized fat sample using six different analysis methods. The results given in Table 2 suggest that SFC-FID analysis yields comparable data for an equivalent analysis time to that obtained using the GC-FID and HPLC-ELSD methods. However, the SFC method does not require the time and effort for sample preparation associated with the alternative techniques and, in addition, saves on the cost of solvents and chemical reagents. A further illustration of the cost- and time-saving advantages of SFC is noted by its ability to monitor free and methylated fatty acids, thereby providing a reasonably quick and accurate assay for these compounds in foodstuffs to support nutritional analysis claims and the detection of frying oil deterioration as a function on time.

Preparative or production scale SFC is now being used as a separation technique in the food industry. Fractionation and isolation of higher value food components, such as tocopherols and phospholipids, or the ω -fatty acids/esters from fish oils, have been cited in the literature. Recently, a production plant for the separation of fish oil ethyl esters has been constructed in Spain to produce $\geq 95\%$ pure polyunsaturated fatty acids for the nutraceutical market. The basic separation design of this production scale plant is

based on chromatographic fractionations initially developed using analytical scale packed SFC columns.

Supercritical Fluid Extraction

In the food industry, supercritical fluid extraction (SFE) is currently being used in a number of areas, shown in Table 1. The most attractive features of SFE in food processing is the fact that separation can be carried out at relatively low temperatures (40–60°C) using benign solvents. The solvent most widely used thus far is carbon dioxide, which is inexpensive, nontoxic, nonflammable, easily recoverable, and

nonpolluting. The solubility and selectivity properties of SC-CO₂ has been compared with hexane. While both are nonpolar solvents, the selectivity of SC-CO₂ is enhanced in the presence of modifiers (entrainers). For example, in the absence of such polar modifiers as water and ethanol, SC-CO₂ alone is a poor solvent for extraction of caffeine from coffee beans or nicotine from tobacco. While the selectivity of SC-CO₂ and the mechanism of modifier action are not completely understood, studies in the area of supercritical fluid chromatography (SFC) have indicated that Lewis acid–base pairing, induced-dipole interactions

Table 1 Selected applications of supercritical fluid extraction in food processing

and hydrogen bonding play an important role in determining the selectivity of SC-CO₂.

The principal disadvantage of SFE is that relatively high pressures (typically 50–100 atm or more) are required. Even though the energy savings make SFE attractive, the initial capital cost of high-pressure equipment overrides these considerations, especially at current energy prices. While the overall cost of SFE is dictated by such other factors as volume, price and the continuous or batch nature of the process, economic considerations have slowed its commercialization. Generally, SFE is best suited for difficult separations, not attainable by conventional processes. In situations where SFE can produce a new product or when environmental or regulatory concerns make its use more attractive, the application may more than justify the cost. The hazards of high pressure and the use of flammable solvents are also perceived unfavourably by many not experienced in these areas. While common in the petroleum industry, the food industry also uses a number of processes like homogenization, extrusion and compression routinely and thus should be able to deal with moderate pressures.

Another frequently overlooked problem associated with SFE is patent infringement. There are over one

hundred patents on SFE of biomaterials in the United States alone. A potential user of these processes is likely to be faced with the involved task of determining if patent infringements exist or identify sources of legitimate licensing agreements. While SFE developments are growing globally, further research is needed both in terms of fundamental studies and applications.

The feasibility of extraction of a number of food materials using supercritical fluids has been investigated over the past two decades. In particular, much activity has focussed on extracting and refining fats, oils and their derivatives. The equilibrium solubility values of some of these are shown in Table 2. A number of advantages have been cited for the use of SFE in the processing of food-grade fats and oils from both animal and plant sources. These include:

- Low temperature processing reduces degradation of temperature and oxygen-sensitive components.
- Both extract and raffinate are free of solvent and can be used in food.
- Extraction and fractionation into various cuts of different physicochemical properties can be performed simultaneously.

Table 2 Solubilities of selected food materials in supercritical fluids

Food material	SC solvent	Solubility (%wt/wt)	Extraction (°C)	Conditions (bar)	Co-solvent	Reference

*Estimated from graphs.

- A continuous and large-scale process can be economically competitive to hexane-based operations.

Exploiting the commonality of high pressure between supercritical fluid and extrusion processing operations, a hybrid unit operation called supercritical fluid extrusion (SCFX) has been recently developed. This new process permits generation of microcellular structure at low temperature by using SC-CO₂ as a blowing agent instead of steam to puff the extrudate, thus decoupling the conventional dual role of water, which otherwise serves both as a blowing agent as well as a plasticizer. The use of supercritical fluid also permits deposition of solute into the extrudate matrix.

Significant progress has also been made in the analysis of food and related materials using SFE with SFC. Sample preparation for analysis often requires orders of magnitude more time than the analysis itself and the use of supercritical fluids obviates the need for hazardous organic solvents with no additional treatment prior to identification of the analyte by other techniques such as GC, GC-MS, FTIR, etc. The solubility of lipid-like materials in SC-CO₂ ranges from 1 to 30 wt%, depending on the density of the fluid used, and therefore, SFE has become a method of choice for rapid extraction of fats and oils from a variety of food matrices such as animal, vegetable, grain and seafood products. Other successful applications include extraction of fat-soluble vitamins, pesticides, sterols, and fatty acids. As an analytical tool, SFC has also made significant progress over the past decades but has yet to prove its superiority over the more conventional techniques.

FORENSIC SCIENCES

Capillary Electrophoresis

J. Sadecka, Slovak Technical University,
Bratislava, Slovak Republic

Copyright © 2000 Academic Press

Several slab electrophoretic techniques have frequently been used to discriminate between red cell

enzyme markers as a means of identification in criminal cases over many years. In 1991 capillary electrophoresis (CE) was introduced to forensic analysis. The separation of bulk heroin, heroin impurities and degradation products using micellar electrokinetic capillary chromatography (MEKC), the determination of drugs of abuse in urine and also the determination of benzodiazepines and sulfonamides in urine by CE-mass spectrometry were described in the same

year. Today, forensic applications of CE include analysis of drugs of abuse, gunshot residues, explosives, pen inks and toxins as well as polymerase chain reaction (PCR) amplified DNA.

Drugs of Abuse

One of the major tasks for forensic laboratories is the analysis of illicit and controlled drugs, in both the seizure and biological samples.

Seizure Samples

Seizure samples are analysed in order to identify the major compounds. In addition, the determination of trace compounds permits the samples to be allocated to the source and production procedures. Seizure samples may consist of a mixture of acidic, neutral and basic compounds that may be nonpolar and/or polar. At least two independent analytical parameters should be used to establish the identity of the drug, and infrared spectroscopy and thin-layer chromatography (TLC) are widely used for this purpose. Quantitation is usually carried out by gas chromatography (GC) and high performance liquid chromatography (HPLC). GC is a high resolution technique, but problems can arise for thermally degradable, polar and nonvolatile substances. HPLC is less suited to drug profiling, because it is a relatively low resolution technique compared with GC.

CE is a relatively new technique in forensic drug analysis. The three main separation mechanisms have been used for seizure samples: (i) low pH to analyse basic compounds; (ii) high pH to analyse acidic com-

pounds; and (iii) MEKC to analyse neutral and/or charged compounds.

Most abused drugs are bases which are generally water-soluble and ionized as cations at low pH. The use of simple electrolyte solutions such as phosphate, citrate and formate at pH values of 2–3 gives a useful initial separation. Basic drugs can be analysed by TLC and HPLC, but interactions with the stationary phases can lead to peak tailing. This problem does not occur so frequently in CE. In addition, these simple electrolytes have low background UV absorbance and can be operated at low wavelengths of 190–200 nm, where many drugs have significantly enhanced UV absorbance coefficient. CE at low pH can be used to detect by-products in purified codeine, to investigate amphetamine derivatives in Ecstasy tablets, and for assay for various pharmaceutical formulations which contain 1,4-benzodiazepines and phenothiazines.

At high pH the migration direction of acidic compounds is against the electroosmotic flow, which maximizes mobility differences. Operation with simple electrolytes such as phosphate pH 7 or borate pH 9.5 often leads to useful initial separation for acidic compounds.

MEKC can be used when dealing with uncharged solutes or mixtures of charged and neutral species. This approach may also be considered when simple mobility differences prove insufficient in capillary zone electrophoresis (CZE). Both anionic and cationic surfactants have been used as micelle modifiers, which, furthermore, are complementary approaches. MEKC has been applied to a wide range of controlled substances, including heroin, cocaine, opium alkaloids, amphetamines, hallucinogens,

Figure 1 Typical example of a MEKC separation of the components of a drug mixture. Buffer: 25 mmol L⁻¹ borate (pH 9.24)–20% methanol–100 mmol L⁻¹ SDS. Capillary: bare fused silica, i.d. 50 μm, total length 55 cm (35 cm to detector). Potential 20 kV. UV detection at 200 nm. Peak identification: a, caffeine; b, barbital; c, pentobarbitone; d, morphine; e, narceine; f, 6-monoacetylmorphine; g, codeine; h, nalorphine; i, lidocaine; j, procaine; k, heroin; l, flunitrazepam; m, acetylcodeine; n, thebaine; o, papaverine; p, amphetamine; q, narcotine; r, cocaine; s, diazepam; t, tetracaine. (Reprinted with kind permission of Elsevier Science from Tagliaro F *et al.* (1996) *Journal of Chromatography A* 735: 227–235.)

barbiturates, benzodiazepines and cannabinoids. An electropherogram of a complex mixture of 20 drugs (acidic, neutral and basic) is shown in **Figure 1**.

It is clear that MEKC represents an excellent technique for drug screening. In addition, photodiode-array UV, laser-induced fluorescence (LIF) and mass spectrometry (MS) detection can greatly increase specificity of the analysis. Greater specificity of screening could be obtained by using two complementary separation techniques, e.g. MEKC with either GC or HPLC. The complementary nature of MEKC and CZE for the identification of 17 illicit drugs and related compounds ionized at pH 2.35 has also been demonstrated. MEKC with sodium dodecyl sulfate (SDS) at pH 9.2 gave a highly noncorrelated separation compared to that obtained on a CZE system at pH 2.35. MEKC was found to be significantly, but inversely, correlated with a CZE system at pH 9.2. The reproducibility of migration times or relative migration times in MEKC is most important for screening applications. Migration time precision of 1% relative standard deviation (RSD) for repeated injection has been shown; this is essential to allow confirmation of the identity of each individual compounds present. Relative migration times generally give better repeatability, with RSD values of less than 1%.

The results generated by MEKC are often compared with those of HPLC and/or GC. GC affords higher resolution than MEKC; however, derivatizations are commonly required. MEKC offers significantly greater efficiency, selectivity, peak symmetry and speed compared to HPLC. In addition, the drugs that are poorly chromatographed by HPLC or not at all by GC exhibit good electrophoretic behaviour using MEKC. A recognized deficiency of MEKC is sensitivity, which is below that for HPLC-UV.

Biological Samples

The analysis scheme of drugs of abuse in biological samples involves screening using an immunoassay test. This does not enable positive identification to be made, but permits negative samples to be detected and discarded. Subsequently, the results must be confirmed by a more specific method. Without doubt, GC-MS is the reference method to confirm positive screening tests. At present, blood and urine represent most samples analysed for abused drugs and toxicants in most laboratories. If analyte concentrations are high enough, biological fluids, even those containing high concentrations of ions and proteins, can be directly injected on to a CE system, after simple filtration/centrifugation of the sample. Urine analysis can be very fast and simple, while SDS additive must be used with plasma to solubilize protein.

The important problem faced by CE in the field of biological sample analysis is still its relatively low concentration sensitivity. Increased sensitivity can be obtained both instrumentally and by processing the sample before analysis. Liquid-liquid extraction (LLE) and solid-phase extraction (SPE) methods have been used as sample pretreatment for CE. After LLE and SPE, extracted mixtures can be dried and resolved with a small volume of solvent, thus achieving detection limits of about 10 ng mL^{-1} . The sensitivity can be gained from employing more sensitive fluorescence detection. When LIF can be applied, the sensitivity limit of CE can be improved by a factor of about 1000 or more over UV absorbance detection. Unfortunately, the choice of wavelength emitted by laser is limited and this is the main limitation of LIF application to drug analysis. Concentrating the sample on the capillary – ‘stacking’ – is a simple technique that overcomes the poor detection limits of CE. Three general stacking methods are used in CE: (i) low ionic strength buffer in the sample; (ii) stacking by including acetonitrile in the sample; and (iii) isotachopheresis (ITP).

For forensic purposes it is often more appropriate to identify the metabolite rather than the parent drug, since additional information yielded by the full metabolic profile of a drug may be important in ascertaining the route of administration. Drug metabolites are most often studied by HPLC; however, phase II metabolites, e.g. glucuronide and sulfate conjugates, are acidic and highly polar and elute with little resolution in reversed-phase HPLC systems. Phase II metabolites are ideal for direct analysis by CE without the need for previous derivatization or hydrolysis. MEKC with diode array detection has been used for the determination of morphine, morphine-3-glucuronide, morphine-6-glucuronide, normorphine, meclofenamic acid and its metabolites in equine urine. SPE procedures were developed to concentrate and purify the analytes from post-administration urines. The low concentration sensitivity of MEKC in comparison with HPLC and GC-MS can be overcome by using a suitable sample preparation procedure, in particular offline SPE.

Hair analysis is a tool to prove drug abuse in questions of drug-related fatalities, revocation and restoration of driver licences, criminal responsibility, prenatal drug exposure and offences of narcotics law. The concentration of drugs in the hair are in the ng mL^{-1} range, at least in cases of chronic abuse. CE applications in hair analysis are still in an early stage of development. The few reports published until now come from Tagliaro's group. The use of CE with UV detection, at 238 nm for cocaine and 214 nm for morphine, has permitted the achievement of

moderate sensitivity 0.2 ng mL^{-1} for both analytes. Later, stacking techniques were developed in order to increase sensitivity (about five times). MEKC has also been applied to hair analysis. The sensitivity was slightly worse – 0.4 ng mL^{-1} – than with CZE, but selectivity was much higher. Good resolution and efficiency were obtained with both methods. The same-day RSDs of migration time were $< 1\%$ in CZE and $< 2\%$ in MEKC. Same-day precision RSD was 3–5%.

Among banned pharmaceutical substances, those which are of greatest relevance to sport medicine are anabolic agents, stimulants, diuretics, narcotics and β -blockers. In addition to several methods for screening (immunoassays, GC and HPLC), confirmation by MS, if needed, is used. Also, CE is a useful technique for the simultaneous screening of different types of drugs, e.g. β -blockers, anabolic steroids, diuretics and narcotics. LIF detection provides ultimate sensitivity while maintaining the extreme separation efficiency of CE. Both CE and MEKC have been applied. The main advantage of MEKC over CZE is that neutral and charged compounds as well as compounds which are insoluble in water can be separated in a single run.

Chiral Separations

The chiral resolution of drugs is of forensic significance for legal and intelligence purpose. In many instances, only one enantiomer is controlled under legal status, and proper identification is therefore critical. For example, only the (+)-enantiomer of nerpseudoephedrine and the (–)-enantiomer of propoxyphene are controlled. In addition, the enantiomeric composition of seized samples can provide information on the possible different synthetic routes. The enantiomeric purity of drug detected in urine or other biological samples may exclude the possibility that the subject has taken that drug in a racemic preparation.

CE is a technique that has been shown to be ideally suited for chiral separations. When compared to other techniques, such as liquid chromatography, CE has the advantages of efficiency, resolution, selectivity, speed and direct chiral separation. Therefore, CE has become a method of choice in the chiral analysis of therapeutic drugs, but the attention paid to controlled or illicit drugs is still low. As for chromatography, it is possible to separate enantiomers directly or after a pre-derivatization step.

In the separation of amphetamine analogues, 2,3,4,4-tetra-*O*-acetyl- β -D-glucopyranosyl isothiocyanate as a derivatization reagent was used and enantiomers were separated using MEKC. However, more applications are conducted by CE with β -cyc-

lodextrin (β -CD) as a chiral selector. Different β -CD derivatives have been used with success to separate ephedrine and analogous compounds, amphetamines, methamphetamine and methylenedioxy-derivatives of amphetamines.

The versatility of modified uncharged and charged β -CDs in the direct resolution of β -agonists, β -antagonists, phenylethylamines, alcohol stimulants and thalidomide and its metabolites by CE was shown. A total of 42 compounds were optically resolved using hydroxypropyl- β -CD and 20 with sodium sulfobutyl ether- β -CD. The preliminary analysis of ephedrine, amphetamine, methamphetamine and methylenedioxy-derivatives of amphetamine in urine (Figure 2) and hair (Figure 3) showed that after a liquid-liquid extraction, urine samples could be analysed with a sensitivity below 500 ng mL^{-1} . For hair analysis, it is necessary to increase sensitivity (0.1 ng mL^{-1}) by applying a stacking procedure.

Forensic DNA Samples

DNA polymorphism analysis has recently been recognized as a source of identification for individuals in criminal cases and unidentified human remains. The conventional technique for DNA typing based on restriction fragment length polymorphism (RFLP) has been replaced by more accurate, sensitive and faster PCR procedures. In contrast to RFLP, the PCR procedures require less DNA and can be used on DNA which is degraded. There are several PCR-based procedures under development; however, short tandem repeat (STR) sequences are currently of major importance in the field of identification of individuals in forensic cases. STRs are DNA segments, typically found in noncoding regions, which are composed of repeating units of 2–5 base pairs (bp). Co-amplification of two or more of these loci in one PCR provides an efficient mechanism for typing multiple genetic loci simultaneously. The detection of STRs is based on the variation in the length of STR-containing PCR products. These PCR-amplified STRs must be separated to determine the size, quantity and/or sequence of each fragment.

DNA restriction fragments and PCR products have traditionally been separated by slab gel electrophoresis.

Recently, CE has emerged as a novel, high performance DNA analysis tool. Early work on DNA separation was done on cross-linked polyacrylamide gel-filled capillaries. However, gel-filled capillaries are difficult to prepare and have a short life time. The utility of CE has been greatly enhanced by using noncross-linked polymer networks instead of rigid gel media. These polymer solutions offer low-to-medium

Figure 2 Typical electropherograms of: (A) blank human urine extract; (B) extract from blank human urine spiked with: 1, racemic ephedrine; 2, amphetamine; 3, methamphetamine; 4, 3,4-methylenedioxyamphetamine; 5, 3,4-methylenedioxymethamphetamine; 6, 3,4-methylenedioxyethylamphetamine, at concentrations of $1 \mu\text{g mL}^{-1}$ for every racemic analyte. Conditions: buffer, 100 mmol L^{-1} phosphate, pH 2.5, containing 10 mmol L^{-1} β -cyclodextrin. Capillary, uncoated fused silica, $45 \text{ cm} \times 50 \mu\text{m}$ i.d. Potential, 10 kV. Detection, UV absorbance at 200 nm. (Reprinted with kind permission of Wiley-VCH from Tagliaro F *et al.* (1998) *Electrophoresis* 19: 42–50.)

viscosity, which makes replacement of separation medium possible after each electrophoresis run. The polymer solution also has a broader effective DNA size range due to its flexible and larger effective pore size structure.

The CE system produced results which were comparable to those obtained on slab gel electrophoresis, with a level of precision of $\pm 0.1\%$ bp (between instruments). This comparison is very important if a comparison is to be made of results obtained by different laboratories and to standardize available procedures.

DNA fragments cannot normally be separated in free solution. However, the first clinical experimental results demonstrated that adding an uncharged mol-

ecule at the end(s) of the DNA fragments could lead to efficient separation of relatively large DNA fragments (100–900 bp) in free solution. Contrary to current electrophoretic methods, this method requires no sieving matrix, provides better results at high voltage and leads to shorter preparation time and faster separations.

Detection of PCR products has been achieved in three ways: (i) UV absorbance by the DNA fragment; (ii) LIF using intercalating dyes; and (iii) fluorescence of primers tagged with fluorescence dyes.

In automated fluorescence analysis the alleles from an STR locus are PCR-amplified from human genomic DNA using an unlabelled primer and one primer labelled at the 5'-end with a fluorescent dye.

Figure 3 Typical electropherograms of: (A) blank human hair extract; (B) extract from blank human hair spiked with: 1, racemic ephedrine; 2, amphetamine; 3, methamphetamine; 4, 3,4-methylenedioxyamphetamine; 5, 3,4-methylenedioxymethamphetamine; 6, 3,4-methylenedioxyethylamphetamine, at concentrations of 1 ng mg^{-1} for every racemic analyte. Conditions: Buffer, 100 mmol L^{-1} phosphate, pH 2.5, containing 15 mmol L^{-1} β -cyclodextrin. Capillary, uncoated fused silica, $45 \text{ cm} \times 50 \text{ }\mu\text{m}$ i.d. Potential, 10 kV. Detection, UV absorbance at 200 nm. (Reprinted with kind permission of Wiley-VCH from Tagliaro F *et al.* (1998) *Electrophoresis* 19: 42–50.)

Denatured PCR products are then analysed by CE with in-lane size standard (DNA-fragments of known size labelled in a different colour dye) on slab gel or CE capable of real-time multicolour fluorescence detection. The collected data are then analysed by software which automatically determine allele size based on a standard curve for the in-line size standard. STR loci which overlap in size can be distinguished using different dyes that fluoresce at different wavelengths. Results have indicated that the sizes obtained for STR alleles can differ depending on the gel and electrophoresis conditions and depending on the instrument used, however, high precision can be obtained in multiplex PCR analysis by using an in-line internal standard (< 0.16 nucleotide SD).

Recently, a new CE instrument capable of simultaneous multicolour detection and high resolution of DNA fragments was developed. This instrument, the ABI Prism 310 Genetic Analyser, is highly automated. Multiplex STR products are sequentially injected into a single capillary and detected by LIF. LIF is detected on a charged coupled device camera, which simultaneously detects all wavelengths from 525 to 680 nm. Ninety-six samples in a single tray can be analysed by the instrument. The polymer used on the instrument has many performance features that are critical to the success of STR analysis in forensic work: alleles differing in size by a single base (up to 250 bp in length) can be detected; sizing precision (between alleles of the same length) of less than 0.15 nucleotide SD is

possible; analysis time per sample is less than 30 min; capillary life is at least 100 injections; and the run temperature is set at 60°C to provide a highly denaturing environment for the DNA samples.

The disadvantage of CE is that it is a serial technique, making its total throughput no better than the long run times and parallel separations in conventional slab gel electrophoresis. Several attempts to obtain faster and higher throughput separations have been reported. These include capillary array electrophoresis in ultra thin slab gels. These two techniques are limited by difficulty in assembling the separation system and in carrying out sample introduction. The use of CE to provide continuous automated loading of PCR products on to ultra thin slab gels shows new potential for increasing sample throughput in STR analysis, although separation resolution still needs to be improved.

Over the years CE has become widely used as a power tool in post-PCR analysis. However, it is difficult to introduce PCR to routine laboratories, because of the possibility of false-positive results. These false positives may be caused by sample-to-sample contamination or by the carry-over of previously amplified PCR product. The online coupling of fused silica capillary as the microreactor for PCR

and CE for separation and detection can be recommended in order to avoid false-positive results.

Other

The analysis of inks as part of the detection of fraudulent documents is a small but important part in the operation of a forensic laboratory. TLC and HPLC have been extensively used to separate and distinguish inks during the last decades. In comparison, CE has been applied only rarely. UV-Vis, fluorescence and particle-induced X-ray emission (PIXE) detection of electrophoretically separated diluted original inks and ink extracts (Figure 4) from substrate material provide sufficient information for the comparison of different inks (Table 1). The possibility of comparison of 50 forensic inks by MEKC has also been investigated. The separation patterns of individual dyes were compared with those obtained by HPLC and TLC, showing a much higher separation efficiency for MEKC. Some inks, which cannot be discriminated by applying the HPLC and TLC method, can definitely be distinguished using MEKC.

Nicotine, nornicotine and anabasine, the active principal components in all tobacco products, have been separated by CE and the potential for CE to

Figure 4 Electropherograms of extracts from dried blue and black inks see (see Table 1) and original inks diluted 100-fold in 5 mmol L⁻¹ borate buffer, pH 8.25. Capillary, fused silica 45 cm × 50 μm i.d. Potential, 25 kV. Detection, laser-induced fluorescence at λ_{exc/em} = 320/436 nm. characterize tobacco products on their alkaloid profiles for classification purposes has also been demonstrated.

Marine phytotoxins present a major public health problem because they can contaminate seafood. CE and MEKC enable okadaic acid, microcystins and maitotoxin to be detected in the picogram range.

Since any case of mushroom intoxication may have legal consequences, the accurate determination of mushroom toxins is of primary importance for forensic pathologists and toxicologists. The analysis of amatoxins by CE instead of radioimmunoassay has several advantages: analysis is faster, less costly and it requires smaller amounts of sample. Rapid and sensitive CE method for the separation and determination of the psilocybin and baeocystin in hallucinogenic mushrooms has also been reported.

Many types of explosives consisting of inorganic and organic components have been used in criminal cases. It has been demonstrated that the original composition of some explosive devices can be derived from the components of the post-blast residue. In short, CE offers a powerful tool which is suitable for both high and low explosive and gunshot residue analysis. CE is suitable for the determination of both inorganic and organic components, showing greater versatility than the traditional methods such as atomic absorption spectrometry and PIXE.

Conclusion

CE is a new technique in the forensic laboratory for the separation and quantitation of a wide variety of

molecules based not only on charge, but also on size, hydrophobicity and stereospecificity. CE offers certain advantages for forensic analysis:

1. higher theoretical plate number than HPLC;
2. in many instances CE is faster than GC and HPLC;
3. with regard to sample preparation, CE is easier than GC and HPLC. In many instances the sample can be injected directly with little or no preparation;
4. lower cost per analysis;
5. full automation;
6. CE is complementary to GC and HPLC;
7. two complementary techniques such as CE and MECC can be carried out with the same instrument.

Despite these features, the technique has not yet been widely accepted in the forensic community. This may be in part due to the legal system. Different countries have different standards to achieve legal defensibility of analytical results in court and forensic laboratories rely to a large extent on commercial instruments which are specially built and approved by a governmental agency for specific analysis. Even so, the US Drug Enforcement Agency is now using CE for general drug screening to quantitate heroin samples.

Two drawbacks of CE are often stated: low reproducibility and low sensitivity. However, due to several recently presented results (e.g. detection limits in the region of ng mL^{-1} , the precision of migration times $< 1\%$ RSD, same-day and day-to-day repeatability characterized by RSD values in the range of 1–4%, when peak area ratios were used), these drawbacks seem not to be so critical.

As stated by Kuffner *et al.*: 'The legal criteria of Daubert, as long as they are met by the scientific community, will allow CE into evidence as acceptable expert testimony'.

Forensic science is the application of the sciences to the court of law. Consequently, forensic science and the legal system are intimately intertwined. Results obtained from the examination and analysis of forensic samples and the forensic samples themselves comprise evidence of a crime. It is the individualization of the sample, i.e. the singular association between the sample(s) and an illegal act, that is unique to forensic science. Because of the legal consequences, results require a high degree of certainty and the techniques used must be admissible in court. The Daubert rule, a 1993 decision upheld by the US Supreme Court, assigns to the judge the role of determining admissibility of scientific evidence. Among the factors considered by the judge are: (i) whether the technique has been tested and subjected to peer review; (ii) whether error rates have been defined; (iii) whether standards controlling the operation of a technique exist; and (iv) whether the technique has been widely accepted in the scientific community. Techniques used in a forensic laboratory may be applied to the investigation of a wide variety of crimes. Some examples are illegal drug use, counterfeiting, arson, tampering, fraud, poisoning, terrorism and environmental crimes. It is this diversity of cases, variety of sample matrices and the staggering number of potential analytes that necessitate a continuous evaluation of the testing that is needed to constitute proof in each situation.

Analytical requests in a forensics laboratory may be classified into four categories: (i) screen for the

presence or absence of known compounds or class of compounds; (ii) screen for unspecified analytes; (iii) perform a comparative analysis; and (iv) verify and/or quantify substances in a sample. Many qualitative tests are used in forensic laboratories for their speed and ability to identify unknowns. In some cases qualitative results (identity) suffice, while in others quantification is important. Like gas chromatography (GC), high performance liquid chromatography (HPLC) can be used for both qualitative and quantitative analyses. However, 80–85% of all known compounds are not amenable to GC. The stationary and mobile-phase combinations available and the many detection modes possible make HPLC a universal separation scheme. Unlike GC, it is not limited by the volatility or thermal stability of an analyte. HPLC can analyse solutes encompassing a wide molecular weight range, from monatomic species to proteins. A range of solute hydrophobicities and polarities can be accommodated, from acidic and basic species that incorporate many drugs of abuse, pharmaceuticals, dyes and food colourings, to neutral and/or hydrophobic molecules such as pesticides and herbicides, hydrocarbons in petroleum products and carotenoids in foods. In situations where GC can determine certain compounds more readily with greater selectivity, resolution and sensitivity, HPLC offers a secondary, confirmatory method. In other cases, the use of HPLC avoids sample derivatization required by GC, and eliminates steps that could contribute to sample loss and increase analysis time. Another advance in HPLC in recent years involves the introduction of narrow-bore (2.1 mm inner diameter) and microbore (1 mm inner diameter) columns. These smaller columns decrease the sample size required for injection and increase mass detection sensitivity versus the typical 4.6 mm inner diameter analytical columns.

Thin-layer chromatography (TLC) is also utilized in forensic chemistry, particularly for sample screening. Although TLC permits analysis of many samples at one time, facilitating the side-by-side comparison of suspect and authentic samples, it can suffer from a lack of resolution and from difficulties in both quantification and isolation of an individual component. Immunoassays are generally more sensitive; however, they may provide class-only determinations, may be prone to interferences and may not be available for classes such as neuroleptics and β -blockers. HPLC is useful for sample screening, comparison and quantification, and fraction collection for further analysis is more straightforward.

The UV-visible detector, and more recently the diode array detector (DAD), are the most commonly used detectors for HPLC analyses. As an alternative, one may utilize more specific devices such as fluorescence, electrochemical, chiral or mass spectrometric detectors. Because these detectors take advantage of specific molecular characteristics of the analyte(s) of interest, they are less susceptible to background interferences from sample matrix, and tend to be more sensitive. The choice of a particular detector and method depends upon the requirements of the case in hand – whether the sample is being screened for unknowns, analysed for a particular compound, compared against another sample, or quantified.

Sample Preparation

Each manipulation of the forensic sample may irreversibly alter the evidence and introduces the possibility of incomplete analyte recovery and inadvertent contamination. Therefore, sample preparation requires careful consideration and always follows a preliminary visual, and perhaps microscopic, examination. Sample preparation steps may also affect the form of the analyte, which is problematic for speciation work and subsequent toxicological evaluation. Additional complications in forensic work are the variety of sample matrices (drugs, body fluids, food, soils, etc.) and limited sample sizes (arson residues, traces of blood in a syringe, a spot on blotter paper, etc.) frequently encountered. Ideally, a portion of the sample should be reserved in case of trial to allow independent analysis. If appropriate, the sample can be homogenized. However, portions may need to be analysed separately to characterize the sample accurately. Individual samplings may also be advisable when there are visual differences within portions of a sample. Sampling in the vicinity of a visual contaminant reduces dilution with the matrix and improves detection limits.

Analytes must be in solution for determination by HPLC. Sample preparation is necessary to remove compounds such as proteins that might damage an HPLC column, as well as compounds that interfere with an analysis. Liquid-liquid extractions (LLE) are commonly used, and can be manipulated by choice of solvent, addition of salts (salting-out effect) and control of pH. For biological matrices, extractions using chloroform/2-propanol/*n*-heptane under alkaline conditions provide clean extracts with good recoveries of basic and neutral compounds. However, acidic compounds such as barbiturates and salicylates are poorly recovered (20–50%). LLE is not easily automated and can require large volumes of solvent. Solid-phase extraction (SPE) cartridges are now widely used in toxicology screens, mainly for low viscosity samples such as urine or serum. SPE has the advantages of higher efficiencies and selectivity, lower solvent volume requirements, absence of emulsions, and automation options. However, the packing materials can be irreproducible, even within batches of the same brand, resulting in variable recoveries and poor analytical reproducibility. The use of an internal standard is highly recommended for quantitative results. SPE cartridges should not be re-used due to decreased extraction performance and increased possibility of the introduction of contaminants.

General Unknowns

Screening for unknowns is a very challenging task due to the vast number of potential contaminants. Screening methods in a forensic laboratory are designed to detect the most relevant drugs and potentially hazardous chemicals. Often, screens are performed in response to a crisis such as an acute poisoning and as such require rapid response. While immunoassay techniques and TLC remain invaluable for initial screening, these methods must be supplemented by HPLC-DAD for those analytes for which the initial screen does not offer sufficient selectivity or sensitivity. Identification of a compound by HPLC-DAD is based on retention time match and spectral match, as shown in **Figure 1**.

Additionally, plotting the ratios of absorbance measurements obtained during a chromatographic analysis, taken at well-separated and characteristic wavelengths, permits evaluation of interferences and a more confident identification. For example, variation in the ratio across a peak indicates co-elution, as seen in **Figure 2**.

Since forensic screens for unknowns are often performed in biological matrices, which are inherently variable, the analysis of blanks is an additional safeguard against false positives that could be caused by

Figure 1 Spectrochromatogram showing spectral and chromatographic data for the separation of six benzodiazepines. Solutes: 1, midazolam; 2, flurazepam; 3, oxazepam; 4, nitrazepam; 5, alprazolam; 6, clonazepam. Column, 25 cm Lichrosorb RP-8; mobile phase, 35% CH_3CN in $0.05 \text{ mol L}^{-1} \text{ KH}_2\text{PO}_4\text{-H}_3\text{PO}_4$ buffer, pH 3; flow rate, 1.5 mL min^{-1} ; spectra collected between 190 and 400 nm. Reproduced from Logan (1994), with permission from Elsevier Science.

the effect of poisons on the matrix or due to putrefaction processes. Blanks should include reagents, and matrix that is contaminant-free. Screening methods also need to detect indirect indicators of the compound of interest. A screen of biological fluids should include major drug/poison metabolites such as benzoylecgonine, the primary indicator of cocaine use, which is found in urine. The addition of bleach to carbonated beverages leads to the formation of chlorate, chloride and sometimes chloroform.

Figure 2 Use of wavelength ratioing to indicate peak impurity in the analysis of tricyclic antidepressants and metabolites by LC-photodiode array detection. (A) Chromatogram at 252 nm; (B) ratiogram 252 nm/230 nm. Asymmetric ratio of peak 3 indicates inhomogeneity and co-elution. Solutes: 1, 10-hydroxynortriptyline; 2, 10-hydroxyamitriptyline; 3, protriptyline/imipramine (co-elution); 4, nortriptyline; 5, amitriptyline. Column, 25 cm Lichrospher RP-8 (CH100); mobile phase, 40% CH_3CN in 0.05 mol L^{-1} phosphate buffer, pH 3; flow rate, 2.0 mL min^{-1} . Reproduced from Logan (1994), with permission from Elsevier Science.

Statistical toxicological analysis (STA), a general screening method for toxins in biological matrices as described by Tracqui *et al.*, often utilizes HPLC-DAD. Many laboratories have had success in creating their own databases and/or using multicomponent analysis for the identification of hundreds of substances from several classes in one run. Widespread use of HPLC-DAD for STA requires libraries that can be shared among laboratories. Unfortunately, libraries are not as common for HPLC as they are in GC work. Because the mobile phase in HPLC interacts much more strongly with analytes than the carrier gas in GC, small deviations in chromatographic conditions such as column type and batch, mobile-phase composition and pH, temperature and flow rate may affect retention time. The use of retention indices is necessary to minimize interlaboratory differences. Bogusz *et al.* proposed the use of a 1-nitroalkane index scale for toxicological screens since the C_1 to C_6 homologues are commercially available and have high UV absorbance between 200 and 220 nm. The retention times of 1-nitroalkanes are not affected by pH changes between 3.2 and 8.5, but are affected by changes in acetonitrile concentration. Because compounds are affected differently by changes in chromatographic conditions, the use of selected drugs as retention markers to correct retention indices improves accuracy and precision. One toxicological screening library that includes 900 substances is available commercially. To improve the possibility of obtaining a match, it is important to use the same chromatographic conditions as the library.

Figure 3 Chromatograms obtained from extracts of two gastric contents (A and B). Solutes; 1, zopiclone, 2, mesoridazine; 3, perphenazine; 4, thioridazine; 5 and 6, co-elution of ketoprofen and naproxen. The spectral library was developed over the wavelength range of 210–367 nm. Solute identification utilized a retention time window of $\pm 5\%$ and a peak purity parameter of ± 1 nm. Columns: 250×4.6 mm i.d. Supelcosil LC-DP (diphenyl) and 250×4.0 mm. i.d. LiChrospher 100 RP-8; mobile phase, isocratic CH_3CN -0.025% (v/v) H_3PO_4 -TEA buffer, pH 3.4; flow rate, 0.6 mL min^{-1} ; detection, 229 nm. Reproduced from Kovacs (1995) with permission from Elsevier Science.

Figure 3 is an illustration of the process used to identify substances found in gastric contents. The search window needs to be set wide (20%), and peak

purity should be considered. Consequently, a library search may yield as many as 10 possible matches. Spectra should be compared between a sample and

a standard run in-house for a positive identification. Even in the absence of a positive identification, the diode array spectrum can give class indications. The analysis can then be pursued by modifying the HPLC conditions or by utilizing another technique.

Analysis for a Known Analyte or Analyte Class

In contrast to screening for unknowns, sample preparation and separations can be optimized for the analysis of a known analyte or class of analytes. In order to avoid interferences and to maximize analyte recovery from the sample matrix, experimental conditions can be tailored for the class of compounds of interest. It is often necessary to determine components such as diluents, excipients, metabolites and synthesis or degradation products. **Table 1** lists examples of compounds that are analysed by HPLC in forensic laboratories. HPLC may be not be the primary method for all of these analytes but may instead be the confirmatory technique.

Analysis of drugs of abuse constitutes a major portion of forensic work. While UV may lack the necessary sensitivity, electrochemical detection offers sensitivity and selectivity for compounds such as morphine, benzodiazepines, cannabinoids, hallucinogens, fentanyl and some cyclic antidepressants. Additional compounds can be analysed using post-column photolytic derivatization followed by electrochemical detection. Sample preparation may be minimized de-

pending on detector selection. For example, morphine can be analysed directly in poppy seed extract with electrochemical detection because it is easily oxidized at low potentials, unlike most opium alkaloids from natural products. **Figure 4** compares the sensitivity and selectivity obtained with UV, fluorescence and electrochemical detection of various alkaloids.

HPLC separations can resolve lysergic acid diethylamide (LSD) from ergot alkaloids. Because LSD is typically ingested in small amounts, fluorescence detection is commonly used for its sensitivity and selectivity. Analysis of opium alkaloids by HPLC must also separate caffeine, quinine and strychnine – common additives or diluents.

Although there are more than 2000 known steroids, only a portion are controlled substances. Analysis of steroids is required in a variety of matrices, including dosage forms, oils, body fluids and tissues. Spot tests are useful for the rapid initial verification of the presence of steroids. A more specific identification is possible by either GC or HPLC with similar resolving power but different co-eluting pairs. HPLC-DAD adds the potential of distinguishing between some steroids based on differences in UV spectra.

In drug abuse cases, creatinine is analysed using ion pair reversed-phase separation and UV detection at 220 nm to determine if urine samples have been diluted. The HPLC method suffers from fewer interferences than other methods. HPLC reversed-phase or ion exchange separations of proteins for blood grouping or species identification are rapid and efficient.

Pesticides, herbicides and rodenticides may be determined by HPLC in poisoning cases. Warfarin and its metabolites have been identified in matrices such as urine and food. Carbamates are more readily analysed by HPLC with post-column derivatization than by GC because they are thermally labile.

Explosives are difficult to analyse by GC due to their thermal instability. HPLC is used for the analysis of nitroglycerin, propellants, stabilizers, plasticizers and weapon discharge residues. Inorganic explosives and explosive residues can be determined with ion chromatography. Explosives such as ammonium nitrate and residues such as chloride, chlorate, sulfide and sulfate can be determined by anion exchange with UV or conductivity detection, as illustrated in **Figure 5**.

Separations in ion chromatography (IC) are based on ion exchange, ion exclusion and reversed-phase adsorption. The use of a suppressor column to reduce the mobile-phase background chemically and increase the analyte signal permits conductivity detection of inorganic ions. There are also methods known

Table 1 Types of analytes determined by HPLC in forensic laboratories

Analgesics
Anticonvulsants
Antidiabetic drugs
Creatinine
Digitalis glycosides
Drugs of abuse (barbiturates, benzodiazepines, cannabinoids, cocaine and related compounds, LSD, opium alkaloids)
Dyes and colourings (natural and synthetic)
Ergot alkaloids
Explosives, propellants, stabilizers
Hydrocarbons (petroleum distillates, engine oils, greases)
Inks
Inorganic and organic anions (fluoride, chloride, phosphate, sulfate, azide, citrate)
Inorganic cations (sodium, potassium, calcium, ammonium)
Pesticides, herbicides, rodenticides
Pharmaceuticals
Phenothiazines
Plastics, plasticizers, polymers
Proteins
Sugars
Tricyclic antidepressants

Figure 4 Comparison of detector signals. (A) UV; (B) fluorescence; (C) electrochemical. Chromatograms of orange juice samples spiked with: A, morphine; B, codeine; C, eserine; D, apomorphine. Column, 250 × 4.6 mm i.d. Interaction chemicals C_{18} ; mobile phase, 55% methanol, 15 mmol L⁻¹ KH₂PO₄, 3.75 mmol L⁻¹ 1-octanesulfonic acid, 7.5 mmol L⁻¹ KCl, adjusted to pH 4.00 with 10% H₃PO₄; flow rate, 1.0 mL min⁻¹; 30°C. Detection: UV, 254 nm; fluorescence, $\lambda_{ex} = 254$ nm, $\lambda_{em} = 408$ nm; electrochemical, 1.2 V vs. Ag/AgCl reference electrode with a glassy carbon working electrode. as single column which do not utilize a suppressor, but instead utilize low capacity columns and low ionic strength, low conductance mobile phases.

Although conductivity detectors are the most commonly used, a variety of other detectors are available: UV-visible (direct or following post-column

Figure 5 Analysis of residue taken from a black powder pipe bomb using ion chromatography. Solutes: 1, chloride; 2, nitrite; 3, nitrate; 4, sulfate; 5, sulfide; 6, hydrogen carbonate. Column, Vydac 302IC4.6; mobile phase 0.75 g isophthalic acid in 3 L H₂O, adjusted to pH 4.6 with 2 mol L⁻¹ KOH; flow rate, 2.5 mL min⁻¹; detection, 280 nm. Adapted from Hargadon and McCord (1992) with permission from Elsevier Science.

reactions), amperometry, fluorescence and atomic spectroscopy. IC analysis of strong acids and alkalis can be important in poisoning cases. Speciation by IC of compounds such as arsenic may be important due to the higher toxicity of inorganic anions compared to the methylated forms. IC can also be used to determine counterions of drugs, as well as cleaning products and their components.

Comparison of Samples

HPLC analysis may be required to compare samples, either to differentiate one from another or to trace the source of a sample. Although retention times can be used for tentative identification of specific compounds, it is not always necessary to identify every component in the sample. Often, pattern recognition will suffice when comparing the content of a class of compounds from one sample to the next. IC has been used in the analysis of sugars present in suspect infant formulas, as seen in Figure 6. HPLC with refractive

index detection can be used to analyse the types and amounts of sugars found as diluents in illicit street drugs, possibly linking seized evidence from several cases. Figure 7 demonstrates an excellent separation of cannabinoids and their metabolites. Comparative analysis of cannabinoids in cannabis samples by HPLC has been shown to connect suppliers with customers.

Through the knowledge of peak area ratios among carotenoids that occur naturally in orange juice, a suspect orange juice can be analysed to determine whether carotenoids have been added to enhance the colour. Dyes extracted from fibres gathered at a crime scene and from fibres from a suspect could be profiled and compared. The profile of the subunits of haemoglobin present in a blood drop permits its source identification as human adult, human neonatal or animal.

When comparing chromatograms, the presence of extra peaks in a profile may suggest the deliberate addition of a foreign substance, or simply sample

Figure 6 Comparison of sugar profiles using IC; (A) a known formula and (B,C) suspect infant formulas labelled as the known. Column, 4 × 250 mm Dionex Carbopac PA-1; mobile phase, 150 mmol L⁻¹ NaOH in 0–600 mmol L⁻¹ sodium acetate; flow rate, 1.0 mL min⁻¹; detection, pulsed electrochemical detection with a gold working electrode and a pH/Ag/AgCl reference electrode. Figure 7 HPLC of cannabis resin at (A) 254 nm and 26°C, (B) 220 nm and 26°C. Solutes: 1, cannabidiol and cannabigerol (shoulder); 2, cannabidiolic acid; 3, cannabinol and cannabigerolic acid; 4, tetrahydrocannabinol; 5, cannabichromene; 6, cannabinolic acid; 7, tetrahydrocannabinolic acid; 8, cannabichromenic acid; 9, di-*n*-octyl phthalate (internal standard). Chromatographic conditions: 100 mg resin extracted with 1 mL chloroform–methanol (1:9) containing 8 g L⁻¹ di-*n*-octyl phthalate; 2 μL extract injected. Column, 250 × 4.9 mm Partisil 5 C₁₈; mobile phase, 80% methanol–20% 0.02 mol L⁻¹ H₂SO₄; flow rate, 2 mL min⁻¹. Reproduced from Smith and Vaughan (1976) with permission from Elsevier Science.

degradation. The lack of expected peaks may suggest that the sample is not what it claims to be. However, because many species absorb at lower wavelengths, the mobile-phase composition may affect the outcome of an analysis. The molar absorptivity of a compound may change with small changes in the mobile-phase composition, affecting quantification. A high background absorbance from the mobile phase may obscure species that are present in the sample at low concentrations. This could lead to the erroneous conclusion that there are no apparent differences between suspect and authentic samples.

Whenever the analysis of samples requires a long period of time, e.g. for a large number of samples, the variation of retention times due to chromatographic factors must be considered. An internal standard may be added to samples, or a control sample may be analysed with each set of suspect samples. For comparative analysis, there is added importance to representative sampling and replicate analyses. It is easier to state that samples are different, rather than identical. Results of comparative analyses indicating two samples appear the same might be worded as ‘the samples were analytically indistinguishable using techniques *x*, *y*, *z*’. In some cases, the individualization of a sample can be quantified. For example, a statistical probability of a blood sample matching a specific person can be based upon the

analysis of blood group and Rh antigens if the distribution of these factors among the population is known.

Verification of Analyte Identity

A high degree of certainty is required for the identification of solutes in forensic cases in order to defend the work in court. An orthogonal technique may be used for confirmation, and the use of selective detectors aids in the certainty of identification. In HPLC, diode array detectors add the ability to match spectra, while fluorescence and electrochemical detectors are more specific. Both the excitation and emission wavelengths can be selected for fluorescence detection. The oxidation potential can be adjusted to reduce interferences of some analytes determined electrochemically.

GC-mass spectrometry (GC-MS) and GC-MS-MS are widely used in forensic analysis to verify analyte identification, particularly in cases concerning illegal drugs and drugs of abuse. The retention time identifies an analyte, and the mass spectrum serves as confirmation. Until recently, the argument against the use of HPLC as the primary method in forensic analysis was the difficulty of solute confirmation. Tremendous improvements in instrumentation and interface designs have made the coupling of HPLC to a mass spectrometer straightforward, particularly with the

recent introduction of relatively inexpensive bench-top models.

The ionization methods that are available permit the analysis of a wide variety of compounds. Particle beam is effective for moderately polar compounds (certain steroids and rodenticides), operates more efficiently with narrow-bore columns, and causes fragmentation during the ionization process. Both atmospheric pressure chemical ionization (APCI) and electrospray ionization (ESI) are amenable to gradient elution methods, thereby permitting their use in the analysis of a group of compounds. APCI is compatible with conventional columns and is used primarily to determine moderately polar analytes that are not thermally labile (clenbuterol, basic pharmaceuticals). Polar (conjugated oestrogens, proteins, peptides) and/or thermally fragile molecules (glucuronide metabolites of morphine and codeine) are analysed more effectively by ESI. ESI requires narrow- and microbore columns. In any of these methods, quantification can be performed in either the full scan mode or in the selected ion monitoring (SIM) mode. SIM offers greater sensitivity (10–100×), comparable to that obtained with GC-MS.

The utilization of MS-MS provides even greater specificity, further decreasing the chance of the incorrect identification of an analyte. Even if two compounds co-elute and have the same $[M + H]^+$ ion exiting the first quadrupole, it is unlikely that they would produce the same fragmentation pattern in the third quadrupole. The technique called selected reaction monitoring utilizes the known losses that occur during fragmentation of an analyte or a particular group of analytes. The method is useful when co-elution of two or more compounds is suspected. Another benefit to this method is that its sensitivity is typically 10–100 times greater than that obtained in the full scan mode.

Conclusions

Numerous aspects of separation science are applicable to forensic science. Because HPLC is so versatile and can be used to determine so many different compounds, the technique is particularly well suited to the demands of a forensic laboratory. Both qualitative and quantitative information can be obtained, often with minimal sample preparation. Because only small volumes are needed for analysis, sample consumption can be minimized. Eluting fractions can be collected for further analysis – an important consideration when dealing with trace evidence. HPLC offers a cost-effective technique with the ruggedness and reliability necessary for forensic testing and

consequently is widely used in forensic laboratories today.

FORENSIC TOXICOLOGY: THIN-LAYER (PLANAR) CHROMATOGRAPHY

I. Ojanperä, University of Helsinki, Helsinki, Finland

Copyright © 2000 Academic Press

The selection of appropriate analytical methodology for forensic toxicological investigations depends on the scope of the laboratory. Postmortem forensic toxicology investigates the cause of death, and consequently a very broad-range screening is needed to detect all potential poisons. In traffic toxicology, only such substances are relevant which may impair the driver's ability to control the vehicle. Doping control focuses on those substances that have been banned by the International Olympic Committee. Prisoners and rehabilitation clinic patients are tested for psychotropic drugs, whereas the US Mandatory Guidelines for Federal Workplace Drug Testing Programs are limited to the major drugs of abuse, cannabis, cocaine, amphetamine, opiates and phenylcyclidine.

Thin-layer chromatography (TLC) has found extensive use in forensic toxicology since the early 1960s when the famous book of Stahl made the technique well known. The first edition of the classic laboratory manual by AS Curry, *Poison Detection in Human Organs* from 1963 (Charles C. Thomas, Springfield, IL), still relies on paper chromatography but the second edition in 1969 utilizes TLC as a major technique for drugs. Gas chromatography (GC) and gas chromatography-mass spectrometry (GC-MS) in the 1970s, and especially high performance liquid chromatography (HPLC) in the 1980s gradually began to replace TLC but today the planar technique is having a renaissance due to the progress in instrumentation and software. From 1990 to 1996, 26% of published TLC applications were in the field of medical, clinical and biological analysis, which also includes forensic toxicology.

The commonly recognized advantages of classical manual TLC are high throughput, low cost, easy sample preparation and versatile visual detection possibilities. Instrumental TLC extends the scope to reproducible quantitative analysis and allows the utilization of *in situ* UV spectral information for identification. The main disadvantage of TLC is low chromatographic resolution, which can be partly overcome by instrumental techniques. Another disadvantage is that quantitative calibration curves are not reproducible enough to be stored, making it necessary to co-analyse several standards along with samples on each TLC plate. Most of the substances frequently encountered in forensic toxicology can be readily analysed by TLC. These include therapeutic drugs, drugs of abuse, pesticides and naturally occurring alkaloids, which are all relatively small molecular weight organic compounds with functional groups amenable to visualization by colour reactions.

It is practical to divide the discussion of TLC in forensic toxicology into two categories, the broad-scale screening analysis and target analysis. The former approach is related to the concepts of systematic toxicological analysis or general unknown, i.e. the search for a rational qualitative analysis strategy for hundreds of potential poisons. TLC drug screening is often performed in urine or liver, where the drug concentrations are higher than in the blood. In target analysis, the aim is specifically to detect and often also to quantify a substance or a limited number of substances.

Broad-scale Screening Analysis

Chromatographic Systems

Evaluation of systems The rational selection of TLC systems for screening analysis differs from the optimization of the separation of a few-component

mixture. In screening systems, the most important features are the distribution of R_F values across the plate, the reproducibility of the measurement of those values, and the correlation of chromatographic properties between systems. The computational methods capable of taking into account these features include discriminating power, mean list length (MLL), in-

formation content, quotient of distribution equality and principal component analysis. The (MLL) method has found widespread use, and it can also be used in computerized substance identification. The MLL approach is not related to the separation number (SN), i.e. the number of spots that can be separated by a system with a certain resolution. **Table 1**

Table 1 TLC systems for broad-scale toxicological screening analysis

<i>Mobile phase</i>	<i>Stationary phase</i>	<i>Correction standards</i>	hR_F^c	<i>Application</i>
1 Chloroform–acetone 80 + 20	Silica gel	Paracetamol Clonazepam Secobarbital Methylphenobarbital	15 35 55 70	Acidic and neutral drugs
2 Ethyl acetate	Silica gel	Sulfathiazole Phenacetin Salicylamide Secobarbital	20 38 55 68	Acidic and neutral drugs
3 Ethyl acetate–methanol– conc. ammonia 85 + 10 + 5	Silica gel	Hydrochlorothiazide Sulfafurazole Phenacetin Prazepam	11 33 52 72	Acidic and neutral drugs
4 Methanol–water 65 + 35	Silica gel RP 18	Diazepam Secobarbital Phenobarbital Paracetamol	16 35 54 74	Acidic and neutral drugs
5 Methanol–water– conc. hydrochloric acid 50 + 50 + 1	Silica gel RP 18	Hydroxyzine Lignocaine Codeine Morphine	20 46 66 81	Basic, amphoteric and quaternary drugs
6 Toluene–acetone–ethanol– conc. ammonia 45 + 45 + 7 + 3	Silica gel	Codeine Promazine Clomipramine Cocaine	16 36 49 66	Basic and neutral drugs
7 Ethyl acetate–methanol– ammonia 85 + 10 + 5	Silica gel	Morphine Codeine Hydroxyzine Trimipramine	20 35 53 80	Basic and neutral drugs
8 Methanol	Silica gel	Codeine Trimipramine Hydroxyzine Diazepam	20 36 56 82	Basic and neutral drugs
9 Methanol–ammonia 100 + 1.5	Silica gel ^a	Atropine Codeine Chlorprothixene Diazepam	18 33 56 75	Basic and neutral drugs
10 Cyclohexane–toluene– diethylamine 75 + 15 + 10	Silica gel ^a	Codeine Desipramine Prazepam Trimipramine	6 20 36 62	Basic and neutral drugs

^aImpregnated with 0.1 mol L⁻¹ KOH and dried.

shows TLC systems for broad-scale toxicological screening analysis, chosen partly on grounds of the MLL method, while the corresponding R_F libraries can be found from the books of de Zeeuw *et al.* and Fried and Sherma. For acidic and neutral drugs, recommended combinations of systems which possess low mutual correlation are 2 and 3, and 1 and 3, for basic drugs 5 and 6, and 8 and 10.

R_F correction In screening analysis, where R_F libraries of hundreds of compounds are utilized, the reproducibility of the values is an essential factor. TLC is an open technique, and the R_F values, and consequently the separation, are affected by environmental factors, such as humidity, layer activity and temperature. In contrast to column chromatography, the use of a single R_F standard for compensating the variation, corresponding to the relative retention time, may produce erroneous results. The method, which uses three to five correction standards that are structurally close to the analytes and linear interpolation between the standards, is now generally accepted to obtain corrected R_F values (hR_F^c). Table 1 indicates the correction standards chosen for the screening systems listed.

Identification

Migration distance By carefully adjusting the chromatographic and environmental conditions it is possible to obtain reproducible results with precoated plates. Reversed-phase (RP) layers show more batch-to-batch variation than silica gel but RP separations,

using aqueous mobile phases, are less dependent on humidity. The R_F and hR_F^c values can be determined manually or by using a scanning densitometer. The correction of R_F values makes it possible to obtain reproducible values in varying conditions and allows the use of the large hR_F^c libraries even in interlaboratory use.

Commercial software are available that utilizes the concept of hR_F^c for identification. Chrom TOX (Merck Tox Screening System, Merck, Darmstadt, Germany) is statistical search software that utilizes the MLL method for identification by R_F values and digitally coded colour reactions, giving a hit list of candidates with probability values. The software is also capable of adding information from other analytical techniques, such as retention indices from GC, molecular weights from MS and UV spectra from HPLC. A drawback is that the TLC data have to be fed manually. CATS software (Camag, Muttenz, Switzerland) combines instrumental densitometric evaluation of chromatographic plates with substance identification by hR_F^c values and *in situ* UV spectra (see below).

Visualization reagents The possibility of using visualization reagents for the detection and identification of fractions is a unique feature of TLC. Post-chromatography derivatization by spraying or dipping has been used more extensively than pre-chromatography derivatization. The limits of detection by colour reactions generally range from 0.1 to 1 µg per fraction and by fluorescence reactions,

Table 2 Visualization reagents for broad-scale screening analysis

Reagent	Application
Bratton-Marshall reagent (diazotation and coupling)	Benzophenones (from benzodiazepines), sulfonamides
7-Chloro-4-nitrobenzo-2-oxa-1,3-diazole (NBD-Cl)	Amphetamines, amino acids
2,6-Dibromoquinone-4-chlorimide (Gibbs reagent)	Pesticides
2,6-Dichlorophenol-indophenol (Tillmann's reagent)	Organic acids
<i>p</i> -Dimethylaminobenzaldehyde (Van Urk's reagent)	Drugs, sulfonamides, pesticides
Dragendorff's reagent	Drugs and alkaloids
Fast Black K salt	Amphetamines, adrenergic β -blocking drugs, nor-metabolites
Fast Blue B salt, Fast Blue BB salt	Cannabinoids
Fluorescamine	Amphetamines, amino acids, sulfonamides
Forrest reagent	Phenothiazines, antidepressants
FPN reagent	Phenothiazines, dibenzazepines
Furfuraldehyde	Carbamates, phenothiazines
Iodoplatinate, acidic	Alkaloids, drugs, quaternary ammonium compounds
Mandelin's reagent	Drugs
Marquis reagent	Drugs
Mercuric chloride-diphenylcarbazone	Barbiturates
Mercurous nitrate	Barbiturates
Ninhydrin	Amphetamines, amino acids
4-(4-Nitrobenzyl)pyridine-tetraethylenepentamine	Pesticides
Salkowski reagent ($\text{FeCl}_3 + \text{H}_2\text{SO}_4$)	Phenothiazines, thioxanthenes
3,3',5,5'-Tetramethylbenzidine, <i>o</i> -tolidine, after Cl_2	Pesticides, acidic and neutral drugs

especially using pre-chromatography derivatization, 20–100 ng per fraction. The visualization reactions can be divided into class and substance selective. In visualization sequences, several reagents can be oversprayed one after another to amplify the amount of information obtained from a single plate. An example of such sequence for basic drugs is ninhydrin, FPN ($\text{FeCl}_3 + \text{HClO}_4 + \text{HNO}_3$) reagent, Dragendorff's reagent and acidified iodoplatinate. Table 2 lists reagents that are commonly used in forensic toxicology.

In situ spectra Earlier it was common to scrape off a separated fraction from the TLC plate and submit it to a further spectrometric or spot test analysis. Today it is possible to measure the *in situ* UV spectrum of a fraction and compare this with stored spectrum libraries for identification. Representative spectra can generally be obtained from well-separated fractions with substance amounts over 0.5 μg on standard TLC plates and over 0.1 μg on high performance thin-layer chromatography (HPTLC) plates, although these limits depend on the shape of the fraction and on the absorption characteristics of the compound in question. The upper limit is not a problem as the reflectance saturates after certain level and the spectra remain practically the same. The CATS software from Camag allows the complete sequence of instrumental screening analysis, including R_f correction, spectrum measurement, automated search against hR_f^c /UV libraries and reporting (Figure 1).

Other spectrometric techniques than UV have been tested for the measurement of TLC fractions. *In situ* diffuse reflectance Fourier transform infrared (FTIR) measurements have proved to be feasible for the identification of drugs using a spectral region where silica gel has no strong absorption, and a commercial TLC-FTIR interface is available.

Proprietary Drug Screening Schemes

Particularly in North America, a TLC scheme called Toxi-Lab (Ansys, Irvine, CA, USA) has gained popularity in analytical toxicology. This product comprises the extraction, development, visualization and interpretation steps of analysis. The Toxi-Lab A detects basic and neutral substances and the Toxi-Lab B detects acidic and neutral substances. The plates consist of silica, impregnated with a vanadium salt for detection purposes, in a glass fibre matrix. The Toxi-Gram C8 are octylsilica bonded phase plates for the confirmation of basic and neutral drugs. All the plates have holes at the origin for the inoculation of factory-made standard substance discs and discs containing the evaporated sample residues. Detection is carried out by using a standardized four-stage

The reports were obtained by comparing the hR_f^c values (window ± 9 units) and *in situ* UV spectrum correlation against a library of 325 drug substances on each system.

visualization sequence, and the interpretation of the colour patterns is performed with a help of the Toxi-Lab Drug Compendium showing indexed colour photograms for hundreds of compounds. The sequence consists of formaldehyde vapour + Mandelin's reagent, water, fluorescence under 366 nm UV light and modified Dragendorff's reagent. There are also procedures and tests available for specific substances and classes of substances, such as opiates and cannabis. There is ample literature available on the applications of Toxi-Lab to clinical and forensic toxicology.

Another TLC screening scheme, Spot Chek (Analytical Bio-Chemistries, PA, USA), relies on a single mobile phase, a set of visualization reactions, and computerized interpretation of the patterns. Acidic/neutral and basic drugs are developed on separate plates, and on each plate the sample is divided into two or three equal portions that are developed in parallel to facilitate the use of visualization reactions. The migration distance is divided into five R_F zones with reference compounds. The computer program database is based on nine colour reaction responses and the plate zone locations for 243 drug substances but requires entry of only one TLC property to generate a matching list.

Automated Multiple Development

There are currently two alternative instrumental means to improve the Separation number (SN) in TLC: automated multiple development (AMD) and overpressured layer chromatography (OPLC). In AMD, the plate is developed repeatedly in the same direction, and each partial run goes over a longer solvent migration distance than the previous one. Each partial run uses a solvent of lower elution strength than the previous one and in this way a step-wise gradient is formed. SN values of up to 40–50 can be obtained by AMD but a disadvantage is the time

required for the analysis, which may be several hours. There are no strictly forensic toxicological applications of AMD in the literature but the technique has an established position in the broad-scale screening for pesticides in the environment and has great potential in toxicology.

Overpressured Layer Chromatography

OPLC is based on the forced flow of the mobile phase against an external pressure, which results in short development times and decreased diffusion of the analyte fractions, making it possible to take advantage of longer developing distances. Silica gel plates are exclusively used in OPLC as reversed-phase chromatography has become complicated. Method development may be laborious due to disturbing adsorption zones, often obtained with multicomponent mobile phases. A commercial OPLC instrument is available from OPLC-NIT (Budapest, Hungary). OPLC has found use in the separation of closely related compounds in a particular pharmacological category or compounds originating from a particular botanical source. Two complementary OPLC systems have been developed for broad-scale screening for basic and neutral drugs with SN values close to 30, which is more than twice the values obtained typically with ordinary TLC: trichloroethylene-methylethylketone-*n*-butanol-acetic acid-water 17 + 8 + 25 + 6 + 4, and butyl acetate-ethanol-triethylamine-water 85 + 9.25 + 5 + 0.75, with layer pre-saturation.

Target Analysis

Drugs of Abuse

Amphetamines and related stimulants, especially amphetamine, methamphetamine and 3,4-methylenedioxyamphetamine (MDMA, an Ecstasy

Figure 2 Separation of (1) methamphetamine and (2) amphetamine on the TLC system 6 of Table 1.

component), can be separated by a variety of TLC systems, such as those in Table 1 (Figure 2), and sensitively detected as fluorescent derivatives of, for example, fluorescamine or NBD-Cl (4-chloro-7-nitro-2,1,3-benzoxadiazole). Ninhydrin is a traditional reagent for amphetamines. Fast Black K salt reagent is capable of differentiating aliphatic primary and secondary amines, giving violet and orange-red colours, respectively, while tertiary amines do not react. Thus amphetamine and methamphetamine, or MDMA and 3,4-methylenedioxyamphetamine, are readily separated. Amphetamines possess poor UV characteristics, so they cannot be analysed by UV densitometric methods at low levels without derivatization. However, the methylenedioxy-derivatives can be easily recognized by their UV spectra (Figure 3). Despite the low limits of detection obtained with pure amphetamine-like substances, the limits of detection in urine are of the order of 250–500 ng mL⁻¹ which is close to the standard immunoassay cutoff value (300 ng mL⁻¹).

The analysis of the main urinary cannabinoid, 11-nor- Δ^9 -tetrahydrocannabinol-9-carboxylic acid (THCA), is usually carried out with dedicated TLC systems, such as ethyl acetate-methanol-water-conc. ammonia 12 + 5 + 0.5 + 1. The detection of THCA is performed with various diazonium salts, such as Fast Blue B salt, Fast Blue BB salt and Fast Blue RR salt. Detection limits of 2–10 ng mL⁻¹ can be obtained for THCA, and these concentrations compare favourably with the standard immunoassay cutoff level of 20 ng mL⁻¹.

Screening for cocaine is usually based on the detection of its metabolite benzoylecgonine (BE) in urine. The combination of the following two mobile phases can be applied to the separation: methanol-chloroform-ammonia 60 + 60 + 1, and ethyl acetate-methanol-water-ammonia 85 + 13.5 + 1 + 0.5. The detection of BE is performed with Dragendorff's reagent or Ludy Tenger reagent, followed by sulfuric acid, with the limit of detection of 200 ng mL⁻¹ in urine. The standard immunoassay cutoff level is 300 ng mL⁻¹.

The opiates of interest in drug abuse testing programmes include the heroin metabolites, 6-monoacetylmorphine and morphine, and codeine. The combination of the following two mobile phases can be applied to the separation: ethyl acetate-isopropyl alcohol-methanol-ammonia 80 + 15 + 3 + 8, and 1,2-dichloroethane-isopropyl alcohol-methanol-ammonia 20 + 20 + 20 + 7. The limit of detection for opiates with iodoplatinate ranges from 100 to 500 ng mL⁻¹ in urine, depending on the compound, while the standard immunoassay cutoff level is 300 ng mL⁻¹.

Figure 3 The *in situ* UV spectra of (A) amphetamine, (B) methamphetamine and (C) methylenedioxyamphetamine (MDMA). Amphetamine and methamphetamine have similar spectra but they can be differentiated, e.g. by using the Fast Black K reagent.

Other Substances

Toxicological Analysis by Müller lists 1453 published TLC systems for potentially toxic compounds. A TLC bibliography is available from Camag on CD-ROM, listing 5500 abstracts of papers from 1982 to 1996. The biennial TLC reviews by Sherma in *Analytical Chemistry* provide a wealth of information on systems for individual substances in forensic toxicology.

Status of TLC in Forensic Toxicology Laboratory

In forensic toxicology, the unique features of TLC are best utilized in the broad-scale screening analysis for drugs and poisons in urine or liver samples. For this application, there are equipment, dedicated software and reference libraries available from several manufacturers. Compared to HPLC or capillary electrophoresis, TLC allows the detection of even poorly UV-absorbing compounds using selective visualization reactions. Compared to GC or GC-MS, TLC allows the chromatography of polar compounds without prior derivatization. Another important application of TLC is the screening or confirmation of drugs of abuse, although the supremacy of the combination of immunoassay and GC-MS in this area has hindered the development of modern dedicated TLC methods. Immunoassay screening, however, is vulnerable to sample adulteration and high background noise. In larger, broad-service laboratories, the various techniques available today, including TLC, are considered complementary rather than exclusive.

Introduction

It is difficult to distinguish between aromas, flavours, taints and perfumes, because to a large extent these are artificial categories that overlap. An aroma may be defined as the smell emanating naturally (possibly in the process of cooking or other method of prepara-

tion) of a foodstuff or beverage. The aroma from coffee beans on roasting is a prime example but there are many others. The main criterion is that the aroma material is essentially all in the vapour phase and the nose is responsible for sensing the aroma. A flavour is intimately related to an aroma but may contain involatile compounds that give rise to the sensation of taste but in practice it is common to have a flavour with an associated aroma. A tainted foodstuff or beverage is often unsatisfactory for consumption because there are compounds present that have an unpleasant smell or taste. Taints may arise from natural

chemical reactions such as the oxidation of the acids in an oil or fat to turn it rancid or the production of amines in fish. Other taints may occur because of leaching of material from packaging such as phenolic compounds from paper wrapping and solvents from the ink used in printing labels. Perfumes are natural or synthetic mixtures that have a pleasant smell to most people, although some of the constituents may have an unpleasant odour, a different odour or no odour when present in bulk. For example, coumarin in low concentrations has the smell of new-mown hay but this is not apparent at high concentrations. Although this article is specifically about aromas most, if not all of the techniques described are equally applicable to perfume studies. The only significant difference is that perfumes, in their final commercial form, normally exist as a solution (usually in ethanol) so that in this form they may be analysed as conventional liquid samples.

Another group of compounds that have much in common with aromas are pheromones, which cause specific behavioural effects in animals and insects. Indeed, it could be claimed that aromas and perfumes are the equivalent materials in humans (although there are true human pheromones, they are of small importance compared to those in the insect world).

Aromas frequently occur as complex, multicomponent mixtures with many of the important components (from an olfactory point of view) in very low concentrations – often at the ppm level or less.

Aroma Compounds

Since, by definition, aromas are volatile mixtures that produce an olfactory response, it follows that they should be amenable to analysis by gas chromatography (GC). This was appreciated quite early in the development of GC and Teranishi *et al.* did a considerable amount of work in the 1960s on strawberry aroma. The work was hampered by the use of packed columns and detectors of relatively low sensitivity and poor qualitative diagnostic information, but these investigations still go on today with modern equipment (see Further Reading).

Aromas contain many different types of compounds. Among the commonest are aliphatic, olefinic and aromatic hydrocarbons. A number of essential oils fall into this category but many aroma compounds have hetero-elements such as oxygen, nitrogen and sulfur in the molecule as well as a variety of functional groups such as alcohol, aldehyde, acid, phenol, ester and ether moieties. The smell of cheeses such as Camembert is due to the presence of fatty acids such as butyric acid. The smell of garlic is due to a fairly simple mixture of sulfur compounds including

Figure 1 Structure of capsaicin, the hot agent of peppers.

diallyl disulfide, $\text{CH}_2=\text{CH}.\text{CH}_2.\text{S}.\text{S}.\text{CH}_2.\text{CH}=\text{CH}_2$, and lager owes its distinctive aroma to the presence of p.p.m. concentrations of lower mercaptans. As can be imagined, the actual amount is a vital part of quality control.

Figure 1 shows the structure of capsaicin, the hot agent in peppers. It contains a nitrogen-containing amido group, a phenolic group and an ether group as well as olefinic double bonds. Aroma compounds frequently exist as *cis* and *trans* isomers arising from such double bonds and there is also a possibility of the presence of chiral compounds.

Identification of geometrical and optical isomers is of great importance since the isomers often exhibit a very large variation in physiological properties, including smell. An example of this is carvone (**Figure 2**) where the *D* isomer has an odour of dill, whereas the *L* isomer has a spearmint smell. In **Figure 2** it can be seen that the centre of asymmetry is at the carbon atom at which the isopropenyl group is attached to the cyclohexene ring. The situation is also complicated by the reverse situation, i.e. it is possible to have two compounds of quite different chemical structure that smell the same. The best known examples of the latter are benzaldehyde and hydrogen cyanide, both of which have a smell of bitter almonds and both give rise to this smell in natural products.

Sampling

Since the sample is gaseous but is in contact with a liquid or a solid, all the methods of gas sampling may be used as appropriate but the most important are static and dynamic headspace sampling. Dynamic headspace sampling results in greater sensitivity since all the volatile material from a given sample is removed from the headspace but it has to be retained in a trap packed with a sorbent such as Tenax. It is difficult to adjust the purge gas conditions so that all

Figure 2 Structure of carvone showing the position of the chiral centre.

the compounds of low volatility are removed without losing those of high volatility in the trap and vice versa. Whilst this may not be a problem if the volatility range of the compounds is small, it may make accurate quantitative analysis in one run impossible if the range of volatility is large. One way to circumvent this problem is by closed-loop stripping but this is at the expense of considerable extra experimental complications. Quantitative analysis is much easier by static headspace sampling but this technique has a poorer lower limit of detection, especially for compounds of low volatility. When using the term volatility, it must be remembered that many samples are in an essentially aqueous medium and a nonpolar compound will have a large activity coefficient in an aqueous system and a much higher volatility than might be expected from the boiling point of the pure compound.

Transfer of the aroma sample from the sorbent trap to the GC is by thermal or solvent desorption. Both have advantages and disadvantages. Thermal desorption is a one-shot method and may cause decomposition of some of the components of the sample. It has the complication of the need for a secondary trap that can be heated very rapidly so that the sample enters the column with a plug profile. The presence of water from aqueous samples may also cause problems if steps are not taken to remove most of it. Solvent desorption has the disadvantage that the solvent may give a large peak early in the chromatogram that masks some of the volatile components of the sample. The use of CS₂ minimizes the problem if a flame ionization detector (FID) is used as the detector since this compound has a small FID response but it is toxic and highly flammable.

A more recent method of sampling is the use of solid-phase microextraction (SPME) where a quartz fibre coated with a film of stationary phase is exposed to a liquid or gaseous sample followed by thermal or solvent desorption. Although it is very convenient to use, the limit of detection is not likely to be as good with SPME as with dynamic headspace sampling since SPME is essentially the same as static headspace sampling and the mass of the sorbent film on the quartz fibre is much smaller than in a conventional headspace trap. Discrimination is also possible if the correct choice of fibre coating is not made. To find a polymeric stationary-phase material that is equally selective for a broad range of compounds of different polarity is difficult and there may be memory problems with the fibre and low recoveries. In spite of this problem, SPME is becoming more popular and many recent publications use this technique with excellent results.

The concentration of the important compounds in an aroma sample may be extremely small and it may

be necessary to carry out a large scale GC separation or some other enrichment procedure before GC analysis. One way of effecting preconcentration is by using supercritical fluid extraction (SFE) with CO₂ containing small amounts (\approx 5–10%) of a more polar solvent such as methanol. The great virtues of SFE are that it is conducted at around ambient temperature and that it is very easy to remove the solvent (CO₂).

GC Separation Conditions

Columns

All analysis of aroma samples is now carried out on open tubular columns except if small scale preparative GC is carried out for prior enrichment.

Aroma samples consist of compounds ranging from nonpolar hydrocarbons to polar aldehydes, alcohols and acids but since they are in the gas phase under ambient conditions they will be of relatively low boiling point. These two conditions point to the use of polyglycol (CarbowaxTM) phases which can be operated up to about 230°C. Wax columns are particularly favoured for the analysis of fatty acid methyl esters because of their ability to separate *cis/trans* isomers (Figure 3).

Other phases such as phenyl, trifluoromethyl, cyano and hydroxy silicones have also been used. For chiral separations silicone phases containing β -cyclodextrins dissolved in the silicone have been employed. Figure 4 shows the chiral separation of + / - 1-octen-3-ol and + / - carvone and Figure 5 shows the separation of the chiral components of rosemary oil.

The columns should be capable of handling as large a sample as possible since some of the important aroma constituents may be present at p.p.m. level or less. In order to have a large sample capacity, the stationary-phase film should be relatively thick and films up to 5 μ m have been used in large bore columns (0.53 mm i.d). Thick films cause a significant reduction in resolution so a compromise is a film of 1 μ m thickness. For higher resolution and with mass spectrometric detection, standard 0.25 mm and 0.32 mm i.d columns are used with a film thickness of 0.25 μ m or less. Most applications now standardize on columns 30 m long, with some samples requiring 60 m length; columns longer than this are now seldom employed in the aroma field since they carry the penalty of longer analysis time and a greater possibility of decomposition.

Carrier Gas

The carrier gas is not of great importance on aroma analysis; nitrogen gives the highest resolution but the

Figure 3 Separation of *cis* and *trans* isomers of fatty acids. 60 m, 0.25 mm i.d., 0.25 μm Rtx-Wax; on-column concentration 40–75 ng. Oven temperature 165–250°C at 2°C min⁻¹. Injection/detection temperature 220/250°C; carrier gas, helium. Linear velocity 20 cm s⁻¹ set at 165°C; split ratio 50 : 1. Peak identification 1, C₁₄ : 0; 2, C₁₄ : 1 n5*cis*; 3, C₁₄ : 1 n5*trans*; 4, C₁₆ : 0; 5, C₁₆ : 1 n7*cis*; 6, C₁₆ : 1 n7*trans*; 7, C₁₈ : 0; 8, C₁₈ : 1 *cis* isomers (n12, n9, n7); 9, C₁₈ : 1 *trans* isomers (n12, n9, n7); 10, C₁₈ : 2 n6*cis*; 11, C₁₈ : 2 n6*trans*; 12, C₂₀ : 0; 13, C₂₀ : 1 n9*cis*; 14, C₂₀ : 1 n9*trans*. slowest analysis, as may be seen from van Deemter curves for hydrogen, helium and nitrogen. Helium is the most commonly used carrier gas.

Detection

The FID is the workhorse detector for aroma analysis. It has many advantages but lacks the sensitivity of some of the selective detectors which may exhibit up to 10³ times better lower limit of detection as well as giving qualitative information. **Figure 6** gives two headspace chromatograms of coffee aroma, one obtained with an FID and the other with a helium

ionization detector with less than half the gas volume (40 μL as opposed to 100 μL for the FID) which shows the much bigger response of the latter; the tailing in the helium detector chromatogram is due to the response to a water peak. In this instance,

Figure 4 Chiral separation of +/– octen-3-ol and +/– carvone. 30 m, 0.32 mm i.d., 0.25 μm , Rt- β DEXsa. Oven temperature: 40°C (hold 1 min) to 230°C at 2°C min⁻¹ (hold 3 min). Carrier gas: hydrogen 80 cm s⁻¹ set at 40°C. Detector: FID set at 220°C. Reproduced by permission of Restek Corp.

Figure 5 Chiral separation of the components of rosemary oil. 30 m, 0.32 mm i.d., 0.25 μm Rt- β DEXsm. Oven temperature 40°C (hold 1 min) to 200°C at 2°C min⁻¹ (hold 3 min). Carrier gas: hydrogen 80 cm s⁻¹. Detector: FID set at 220°C. Peak identification: 1, (-/+) α -pinene; 2, (+/-) camphene; 3, (+/-) β -pinene; 4, (-/+) limonene; 5, eucalyptol (1,8-cineole); 6, (-/+) linalool; 7, (+/-) camphor; 8, (-/+) teripinen-4-ol; 9, (+/-) isoborneol; 10, (+/-) borneol; 11, (+/-) α -terpineol. Figure 6 Helium ionization detector and FID chromatograms of coffee aroma. Column: 100 m \times 0.5 mm i.d. stainless steel coated with Witconol LA-23. Column temperature 60°C isothermal. Sample introduced via a gas sampling valve. (Reproduced from Andrawes FF and Gibson EK *Journal of High Resolution Chromatography* (1982), with permission from Wiley-VCH.)

Figure 7 Pulsed flame photometric detector (in S mode) and FID chromatograms of coffee aroma. (From Varian publication 03-914625-00, 1998. By courtesy of Varian Associates.)

the helium detector clearly has great advantages over the FID.

As pointed out earlier, many aroma compounds contain hetero-elements and **Figure 7** shows headspace chromatograms of coffee aroma obtained with an FID and the pulsed flame photometric detector in the sulfur mode, which shows the presence of a large number of sulfur compounds. This detector can also be used in a nitrogen-selective mode to reveal the presence of pyrroles, pyrazines and caffeine in the coffee aroma.

The Fourier transform infrared detector (FTIR) should be extremely useful in aroma analysis because of its ability to give a response to specific functional groups in a molecule. This detector is gradually coming into use for this type of work (see Further Reading) but the sensitivity to different functional groups varies considerably and the capital cost is quite large. The mass spectrometer in the selective ion monitoring mode probably gives the best all-round sensitivity. Full scan mass spectra can give sensitivities in the pg range under favourable circumstances. **Figure 8** shows a mass chromatogram and a Gram-Schmidt FTIR chromatogram of a dynamic headspace sample of the vapour above a particular variety of strawberries. The identity of the peaks is given in **Table 1**. Although there is a general similarity between the two chromatograms, there is a considerable difference in detailed quantitative response, with

some minor peaks in the mass chromatogram giving a large FTIR response.

One detector specific to aroma/perfumery studies is the human nose. The effluent from the GC is split between a conventional detector such as the FID and a sniffing port which is purged with humidified nitrogen. Because the ability to recognize the presence of an odour varies considerably from one individual to another it is necessary to select a panel from people who have been shown to possess a keen sense of smell and to train them to recognize the odour of particular compounds. Although it is always stated how insensitive the human nose is compared to those of animals, nevertheless it is still a highly sensitive organ. It is possible, apparently, for trained panellists to indicate the emergence of an odoriferous compound from a GC column in parts of the chromatogram where no signal is obtained from conventional detectors. Under these circumstances the procedure is to use small scale preparative GC and to collect fractions at the points indicated by the panel; these fractions are then re-run under analytical GC conditions.

Conclusion

The study of aromas is intimately connected to the study of flavours, taints and perfumes in that they all make extensive use of GC with a variety of detectors,

of which the mass spectrometer is the most important. Advances in this type of work will depend on advances in the instrumentation, particularly in the sensitivity of the mass spectrometer and on general advances in knowledge of food components under various circumstances.

Further Reading

There do not seem to be any modern texts which deal specifically with aroma analysis but the literature contains numerous references. The following is a partial list of papers published from 1997 to 1999 showing the wide variety of foodstuffs and drinks covered, ranging from wine, yogurt and tomato juice to strawberries and alligator meat. Although mass spectrometry is the main method of detection, other techniques are covered, together with a variety of methods for extraction prior to analysis.

FUELS AND LUBRICANTS: SUPERCRITICAL FLUID CHROMATOGRAPHY

M. M. Robson, University of Leeds, Leeds, UK

Copyright © 2000 Academic Press

Supercritical fluid chromatography (SFC) has a number of advantages over gas chromatography (GC) and high performance liquid chromatography (HPLC) for mixtures such as polyaromatic hydrocarbons

(PAH). SFC operates with diffusivities that are more gas-like, viscosities that are lower than liquids, and densities that are more liquid-like. The resulting mass transfer coefficients lead to more rapid analysis in SFC than in HPLC. The diffusion and viscosity range available in SFC allows GC-like separations on capillary columns but at much lower temperatures.

SFC on Packed Columns

During the initial development of SFC, commercial HPLC columns were used. The length and internal diameter of SFC packed columns are constrained by the large pressure drop as compared to open tubular columns and high mass flow rates, making interfacing to GC detectors more difficult. Therefore, narrow-bore packed columns with diameters of 1–2 mm were frequently used because they can be installed in a capillary SFC instrument and are compatible with many GC detectors. Packed fused silica columns have significant advantages, allowing the use of a large variety of liquid chromatography (LC) stationary phases with GC-based detectors.

The separation of PAH standards has been used throughout the development of SFC to determine chromatographic efficiency and performance of the system. Various-size stationary-phase particles have been used (10, 5 and 3 μm particle diameter) and it has been shown that the particle size influences the efficiency of the columns and that SFC reduced analysis times considerably in comparison with HPLC.

The elution order of PAH in SFC can be varied by changing the operating temperature and/or the pressure. Also, the mobile-phase modifier used in SFC can significantly affect the retention behaviour of PAH; dramatic changes in retention together with different selectivities have been demonstrated. The addition of

a modifier to the CO_2 mobile phase substantially reduces the retention times of the PAH. This effect is due to the intermolecular attraction between the modifier and the solute molecules and the subsequent increased solvating power. The successful separation of the 16 Environmental Protection Agency (EPA) target list of PAH using a single (15 cm \times 4.6 mm) column packed with specially bonded C_{18} silica has been achieved in 6 min (Figure 1).

The analysis of PAH and their derivatives from particulate matter has been of recent interest due to possible human exposure of the highly toxic nitro-PAH compounds. Sandra *et al.* provides an interesting approach to the analysis of PAHs using semipreparative SFC to separate the PAHs initially into the required types to analyse the peaks of interest, including nitro-PAH (Figure 2). A large amount of work has been carried out using supercritical fluid extraction (SFE) of particulates to extract the organic material followed by GC to characterize the extract.

Open Tubular Columns

The use of open tubular capillary columns in SFC for petroleum-derived mixtures was initiated by Lee *et al.* Capillary column SFC is mainly preferred because it provides the highest resolution. SFC can be carried out on capillary columns to achieve unique separations, especially for complex hydrocarbon mixtures

Figure 1 SFC of the EPA 16 priority PAH using 5 μm Waters Spherisorb PAH. Peak identification: 1, naphthalene; 2, acenaphthene; 3, acenaphthylene; 4, fluorene; 5, phenanthrene; 6, anthracene; 7, fluoranthene; 8, pyrene; 9, benzo[*a*]anthracene; 10, chrysene; 11, benzo[*b*]fluoranthene; 12, benzo[*k*]fluoranthene; 13, benzo[*a*]pyrene; 14, dibenzo[*a,h*]anthracene; 15, benzo[*ghi*]perylene; 16, indeno [1,2,3-*cd*]pyrene. Figure 2 Semipreparative SFC separation of PAHs from particulate matter. Using a 25 cm \times 4.6 mm i.d. silica column at 50°C and 200 bar, supercritical fluid flow rate 2 mL min⁻¹, a 1 : 1 methanol : acetonitrile modifier was used and programmed from 1% (up to 5 min) to 2.5% at 0.15% min⁻¹, and then 27.5% and 5% min⁻¹. With ultraviolet detection: 1.5–3.7 min 2–3-ring PAH; 4.4–5.8 min 4-ring PAH; 7.0–8.3 5-ring PAH; 9.0–10.9 6 ring PAH. (Reprinted with permission of Sandra *et al.* (1998) *J. Microcol. Sep.*, 10: 89.)

such as PAH. Capillary columns provide selectivity and high efficiency. Essentially, the same range of stationary phases that have been used for analysis in capillary GC have also been used in capillary SFC. These stationary phases include 100% methyl, 100% phenyl, 5% phenyl, 5% biphenyl and cyanopropyl siloxanes. An *n*-octylpolysiloxane coated stationary phase has been used to perform SFC on petroleum-derived vacuum residues. The increased alkyl content of the *n*-octyl phase over methyl phases provides an increase in van der Waals interactions of the stationary phase with solutes.

SFC separations on liquid crystal phases are based on the length-to-breadth (*L/B*) ratio and the planarity of the PAH, and they interact with the ordered rod-like structure of the liquid crystal phase. In addition, interactions such as dispersion, dipole and induced dipole interactions contribute to a good separation. Kithinji *et al.* optimized chromatographic conditions (pressure and temperature) to achieve better SFC separations of high-molecular-weight PAH on a capillary column coated with a smectic mesomorphic crystalline phase with simultaneous temperature and density programming. The separation of PAH isomers on a liquid crystalline polysiloxane stationary phase is shown in **Figure 3**. Many of these isomers cannot be resolved on any other stationary phase.

Raynor *et al.* used dual capillary column SFC with phases of different polarity and selectivity to perform

simultaneous separation of a mixture of PAH isomers. The method not only reduces the development time by 50% but also provides two sets of retention data for identification of unknowns. The simultaneous separation of a mixture of three-, four-, five-ring, PAH isomers on biphenyl and smectic columns is shown in **Figure 4**.

However, unless column diameters are greatly reduced, open tubular column SFC cannot compete with conventional packed column SFC in terms of analysis time. Comparison of Figures 1 and 3 shows that separation of high-molecular-weight PAH can be achieved in less than 6 min with a conventional packed column, while more than an hour is required for an open tubular column.

Hydrocarbon Group-type Separations

Hydrocarbon group-type separations refer to the separation of alkanes, alkenes and aromatic compounds in petroleum feedstocks and products. LC is commonly used for this purpose but suffers from a lack of resolution, lack of a universal detector and long analysis time. GC has also been used but is limited to the analysis of light distillates due to the column temperatures required. Packed column SFC with CO₂ as the mobile phase has been used for the determination of saturates, olefins and aromatics in petroleum products boiling below 350°C. Separation is achieved

Figure 3 Chromatogram of total coal tar PAH obtained with linear density programming at a constant temperature of 110°C, 10 m × 50 μm, SB-smectic column. (Courtesy of the University of Leeds.)

using two different columns connected in series – a silica and a silver nitrate-impregnated silica column – the analysis takes only 4 min per sample. The effect of temperature, pressure and column stationary phase on the separation has also been studied. At a low temperature (35°C), the saturates are better separated from the monoaromatics.

Another advantage of using a low column temperature is the shorter retention times and hence shorter analysis time per sample. An increase in pressure also results in improved separation between saturates and aromatics. Separations using a combination of silica and cyano or amino columns or the combination of silica and 20% silver nitrate column are not as good as the separation obtained with a single 5 μm silica column at the same temperature.

The separation of aromatic types in middle distillates according to ring number has been studied. Two packed columns, a silica and an amino-modified silica, were used with a switching valve. The saturates are separated as a group from the aromatics on the silica column. The aromatics are then switched to the amino column where further separation into mono-, di- and polyaromatic types can be performed.

It has generally been found that the separation of saturates from olefins is incomplete when CO₂ is used as the mobile phase. This observation was thought to be due to the polarizability of CO₂ compared to the

hydrocarbons used as solvents in LC. Another approach uses supercritical sulfur hexafluoride (SF₆) as the mobile phase. SF₆ provided less peak tailing and a shorter analysis time. Although SF₆ is reasonably compatible with the flame ionization detector (FID), the detector has to be protected against the decomposition product hydrogen fluoride, either by being gold-plated or by having a platinum jet and upper electrode.

A more accurate, reproducible and rapid SFC method to separate hydrocarbon mixtures by chemical class for samples ranging from C₄ to C₄₀ uses a column-switching technique which allows interchange between a microbore (1 mm i.d.) silica gel column and a silver-ion loaded strong cation exchange silica gel microbore column, with 10% CO₂ in SF₆ as mobile phase. The silver-loaded cation exchange column gives the saturate and olefin separation, while temperature programming is used to elute the aromatic peaks. The only problem encountered with the use of silver-modified columns is that certain types of compounds can react with the silver ions, causing column instability.

The three-column system with column switching and backflushing can be used to separate saturates, aromatics and polar compounds in high-boiling residues. A multicolumn system for quantitative determination of crude oil and high-boiling fraction class separation has been developed. Three different col-

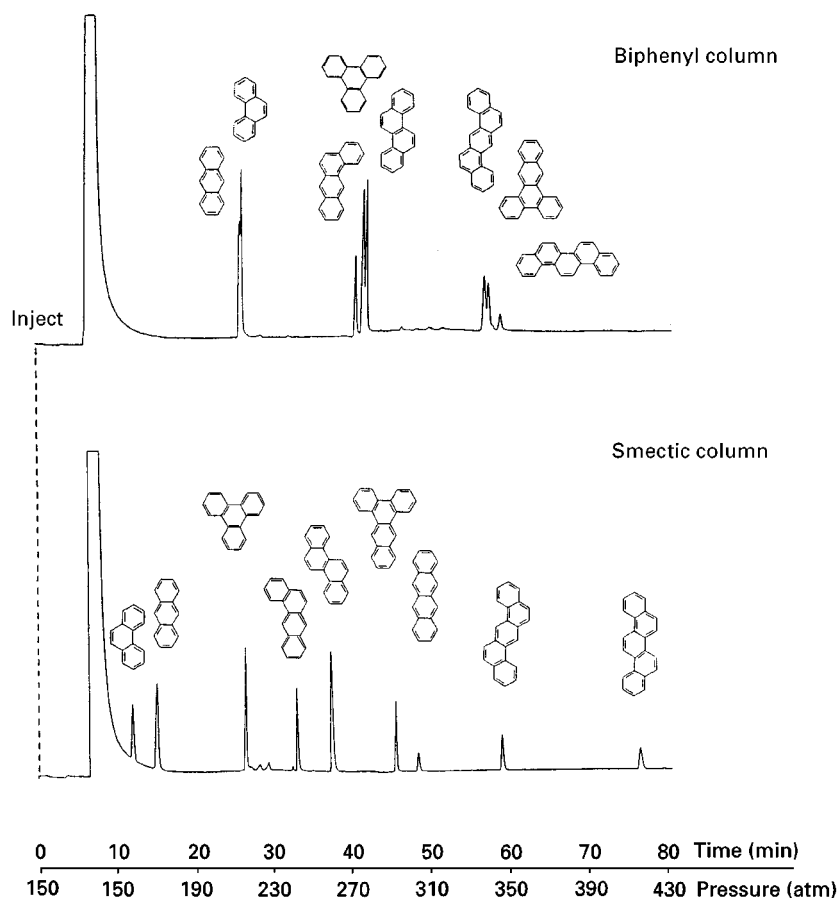

Figure 4 Simultaneous separation of three-, four- and five- ring PAH isomers on biphenyl and liquid crystalline columns. Conditions: CO_2 at 120°C ; programmed from 150 bar (10 min) to 450 bar at 4 bar min^{-1} . (Courtesy of the University of Leeds.)

umns are used – cyano, silica and silver-loaded silica – in order to separate saturate, aromatics and resins. The replacement of the silver-loaded silica column with a silver-loaded cation exchange column results in a more stable system. Similar effects have been observed when the silica column is replaced with a cyano column. The silica column prevents the aromatic components with strong π -interactions from entering the silver-loaded silica column and thus allows the aromatics to be backflushed from the silica column as a narrow band. The cyano column is used to trap the resins. Both carbon dioxide (CO_2) and nitrous oxide (N_2O) can be used as mobile phases; the latter provides better solubility of the resins and less tailing of the peaks.

A quantitative study of the determination of aromatics in jet and diesel fuels by SFC with FID used a single column (25 cm \times 2.0 mm i.d. column packed with 5 μm Chromegasphere SI-60 silica), a CO_2 mobile phase under constant density and no temperature programming. It was found that the nonlinear response of the detector can be significantly improved

by the addition of air as make-up gas (approximately 15 mL min^{-1}).

The use of a specially treated silica-based packed column to separate saturate and aromatic compounds in diesel fuels by SFC has been reported. Separations are achieved in less than 8 min, with good resolution (greater than 9) being achieved in the separation of one-, two- and three-ring aromatics.

In 1991, SFC was approved for the separation of saturate and aromatic hydrocarbons in diesel fuels. The American Society of Testing Materials (ASTM) method D5186 requires that temperatures in the range of 30 – 40°C be used for this separation. At these low temperatures, the separation of saturates and monoaromatics is easily achieved. However, low temperatures are not adequate for separation between the mono- and polyaromatics.

A packed capillary column has also been used with the same methodology, and showed that good separation can still be achieved at temperatures as high as 85°C . A further increase in pressure and temperature also results in apparently higher efficiencies for the

Figure 5 Chromatogram of base oil mixture containing 57.8% aromatic content. Operating conditions: column $1.3 \times 250 \mu\text{m}$ i.d. packed with Waters Spherisorb S5W. (Courtesy of the University of Leeds.)

heavier aromatic peaks with reduced analysis time. However, the ASTM method requires a minimum resolution of 4 between the saturates and aromatics peaks. As the temperature is raised, the separation between the saturates and aromatics decreases. For highly complex mixtures, such as coal liquefaction recycle solvents, an optimized group-type separation procedure involves SFC on a $250 \mu\text{m}$ i.d. \times 1.3 m long silica column operated at 80°C and 300 bar (Figure 5).

The separation of petroleum distillate into aliphatic and aromatic fractions has been achieved using a two-dimensional SFC-SFC system with a flow-switching interface. The columns used were a liquid crystal polysiloxane capillary column and a SB-Biphenyl-30 capillary. The use of a liquid crystal column in the second dimension to provide shape selectivity allows separation of various isomers, including chrysene, triphenylene, benz[*a*]anthracene and the benzofluoranthenes.

Simulated Distillation of Petroleum Compounds and Crude Oils

Distillation is the primary separation process in the petroleum used to characterize petroleum products before processing. Distillation data can be obtained

by using true distillation techniques or analytical techniques which simulate the distillation process. Simulated distillation (SD) is a technique which is inexpensive and rapid compared to distillation techniques but does not yield fractions for further characterization. GC simulated distillation techniques require the use of special high-temperature columns, and the high temperatures (up to 400°C) may compromise the integrity of the sample. SFC uses much milder conditions (typically below 150°C) than those necessary for simulated distillation by GC and can be used for the characterization of heavy crude components, with boiling points up to 760°C . The effect of temperature and pressure on resolution and retention have been studied, and generally analysis is conducted by pressure programming while keeping the temperature constant, although simultaneous temperature and pressure programming has been successfully used. A relatively nonpolar, 5% phenyl-95% dimethylpolysiloxane (DB5) phase is used. Such columns are very stable at SFC temperatures and, with the use of an integral restrictor installed at the end of the column, good results are obtained.

Linear density programming of the supercritical mobile phase provides a more nearly linear relationship between the elution pressure and homologous series boiling point. The use of open tubular columns eliminates the pressure drop effects which are common in packed columns. If an *n*-octylpolysiloxane stationary phase is used, the discrimination between aliphatic versus aromatic boiling points is minimized.

While SFC with open tubular columns seem to be well suited to SD, low sample capacity and loadability pose difficulties for complex mixtures. Recently, the analysis of hydrocarbon mixtures up to *n*- C_{130} has been achieved using a $300 \times 0.3 \text{ mm}$ i.d. column packed with $5 \mu\text{m}$ C_{18} bonded silica. The true boiling points and retention times of *n*-alkanes, alkylbenzenes, PAH and thiophenes have been correlated and it has been found that the retention time differences do not exceed 1 min for chemically different solutes with similar boiling points.

The effect of C_1 to C_{18} alkyl groups bonded to silica has been investigated and the oligomer peak resolution obtained with packed capillary columns approaches that obtained with open tubular columns. Figure 6 shows the SFC chromatogram of the SD calibration standard on a packed capillary hexylsilyl (C_6) column. The SD data from SFC correlated well with those obtained by GC. Higher-molecular-weight hydrocarbons can easily be eluted at operating pressures below 415 bar (density of CO_2 mobile phase approximately 0.71 g L^{-1}). At this maximum pressure a column packed with hexyl (C_6) bonded silica elutes hydrocarbons boiling at more than 756°C ,

Figure 6 Simulated distillation chromatogram of Polywax 655 on a $0.25 \text{ m} \times 250 \text{ }\mu\text{m}$ i.d. column packed with Waters Spherisorb S5W C_6 . Conditions: linear pressure programming from 100 to 415 bar (hold for 60 min) at 3.5 bar min^{-1} , FID detection. (Courtesy of the University of Leeds.)

whereas a column packed with octadecyl silanol (ODS-2) (C_{18} ; **Figure 7**) is more retentive and only elutes hydrocarbons boiling up to 686°C . Hydrocarbons of even higher boiling points can be eluted if the column length is changed. The significant deviation

Figure 7 Graph of elution pressure versus the boiling point for packed columns. Diamonds, methyl (C_1); squares, hexyl (C_6); triangles, octyl (C_8); circles, ODS2 (C_{18}). (Courtesy of the University of Leeds.)

between the retention times of aromatics and straight chain alkanes of apparently similar boiling points which occurs when SD is performed by GC may be reduced using open tubular SFC and further minimized when packed capillary columns are used, especially for aromatic compounds with three or more rings. However, comparisons may not be valid in view of the discrepancies between published values of PAH boiling points.

Analysis of Zinc Dialkyldithiophosphate in Lubricating Oil

Zinc dialkyldithiophosphates (ZDDPs) are used in lubricating oils as extreme-pressure anti-wear additives. It is possible to analyse ZDDPs using SFC; if the sample is in a lubricating oil matrix then it is essential that a phosphorus-specific detector is used, i.e. nitrogen phosphorous detector (NPD) (**Figure 8**). This removes the interference from the base oil which is obtained if FID detection is used. **Figure 8** also shows that it is possible to determine other lubricating oil additives e.g. Irgafos 168.

Conclusions

The analysis of high-boiling hydrocarbon mixtures has historically been difficult due to their complex nature. Because of the favourable properties of supercritical fluids – low viscosity, low density and high diffusivity – SFC has found many applications in this area. The technique is becoming increasingly popular in the petroleum industry, especially for group-type separation and for simulated distillation. The main

Figure 8 Chromatogram of used lubricating oil. Conditions: Diol packed column, temperature 50°C; ramp rate of 3 bar min⁻¹, NPD detection. (Courtesy of the University of Leeds.)

advantages of SFC are its speed of analysis and improved column efficiency when compared to liquid chromatography. The lower column temperature than needed for GC allows the analysis of higher-molecular-weight mixtures with carbon numbers up to C₁₂₀ and beyond.

FULLERENES: LIQUID CHROMATOGRAPHY

Introduction

Since the first separation in 1990 of C₆₀ and C₇₀ using column liquid chromatography (LC), this technique has played a very important role in fullerene chemistry. LC has allowed macroscopic quantities of fullerenes (particularly C₆₀) to be isolated and purified from the processing products. Obtaining sufficient amounts of pure fullerenes has been crucial both for determining physical and chemical properties in order to investigate practical applications of this new variety of carbon, and for developing a chemistry of these spherical and polyfunctional carbon molecules. A very rich chemistry has been developed in less than

a decade based mainly on C₆₀, and to a lesser extent on higher fullerenes. The starting reactives for this chemistry have been the compounds previously isolated by LC. It is now possible to bind covalently many types of compounds to the fullerene molecule.

LC is currently the method of choice for the separation, isolation and purification of fullerenes. Progress in fullerene chemistry therefore depends on the development of improved chromatographic methods, i.e. those with the highest efficacy and best resolution between the different components of fullerene mixtures, at both analytical and preparative scales, and at the lowest cost.

Contribution of LC in the Field of Fullerene Production

In early 1990, the design of LC methods was mostly geared towards isolating the most abundant

fullerenes obtained from the different production methods (e.g. laser vaporization of graphite, electric arc discharge, hydrocarbon flame combustion process, pyrolysis of carbon material). Each of these methods has its own specificity, with its advantages and drawbacks. In general, the objective of these methods was to obtain C_{60} and, to a lesser extent, C_{70} . On occasions, endohedral metallofullerenes (i.e. $M@C_{60}$) were also isolated. Therefore, chromatographic methods developed for this purpose should be (semi-) preparative. Likewise, the presence 'as impurities' of higher fullerenes and metallofullerenes (in low or very low concentration), polyaromatic compounds (PACs, created during production), residual solvents, solvates (due to strong interactions between fullerenes and some solvents), fullerene adducts (mostly with oxygen), and other artefacts produced during the production must be taken into account when designing an analytical procedure.

In this case, an extraction step for pre-purification is required. The origin of the soots, which is determined by the starting carbon material and the production method, influences the extraction yields and the nature of the fullerenes extracted.

LC in the Field of Organic and Organometallic Chemistry of Fullerenes

At the same time that C_{60} and C_{70} became available in significant amounts, the organic chemistry of fullerenes started to be developed. New reactions were performed and plentiful data about C_{60} reactivity were obtained. C_{60} was initially considered to be a polycyclic aromatic hydrocarbon (PAH), and the chromatographic methods that were developed were based on previous knowledge accumulated on PAHs. Further research, to which LC contributed significantly, demonstrated that the reactivity of C_{60} is more like that of a localized polyolefin. The LC contribution to this chemistry includes separation, identification and isolation of products. LC is also used to monitor the reactions typical of fullerenes: nucleophilic additions, cycloadditions, hydrogenation reactions, and oxidation and reactions with electrophiles. In addition, different isomers, diastereomers and enantiomers have been separated (Figure 1). Different examples of these separations are shown in Table 1.

The analytical designs required to separate fullerene derivatives from organic reactions differ considerably from those used to isolate fullerenes from their production methods. Several points must be considered. First, the structural similarities of these fullerene derivatives are often an obstacle in fullerene separations. Furthermore, the matrices and relative

percentages of compounds to be separated are different. Finally, some addends on the fullerene core have a dramatic influence on the solubility properties and the retention behaviour.

Separations Using Normal and Reversed Stationary Phases

In general, the poor solubility of fullerenes in most organic solvents limits the choice of mobile and stationary phases that can be used. Conventional stationary phases used for normal- and reversed-phase elution may exhibit reasonable fullerene selectivity, but only when using mobile phases in which the fullerenes are poorly soluble (e.g. *n*-hexane, dichloromethane, acetonitrile). These phases usually provide weak interactions with fullerenes when using eluents in which fullerenes are most soluble (e.g. *o*-dichlorobenzene, CS_2), which produce elution without adequate separation. Detection of fullerenes is not a problem: conventional or diode-array UV are used in the range 230 to 600 nm, depending on the cutoff of the solvent used.

Normal-Phase Elution

Open-column and low-pressure liquid chromatographic techniques, rather than HPLC, have been used for separations based on adsorption chromatography and performed with conventional normal-phase stationary phases (e.g. silica gel or alumina). In this subsection, we summarize the application of these methods, including the use of charcoal columns, to fullerene separations.

C_{60} was first separated from C_{70} using open-column LC on alumina as stationary phase, and *n*-hexane or *n*-hexane/toluene (95 : 5) as mobile phase. This method presents several disadvantages: as *n*-hexane is not a good solvent for fullerenes, a high consumption of both mobile and stationary phases is required; it is time-consuming, because several sequential separations are necessary in order to obtain sufficient amounts of C_{70} and other higher fullerenes, owing to peak tailing; and on-column degradation of C_{70} and higher fullerenes occurs (this phenomenon had been already described for PAHs). The preadsorption of fullerenes on alumina did not solve these problems.

A modification was introduced to overcome these deficiencies: the combination of Soxhlet extraction and LC on alumina, in which hot solvent was continuously recycled, allowed solvent consumption and labour to be reduced. However, the most inexpensive and efficient method for rapid separation of C_{60} and C_{70} involves an activated charcoal (Norit A) and silica gel mixture (1 : 2) as the stationary phase. As carbon

Oxidation and reactions with electrophiles	Oxygenation of C ₆₀ and C ₇₀	C ₆₀ O, C ₇₀ O and others isolated from fullerene extracts by preparative HPLC (neutral alumina)
	Thermal treatment of fullerene systems	Isolation of C ₁₂₀ O, C ₁₂₀ O ₂ , C ₁₈₀ O ₂ using Cosmosil Buckyrep® and PBB® in several steps, with <i>o</i> -dichlorobenzene, and toluene
	Bisosmylation of C ₆₀	Isolation of five regioisomers of C ₆₀ [OsO ₄ (t-bupy) ₂] ₂
	Asymmetrical osmylation of chiral C ₇₆ using chiral ligands (L*)	HPLC analysis of C ₇₆ [OsO ₄ L*] shows that two regioisomers are predominantly formed upon osmylation

compounds can adsorb fullerenes in a similar manner to alumina, silica gel is added to mitigate this effect. This system readily elutes C₆₀ (using toluene, at low pressure or even slight vacuum). By adding *o*-dichlorobenzene to the solvent system, gram quantities of both C₆₀ and C₇₀ can be purified and a fraction enriched in higher fullerenes collected, all in a single column pass.

Silica gel, in contrast, is not able to separate parent fullerenes on its own. However, column chromatog-

raphy on silica gel has occasionally been able to isolate pure C₆₀ and C₇₀ derived adducts from organic reactions (see Table 1). Likewise, silica gel has been used to separate PAHs cosynthesized during fullerene production.

Normal Elution Using Nonconventional Phases

γ -Cyclodextrin bound to silica gel, in HPLC mode, is mostly used for enantiomer separations. However, in the field of fullerenes, it has been used for separating

C_{60} from C_{70} . γ -Cyclodextrin is a cyclic oligosaccharide that forms complexes with fullerenes. The interaction of C_{70} with cyclodextrin is stronger than that with C_{60} , and both molecules can be separated, at analytical scale, even using *n*-hexane or *n*-hexane/toluene (70 : 30). However, the problem of fullerene solubility in these solvents has hampered further research on this stationary phase.

Bonded-Phase Sorbents

Octadecylsiloxane-bonded silica phases (C_{18}) have been used in HPLC mode for analytical-scale separations of fullerenes. Although *n*-hexane or *n*-heptane have been used as mobile phases, toluene has been mostly used, together with a counter solvent (e.g. acetonitrile, methanol) in variable proportions. Although the solubility of parent fullerenes is low in these solvent compositions in general, the use of toluene/acetonitrile provides adequate separation between C_{60} and C_{70} with selectivities (expressed as $\alpha_{C_{70}/C_{60}}$) near 2 for a 50 : 50 mixture. The use of toluene/methanol, in turn, shortens the analysis time in comparison with toluene/acetonitrile mixtures. Other profile phases, such as $CHCl_3$ /acetonitrile on CH_2Cl_2 /acetonitrile, have also proven suitable for separation of C_{60} and C_{70} .

Monomeric and polymeric C_{18} phases have also been used. They provide differences in retention for fullerenes. A 'topological' recognition ability of the polymeric phase has been invoked to explain these differences. Therefore, fullerenes would be separated as a function of their spherical diameters or their geometries in general.

Separations Using Charge-Transfer Stationary Phases

Considerable research has been carried out in developing supports that can provide strong interactions with fullerenes when using eluents that solubilize fullerenes. Charge-transfer chromatography is based on the donation or acceptance of electrons between the stationary phase and, in this case, the fullerene derivatives. The migration of fullerenes through the column is selectively retarded to a degree depending on the strength of the charge-transfer complex formed. Based on research on separation of PAHs, phases such as dinitroanilinopropyl silica (DNAP) or tetrachlorophthalimidopropyl silica (TCPP) were studied in the early 1990s. The latter presented adequate selectivity for C_{60} and C_{70} ($\alpha = 2.75$ in the best case).

Many of these phases, called Pirkle-type, have been synthesized and tested. In general, they are based on electron-deficient aromatic rings capable of simultaneous interaction with the spherical, electron-rich,

fullerene molecules. These phases afford greater interaction with fullerenes, thus allowing the use of toluene-based mobile phases.

In the second-half of the 1990s, several of these stationary phases became commercially available and are used now in many different types of fullerenes separations, at both analytical, semipreparative or preparative scale. Figure 2 shows, among other phases described in this work, the chemical structures of Buckyclutcher® (tri-(dinitrophenyl)-silica), Cosmosil PBB® (pentabromobenzyl-silica) and Cosmosil Buckyprep® (2-[(1-pyrenyl)ethyl]-silica). The Buckyclutcher column, developed by Pirkle, can be used in both normal and reversed phase mode. The capacity of this phase to separate fullerenes seems to be due, in addition to electron donor-acceptor interaction, to a steric effect created by a cone-shaped arrangement of dinitrophenyl groups.

High-capacity stationary phases containing condensed aromatic systems (e.g. Buckyprep®, 5-corononylpentyl-silica, COP) or heavy heteroatoms such as sulfur, chlorine or bromine (e.g. Cosmosil PBB®) showed high retentivity with excellent efficiency for separation of fullerenes, particularly Cosmosil PBB®. This phase allows the use of solvents providing high fullerene solubilities, such as CS_2 or 1,2,4-trichlorobenzene, for gram-scale separations with ordinary HPLC equipment. These solvents exceed toluene in solubility of fullerenes.

Although large aromatic systems were expected to show high fullerene retentivity according to electron donating-accepting the positive effect of heavy atoms is not correlated with the electron-withdrawing or donating properties and more research is needed on this point.

The use of the above-mentioned commercially available columns usually involves two or three steps in the process of separation, isolation and purification of fullerene derivatives. As an example, a typical scheme of proceeding may be a first step using an analytical Cosmosil PBB column® (with CS_2 , *o*-dichlorobenzene or 1,2,4-trichlorobenzene as eluents) and a second step using a preparative Buckyprep® or Buckyclutcher® column (e.g. with toluene). HPLC with these columns has allowed the identification, separation and/or isolation of endohedral metallofullerenes (e.g. $M@C_{74}$, $M@C_{60}$, $M@C_{70}$), fullerenes higher than C_{60} (e.g. C_{86} , C_{92} , C_{94} , C_{120}), odd-numbered clusters (e.g. C_{119}), products derived from fullerene oxidation (e.g. $C_{120}O$, $C_{120}O_2$, $C_{180}O_2$), and the separation of isomers (e.g. $C_{60}H_4$).

Tetraphenylporphyrin (TPP)-silica based stationary phase is another promising family for fullerene separation at both analytical and preparative scale. Figure 2 shows chemical structures of

Figure 2 Some charge-transfer stationary phase used for fullerene separation (for abbreviations, see text).

[5-(*p*-hydroxyphenyl)-10,15,20-triphenyl]porphyrin-silica (HPTPP) and [5-(*p*-carboxyphenyl)-10,15,20-triphenyl]porphyrin-silica (CPTPP).

These phases have demonstrated strong retention and unmatched selectivity in the separation of C₆₀ and C₇₀ using strong mobile phases such as

Table 2 Fullerene selectivity, expressed as $\alpha_{C70/C60}$, of different stationary phases, using toluene as the mobile phase, under similar conditions

Stationary phase	$\alpha_{C70/C60}$
Buckyclutcher	1.5
PBB	2.5
Buckyprep	1.8
CPTPP	5.7
HPTPP	7.0

1,2-dichlorobenzene or CS_2 . **Table 2** gives a rough picture of the influence under similar conditions of different stationary phases on fullerene selectivity, expressed as $\alpha_{C70/C60}$, using toluene as the mobile phase. Selectivity using toluene is the highest for all phases with regard to stronger eluents: $\alpha_{tol} > \alpha_{CS_2} > \alpha_{dichlorobenzene}$. Another important point for TPP-silica stationary phases is their potential for preparative-scale separations. This includes higher fullerenes. Owing to the usually low percentage of these kinds of fullerenes in the parent mixtures, their efficient separation using conventional or commercial phases becomes difficult and usually involves several reinjections, which are both solvent- and time-consuming. Currently, TPP phases present a good resolution in the separation of higher fullerene isomers in a single column pass, using strong eluents such as 1,2-dichlorobenzene, as shown in **Figure 3**.

Enantiomer Separation

Some charge-transfer stationary phases, such as (*R*)-*N*-(3,5-dinitrobenzoyl)phenylglycine or *R*-(–)[2-

Figure 3 Separation of higher molecular mass fullerenes on a 250 mm \times 4.6 mm column packed with HPTPP(4)-silica. Injection of 12 mg of fullerene soot; mobile phase = 100% 1,2-dichlorobenzene; flow rate = 0.85 mL min⁻¹; detection wavelength = 410 nm; ambient column temperature. (Reprinted from Coutant DE, Clarke SA, Francis AH and Meyerhoff ME (1998) Selective separation of fullerenes on hydroxyphenyl-triphenylporphyrin-silica stationary phases. *Journal of Chromatography A* 824: 147–157, with permission from Elsevier Science.)

(2,4,5,7-tetranitro-9-fluorenylideneaminoxy)propionic acid] (TAPA) bound to silica gel (see **Figure 2**), have been used for the separation of enantiomeric fullerene derivatives.

Taking advantage of the fact that (*R*)-*N*-(3,5-dinitrobenzoyl)phenylglycine (DNBPhG) was able to separate fullerenes, other chiral stationary phases were designed. A stationary phase derived from *S*-naproroxen (Whelk-O columns; see **Figure 2**) has provided successful separation of chiral fullerene derivatives (**Table 1**).

A strong charge-transfer interaction is necessary but on its own it is not a sufficient requirement for chiral discrimination. Both π -donor–acceptor interactions and one stereochemically significant interaction via hydrogen bonds are required.

TAPA-bounded silica gel has also been used for nonchiral separations (e.g. separation between C_{60} and C_{70}).

Size Exclusion Chromatography (SEC)

SEC is a molecular sieving technique that separates molecules according to their selective permeation into the gel pores on the basis of differences in their size in solution. Solute permeation into the gel increases with decreasing molecular size, resulting in later elution. By virtue of these particular characteristics of SEC, the total time of the chromatographic runs is previously known. This technique is also named GPC (gel permeation chromatography) when carried out using organic solvents.

SEC stationary phases consist of a gel, typically a three-dimensional network of cross-linked polymeric chains of controlled porosity. Compatibility between solvent and stationary phase is of prime importance. If the mobile phase is not suitable, gels can swell or shrink, often damaging the packing bed; this changes the pore distribution and hence the exclusion volume. SEC is therefore confined to isocratic elution using a limited range of pure solvents.

The differences in size between the fullerenes are sufficient to allow SEC separation. Because pure toluene can be used as the mobile phase (allowing fewer constraints for solvent recycling) and these columns have a greater lifetime than other LC columns (owing to the theoretical absence of interaction between the fullerenes and SEC stationary phase) it is possible to use SEC at preparative scale.

Polystyrene-divinylbenzene-based columns, from 10 to 100 nm pore size, have been used for fullerene separations. In spite of their low selectivity ($\alpha_{C70/C60} = 1.1$), the possibility of using automated systems with reinjection/sample collection and solvent recycling has allowed the separation of 10 g of

an extract (from production) a day, yielding C₆₀ with high purity. The relatively short time of SEC runs allows the frequency of injections to be increased with respect to other LC techniques.

This kind of automated system has also been used to separate and isolate metallofullerenes from empty cage fullerenes in sufficient amounts, despite their low concentration in the production mixtures (e.g. 200 mg of metallofullerenes isolated in 16 h).

However, the fact the C₆₀ is eluted before C₇₀ and other higher fullerenes, regardless of the mobile phase used (e.g. toluene, CHCl₃), means that solutes are not separated according to their size. Non-size effects (due to adsorptions and other types of interactions) have been described in the case of other relatively small molecules (e.g. PACs) with relative molecular masses lower than 1000.

Further Trends

Research is now focused on finding more selective stationary phases (mainly based on charge-transfer chromatography) to improve fullerene separation. An efficient method for separating individual fullerenes on a large (preparative) scale is still required. Most of the separation methods reported here are limited to gram scale. This has hampered the study of higher molecular mass fullerenes.

FUNGICIDES

Gas Chromatography

José L. Bernal, Department of Analytical Chemistry, Faculty of Sciences, University of Valladolid, Valladolid, Spain

Copyright © 2000 Academic Press

Fungicides, a class of pesticides, are toxic substances that are used to prevent or kill the growth of fungi which are hazardous for plants, animals and human beings. Most fungicides for agricultural use are fumigated or sprayed over seeds, leaves or fruits to control and avoid a variety of economically important fungal

diseases. The first fungicide of proven efficiency was the Bordeaux mixture, developed in 1882. This is a mixture of lime and copper(II) sulfate that has been used for a long time; nowadays a wide variety of compounds are used in a more selective way to fight specific fungi in specific plants. It is necessary to pay attention to their environmental impact (on water, the atmosphere, soil and food) and also to their presence in vegetables which are intended for direct human consumption. Among the important fungicides are those which are applied in greenhouses and in wine production.

There are two options for fungicide analysis: the determination of the composition of formulations, where the concentrations are relatively high, and the

evaluation of residues which appear after their use. Theoretically, it is assumed that the correct use of fungicides does not imply problems with residue because they should always be applied at nonhazardous levels. New pesticides are being developed with the aim of greater efficiency and lower environmental risk.

In formulation analysis there are not many analytical problems. In most cases high performance liquid chromatography (HPLC) is successfully applied. In some cases UV-Vis spectrophotometry or gas chromatography (GC) is used. In contrast, residue determination presents serious problems not only because it is focused on trace levels but also because the compound is usually found with other compounds or degradation products, and in a matrix that can present problems. This implies that the analyst must pay attention to all the steps in the analytical method from sampling to the interpretation of results. According to the problem the analyst will choose the best technique. This choice will affect other steps, especially which sample treatment is selected to achieve the lowest quantity of possible interference, good reproducibility and high recoveries. Sensitivity and selectivity always appear as opposed criteria, so it is necessary to balance the chance of a better signal-to-noise ratio against the risk of incompletely determining all the residues present.

There are three types of required analyses: the global determination of a group of compounds, e.g. ethylenbis(dithiocarbamate) (EBDCs); individual determinations; and, separation and quantification of chiral compounds. The method of analysis will vary according to the objective.

Table 1 summarizes common fungicides. The trend is to use several compounds of the same or a different chemical family, with the aim of achieving several modes of action over the development of the fungi. Because of this, a number of methods are devoted to the determination of several compounds in the same sample. Not all fungicides are shown in the table: inorganic materials such as sulfur, borax, mercury salts, arsenic and copper salts have been omitted. Recently developed compounds whose efficacy has not yet been proved or which are not registered in many countries, or whose mode of action is still unknown, are also omitted. As can be observed, there are a number of chemical families, the most important being phthalimides, benzimidazoles, dicarboximides, carbamates, sulfamides, anilinopyrimidines and phenylpyrrols. The nitrogen atom is common to all of them. In several cases there is a halogen atom and in fewer cases, sulfur or phosphorus atoms are included.

Technique Selection

Chromatographic techniques are the common choice for determining pesticide residues, and among them GC is useful for analysing organochlorine and organophosphorus residues because they have good thermal stability, they are volatile and they have a strong hydrophobic character. That this is valid for a great number of fungicides can be appreciated by the entries in the last column in **Table 1**. Nevertheless the thermal instability of some groups – EBDCs and benzimidazoles particularly – make the use of HPLC more appropriate, although it is also possible to produce derivatives that allow their determination by GC.

Column

Due to the large range of polarities of fungicides, it is difficult to select just one specific column, but many compounds can be separated using the mid-polarity columns. In several official methods for fungicide, glass columns (185 cm × 4 mm i.d.) packed with OV-101 or similar, on Chromosorb WHP (80–100 mesh) are still recommended, although nowadays fused silica open tubular capillary columns (FSOT) are preferred with lengths up to 60 m, inner diameter 0.2–0.7 mm and film thickness between 0.15 and 0.5 μm (DB-35, DB-1301, DB-1701 or similar). In commercial catalogues or application notes, many examples of fungicide separations are shown, together with the main chromatographic conditions and the equivalence between the different manufacturers.

Detectors

From the molecular formulae shown in **Table 1**, it is clear that the use of a nitrogen–phosphorus detector (NPD) is advantageous, although it is not as stable as the flame ionization detector (FID) and because of that it must be calibrated frequently. The electron-capture detector (ECD) is useful for many compounds, but in several cases, the co-extracted compounds can interfere with its response. As there are fungicides that have S and/or P atoms, the flame photometric detector (FPD) is also useful. Confirmation of identity can be obtained using two columns, one a 5% phenyl 95% methylsilicone bonded-phase column coupled to ECD and NPD and the other a 50% phenyl 50% methylsilicone column coupled to ECD and FPD. Such a system is very versatile and sensitive, allowing easy identification of the eluted compounds. Nevertheless, the best option to confirm compound identity is the use of coupled techniques such as gas chromatography–mass spectrometry (GC–MS); the specificity of GC–MS provides low

Table 1 Chemical group, molecular formula and recommended method of residue analysis of the most common fungicides

<i>Fungicide</i>	<i>Chemical group</i>	<i>Molecular formula</i>	<i>Method for residues</i>
Anilazine	Triazine	C ₉ H ₅ Cl ₃ N ₄	GC, HPLC

Fungicides which appear in **bold** are those which are used most widely. (Reproduced from Jiménez JJ, Bernal JL, del Nozal MJ, Toribio L and Martín MT (1998) *Journal of Chromatography A* 823: 381–387, with permission from Elsevier Science.)

detection limits and unambiguous spectral confirmation in complex matrices.

Taking into account that the presence of heteroatoms is common, it is also possible to use the atomic emission detector (AED) to monitor characteristic wavelengths. Monitoring the emission lines for elements such as nitrogen, chlorine, phosphorus and sulfur ensures specific chromatograms for those elements, increasing the selectivity, which is especially desirable when dealing with environmental and food samples.

Multiresidue Methods

Multiresidue methods are desirable for the determination of specific components in samples of unknown origin or those which have been subjected to unknown pretreatments. Unfortunately, nitrogen-containing pesticides have been poorly investigated in comparison to the halogen- or phosphorus-containing pesticides as regards their possible combination in multiresidue methods. Nevertheless, there are several methods in which the behaviour of some fungicides is considered; some include up to 20 different fungicides. This type of research commonly relies on the use of more than one type of capillary column for the separation of broad groups of pesticides; usually the main column has a low polarity stationary phase, employing another one of mid or high polarity as a confirmatory column. The detection can be made directly or after derivatization, and using either a single or several detectors (ECD, NPD, FPD, AED, MS).

The use of the AED for multiresidue analysis partially overcomes some of the problems derived from

poor resolution between compounds, as does GC-MS. However, many laboratories cannot afford GC-AED or GC-MS because they are more expensive than other options.

Practical Considerations

According to the aim, a technique will be selected, as mentioned before and this will determine the prior steps in the method. There are always some general recommendations, such as the need to employ standards and surrogates, whose addition (spiking) gives recoveries (which should be higher than 80%). The use of solvents of adequate purity is necessary; each batch must be tested for a potential source of interference; at the same time all glassware must be adequately cleaned. Apart from these general precautions, it is necessary to be aware of the importance of other aspects that have a notable influence in the analysis of fungicide residues. Some are summarized here.

Standards

One of the first and most important steps in fungicide residue evaluation in food and environmental samples is the correct preparation of standard solutions, preferably from solid reagents of certified purity, because of their low stability in solution. For example, Imazalil solutions are sensitive to light; Fosetyl residues decompose during storage at -18°C . It is very common for derivatives to not last more than 24 h in a refrigerator; the stability should be checked for longer storage times. It has also been demonstrated

that the amount of fungicide residue in food is influenced by storage, handling and processing.

Sample Treatment

The sample may be simple or very complex; this will clearly have a great influence on the sample treatment. Isolation of the compounds using an extraction technique frequently needs a further clean-up step before determination. There are a great variety of possible approaches, from classic liquid-liquid extraction (LLE) to the use of supercritical fluids (SFE), and offline or online procedures.

Liquid-Liquid Extraction

There are many methods based on the use of a separating funnel, drying over anhydrous sodium sulfate and clean-up; Soxhlet extraction is also employed.

The commonly used solvents are ethyl acetate, acetonitrile, methanol, dichloromethane, acetone and *n*-hexane. Frequently, phase separation is hindered by emulsion formation in the separatory funnel, in which case filtration through a loose glass wool plug may be appropriate or another extraction procedure may be more suitable.

It is usual to find anomalous results for Vinclozolin, Captan, Folpet and Iprodione when LLE is used.

Solid-phase Extraction (SPE)

The laborious liquid-liquid partitioning clean-up procedures described in the literature have been re-

placed by fast SPE clean-up, with the additional advantage of a high enrichment factor.

The most recommended phase is octadecylsilane, although for some groups, the diol or cationic exchange phases may be better; graphitized carbon black is also a possibility nowadays. Florisil is frequently used to remove co-extractive interferences. When this is not sufficient, further clean-up can be achieved by gel permeation chromatography.

Solvent selection for recovery of fungicides from cartridges is very important. The results vary for individual compounds. **Figure 1** provides an example of the recovery of different fungicides and acaricides from the analysis of must samples.

In all cases it is necessary to optimize the type of sorbent, sorbent mass, flow rate, sample volume, pH, ionic strength, drying time and soaking time. Sometimes the complete elution of the compounds from the disposable extraction column requires several portions of eluting mixture instead of only one. It is well known that, for conazole fungicides and Captan, low recoveries are obtained because the sample volume and flow rate of extraction seriously affect the recoveries.

In the analysis of modern fungicides, extraction with methanol, partitioning with chloroform, purification of the extract by column chromatography on sodium sulfate/Florisil/celite/charcoal is often recommended.

In the multiresidue methods acetonitrile is usually preferred, with SPE offline using C₁₈ or polymeric cartridges, followed by GC-MS. This gives better

Figure 1 Recovery of pesticides from 500 mL of synthetic sample spiked with $4 \mu\text{g L}^{-1}$ by octadecylsilica cartridges eluted with 2 mL of solvent. (Reproduced from Bernal JL, del Nozal MJ, Jiménez JJ, and Rivera JM (1997) *Journal of Chromatography A* 778: 111–117, with permission from Elsevier Science.)

results than online HPLC-diode array detection (DAD) which has drawbacks for trace level determination as a result of many interferences.

In water analysis, SPE on disc (C_{18} Empore) gives good results and it has been successfully applied to the determination of fungicide residues, but in Vinclozolin determination errors are obtained, with the major losses occurring when the fungicide was collected from the surface of the disc.

Solid-phase microextraction is also useful for the analysis of fungicide residues in water samples, although in complex matrices it gives low reproducibility, which suggests that it is only useful for semiquantitative purposes. In addition, the duration of the process in relation to other extraction procedures can seriously limit its application to large numbers of samples. The extraction conditions – stationary phase, time, temperature, type and concentration of compound and matrix – must be taken into account. In Vinclozolin and Captan residue analysis on semi-solid spiked samples, lower recoveries are obtained when the amount added increases.

To prevent degradation or hydrolysis of certain fungicides (e.g. benzimidazoles), sometimes other extraction techniques such as those based on the use of pressurized hot water or supercritical CO_2 are recommended; even a cloud point preconcentration has been used, nevertheless, these procedures are not common as yet. The importance of sample preparation on the final chromatogram is seen from

Figure 2 Chromatograms by EI-MSS (scan mode) for Vinclozolin residues in a larvae extract. (A) Hexane–acetone (70 : 30, v/v); (B) SPE. (Reproduced from Bernal JL, del Nozal MJ, Rivera JM, Jiménez JJ, and Atienza J (1996) *Journal of Chromatography A* 754: 507–513 with permission from Elsevier Science.)

Figure 2; it can be observed that SPE gives the simplest chromatograms.

Matrix Effects

GC analysis for fungicides frequently presents considerable errors due to the so-called matrix effect which has been described in the analysis of diverse compounds in wine, grape juice, honey, milk, butter, fruits and vegetables. This effect is explained by a higher transference of analytes from the injection port to the chromatographic column either as a result of the presence in the extract of associated carrier substances from the matrix or of a protective effect in the injection port performed by these substances.

The matrix effect is usually greater for lower quantities of analyte, as can be seen in **Table 2**, where some data for common fungicides are shown. The recovery can also be influenced by the total amount of sample (**Table 3**). From both tables it can be deduced that serious errors can arise when the effect is not considered.

Once the sample preparation has been checked, attention must be paid to calibration. To reduce quantitative errors from the matrix effects, a standard addition method or an external standard calibration with standards dissolved in an unspiked sample extract can be used. The use of two or more certified reference materials to establish a calibration curve can help recognize matrix effects. If the measurement shows the same slope with the regression, it can be concluded that the matrix has no dominant influence.

In general, an analyte addition method (AAM), a sample variation AAM (varying the test sample mass and keeping the added analyte amount constant) or, better, a sample and analyte variation AAM must be used for calibration.

The Analysis of Various Fungicide Groups

Phthalimides

Captan, Captafol, Folpet There are several methods devoted to the analysis of residues of these compounds. Usually an extraction with *n*-hexane–acetone mixtures is carried out; after drying with sodium sulfate and evaporating the solvent, *n*-hexane is added. This is followed by clean-up on a Florisil cartridge, eluting it with an *n*-hexane–acetone mixture, evaporating and dissolving the residue in toluene and injecting an aliquot of the solution into the GC.

To prevent hydrolysis, cloud-point preconcentration employing the nonionic surfactant Triton X-114 has been proposed.

Table 2 Recovery (%) of some fungicides from honey samples, after conventional solvent extraction, spiked at different levels (average seven determinations)

Fungicide	0.025 mg kg ⁻¹	0.125 mg kg ⁻¹	0.25 mg kg ⁻¹	1.0 mg kg ⁻¹	2.5 mg kg ⁻¹
Captan	1028	329	165	99	99
Folpet	2380	321	164	108	107
Iprodione	948	405	350	259	174
Vinclozolin	647	335	250	209	171

Captan and Captafol tend to decompose on columns that have been in use for some time. To avoid decomposition removal of the glass wool from the inlet of the GC column is recommended.

Benzimidazoles

Benomyl, Carbendazim, Thiabendazole, Thiophanate methyl This group is usually analysed by HPLC; nevertheless there are GC-MS methods using acid hydrolysis, re-extracting the amine and forming the *tert*-butyldimethylsilyl derivatives.

Carbendazim is a fungicide and the main metabolite for Benomyl, both of which are widely used on vegetables intended for direct human consumption. Methods usually provide residual levels in terms of Carbendazim because Benomyl degrades rapidly. To analyse Carbendazim by GC, the compound is usually extracted with ethyl acetate and derivatized with pentafluorobenzylbromide. After clean-up on a silica column, the product is determined by GC-ECD or GC-NPD.

Dicarboximides

Chlozolate, Iprodione, Procymidone, Vinclozolin

These compounds are frequently included in multi-residue methods and in many applications a significant influence of the spiking levels on recovery is observed. The most used techniques are GC-FID, GC-ECD and ion trap GC-MS in multiple ion-monitoring

Table 3 Recovery of Vinclozolin from honey and larvae samples, spiked with 25 mg kg⁻¹, by solvent extraction with hexane-acetone at different proportions and octadecylsilica clean-up ($n = 5$) (Reproduced from Bernal JL, del Nozal MJ, Rivera JM, Jiménez JJ, and Atienza J (1996) *Journal of Chromatography A* 754: 507-513, with permission from Elsevier Science.)

	Honey		Larvae
	1 g	5 g	1 g

Hexane-acetone (80 : 20, v/v)	81	82	78
Hexane-acetone (70 : 30, v/v)	99	98	95
Hexane-acetone (60 : 40, v/v)	99	98	96
Acetone (100)	99	98	95

mode, with detection limits in the range of p.p.b.-p.p.t.

These fungicides are frequently investigated in wine analysis where it is known that the recovery not only depends on the concentration level but also on the variety of wine; attention must be paid to their metabolites, mainly those belonging to the 3,5-dichloroaniline group.

Triazole

Bitertanol, Triadimefon, Triadimenol, Tricyclazole Usually they are analysed by GC-NPD and GC-MS in the selected ion monitoring mode. Triadimefon is easily reduced to Triadimenol, so both appear together.

Bitertanol and Triadimenol have diastereoisomers that cannot easily be separated; depending on their relative proportion they frequently produce peaks with shoulders.

Dithiocarbamate fungicides

These are habitually classified into three families of compounds depending upon their structure:

1. Dimethyldithiocarbamates (Ferbam, Ziram, Thiram)
2. Ethylenebisdithiocarbamates (Mancozeb, Maneb, Zineb, Nabam)
3. Propylenedithiocarbamates (Propineb)

It is very difficult to isolate and determine specifically the fungicides which belong to the same family due to the fact they possess the same organic moiety. Thus, the typical determination of these compounds is carried out as a group, performing an acid hydrolysis to carbon disulfide which is then quantified by techniques such as headspace GC-ECD.

When an FPD is used to detect CS₂, *n*-hexane must be avoided because it may co-elute, resulting in the quenching of the S emission in the detector.

EBDCs differ chemically from dithiocarbamates because they have reactive hydrogen on the nitrogen atom, which reduces their stability and results in different biological behaviour. One of the most characteristic decomposition products is ethylenethiourea (ETU). GC determination of ETU can only be achieved after derivatization, forming

trifluoroacetylated *S*-benzyl or butyl ETU derivatives that can be analysed by GC-NPD, GC-ECD or GC-MS. In real samples EBDCs and ETU content decrease with storage time. To prevent this, the addition of cysteine hydrochloride has been recommended.

Introduction

There are some groups of fungicides of wide use (benzimidazoles, ethylenebisdithiocarbamates) whose thermal instability, high polarity and low volatility make them difficult to determine by gas chromatography (GC) unless derivatization methods are employed. This usually makes the process longer and introduces new errors. These compounds are easily measured by high performance liquid chromatography (HPLC) as are many pesticides that were typically analysed by GC in the past. Integrated systems of solid-phase extraction sample cleanup and on line HPLC allows multiple options, not only by including fungicides of very different polarity in the same analysis but also by achieving very high concentration factors and, at the same time, analysing a large number of samples. The use of pre- or post-column derivatization reactions allows the analysis of compounds that are very difficult to determine or have a low sensitivity.

Given these advantages HPLC not only complements GC in fungicide residue analysis but is

tending to displace it for many applications. Some considerations related to the use of HPLC are summarized below, with more attention being paid to the groups of fungicides most frequently determined by this technique.

Technique Selection

Most applications are based on the use of reversed-phase HPLC, nevertheless for some fungicides ion-pair HPLC (ethylenebisdithiocarbamates) (EBDC), micellar HPLC (Thiram) or chiral HPLC (Metalaxyl) are used. Normal phase HPLC, with amino-bonded stationary phases, is sometimes recommended, mainly for the benzimidazole group.

Chiral HPLC is very important for the determination of enantiomeric purity, mainly for large-scale synthesis. Resolution of C-chiral enantiomers seems to be easier than that of axial-chiral enantiomers (atropoisomers).

Columns

The most widely used stationary phases for fungicide residue analysis are the *n*-octyl and *n*-octadecylsilica because they allow the separation of compounds with a wide range of polarity. Some fungicides, mainly EBDCs, are easily ionized and because of this some

methods propose the use of ion-exchange phases. It may, however, be better to use C_{18} in the ion-pairing mode, adding a counter ion to the mobile phase. When it is necessary to separate enantiomers, then chiral columns are preferred although there is also the possibility of using the C_{18} with a chiral mobile phase.

Usually columns with a diameter of 4.6 mm, packed with 5 μm material are employed, but nowadays it is possible to use shorter columns or even narrow bore, microbore or packed capillary columns. These later make the coupling to an MS detector easier. In both cases the lower mobile phase flow rate provides a big reduction in reagent consumption.

Several manufacturer's offer equivalent columns. Attention must always be paid to batch-to-batch reproducibility. The use of a pre-column helps to preserve the life of the column, and, if it is possible to work at room temperature, the column will last longer than when used with higher temperatures.

Mobile Phase

The selection of the stationary phase and the mode of detection is determined by the characteristics of the analytes to be separated; both, also, control the selection of the mobile phase. As C_{18} is usually employed, the mobile phase is frequently composed of a mixture of water with an organic solvent, mainly methanol or acetonitrile. To improve the peak shape or to separate compounds with acidic or basic character the addition of acid or buffer to vary the pH can be very useful. Also the temperature at which the separation is made, must be established when looking for the best resolution. The reagents used to prepare the mobile phase must be compatible with the detection mode. It is very important when a UV detector is used, because not all commercial methanol or acetonitrile are transparent enough in the low UV region. Attention must be paid to the transmission spectrum of the solvents and to the changes in batch or manufacturer. When there is a great difference between the polarity of the (aqueous) mobile phase, and the organic solvent used to inject the sample, it is possible that the first peaks will be distorted and in this case it is better to reconstitute or dilute the sample in the mobile phase.

Detection

Most of the fungicides that are analysed by HPLC can be detected in the UV region. In multiresidue methods it is more convenient to employ a diode array detector (DAD) which allows multiple wavelengths to be employed and peak purity to be checked.

The fluorescence detector gives higher sensitivity and selectivity, so it is preferred for residue analysis (e.g. benzimidazoles, bitertanol). It is also possible to programme the excitation and emission wavelengths to optimize the signal for all eluted compounds.

Occasionally the use of an electrochemical detector is recommended (Phthalimides, Thiram, Disulfiram, etc.); although it gives great sensitivity, it is more difficult to operate, and frequently the electrodes are contaminated; sometimes, for example for EBDC determination, it is coupled on-line after the UV detector.

Nowadays there is an increasing trend to MS detection but some difficulties are still encountered when coupling it to HPLC. It is advisable to use micro-HPLC and avoid, if possible, the presence of salts in the mobile phase. This, in addition to its high cost, means that only a few applications of its use to fungicides have been published.

Derivatization

A very useful option, in HPLC, is derivatization made pre- or post-column, which facilitates compound detection. A great number of derivatizing reagents lead the formation of products with a high absorbance or fluorescence, and in fungicide analysis they are often used in post-column reactions but care is needed to minimize band broadening, particularly for slow reactions. The present use of solid phase reactors has several advantages such as the simplicity in the instrumentation and compatibility with most mobile phases. A clear example is the monitoring of the carbamate pesticides.

As pre-column derivatization can be carried out with an automatic injector and post-column derivatization can be automated with modern devices, this facilitates improved precision.

Sample Treatment

Many applications of fungicide determination require a preliminary sample extraction using an organic solvents such as ethyl acetate followed by clean up by liquid-liquid partitioning. Obviously, the matrix has a great influence on the method. The heavy pigment content in many crops and vegetables has made the popular UV detector almost unusable; even when analysing fungicides in, for example, citrus, celery heart, mint and coriander. A large amount of fluorescent coextractives can appear, causing inference in detection. In these cases the sample treatment must be optimized, including for example a clean up with Florisil or changing the mobile phase polarity, so the coextracted interference elutes together with the solvent front. If the sample preparation step can be

carried out using solid-phase extraction, this favours direct coupling to HPLC and overall automation, facilitating routine multiresidue analysis.

Analysis of some specific fungicide groups

Phthalimides (Captan, Captafol, Folpet)

For formulation analysis extracting the compound with diethylphthalate in methylene chloride and chromatography on silica gel using degassed CH_2Cl_2 as mobile phase is recommended while for residue analysis GC is usually preferred. Nevertheless, recently an isocratic HPLC method using electrochemical detection with single and dual glassy-carbon electrodes has been evaluated, showing good recoveries and precision and with detection limits of about $4 \mu\text{g L}^{-1}$.

Benzimidazoles (Benomyl, Carbendazime, Thiabendazole, Methyl Thiophanate)

The high use of these post harvest fungicides means that many methods have been proposed for the determination of their residues.

It is possible to evaluate the total content (benomyl, carbendazime, methyl thiophanate) by transforming them into carbendazime, by refluxing at $\text{pH} = 6.8$. Multiresidue methods have been proposed, extracting the sample with HCl and analysing on LiChrosorb Si 60. Recently a clean up on strong cation exchange cartridges and analysis on C_{18} with UV and water-acetonitrile as mobile phase has been proposed, although ion-pairing HPLC coupled to UV or fluorescence detection can be used. Normal phase HPLC for carbendazime can be employed after extraction with methanol, partitioning in n-hexane-dichloromethane and fluorescence detection at 285/315 nm. Nevertheless, the majority of the proposed methods are devoted to the study of the pair benomyl-carbendazime, using reversed-phase HPLC.

This pair of compounds is normally analysed by monitoring carbendazime, although using light petroleum ether and a special drying step it is possible to analyse benomyl without conversion to carbendazime. The analysis involves an extraction with an organic solvent (methanol, ethyl acetate or acetone) followed by partitioning with n-hexane or an alkaline solution, using C_{18} columns and UV detection at 224 nm or better by fluorescence at 285/317 nm. The type of matrix, even quite similar ones, strongly conditions the sample preparation. In Figure 1 some schemes for the determination of carbendazime in apian samples are shown. In the case of pollen an additional partition with n-hexane is required be-

cause of the intense colour of the extracts. As is shown, pollen or beeswax are better extracted with methanol because ethyl acetate extraction gives an emulsion that makes the separation difficult. Another problem that must be taken into account is the influence of the fortification level on the carbendazime-benomyl recoveries. Thus when analysing vegetable samples, higher fungicide concentrations added to the samples results in lower recoveries, even for smaller samples. With samples bigger than 2 g, problems also appear because the pigments are extracted, giving a greenish-yellow colour and therefore the determination of carbendazime is hindered. Some relevant data are shown in Table 1.

Thiabendazole has also received special attention. Several HPLC methods have been proposed for its determination, usually employing ethyl acetate as extractant and C_{18} columns and acetonitrile-water or methanol/aqueous buffer mixtures as mobile phases. A mixture of n-hexane/ethanol/0.2 N HCl, with cation exchange columns or ion pairing HPLC has also been used. Detection can be made by UV (298 nm) although usually fluorescent detection is preferred. Changes in the extractant or of the chromatographic parameters require selection of the wavelength to achieve the best sensitivity. The use of several wave-lengths, mainly the couples 285/350 nm and 305/345 nm have been proposed. In some cases, the metabolite 5-hydroxythiabendazole has also been determined.

Dicarboximides (Iprodione, Vinclozolin)

There are not many HPLC methods to determine residues of these fungicides. Vinclozolin is perhaps the most frequently used compound and so, some methods have been proposed for its analysis, and of its metabolite (3,5-dichloroaniline) using reversed-phase HPLC with UV detection. In complex mixtures analysis it has also been proved that SPE cartridges are more selective than extraction with organic solvents and they provide simpler chromatograms.

Triazoles (Bitertanol, Triadimefon, Triadimenol, Tricyclazole)

Residues of Triadimefon and its metabolite Triadimenol are seldom determined by HPLC, but they can be analysed by reversed-phase HPLC on C_{18} columns with UV detection. The same stationary phase is recommended for Bitertanol, with acetonitrile-water as mobile phase and fluorescent detection at 254/322 nm. The selection of the extracting solvent (acetone/water, acetone, methanol) is very important in order to achieve high recoveries. If a cleanup is required, SPE on C_{18} cartridges eluted with cyclohexane-ethyl acetate seems to be the most adequate.

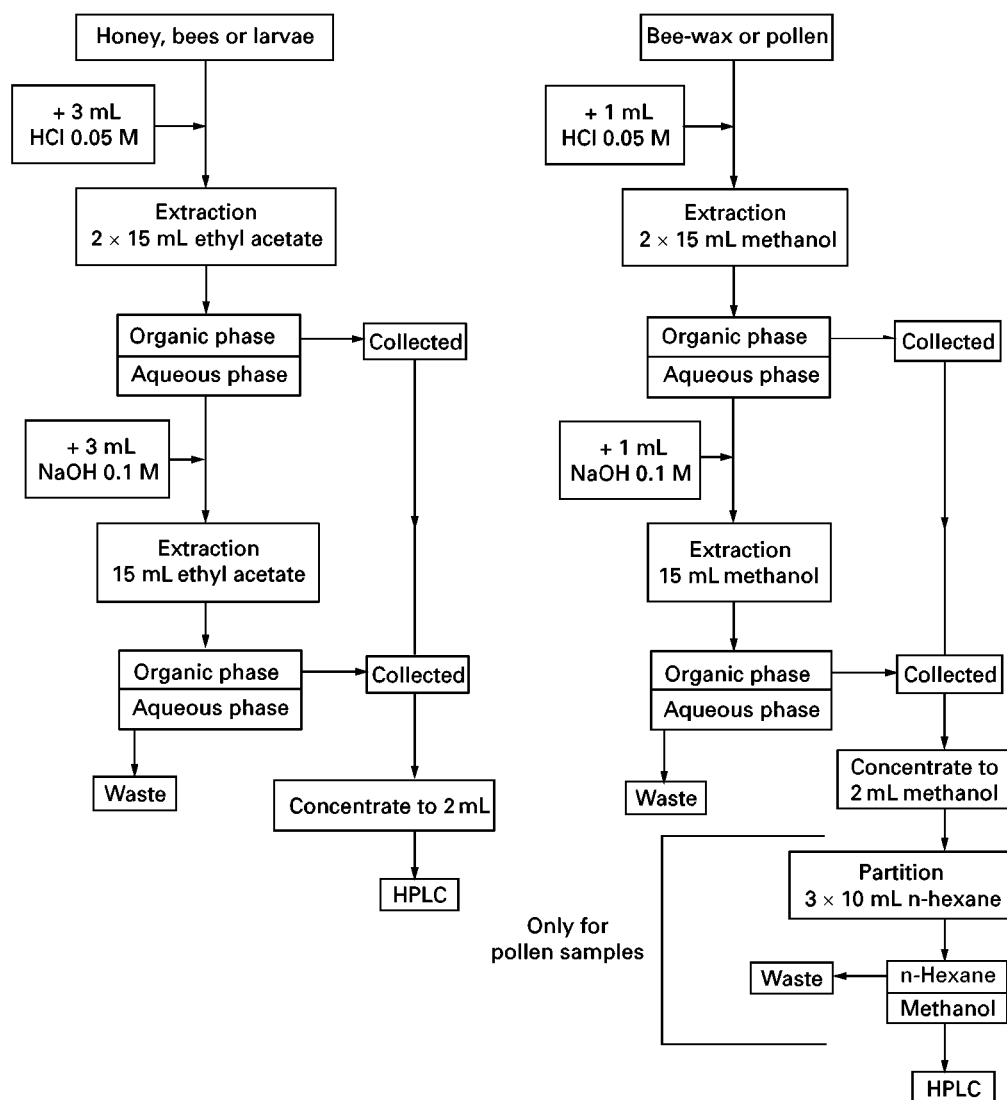

Figure 1 Flow charts showing the sample preparation procedures used in the analysis of carbendazime in apian products. (Reproduced from Bernal JL, del Nozal MJ, Toribio L, Jiménez JJ and Atienza J (1997) *Journal of Chromatography A* 787: 129–136, with permission from Elsevier Science.)

Dithiocarbamate fungicides

The US Food and Drug Administration (FDA) has recommended the evaluation of new uniresidue methods for the analysis of dithiocarbamates in vegetables, because of problems which have arisen from the application of the carbon disulfide method. This lacks specificity because naturally occurring carbon disulfide and degradation products of the EBDCs, such as dialkyldithiocarbamate and thiram disulfide, can give serious interference.

EBDCs have little or no solubility in water and, because of this, in many methods the compounds are converted into their soluble sodium salt by means of EDTA and subsequently hydrolysed to form carbon disulfide, but if the hydrolysis is not carried out the

final product is the fungicide Nabam. This is water soluble so some methods are based on this transformation. On the other hand, ethylene thiourea (ETU), ethylene urea and 2-imidazoline are decomposition products of the EBDCs. The parent compounds have a relatively low toxicity but ETU has been demonstrated to be goiterogenic, carcinogenic and teratogenic, so there is a great interest in determining this compound.

To analyse ETU by HPLC an extraction with methanol, a clean up on a mixture of sorbents and a mobile phase of ethanol–isooctane has been frequently used. The detection can be electrochemical or by HPLC/MS, with similar detection limits. Extraction of ETU from vegetables is preferred with methanol and analysis on a CN column, with a mobile phase of

Table 1 Recovery of carbendazime obtained by using an SFE-hplc procedure on spiked lettuce samples ($n = 5$). (Reproduced from Jiménez JJ, Atienza J, Bernal JL and Toribio L (1994) *Chromatographia* 38: 395–405, with permission from Vieweg-Publishing.)

methanol in chloroform/cyclohexane and detection at 240 nm. Another possibility is to extract ETU and react it with dihaloquinones to produce a yellow derivative that can easily be detected at 385 nm.

There is always a problem with fungicide determination because they are very similar in chemical structure and behaviour. Ferbam and Ziram have the same organic moiety and the difference is in the metallic ion. Nabam, Maneb, Zineb, Mancozeb and Propineb, frequently used in agriculture, have in com-

mon the ethylenebisdithiocarbamate group and therefore it is very difficult to separate them from their mixtures. So in some situations it is easier to determine the residue of only one fungicide. Another approach is to try to separate mixtures of three fungicides belonging to different chemical groups and the third and most difficult one is to try to separate all of them.

Some methods attempt to distinguish between compounds using both HPLC and atomic absorption methods. This can cause problems because in EBDC manufacture there is always an excess of the metallic ion that has not been incorporated into the compound, so if the extraction of the compound is not specific, the extract will contain not only the metal belonging to the fungicide but also the remaining metal coextracted. As a consequence, atomic absorption data are usually very much higher compared with those from HPLC.

To analyse individual fungicides, transition metal salts are frequently employed as ion-pairing reagents for reversed-phase HPLC with detection in the UV region. According to the complex used the wavelength selected is obviously different, so for Ziram, Maneb and Zineb forming as 1:1 Cu(II)-dithioligand the wavelengths are in the 260–287 nm range, with detection limits at the nM level.

Sometimes the problem arises of the presence of Thiram and Disulfiram which could interfere with the dithiocarbamate determination. This situation is usu-

Figure 2 Post-column derivatization reaction for EBDCs.

Figure 3 Chromatogram of a mixture of EBDCs. $1 \mu\text{g L}^{-1}$ each. Detection of 254 nm. Mobile phase: EDTA/MeOH/AcCN (60 : 13 : 27, v/v).

ally solved by using HPLC on a C_{18} column with electrochemical detection or by determining Thiram using micelles of CTAB in the mobile phase, so Nabam, Ziram and Ferbam do not interfere.

Nabam determination is of interest because EBDC fungicides can be converted into this fungicide and so they can be indirectly determined. In this case there is a method, very similar to one devoted to carbamate residues determination, based on a post-column reaction through an acid hydrolysis to form ethylenediamine that is afterwards fluorogenically labelled with *o*-phthalaldehyde-mercaptoethanol and detected at 356/450 nm. The scheme of the post-column reaction is shown in **Figure 2**.

Attention must be paid to carrying out the separation at the lowest possible temperature. The hydrolysis temperature must be considered because when the temperature is near 100°C the possibility of more by-products and background noise increases, and OPA degrades easily at higher temperatures. Separation of Nabam is carried out by micellar HPLC with a mobile phase of cetylpyridinium (CPC) phosphate buffer/acetonitrile.

The real problem is the difficulty to convert quantitatively EBDCs into Nabam and recoveries lower than 30% are usually obtained although if EDTA is used, the conversion is favoured. Thus a simpler method has been proposed based on the transformation into Nabam by means of an aqueous EDTA solution, followed by reverse-phase chromatography on an NH_2 column with acetonitrile-methanol and

detection at 272 nm. However, the lifetime of the column is only about 15 analyses.

A good separation between compounds of the three families (EBDC, PBDC and DMDC) can be obtained using reverse-phase HPLC on a C_{18} column, with a mobile phase of EDTA 0.05 M, pH = 7.7, and detection in series (UV at 280 nm and amperometric at 400 mV), but it is not possible to distinguish between compounds of the same group.

A method that allows the separation of five compounds (see **Figure 3**) uses ion-pair HPLC with tetrabutylammonium bromide as counterion on C_{18} columns, with a mobile phase of EDTA/methanol/acetonitrile and detection at 254 nm. However, there are still some problems because the separation is strongly dependent on the analyte concentration, achieving only the overall separation for very low concentrations.

As a conclusion, it can be said that the analysis of these fungicides is very difficult when there are several of them in the sample and that further work is necessary.

Techniques

Moving Boundary Method

Migrating boundaries can be observed using a cell like that shown in Figure 1.

Flat Bed Methods

Electromigration in a support to eliminate convection is carried out much as in normal electrophoresis,

Figure 2 Apparatus for zone electrophoresis in molten salts. except that here evaporation is negligible and high temperatures are used to keep the molten salt liquid. **Figure 2** shows a typical apparatus. It can be made of glass or fused silica. Glass fibre paper is mainly used as the support material with this apparatus, but it lends itself equally well to electrophoresis on asbestos sheets. This kind of apparatus is best housed in an oven, as shown in **Figure 3**. Here provision is also made to circulate a gas to remove gaseous electrolysis products such as chlorine.

Supports

Asbestos paper and asbestos sheets were initially employed as supports; then glass fibre papers became available (e.g. from Whatman). These papers must be washed to removed impurities and are rather

fragile, requiring careful handling. Some authors recommend converting the surface silanol groups to salt forms, e.g. by dipping into 4–6 mol L⁻¹ KNO₃ at pH 8–9, otherwise the melt does not wet the glass fibre paper.

Powdered thin layers for electrophoresis are made by spraying aqueous suspensions of ceramic oxides onto sintered ceramic strips.

Column electrophoresis is carried out in columns of glass powder, Al₂O₃ splinters, or quartz powder.

Electrodes

Platinum is generally used for the anode, and other materials such as tungsten, nickel, copper or graphite

Table 1 Effect of mass in electromigration of metals

Isotopes of	Fused medium	Effect of mass
Li	LiCl	0.14
Li	LiBr	0.26

as the cathode. Platinum may be attacked by the alkali metals formed on the cathode during electrophoresis.

Column Electrophoresis

Figures 4 and 5 show two arrangements that can be used for column electrophoresis.

Fused Salts Used as Electrolytes

Numerous electrophoretic mobilities of cations and anions have been published. Most work has been done at relatively low temperatures, i.e. between 150 and 300°C. A lithium nitrate–potassium nitrate eutectic (43 : 57) can be used at 160°C, a sodium nitrate–potassium nitrate eutectic (50 : 50) or lithium chlorate–potassium chlorate eutectic (76 : 24) at 250°C and 300°C, respectively, and potassium nitrate or sodium nitrate at 350°C.

Isotope Separations

The separation of isotopes performed in aqueous solutions is generally poorer than expected from mass

Figure 7 Some representative separations of inorganic ions by zone electrophoresis in molten LiNO₃–KNO₃ eutectic–10% NH₄NO₃ at 160°C. A, application point. Reproduced from Alberti *et al.* (1962).

Table 3 Movement of metal ions in fused salts

	Distance moved in 4 h (cm)	KCl-LiCl eutectic ($T = 450^{\circ}\text{C}$; 2 V cm^{-1})	$\text{KNO}_3\text{-LiNO}_3$ eutectic ($T = 160^{\circ}\text{C}$; 5 V cm^{-1})
Anionic	0.5-3	Zn(II), Co(II)	
Isoelectric	0.5-3	Th(IV) ^a	Th(IV) ^a
	3-5.5	Ce(III)	Cd(II)

^aInsoluble precipitate formed. From Alberti *et al.* (1962).

differences, since smaller ions are more hydrated than larger ones and thus mass differences are diminished with fully hydrated ions. This is not the case in molten salts and hence the ionic mobility differences of isotopes are nearer to those expected.

Countercurrent electrophoresis has been used for isotope separation of molten salts. In the system shown in Figure 6 molten lithium chloride is subjected to electrophoresis and the lithium metal formed on the cathode is reoxidized with a stream of chlorine. At 650°C and a current of 0.5 A, using granular quartz medium to decrease convection, rather high enrichments were reported (from 7.3 to

16.1% ^6Li in 4 days). This work served as the basis for a commercial separation of lithium isotopes.

Mass effects depend on the temperature as well as on the anion(s) in the melts. Typical data are shown in Tables 1 and 2.

Analytical Separations of Inorganic Ions

Table 3 gives some data on the movement of metal ions in fused salts and some representative separations by electrophoresis on glass fibre paper are shown in Figure 7.

A number of binary metal mixtures have been separated, as shown in Figure 8.

The main interest in molten salt separations seems, however, to reside in isotope separations and in the study of ionic mobilities in molten salts. It is worthy of note (see Table 3) that Ag^+ travels as a cation in a KCl-LiCl eutectic, while it readily forms an anionic complex AgCl_2^- in aqueous concentrated HCl solution.

GAS ANALYSIS: GAS CHROMATOGRAPHY

C. J. Cowper, GQ Tech, Walton on Thames, Surrey, UK
Copyright © 2000 Academic Press

Introduction

If gases are defined so as to be distinguished from vapours, which is to say only those gases whose critical temperatures are below ambient, and hence cannot be liquefied by pressure at ambient temperature, then the task of gas analysis appears to be a simple one. Applying the criterion of a critical temperature below, say 15°C , produces a very small list of elements and compounds, ranging from helium to ethene. It is, of course, more appropriate to define gases as those which are handled in the gas phase at ambient conditions. Widening the criterion to allow components with boiling points below 15°C produces a rather larger list, ranging from xenon to cyclobutane.

Any gas mixture will be based on one or more of these components, but can in addition contain higher boiling compounds whose low concentration allows them to be present without condensing out from the mixture. As an example, natural gas is treated before it is distributed so that it remains stable in the gas phase over a wide range of temperatures and pressures. It consists predominantly of methane, but contains a large number of other hydrocarbons, up to and including decane, at concentrations which are amenable to direct analysis by gas chromatography.

Analysis for decane and similar components in liquid hydrocarbon mixtures is well established, and similar analytical procedures can be applied to its measurement in natural gas. The main difference is in sample handling and introduction. This will generally be true for other low concentration components of gas mixtures which would normally be liquids or solids. Where techniques exist for analysis of such

materials as liquid or solid samples, they can be modified to handle those components in a gas mixture.

This article is not intended to give details of how to analyse all the chlorofluorocarbons or the hydrides of germanium, but aims to show the characteristic differences in equipment and procedures used for gas analysis.

Equipment and Procedures

A chromatograph which is configured for gas analysis will differ in a number of respects from one designed for liquids' analysis. Sample injection will almost invariably be by valve, and other valves may be used to alter the relative positions of different columns during the analysis. Some columns are specifically used for gas analysis, and others may be used in a different way from that for other applications. Carrier gas must be chosen with some care, as it may be a component of the sample, or have properties which do not favour the measurement of sample components. The thermal conductivity detector (TCD) is likely to play a major role; the flame ionization detector (FID) may be regarded as a selective detector in this context.

Sample Handling and Injection

A packed column will handle sample sizes typically in the region of 0.1 to 10 mg. For samples which are liquid, or solids dissolved in a solvent, this means volumes of 0.1 to 10 μL , which are conveniently measured and injected using microsyringes. For gas samples, this mass range approximates to volumes of 0.1 to 10 mL at ambient conditions.

Gas-tight syringes will easily cope with such sample sizes, but the main drawback with using them is poor repeatability, due to injection of a

compressible sample into an already compressed carrier gas. Most chromatographs equipped for gas analysis will be fitted with a gas sampling valve, sometimes referred to as a bypass injector. **Figure 1** shows a typical design of a six port valve. It consists of a base through which six holes or ports are drilled, equally spaced around the circumference of a circle, and a rotor, which rotates around the axis of the same circle. The rotor has three grooves machined into it, which connect adjacent pairs of ports. Rotation of the rotor through 60° alters the internal plumbing by connecting different pairs of ports. The ports are connected into the chromatograph by small bore tubing.

In **Figure 1**, the carrier gas inlet is connected to port 1, and port 2 goes to the column. Sample gas enters and exits through ports 5 and 4 respectively. A sample loop is connected between ports 3 and 6. The sample loop, usually a length of 2 mm i.d. tubing, defines the size of sample injected. **Figure 1A** shows the sample loading position, with the carrier gas going directly to the column, and **Figure 1B** shows the inject position. Here, the carrier gas sweeps the entire contents of the sample loop on to the column. Provided that the temperature and pressure of the

sample gas in the loop are constant just before injection, the technique is capable of excellent sample size precision, and hence very good quantitative behaviour.

Gas sampling valves can use other configurations – the motion can be linear rather than rotary, but the principle of isolating the sample in a defined volume and then purging it on to the column with carrier gas remains unchanged. Valves with more ports can also be used, to combine gas sampling with other switching operations which may be required.

Capillary columns need much smaller sample sizes for efficient operation, and hence the proliferation of techniques for liquid samples, ranging from sample splitting to solvent effects and retention gaps. It is possible to minimize the dead volume in a gas sampling valve to allow direct injection, but this becomes more difficult as the column i.d. is reduced. If a gas sample is stable when introduced into the chromatograph, it is most likely that splitting the carrier gas flow downstream of the valve will give a representative sample on to the column. In most instances this would be the preferred option.

Columns

Gas chromatographic separations are mainly influenced by the volatility of the components of the mixture. By using selective stationary phases, groups of components of higher polarity can be retained in the column for longer than components of lower polarity. Within similar groups, however, the order of elution will be dictated by boiling point. It is also the case that an isothermal analysis would use a column temperature of somewhere around the middle of the boiling range of the sample, and a temperature programme would very approximately mimic the distillation characteristics.

Permanent gases in particular do not have boiling points which would suggest a convenient choice of column temperature, and polarity differences do not appear to be strong enough to be helpful. Although columns have been operated at liquid nitrogen temperature for the separation of hydrogen isotopes, in general subambient operation is unattractive. Gas analysis, therefore, requires different separation mechanisms to allow use of more or less standard equipment at normal temperatures. The principle difference is the use of adsorption onto stationary phases with active surfaces as the means of separation, rather than partition into a dispersed liquid phase. Such adsorption phases separate, at least in part, by molecular size or shape. As a consequence, some have relatively limited applicability, and are used as part of a range of columns required for a complete analysis.

Figure 1 Gas sampling valve. (A) Sample loading. (B) Sample injection.

Molecular sieve The term is general, but in the context of gas analysis it refers to aluminosilicates of the alkali and alkaline earth metals. The most commonly used are type 5A, based on calcium, and 13X, based on sodium. They have average pore diameters of 0.5 and 1 nm respectively. Molecular sieves are the only materials available which can separate oxygen and nitrogen at normal chromatographic temperatures (35–100°C). On the other hand, they retain carbon dioxide under the same conditions for so long that it is sometimes regarded as being permanently absorbed. They also strongly adsorb water, and are widely used as drying agents.

Molecular sieves must be activated before use, to drive off water and other strongly adsorbed materials and to make the pores available to sample components. This can be done *in situ*, by heating the column to around 300°C for several hours with dry carrier gas flowing. During use, a column will slowly lose separating power due to adsorption of moisture from samples or carrier gas, and will eventually need to be conditioned again. With reasonable precautions, a column should continue to give good separations for a year or longer.

5A and 13X sieves have broadly similar behaviour, with some detail differences which may cause one to be preferred over the other for particular applications. When each is packed into a typical 2 m column, 5A sieve will give longer retention times, most evidently for carbon monoxide. **Figure 2** shows a chromatogram, from a 5A molecular sieve column, of helium, hydrogen, oxygen, nitrogen, methane and carbon monoxide, using argon carrier gas at 50°C. Under these conditions, rare gases can also be analysed, with neon eluting just after hydrogen, argon co-eluting with oxygen, krypton just before nitrogen, and xenon after carbon monoxide. Component relative retention times are influenced by the temperature and time of activation, and so in the unlikely event of rare gases being significantly present in a mixture such as that in **Figure 2**, it should be possible to find an activation procedure which will allow all to be separated.

Argon is the most abundant rare gas (0.93% v/v in air), and so its co-elution with oxygen can create a problem. It can be resolved before oxygen by using, for example, a 2 m column at –50°C, or a 5 m column at 0°C. The obvious drawback is the excessive retention times for other components. An alternative way of measuring oxygen without interference from argon is to use argon as carrier gas, as in **Figure 2**.

Capillary columns containing 5A sieve are available. The finely divided material is dispersed as a layer on the wall of the capillary. This is known as

Figure 2 Molecular sieve 5A.

a porous-layer open-tubular or PLOT column. The combination of high efficiency and high carrier gas linear velocity means that argon and oxygen can be separated within an overall analysis time comparable to that of a 2 m packed column.

5A molecular sieve is also capable of exclusion chromatography, based on molecular shape. Ethane, propane and n-butane have increasingly longer retention times, so as to be unmeasurable, under the conditions of **Figure 2**. However, isobutane (2-methylpropane) elutes as a tailing peak just before methane; **Figure 3** shows this effect. Similar behaviour is found for neopentane (2,2-dimethylpropane), although it is less of a problem, since neopentane is likely to be at much lower concentration than isobutane. A further example is sulfur hexafluoride, which elutes before oxygen. This can be used where SF₆ is measured as an atmospheric tracer by electron-capture detector; oxygen is mildly electron-capturing, but does represent 21% of the atmosphere, and so having the trace of SF₆ eluting first makes detection easier.

Under the same conditions, 13X molecular sieve gives more uniform separation of components, with rather shorter retention times, as shown in **Figure 4**. 13X sieve does not display the exclusion mode of

Figure 3 Molecular sieve 5A.

Figure 4 Molecular sieve 13X.

behaviour shown by 5A. Another difference is that the order of elution of methane and carbon monoxide can be reversed. If the temperature of activation is limited to 150°C, then a chromatogram similar to that in Figure 5 is produced. With this reduced level of activation, the long-term stability of the column is excellent. With the higher activation temperature required for Figure 4, the column performance, as with 5A sieve, slowly deteriorates. 13X sieve must have at least two types of pores, from one of which water is removed at relatively low temperature, giving the chromatogram in Figure 5; the other requiring higher temperatures to give the performance in Figure 4. Obviously, at some intermediate activation temperature, methane and carbon monoxide will co-elute.

Porous polymer beads Porous polymer beads are based on polyaromatic cross-linked resins. They have a regular pore size and form beads of uniform diameter, making a good packing material. They are available in a range of polarities, according to the method of preparation, which allow differences in elution order. They are not hygroscopic and hence need no activation before use, although treatment

Figure 5 Molecular sieve 13X - partially activated.

Figure 6 Porous polymer beads as packing material.

overnight near the maximum operating temperature will remove residual low relative molecular mass material and give more stable baselines. With operating temperatures from subambient to around 250°C, the range of samples to which they can be applied is large. Since there is no change in activity due to adsorbed moisture, porous polymers are frequently used in temperate-programmed applications, which considerably increases their flexibility.

A 2 m column packed with nonpolar material at 50°C does not separate oxygen, nitrogen and carbon monoxide, which elute at the beginning of the chromatogram, closely followed by methane. It does separate carbon dioxide, ethene and ethane in that order, which makes it a natural complementary column to molecular sieve for light gas analysis (Figure 6). Propene elutes just before propane, but C₄ saturated and unsaturated hydrocarbons are mixed together. At higher temperatures, porous polymers can analyse hydrocarbons to C₈. They are also good for sulfur-containing gases, separating H₂S, COS and SO₂ in that order. With temperature programming, organic thiols and sulfides can be included.

Alumina Activated alumina has a high polarity which is suitable for mixtures of saturated and unsaturated hydrocarbons. To avoid tailing peaks for unsaturated components, some controlled surface deactivation is necessary. Originally this was done with water, or a mixture of water and silicone oil to obtain the desired polarity. The water would slowly be stripped off by the dry carrier gas, increasing polarity and the tendency to tailing peaks. Alumina PLOT columns are now available, deactivated with inorganic salts, and these offer the optimum solution for this type of analysis. Figure 7 shows a chromatogram of C₁ to C₄ saturated and unsaturated hydrocarbons. This was produced using an FID, so the lack of

Figure 7 Porous-layer open-tubular (PLOT) alumina column.

separation between methane and inorganic gases is not a problem.

Carbon Active carbon has been used as a packing since the introduction of gas analysis by chromatography. Modern packings are based on graphitized carbon black or on carbon molecular sieve. Both have similar retention characteristics to porous polymers, but carbon molecular sieve, with a high surface area, requires higher temperatures. Another characteristic of carbon molecular sieve is its very low retention for water, typically eluting before CO_2 . Either type of packing is used for samples containing adsorptive components, in which case the inert nature of all the

materials in the sample path, not just the packing material, must be considered.

Column Switching

Most gas analyses require the use of more than one column, given the restricted applicability of each. Rather than use the columns individually in separate chromatographs, they can be combined in a single unit by means of switching valves. Such valves are similar to the gas sampling valve described earlier, but configured for different uses.

Figure 8 shows a configuration suitable for the common combination of molecular sieve and porous polymer columns. V1 is the gas sampling valve and

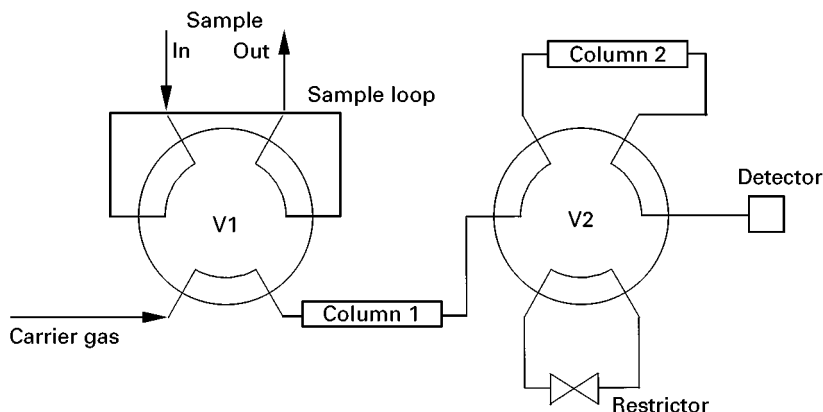

Figure 8 Column isolation.

V2 the column switching valve. Column 1 is porous polymer and column 2 molecular sieve. The restrictor on V2 is adjusted so that the carrier flow to the detector is the same for both positions of V2. Those components for which molecular sieve is appropriate (O_2 , N_2 , CH_4 and CO) are rapidly eluted from the porous polymer column with little or no separation. With V2 in the position shown, they pass into the molecular sieve column. Before CO_2 and other components have reached the end of the porous polymer column, valve V2 is switched, allowing them to bypass the molecular sieve and pass directly to the detector. Switching V2 also isolates the light components in the molecular sieve column, with no carrier gas flow. After the components directly eluted from the porous polymer column have been detected, V2 is switched back, and the light gases are measured. Figure 9 shows a chromatogram.

Another procedure is possible. If the gap on the porous polymer column between the initial unresolved components and CO_2 is sufficiently large, then the flow can continue through the molecular sieve to allow the light components to be measured before CO_2 reaches V2. V2 is then switched, allowing CO_2 and the other components to be measured.

Combined use For certain applications, one 10-port valve can be used in place of two 6-port valves. Figure 10 shows the configuration which would allow the second procedure described above to be achieved with one valve. With the valve in the first position, sample is being purged through the loop, and the carrier gas is following the sequence column 2 → column 1 → detector. Switching the valve injects the sample on to column 1 (porous polymer). After the light gases from column 2 have been measured, the valve is returned to the sample load position for measurement of CO_2 and other components.

Figure 9 Combined column chromatogram.

Figure 10 Combined injection and switching.

Multiple systems Natural gas and refinery gas are two examples of complex mixtures which require more elaborate systems than those described above. Although neither mixture should contain oxygen, a molecular sieve column is recommended because air contamination of the sample is always possible; measurement of the oxygen concentration allows the air content to be calculated and allowed for. A porous polymer column allows optimum separation of carbon dioxide, ethane and, if present, ethene. C_3 , C_4 and C_5 hydrocarbons can be dealt with by an appropriate liquid-phase column, and in a common implementation all heavier hydrocarbons are measured as a backflushed C_6+ group.

Figure 11 shows the configuration. Column 1 is divided into two sections, the longer 1B, on which C_3 , C_4 and C_5 hydrocarbons are separated, and the shorter 1A, from which C_6+ is backflushed. Valve V1 injects the sample and also alters the sequence of columns 1A and 1B. Valve V2 isolates and reconnects the porous polymer (column 2) and molecular sieve (column 3), and V3 does the same for column 3 alone.

After sample injection, V1 is left in that position until the C_5 components have passed on to column 1B, while the C_6 and heavier are still on column 1A. This time is found by trial and error. At this point, V1 is returned to the sample load position, which also reverses the flow through column 1A and places it directly before the detector. All heavier components are rapidly measured as a recombined C_6+ peak. After the light gases have been eluted from column 1B, rotation of V2 isolates them in columns 2 and 3. The timings and column lengths are chosen so that each group of light gases is isolated on the appropriate column. C_3 , C_4 and C_5 hydrocarbons elute from column 1B, pass through column 1A for the second time, and are detected. After that, valves V2 and V3

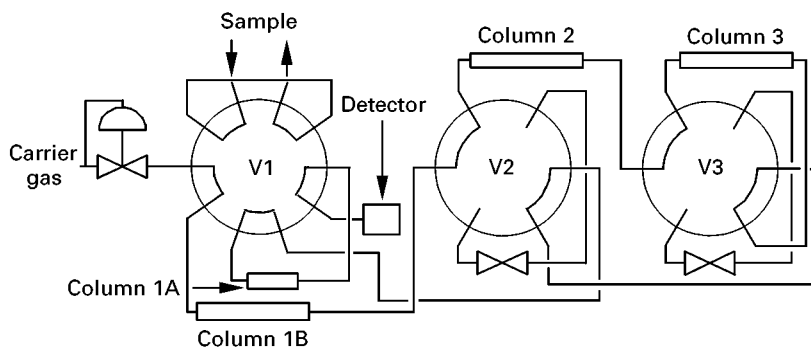

Figure 11 Multiple column analysers.

are rotated to reconnect column 2, and CO_2 and C_2 hydrocarbons are measured. Finally, V3 reconnects column 3, and the components from the molecular sieve column are measured. **Figure 12** shows a chromatogram of natural gas.

Carrier Gas

Since the TCD is normally used for the major components of gas mixtures, the thermal conductivity of the carrier gas is one of its most important properties. Helium and hydrogen have similar high thermal conductivities, and allow other components to be detected with good sensitivity. All other things being equal, helium would be preferred for its inertness. Unfortunately, the thermal conductivities of helium/hydrogen mixtures have a significantly nonlinear relationship to concentration, which makes quantitative measurement of hydrogen in helium carrier gas difficult. Argon or nitrogen is suitable for the measurement of hydrogen and/or helium. As described above under 'Molecular sieve', argon can be used to measure oxygen without interference, and nitrogen may be the

best choice for measurement of other trace components in air.

When other detectors, such as the FID, are used, the choice of carrier gas is less critical. Maximum sensitivity from the FID is obtained with nitrogen or argon, but this is rarely the most important need. Helium allows higher carrier gas linear velocities without loss of efficiency, and is also preferred in cases where both TCD and FID are used in series.

Detectors

For specific applications, most types of detector are used or have been used. Electron capture, helium ionization, ultrasonic and flame photometric detectors are applicable where the properties or very low concentrations of sample components require them. For the majority of applications, however, the TCD is the most popular, followed by the FID. TCDs use either filaments or thermistors as sensing elements. Thermistors give greater sensitivity at lower detector temperatures, but are less good if the application demands a high detector temperature. When

Figure 12 Natural gas chromatogram.

using adsorption columns, it is not always necessary to maintain a detector temperature higher than that of the column oven, and thermistors may still be preferred. The higher temperatures of filaments can cause sample components to react with them. As an example, a sample containing both oxygen and hydrogen sulfide can cause step baseline changes in opposite directions as each component in turn passes through the detector.

Quantitative Analysis

The importance of calibration is as great for analysis of gases as it is for liquid samples. In some respects it is even greater, since the TCD, which is used for the major components of gas samples, does not share the 'carbon counter' characteristic of the FID. If, for example C_3 to C_5 hydrocarbons in a gas are analysed using an FID, it would be possible to calibrate using a standard gas containing C_3 alone, and then quantify the other components by means of relative response factors. This is not the case when using TCD; while the relative response for a particular detector will be stable, they are not predictable as for the FID, and there is not a sufficient basis of knowledge to allow them to be transferred to other models of TCD from other suppliers.

Calibration gas mixtures of the highest accuracy can be prepared in cylinders gravimetrically. Although the mass of the cylinder is very much greater than the masses of the added components, the discrimination and accuracy of weighing are such that the uncertainties of the composition are very small. Such mixtures are, of course, expensive, and for regular use certified calibration mixtures, which have been analysed against a gravimetric mixture, are normal. If components are likely to react with or adsorb on to cylinder walls, then calibration mixtures can be prepared dynamically, at the time and place of use. Permeation tubes, where a component diffuses

through a membrane into a measured diluent gas flow under controlled conditions, are widely used for trace analysis.

If only a few specific components are to be measured, then the individual response factors calculated from the calibration gas are critical. It is necessary to calibrate with sufficient frequency that uncontrollable effects, such as that of barometric pressure on TCD response, do not degrade the result. Consistency of sample size between calibration and analysis is also important. A gas sampling valve (see above under 'Sample handling and injection') allows this, but the operator must ensure that the temperature and pressure of the calibration gas and sample are uniform.

If the analysis is comprehensive, as in the natural gas example shown in Figure 12, then the resulting composition will be normalized to 100%. This procedure effectively converts the individual response factors to relative ones. Since relative response factors for a single detector remain stable over long periods, consistency of sample size is less critical. Regular calibration is still important, but is used as much as a quality control test as for calibration in the traditional sense.

temperature or pressure:

Introduction

Gases are separated on a very large scale by cryogenic distillation, membrane or sorption methods. For instance, the production of pure oxygen from air by cryogenic distillation is one of the most important separation processes. However, the membrane method is preferable when O₂-enriched air is required for medical use or effective combustion, and the sorption method is best for removal of O₂ from packaging. The fundamental mechanism of cryogenic distillation is due to a difference in boiling points of the various gases. In the case of the membrane method, a difference in solubility and diffusion of gases is essential for nonporous membranes, while molecular mass or size of gases is a decisive factor for porous membranes where Knudsen diffusion or molecular sieving occurs. The sorption method involves physical sorption and chemisorption, which are characterized by binding energies of about 5–50 kJ mol⁻¹ and about 150–500 kJ mol⁻¹.

Unlike most physical sorbents, gas adsorbents containing metal complexes adsorb gas molecules by chemical coordination of the molecules to a central metal atom. Some metal complex adsorbents, because of their strong chemical adsorption, can completely adsorb gas molecules, even at low gas concentrations. The equilibrium between the metal complex (S–M) and the gas (G) is shown in eqn [1]. When this equilibrium shifts to the right, the adsorbent adsorbs gas molecules. When the equilibrium shifts to the left, the adsorbent releases the adsorbed molecules. The equilibrium can be controlled by changing

Figure 1 shows a schematic illustration of carbon monoxide separation from a carbon monoxide–nitrogen gas mixture by a solid copper complex. Only carbon monoxide can coordinate to copper to form a complex when the adsorbent is exposed to the gas mixture. The adsorbed gas is released when the adsorbent is subjected to high temperature or reduced pressure.

The characteristics of metal complex adsorbents are as follows:

1. Various combination of metal–ligand systems are available for the development of appropriate adsorbents.
2. Even a very dilute gas component in a mixture can be removed due to strong coordinative binding between the central metal and gas molecules.
3. Selective adsorption can be achieved using suitable functional groups of ligands.
4. Such a selective adsorption can possibly be used as a sensor or an indicator by showing colour change of adsorbents.
5. The amount of adsorbed gas molecules per unit mass of the adsorbents is limited because only one or two molecules can coordinate to a central metal atom.
6. The metal complex adsorption system cannot separate gases by their molecular size.
7. In general, the metal complex adsorbent is less stable than other types of adsorbents, such as active carbon and zeolite.

Metal complexes can be used as free-standing adsorbents, but preferably should be spread on to an inert support, such as activated carbon, porous

Figure 1 A schematic illustration of the separation of carbon monoxide from a carbon monoxide–nitrogen mixture by a supported copper complex.

carbon fibres, zeolite or porous polymer beads. These supports should have a large surface area to increase the adsorption capacity. Also the adsorbent support should be mechanically strong so as not to break up in use.

Polymeric supports have several advantages. Firstly, polymers can be processed into many shapes, such as thin membranes, hollow fibres or porous beads. Secondly, the wide variety of available polymers means that the structure and surface chemistry of the polymer are easily changed. Thirdly, the metal complex can be easily inserted into a hydrophobic domain, which cannot be achieved with inorganic materials. This offers some protection to water-sensitive metal complexes. Finally, composite materials can be easily formed.

Polymer-supported metal complexes or polymer-metal complexes are quite often more stable, more effective, and more easily handled than metal complexes without support for the following reasons:

1. *Diluting effect*: polymers can immobilize the metal complex separately so that aggregation of the metal complex is difficult.
2. *Concentrating effect*: metal complexes fixed in a polymeric support give a reaction field with a higher concentration of active centres than in a solution of the corresponding metal complex.
3. *Field effect*: polymeric supports form a specific reaction field to promote the reaction or to inhibit undesirable side reactions.
4. *Steric effect*: polymeric supports sterically control the approach of molecules to the metal complex.

The polymer-metal complexes can be used for gas separation in the form of adsorbents and membranes. In both cases, the coordination of gas molecules to the metal complex is much stronger than physical adsorption or solubilization into polymers, resulting in higher selectivity for gas separation than metal complexes supported on inorganic materials where the inorganic support itself may adsorb a considerable amount of gas molecules.

The following are industrially important applications of metal complexes for gas separation. However, most have been investigated on just a small laboratory scale. Only the separation of oxygen from air has been the subject of practical research for industrial application on a large scale.

Separation of Carbon Monoxide

Carbon monoxide, one of the most important starting materials for synthesizing organic chemicals, is usually obtained as a gas mixture containing methane, ethane, nitrogen, carbon dioxide and water vapour, by steam reforming of hydrocarbons, partial oxidation processes or gasification of coal. Thus, separation of carbon monoxide from gas mixtures is a significant target for investigation. Although the cryogenic separation process is widely used for carbon dioxide separation, it is difficult to separate carbon monoxide from gas mixtures containing N_2 because their boiling points are close ($CO = -191.5^\circ C$, $N_2 = -195.8^\circ C$). For this reason adsorption of carbon monoxide onto metal complexes is still of use. One process is adsorption of carbon monoxide by a copper liquor process using copper(I) ammonium solution, but dry systems have also been proposed. Some adsorbents investigated are listed in Table 1.

Introduction of copper(II) ion into Y-type zeolite by cation exchange, followed by reduction under 150 mmHg (1 mmHg \approx 133.3 Pa) of carbon monoxide at $400^\circ C$, gives a Y-type zeolite-supported Cu(I) adsorbent which adsorbs 1.65 mmol of carbon monoxide per g-adsorbent at $25^\circ C$, 99 mmHg. The amount of CO adsorbed is almost equal to the moles of attached Cu(I) ion, suggesting that a 1:1 Cu(I)-carbon monoxide complex is formed. A similar adsorbent can be made by replacing Y-type zeolite by ZSM-5. The disadvantages of the Cu(I) zeolite-type adsorbents are as follows:

1. Cu(I) is oxidized to Cu(II) by oxygen in the presence of water vapour or ammonia, losing the ability to adsorb carbon monoxide.

Table 1 Adsorption and release of CO by various adsorbents containing Cu

Adsorbent	Capacity of adsorption (cm^3 g adsorbent $^{-1}$)	Adsorption conditions	Release conditions
Cu/Y-type zeolite	30-40	100 Torr, $< 100^\circ C$	$> 300^\circ C$, vacuum
Cu/ZSM-5	16	200 Torr, $< 50^\circ C$	$> 300^\circ C$, vacuum
Cu(I)/active carbon	24	0.9 atm, $20^\circ C$	$120^\circ C$, 1 atm or $20^\circ C$, vacuum
Cu(I)/PS-NH ₂	20	0.9 atm, $20^\circ C$	$80^\circ C$, vacuum
AlCuCl ₄ /active carbon	28	0.9 atm, $20^\circ C$	$180^\circ C$, vacuum
AlCuCl ₄ /PS	70	1.0 atm, $20^\circ C$	$90^\circ C$, vacuum

2. Release of carbon monoxide requires a temperature of 300–400°C under vacuum because of the strong carbon monoxide coordination of Cu(I). These severe conditions are unsuitable for good carbon monoxide recovery.

Although active carbon is capable of adsorbing gases, it cannot be used as a selective carbon monoxide adsorbent because of the general physical adsorption involved. However, activated carbon, having a very large surface area, can be used as a support. An adsorbent can be made holding 14.1 mmol of CuCl (94%), with a surface area of 744 m² g⁻¹, about 70% of that of the activated carbon (1044 m² g⁻¹) used. The activated carbon-supported CuCl adsorbs 88% carbon monoxide per Cu(I) (24 cm³ STP per g-adsorbent) under a CO–N₂ (9 : 1) mixture at 20°C. The adsorbent totally releases the adsorbed carbon monoxide at 120°C under 1 atm or 20°C under 0.4 mmHg, and can be used repeatedly. The high capacity of carbon monoxide adsorption results from the highly dispersed CuCl₂⁻ on active carbon prepared from CuCl in hydrochloric acid solution. Carbon-supported CuCl prepared in ethanol or water does not show high carbon monoxide adsorption. Carbon-supported CuCl prepared from CuCl in 20% ammonia solution exhibits 83% carbon monoxide adsorption to the Cu(I) content under the same conditions mentioned above. A similar carbon monoxide adsorbent, prepared from CuCl₂ instead of CuCl, adsorbs 67% carbon monoxide to the CuCl₂ added. The active site is however found to be Cu(I) by X-ray photoelectron spectroscopy (XPS), presumably because the Cu(II) is reduced by the activated carbon during the preparation.

Macroreticular (MR) polystyrene (PS) resin with primary and secondary amino groups can be used as a support for CuCl. The polymeric adsorbent adsorbs 15.9% carbon monoxide per Cu(I) (21 cm³ STP per g-adsorbent) under the same conditions described above. The adsorbent partially releases carbon monoxide in 10 min at 80°C under 1 atm, and repeatedly adsorbs 9.1% carbon monoxide per Cu(I). The other ion exchange resins show poor capacity of carbon monoxide adsorption (Table 2), showing that the coordination of the amino groups to Cu(I) is essential. The adsorbent does not adsorb methane, hydrogen or nitrogen, but does adsorb some carbon dioxide (3.7 cm³ per g-adsorbent). The capacity is however much smaller than that of carbon monoxide (21 cm³) because most of the amino groups of the resin coordinate to CuCl, and few free amino groups remain.

Polystyrene-supported CuCl shows very poor capacity for carbon monoxide adsorption (Table 2). Copper(I) chloride is known to make a double

Table 2 Capacity of CO adsorption for various ion exchange resin-supported CuCl^a

<i>Ion exchange resin</i>	<i>Functional group</i>	<i>Adsorbed CO^b</i>
Anion exchange resin	–NH ₂ , –NH–	15.9
Weak cation exchange resin	–COOH	1.2
Strong cation exchange resin	–SO ₃ H	0.8
Polystyrene resin	None	2.2

^a The adsorbents were prepared from 10.0 g of resin and 9.9 g (100 mmol) of CuCl in 80 cm³ acetonitrile.

^b Adsorbed CO under 1 atm of CO–N₂ (9 : 1) mixture at 20°C.

salt with aluminium chloride, and the double salt forms a π-complex with aromatic hydrocarbons such as toluene, giving a stable carbon monoxide adsorbent even in the presence of oxygen or carbon dioxide:

This adsorbent (AlCuCl₄ toluene solution, so-called COSORB solution) is very unstable in water, however, decreasing irreversibly the capacity of carbon monoxide absorption. Therefore, the water content of gas mixtures must be reduced to less than 1 p.p.m. prior to using this solution. Addition of linear PS to an AlCuCl₄–toluene solution dramatically increases the stability to water, presumably because PS coordinates AlCuCl₄, forming a hydrophobic domain around the water-sensitive AlCuCl₄ molecule, thereby protecting it from water.

MR cross-linked PS resin (Bio-Beads SM-2, divinylbenzene content: 20%, surface area: 300 m² g⁻¹) is an excellent support for AlCuCl₄, providing a water-resistant solid carbon monoxide adsorbent. The adsorbent adsorbs an equimolar amount of carbon monoxide in 10 min under 1 atm of carbon monoxide at 20°C, and partially releases the carbon monoxide under 7 mmHg at 20°C. After 10 min desorption of CO, the adsorbent still adsorbs 54% carbon monoxide per Cu(I) the second time, and this is a reversible capacity for carbon monoxide adsorption under the conditions mentioned above. The capacity of reversible carbon monoxide adsorption increases by applying higher vacuum or higher temperatures during the desorption part of the cycle. The water-resistivity of the adsorbent strongly depends on the solvent used for preparation. Carbon disulfide gives a water-resistant adsorbent, while toluene gives a water-sensitive material. The water-resistant adsorbent has a uniform distribution of AlCuCl₄ in PS resin, whereas the water-sensitive adsorbent possesses a lot of crystalline

deposits, consisting mainly of CuCl, in the beads and much salt, mainly AlCl₃, on the surface.

Gel-type PS (divinylbenzene content: 1%)-supported AlCuCl₄ adsorbs carbon monoxide much more slowly than the MR-type adsorbent, and it takes about a day to attain equilibrium. In consequence, the MR-type resin, which possesses macropores even in a dry state, is essential for the preparation of solid gas adsorbents.

Separation of Nitrogen Monoxide (NO)

Nitrogen oxides and sulfur oxides are major air pollutants. Unlike sulfur oxides which have been decreasing in the atmosphere, nitrogen oxides, particularly nitrogen monoxide (NO) in combustion and exhaust gases, still cause difficulties. For removal of nitrogen monoxide, in general, catalytic processes using ammonia, carbon monoxide or hydrocarbons as a reducing agent are applied.

Another possibility of removing nitrogen monoxide from gas mixtures might be the use of metal complex adsorbents at lower temperatures. The nitrogen monoxide adsorbents are expected to adsorb nitrogen monoxide completely, even at very low concentrations of nitrogen monoxide, and to be stable to water vapour, SO₂, dust, etc., which are often contained in combustion and exhaust gases.

Natural jarosite, KFe₃(SO₄)₂(OH)₆, possesses a layer structure in the crystal. Jarosite synthesized from Fe(SO₄)₂ and K₂SO₄ (3 : 1) adsorbs 5.3 × 10⁻⁴ mmol of nitrogen monoxide per g-adsorbent (surface area: 7.3 m² g⁻¹). The other synthetic jarosites, MFe₃(SO₄)₂(OH)₆ (M = Na, Rb), show no difference in nitrogen monoxide adsorption.

α-FeOOH crystals can be prepared from Fe₂(SO₄)₃ and Na₂CO₃ by heat treatment. Powdery crystal α-FeOOH, whose surface area is 60 m² g⁻¹, adsorbs 0.4 mmol of nitrogen monoxide per g-adsorbent at 30°C under 600 mmHg of nitrogen monoxide partial pressure, whereas α-FeOOH supported on activated carbon fibre (surface area: 870 m² g⁻¹) adsorbs 4.67 mmol of nitrogen monoxide under the same condition (a 12 times higher capacity than that without activated carbon fibre as a support). This adsorbent adsorbs 0.043 mmol per g-adsorbent even under 300 p.p.m. of nitrogen monoxide at 100°C, but little more than 10% of the nitrogen monoxide adsorbed can be released under vacuum due to its strong adsorption.

Active carbon-supported FeCl₂ completely adsorbs nitrogen monoxide in 25 min from a 6 dm³ NO-N₂ mixture (NO: 1000 p.p.m.) when the gas mixture is circulated at 1.6 dm³ min⁻¹. The adsorbent releases 28% adsorbed nitrogen monoxide in 15 min at

Table 3 Effects of the washing solvent on the ability for NO adsorption and the surface area for chelate resin-supported Fe(II)

Solvent	Adsorption rate ^a (10 ⁻² mmol min ⁻¹)	Adsorbed NO ^b	Surface area ^c (m ² g ⁻¹)
Chloroform	0.36	0.789	2.3
Water	0.30	> 0.425	3.2
Acetone	1.04	0.933	17.2
2-Propanol			31.7
Ethanol	1.54	0.997	31.1
Methanol	1.54	0.997	43.1

^b Equilibrium NO adsorbed against NO introduced.

^c Measured by a Brunauer-Emmett-Teller (BET) method.

120°C. The apparent equilibrium constant of the adsorbent is around 1500 atm⁻¹.

Iron(II) ethylenediaminetetraacetic acid (EDTA) solution is a well-known nitrogen monoxide absorbent, adsorbing 0.5 mol of nitrogen monoxide per mole of Fe from NO-N₂ mixtures (NO: 1000 p.p.m.) at 55°C. However, the absorbent is easily oxidized by oxygen due to the unstable Fe(II) ion. To overcome this problem, a chelate resin, cross-linked PS with iminodiacetic acid moieties, has been used as a polymeric support. The Fe(II) supported on chelate resin adsorbs almost all the nitrogen monoxide in 15–20 min from a 6 dm³ of NO-N₂ mixture (NO: 1000 p.p.m.) when the gas mixture is circulated at 1.6 dm³ min⁻¹. The adsorbent releases all the adsorbed nitrogen monoxide under 3 mmHg at 100°C, and can be reused repeatedly. The capacity of nitrogen monoxide adsorption for the chelate resin-supported Fe(II) is dependent on the washing solvent. This is because the porosity or the surface area increases (Table 3) when the water-swollen resin-supported Fe(II) is dried after washing with water-miscible organic solvents. Coexistence of a high valent cation such as Fe(III) further increases the surface area to achieve more effective nitrogen monoxide adsorption.

Separation of Ethylene (C₂H₄)

Ethylene is one of the most important raw materials in the petrochemical industry and is also an accelerator for ripening fruit. Ethylene is produced on a large scale by the thermal cracking of naphtha and natural gas, and obtained in mixtures with methane, ethane, propane, propylene, hydrogen, carbon dioxide, nitrogen and water. In this case, a large quantity of gas mixture has to be treated to obtain pure ethylene. On the other hand, a small amount of ethylene must be thoroughly removed from fruit packaging so that fruit does not ripen too quickly.

In industry ethylene is purified mostly by large scale distillation, and sometimes by using membrane separation. For removal of ethylene from fruit packaging, no good adsorbent has yet been developed. The solid metal complex adsorbent mentioned here may provide a new material for both purposes.

Y-type zeolite-supported Cu(I) adsorbs 3.10 mmol of ethylene per g-adsorbent (1.9 mmol of ethylene per mole of Cu(I)) under 250 mmHg of ethylene at 25°C and releases 73% of the adsorbed gas in 60 min. Y-type zeolite-supported Ag(I) adsorbs 3.28 mmol of ethylene per g-adsorbent and releases 54% of the gas under the same conditions.

MR-type PS resin with primary and secondary amino groups, which is used as a support for CuCl as described above for carbon monoxide adsorption, also works as an ethylene adsorbent. An adsorbent prepared from 10 g of resin and 15.0 g (152 mmol) of CuCl in water-acetonitrile (1 : 1) reversibly adsorbs 15 mmol of ethylene and 1.9 mmol of ethane, while the resin itself (10 g) adsorbs 5.0 mmol of ethylene and 6.5 mmol of ethane at 20°C under 1 atm. The coverage of CuCl over the surface of the resin is supposed to restrict physical adsorption and increases chemisorption or coordination.

MR-type PS-supported AlCuCl₄ adsorbs ethylene very rapidly, and the equilibrium ratio of the adsorbed ethylene to the CuCl added is 1.40 mol-C₂H₄/mol-Cu (89 cm³ STP of ethylene per g-adsorbent). The adsorbent releases a part of the adsorbed gas under 8 mmHg at 20°C for 10 min, and adsorbs 0.29 of mol-ethylene per mol-Cu in the second and later passes. When an ethylene-adsorbed adsorbent is cycled at 90°C under 1 atm and at 142°C under 8 mmHg to release ethylene, the adsorbent removes 0.47 and 0.87 of mol-ethylene per mol-Cu, respectively, in the second adsorption cycle. Although the PS-supported AlCuCl₄ adsorbs both ethylene and carbon monoxide, the coordination of ethylene to Cu(I) is stronger than that of carbon monoxide. Thus, the equilibrium molar ratio of adsorbed ethylene-carbon monoxide is 5 : 1 when the adsorbent is exposed to a 1 : 1 ethylene-carbon monoxide mixture.

A similar adsorbent, MR-type PS-supported AgAlCl₄, adsorbs an equimolar amount of ethylene per Ag under 1 atm at 20°C and releases almost all the ethylene under 8 mmHg at 20°C. The adsorbent does not adsorb carbon monoxide at all under 1 atm at 20°C, and therefore can be used as a selective ethylene adsorbent. The adsorbent is water-resistant, although AgAlCl₄ is water-sensitive, as is AlCuCl₄. The stability of the adsorbent is attributable to the location of AgAlCl₄ at the hydrophobic sites of the PS resin surrounded by several aromatic rings.

Separation of Oxygen

Oxygen, which can be prepared by separation from air, is one of the most important industrial chemical products and is produced on the largest scale by weight in the world. Thus, separation of oxygen from air is an important process in industry, and is mainly performed by low temperature distillation. It is also important to increase (or decrease) oxygen concentration for medical use and effective combustion (or inhibition of nitrogen monoxide production).

Haemoglobin and nyoglobin are typical examples of metal complexes which can reversibly bind an oxygen molecule in nature. So, the separation of oxygen from air with solid metal complexes has received considerable attention in the search for alternative procedures to low temperature distillation. Cobalt(II) Schiff's base complexes, such as a complex of cobalt(II) with bis(salicylidene)diaminoethane (Co(salen)), were objects of initial research in the 1940s on reversible oxygen adsorbents and were later developed for on-board oxygen support systems for the US Air Force. Oxygen binds preferentially to cobalt by exposing the complex to air at room temperature to form cobalt(III) superoxide. Heating (thermal swing adsorption: TSA) or reducing pressure (pressure swing adsorption: PSA) facilitates release of oxygen from the complex. Up to 3000 oxygenation/deoxygenation cycles have been carried out with the same sample. After 3000 cycles the remaining activity was still 50%. Chemical engineering research was carried out using the system involving Co(salen)-type adsorbents. The US Air Force studied the cobalt(II) complex of bis(3-fluorosalicylidene)diaminoethane or fluomine for potential use in providing breathing oxygen for crews of military aircraft. This compound gives the best performance among all oxygen adsorbents so far with its fast and reversible binding of oxygen, as well as good stability, but could not be applied in practice due to the high cost.

Several other transition metals, such as manganese, iron, chromium, nickel, copper, titanium, and so on, have been used to synthesize various kinds of oxygen adsorbents by complexing with various types of ligands. They show reversible oxygen binding and release, but none has achieved commercial success for separation of oxygen from air.

Cobalt(II) Schiff's base complex has been tried, fixed in a polymer matrix. A poly(4-vinylpyridine)-attached cobalt(II) Schiff's base complex can be used for gas chromatography because oxygen comes out later than the other gases, such as nitrogen. Cobalt bis(salicylideneamino)propylamine-attached polystyrene and polyoctylmethacrylatecobalt dialicylidenediethylenediamine films have been found to

be useful for concentrating oxygen. Membranes of this latter material concentrate 8.3% oxygen in 5 h and 13.1% in 42 h from air. The permeability coefficient and the separation factor (O_2/N_2) under 10 mmHg of feed gas are 10^{-9} and 15, respectively, for this membrane containing 12 wt% of the complex. The experimental results were analysed using the dual-mode sorption model. Although several interesting studies have been reported on facilitated oxygen transport membranes employing the transition metal-oxygen complexes, they have a number of inherent limitations from a practical viewpoint, for example, the lifetime of membranes, the relationship between quality and quantity of the separation, and so on.

Conclusion

Metal complex adsorbents used for carbon monoxide, nitrogen monoxide, ethylene and oxygen separation have been described in this article. Few examples of adsorbents for other gases are known, but theoretically any gas capable of coordinating to metal complexes can be separated in this way. A variety of metal complexes can be synthesized by changing metal and ligand, and therefore supported metal complexes are promising materials for gas separation.

However, from a practical viewpoint, there are many limitations, for example, lifetime of the materials and the cost of the separation. Since the greatest advantage of systems using solid metal complexes is complete separation, the adsorbents of solid metal complexes may be used for the purpose of the complete removal of small amount of gaseous molecules from closed systems in the future.

Introduction

With the human genome program drawing to a close, attention is now rapidly shifting from obtaining consensus sequences of all human genes to the detection of individual DNA sequence variations. Based on complete sequence information for all human genes, it is theoretically possible to generate a catalogue of all gene mutations and polymorphisms in the human genome and test them directly for association to relevant phenotypes, e.g. of health and disease. Unfortunately, current methods for detecting DNA sequence variants are not optimized for generating data on multiple genes in large numbers of individuals, e.g. in population-based studies or in the clinical setting. The most reliable system for comprehensive gene sequence analysis is still nucleotide sequencing itself, which is not compatible with cost-effective large scale population-based genetic screening.

Recently, various systems have been proposed to analyse gene-coding and regulatory sequences more effectively for all possible variations. Here we review the development and application of one such system, two-dimensional gene scanning (TDGS). This method is based on the two-dimensional separation of polymerase chain reaction (PCR)-amplified gene fragments on the basis of both size and base pair sequence in polyacrylamide gels. Attention will be focused on most recent developments in automation and miniaturization of the two-dimensional electrophoresis procedure. Future developments towards a dedicated fully automated high-throughput system for gene analysis will be discussed.

Two-Dimensional Gene Scanning: Background and Principles

Denaturing Gradient Gel Electrophoresis

TDGS is based on denaturing gradient gel electrophoresis (DGGE) as the mutation detection

principle, in combination with PCR amplification to prepare the target sequences. In DGGE, DNA fragments are subjected to electrophoresis in a polyacrylamide gel against a gradient of ever higher temperature or chemical denaturants (i.e. a mixture of urea and formamide). Unlike nucleotide sequencing, DGGE detects mutations, including base pair substitutions and small insertions and deletions, on the basis of differences in the melting temperature of the target fragments. A given DNA fragment comprises one or more domains, each representing a stretch of between 50 and 300 base pairs with equal melting temperature (the temperature at which each base pair has a 50% probability of being in either the helical or the denatured state). Since the stability of each domain depends on its sequence, mutational differences among different fragments are revealed as migrational differences in the gel (Figure 1A).

In order to obtain virtually 100% accuracy in mutation detection, fragments to be subjected to DGGE can be clamped to a GC-rich sequence (a stretch of 30–50 G and C bases). A convenient way of attaching a GC-clamp to the target fragment is by making it part of one of the primers in a PCR. Without GC-clamping, a DNA fragment consisting of one melting domain will become completely single-stranded upon denaturation and run off the gel. By adding a GC-clamp, a single high-melting domain is artificially created at one end of the target fragment. As the GC-clamped target fragment migrates through the gradient of denaturants, melting of the target domain causes partial branching and halting of the fragment in the gel (Figure 1B). Thus, one function of the GC-clamp is to ensure branch formation after melting of the target fragment. However, when the target DNA fragment consists of multiple melting domains (Figure 1C), only mutations in the lowest melting domain are readily detected. To facilitate detection of all possible mutations, it is imperative that the target fragment represents only one melting domain. Fortunately, since the addition of a GC-clamp allows for stacking interactions with neighbouring bases, the entire fragment will often behave as one melting domain (Figure 1C). However, this is not always the case, and in practice, the target fragment needs to be designed, e.g. through the strategic positioning of PCR primers to achieve the ideal single

Figure 1 Principles of denaturing gradient gel electrophoresis. (A) Single base changes affect the melting temperature of a fragment, which results in a gel shift. (B) After complete denaturation, single-stranded fragments will run off the gel; the addition of a GC-clamp to the target fragment prevents complete denaturation and therefore fragments will be retarded in the gel. (C) The addition of a GC-clamp to a multiple-domain fragment can make the fragment behave as a single-domain fragment. Continuous line: target fragment without a GC-clamp. Dashed line: target fragment, including a 40 bp GC-clamp. (D) The introduction of a heteroduplex cycle at the end of PCR amplification of target fragments facilitates detection of heterozygous mutations as four molecules: two homoduplexes and two (early-melting) heteroduplexes.

melting domain. In general, target fragments in DGGE have an average size of 275 bp, including a GC-clamp and PCR primer sequences.

The sensitivity of DGGE for detecting variants is further enhanced by the introduction of a heteroduplexing step using one round of denaturation/renaturation, usually at the end of PCR amplification of the target fragment. In this manner, a heterozygous

mutation is revealed as four different double-stranded fragments: two homoduplex molecules (one wild-type homoduplex and one mutant homoduplex) and two heteroduplex molecules (each comprising one wild-type and one mutant strand). Since the stability of heteroduplexes is so much lower, they always melt earlier than the homoduplex molecules (Figure 1D).

Figure 1 Continued

Although DGGE has the crucial advantage of having virtually 100% sensitivity in detecting mutations, it has typically been applied in a serial fashion, e.g. on a fragment-by-fragment basis. For analysing large genes or multiple genes this is not practical. A solution for this problem, which we adopted, is to apply the DGGE principle in the format as it was originally described, i.e. a two-dimensional system of separation by size followed by DGGE. Successful implementation of such a two-dimensional DNA electrophoresis system in mutation scanning of large genes requires an efficient multiplex PCR protocol. Indeed, without the possibility to PCR-amplify multiple target fragments (i.e. typically 10 or more) in one single reaction, the application of a parallel

analysis system offers only a limited advantage. Multiplex PCR systems for genes and genetic markers are now becoming available and it has been demonstrated that as many as 26 fragments can be co-amplified in one single tube under the same reaction conditions.

Two-Dimensional DNA Electrophoresis

The major advantage of two-dimensional electrophoresis is that it provides a high resolution system to screen multiple fragments under the same conditions. It has been demonstrated that DGGE provides virtually 100% mutation detection sensitivity even when applied with a broad range gradient of

denaturants. This opens up the possibility to analyse multiple fragments for all possible mutations under the same set of experimental conditions. The total number of target fragments that can be analysed simultaneously depends on the resolution of the gel system used. Although high resolution can be obtained by using one-dimensional denaturing gradient gels, two-dimensional separation allows characterization of each fragment on the basis of two independent criteria, size and melting temperature. In practice, a fragment mixture corresponding to all exons of a gene is electrophoresed in a non-denaturing size gel. Fragments are further sorted out in a denaturing gradient gel as the second dimension (Figure 2). By using the two-dimensional system, it is possible to visualize completely all fragments corresponding to

an entire gene for a particular DNA sample and immediately recognize each exon and variants therein. This has been demonstrated for several large human disease genes, including *CFTR*, *RB1*, *MLH1*, *TP53*, *TSC1*, *BRCA1*, as well as for a part of the mitochondrial genome.

Design Software and Instrumentation for TDGS Tests

Computer-Automated Design of Target Fragments for PCR and DGGE

A potential hindrance to the widespread application of TDGS to multiple novel genes involves the difficulties in the design of PCR primers generating

Figure 2 Schematic depiction of a TDGS test. All exons are amplified in an extensive multiplex reaction, and the fragments are resolved by size separation, followed by separation in a gradient of denaturants. Heterozygous mutations would show up as four spots instead of one.

single-domain fragments which can be resolved under one set of electrophoretic conditions. To design complete gene tests for mutational analysis by TDGS, an automated generally applicable computer program was developed, which was based on a commercially available primer design program (Primer Designer 3; Scientific and Educational Software, State Line, PA), the melting routine MELT87 and a newly generated spot distribution routine. After entering a gene's coding sequence as exons with their flanking intronic sequences, a rank of suitable PCR primers for each exon is designed by the PCR design subroutine. Next, the best primer pair is used in the melt subroutine to check for a one-domain target fragment. The program uses different GC-clamps at either the 5' or 3' end of the target fragment and, if necessary, additional small GC- or AT-clamps at either side of the target fragment. If it is impossible to design a one-domain fragment, the next optimal primer pair is tested, and so on. If a primer pair suitable to create a one-domain fragment cannot be found, the exon is split.

As soon as primers fulfil PCR and melting criteria, the fragment is positioned according to its size (x) and melting (y) coordinates. The spot distribution routine then checks for possible overlap. The output file of the program is a complete list of primers to be used in TDGS. (Questions regarding the use of the TDGS software should be directed to Accelerated Genomics, Concord, NH, <http://www.acceleratedgenomics.com> Tel.: (210) 616-5910; fax: (210) 692-7502.)

Electrophoresis

For two-dimensional DNA electrophoresis, originally two different gels were used for the first-dimen-

sion (separation according to size) and the subsequent second-dimension separation of these fragments by DGGE on the basis of their melting temperature. The first-dimension separation was carried out in polyacrylamide slab gels, which required staining of the gel to visualize the one-dimension separation pattern before this could be excised and transferred to the second-dimension denaturing gradient gel. Alternatively, tube gels have been employed for size separation, which obviated the need for gel staining and lane excision. However, routine application of TDGS requires standardization and automation, which is incompatible with the labour-intensive step of manual interference between the first- and second-dimension separation.

Recently, we developed a simple automated two-dimension instrument, which is based on an existing vertical electrophoresis system with an isolated horizontal unit on top (Figure 3). This top unit consists of two outer chambers and one middle chamber. The necessary contacts between the outer buffer chambers and the gel are provided by two strategically located openings in the inner glass plate.

In this system only one gel (a denaturing gradient gel) is used with the top part nondenaturing. This nondenaturing part functions as the lane for the first-dimension size separation. A slot former is placed in the top left part (Figure 4). In the current configuration, a gel is attached to each side of a gel holder, which can be placed in a buffer tank. Buffer tanks can hold multiple units so that multiple gels can be run simultaneously (Figure 5). The sample is electrophoresed on the basis of size horizontally in the nondenaturing top gel, and the second-dimension

Figure 3 Two automatic dual-gel TDGS systems.

Figure 4 Schematic depiction of the automated two-dimensional electrophoresis unit. Buffer chambers for the first-dimension separation (A) are connected with the gel through openings in the (inner) glass plate (B). During the first-dimension electrophoresis, the middle buffer chamber (C) is isolated from the outer chambers. For the second-dimension run, buffer chamber C is flooded with buffer and the upper electrode is turned on in conjunction with a positive electrode in the lower reservoir (not shown in this figure). The gel cassette is sealed to the top unit with a serpentine silicone gasket (D), and sample is loaded in the single slot (E). The dashed line indicates the beginning of the gradient of urea/formamide.

electrophoresis is carried out vertically in the denaturing gradient gel. All components of the automatic TDGS electrophoresis system are depicted in **Figure 6**.

Gradient gels can be poured, up to nine at a time, using a simple linear gradient maker in combination with a multiple gel caster. The exact gradient that is to be applied is dependent on the GC-content of the gene(s) of interest and is determined by the TDGS primer designer software.

Miniaturization

Miniaturization of gene analysis systems, such as the TDGS system described here, offers two major advantages: increased speed and lower cost.

Speed The duration of electrophoresis depends on the voltage applied. For example, the optimal electrophoresis conditions for the retinoblastoma susceptibility gene *RB1* using standard 1.0 mm thick gels,

Figure 5 The entire automatic TDGS system. In this version of the system, four gels can be run simultaneously submerged in a buffer tank, which is equipped with a heater/stirrer to provide for a constant temperature. For more information, see <http://www.cbssci.com>

are 100 V, 5 h for the size separation and 100 V, 16 h for the second-dimension separation. Increasing the voltage increases the heat production, which negatively affects gel resolution. An obvious strategy is the use of thinner gels, which facilitate rapid heat dissipation into the surrounding buffer and thereby allow increasing the voltage while maintaining a good resolution. Currently, gels as thin as 0.35 mm are now run at 500 V, 0.8 h for the size separation and 500 V, 3.5 h for the second-dimension separation.

Cost The cost factor is of major importance for the large scale implementation of genetic testing. Since this is determined to a major extent by reagent and material cost, as well as space, miniaturization of analytical systems is of crucial importance. Miniaturization of TDGS results in thinner and smaller gels, which require less sample (smaller PCR volumes can now be applied) and lower gel and buffer amounts. Moreover, they take up less space. Instead of the current 17×22 cm format, two-dimensional patterns have already been produced on 10×10 cm mini-gels, and it is not unreasonable to expect that ultimately electrophoresis will be carried out on glass slides.

Detection of TDGS Patterns

After electrophoresis, the two-dimensional DNA fragment patterns can be visualized by incubating the gels with DNA staining dyes. Examples are ethidium bromide or the more sensitive dye Sybr-green. Patterns are photographed under UV light and evaluated

for the occurrence of variations (in the form of four spot patterns; see Figure 1D). An example of a TDGS pattern is shown in Figure 7, depicting the *RB1* gene, containing a mutation in exon 2.

However, for large scale application of TDGS, dye primer technology for the in-gel detection of two-dimensional spot patterns is an obvious strategy. Test results indicate similar two-dimensional patterns and sensitivity for fluorescein-labelled primers compared to Sybr-green-stained gels.

Introduction of fluorescent detection offers two advantages over gel staining. First, the reduction in labour is considerable and loss of gels due to breakage is prevented. Second, since there is no need to release the gel from between the glass plates it has become possible to use thinner gels, which will allow shorter electrophoresis times (see above). To increase the efficiency even further it is possible to label different samples with different fluorophores. Current fluorescence imagers have the option to analyse multiples fluorophores in the same gel.

Future Developments

Routine application of TDGS requires standardization and further streamlining of the procedure. Ultimately, one could envisage a fully automated system of PCR amplification, sample loading, electrophoresis, scanning of gels by a fluorescent imager, followed by online interpretation of gels by image analysis systems.

Much of the labour that is involved in PCR amplification, as well as the error rate, can be greatly

Figure 6 Line drawing of all the components of a 4-gel automatic TDGS system.

diminished by PCR robotics. Such instruments have now become widely available and, in combination with an ongoing effort to increase multiplex groups, are expected to increase greatly the front-end throughput of genetic testing. Multiple two-dimensional gels can be stacked for simultaneous electrophoresis of manifold samples. A simple robot arm could load the gel sandwiches into the fluorescent imager for quick gel scanning. Finally, while the ac-

tual interpretation of spot patterns is currently most conveniently done by eye, automated image analysis software is commercially available. The use of such software may, for example, facilitate the detection of subtle positional changes in the context of other spot variations. In this respect, one could envisage a programme with information on all possible spot positional variants to identify quickly recurrent mutations and polymorphisms on the basis of their unique

Figure 7 Empirical TDGS pattern of the retinoblastoma susceptibility gene *RB1*, containing a mutation in exon 2.

configuration. Such software should also be capable of storing two-dimensional patterns and link subsets of them in particular experiments requiring comparisons of large numbers of individuals. It could also provide for a sample tracking system.

GEOCHEMICAL ANALYSIS: GAS CHROMATOGRAPHY AND GC-MS

R. P. Philp, University of Oklahoma, Norman, OK, USA

Copyright © 2000 Academic Press

Introduction

Geochemical analysis, and more specifically chromatography, is concerned with samples derived from two different sources: those of relatively recent origin, related to environmental problems; and those of a much greater geological age, related to fossil fuel exploration and exploitation. The chromatographic techniques utilized to analyse and characterize such samples are virtually identical regardless of the age and origin of the sample. The extracts from geochemical samples, whether they are rocks, soils, crude oil spills, contaminated wildlife or spills of refined products, are very complex mixtures of a wide variety of organic compounds. Compounds derived from fossil fuels typically will be complex mixtures of hydrocarbons, and the environmental samples from more recent sediments probably will contain a variety of other compounds such as chlorinated compounds, pesticides or herbicides. In view of the similarities of the techniques used for analysing the samples from these different sources, the majority of examples used in this article to illustrate the techniques will be based on the characterization of fossil fuel samples.

The major goal of any geochemical analysis is to take a sample and, through a variety of fractionations and analytical techniques, reach a point where either the presence or absence of specific target compounds can be determined, or fingerprints for specific classes of compounds can be obtained and used for correlation purposes. Applications related to petroleum exploration might use such fingerprints for oil–source rock or oil–oil correlation studies, whereas in environ-

mental studies one is more concerned with correlating a spilled product with its original source material or trying to evaluate the extent of removal during clean-up procedures.

Geochemical samples are extremely complex mixtures of a wide variety of compound classes. The analytical techniques commonly used to characterize such mixtures involve some form of chromatography, such as gas chromatography (GC), gas chromatography–mass spectrometry (GC-MS), gas chromatography–mass spectrometry/mass spectrometry (GC-MS/MS), and more recently gas chromatography–isotope ratio mass spectrometry (GC-IRMS). Liquid chromatography (LC) and combined liquid chromatography–mass spectrometry (LC-MS) are also used in certain applications, but not to the same extent as GC and GC-MS. In addition to the analytical chromatographic separations, most geochemical analyses require some sort of fractionation into compounds classes prior to the actual analysis. There are certain cases where total sediment extracts or whole crude oils are analysed directly but generally the mixtures are so complex that an initial fractionation(s) is required to simplify the extracts for subsequent analyses. For example gas chromatograms of many crude oils (Figure 1) are dominated by *n*-alkanes but, for the most part, compounds that are of much greater geochemical importance are not readily observable in these chromatograms but are hidden in the baseline of the chromatogram. It should be noted that there are also many naphthenic crudes not dominated by *n*-alkanes, e.g. Venezuelan and Russian crudes. Most of these naphthenic crudes are either severely biodegraded or have been generated at relatively low levels of maturity from sulfur-rich kerogens. A fractionation step involving thin-layer chromatography, column chromatography or liquid chromatography, all of which involve partitioning of components between a liquid and solid phase, leads to the separation of

Figure 1 Gas chromatograms of crude oils, rock extracts, or refined petroleum products are typically dominated by *n*-alkanes and isoprenoids. While GC alone does not permit their identification, the fact that the isoprenoids pristane and phytane have very similar elution times to the C₁₇ and C₁₈ *n*-alkanes, respectively, generally make it relatively easy to identify the other members of the homologous series with a reasonably high degree of confidence.

compounds on the basis of factors such as polarity, shape and size. For hydrocarbon-containing samples, the fractionation step typically involves separation into three fractions – saturate and aromatic hydrocarbons and a polar fraction containing nitrogen, sulfur and oxygen compounds. In general it is the saturate and aromatic fractions that receive most attention in terms of additional analyses. Although the nitrogen, sulfur and oxygen fractions contain many compounds that possess useful information, the complexity of these fractions has precluded their detailed analyses. It is not proposed to go into the experimental details of such chromatographic fractionations since these are very basic techniques and descriptions of specific methods for particular classes of compounds are readily available in the literature.

Fractionation of the crude oil used for Figure 1 into various fractions produces saturate and aromatic fractions as shown in Figure 2. It should be noted when comparing Figures 1 and 2 that the result of the fractionation and evaporation of the solvents used in the fractionation process will lead to the loss of some of the more volatile compounds in the C₁–C₁₅ range of the saturate and aromatic fractions. GC analyses of the saturate fraction produces a chromatogram dominated by *n*-alkanes, typically in the carbon number range from C₁₅ to around C₄₀ when the analyses are performed using conventional GC. The isoprenoids pristane (Pr) and phytane (Ph) can also be clearly discerned on these chromatograms. Once again, it should be emphasized that although the *n*-alkanes are the predominant compounds in the chromatograms, there are many more minor compounds in the fraction that generally provide a great deal more information than the *n*-alkanes. These

Figure 2 The whole oil chromatogram shown in Figure 1 does not give a true impression of the complexity of the mixture of compounds in a crude oil. While the *n*-alkanes are the dominant components in the chromatogram, a vast array of branched, cyclic, aromatic and polar compounds are also present. This figure shows the chromatograms for a saturate and aromatic fraction separated from a crude oil by thin-layer chromatography.

compounds can be further concentrated by such processes as molecular sieving or urea adduction, both of which will separate the *n*-alkanes from the branched and cyclic alkanes as shown in Figure 3. At this point fractionation and sieving of the original extract or crude oil will have produced a fraction that is readily

Figure 3 The saturate fraction shown in Figure 2 is again dominated by *n*-alkanes, which tend to mask the presence of a very complex mixture of branched and cyclic compounds also present in this fraction. The *n*-alkanes can be separated from these branched and cyclic compounds by processes such as molecular sieving or urea adduction to produce the branched and cyclic fraction shown in the bottom chromatogram of this figure. The top chromatogram (A), shown for comparison purposes, is the total saturate fraction from which the branched and cyclic compounds were isolated.

amenable to analysis by the techniques mentioned above, such as GC, GC-MS, GC-MS/MS or GC-IRMS. In the following sections a brief description of each technique and typical applications will be given. Again it should be reiterated that for the most part this article uses hydrocarbons for illustration purposes, but the majority of the techniques are equally applicable to the analysis of other samples of geochemical interest such as environmental samples, possibly with some slight modifications in the operating conditions.

Gas Chromatography

As can be seen from the chromatograms used in the Introduction, GC provides a great deal of information on the composition of geochemical samples. With the inclusion of an internal standard, this information can be both quantitative and qualitative in nature. However, it is important to remember that, for the most part, GC does not provide any information on the identification of individual components. In the saturate hydrocarbon fractions, individual compounds such as *n*-alkanes in the chromatograms can be readily recognized and their identification confirmed either by the use of co-injected standards or analysis of the sample by GC-MS as described below. In other cases where it may be necessary to detect certain classes of chlorinated compounds, or organosulfur compounds, additional information on the presence or absence of these compounds can be obtained by using detectors that are specific for these classes of compounds, such as electron capture, flame photometric or Hall detectors. It should also be noted that a number of recent studies have shown that atomic emission detection (AED) is a particularly sensitive and specific method of detection for sulfur-containing compounds. Although the flame photometric detector (FPD) is probably the most widely used detector for sulfur-containing compounds, it has some drawbacks including nonlinear compound-dependent response, and the quenching of sulfur signals by co-eluting hydrocarbons. The AED has a linear response and is compound-independent, permitting easy calibration using any sulfur-containing compounds. This feature is unique because other detectors require the construction of curves using target analytes as standards, which becomes a very time-consuming exercise.

GC has been utilized widely in geochemistry since the 1950s. As column technology and instrumentation have improved, so has the quality of the analytical data. There are many similarities between the gas chromatographs of today and the systems that were developed in the 1950s and 1960s. Detectors and

injectors have improved and temperature control of the ovens has improved, but probably the greatest advances have occurred in the field of column technology. Early columns were short, large-diameter packed columns made of stainless steel or copper. Over the years narrow-bore capillary columns were developed, initially made of stainless steel, then glass and more recently fused silica. At the same time as the evolution of capillary columns, the variety of liquid phases for different applications has also greatly improved. The most recent advance, and one that is quite significant for petroleum exploration and production, has been the development of high temperature GC phases. Traditionally most crude oil analyses have characterized hydrocarbons in the C₁-C₄₀ range but the advent of high temperature GC (HTGC) significantly changed the way in which we look at hydrocarbon distributions of crude oils. The use of HTGC has demonstrated that many crude oils contain a wide range of hydrocarbons significantly above C₄₀, extending to as far as C₁₀₀ and possibly higher. This in turn has also led to changes in one of the very basic premises of geochemistry – that oils with a high wax content were thought to be derived only from higher plant sources. It is now clear that such oils may also be derived from lacustrine and marine source rocks as a result of analysing a number of samples from such source rocks using HTGC. **Figure 4** provides an excellent illustration of the additional information obtained from the use of HTGC. The upper chromatogram shows the analysis of an ozocerite extract by conventional GC and the bottom chromatogram shows the same sample analysed by HTGC. Clearly the distribution of hydrocarbons is quite different in the lower chromatogram. The significance of this is related to the fact that the greater the concentration of the higher molecular weight alkanes, the greater the production problems associated with oils that contain such compounds. In other words, if the oils were only characterized by conventional GC, high molecular weight hydrocarbons would remain undetected. Once a production programme was initiated it would not be long before the wellhead facilities and pipelines would become blocked with paraffin deposits, which require costly measures to remove. While HTGC analyses do not eliminate the problem, production engineers would be aware of the potential for such a problem and steps could be introduced to minimize its occurrence.

With the availability of HTGC an increasing number of samples have been analysed using this approach and steps have been taken to develop methods that will quantitatively separate high molecular weight alkanes from the asphaltene fraction. Analyses

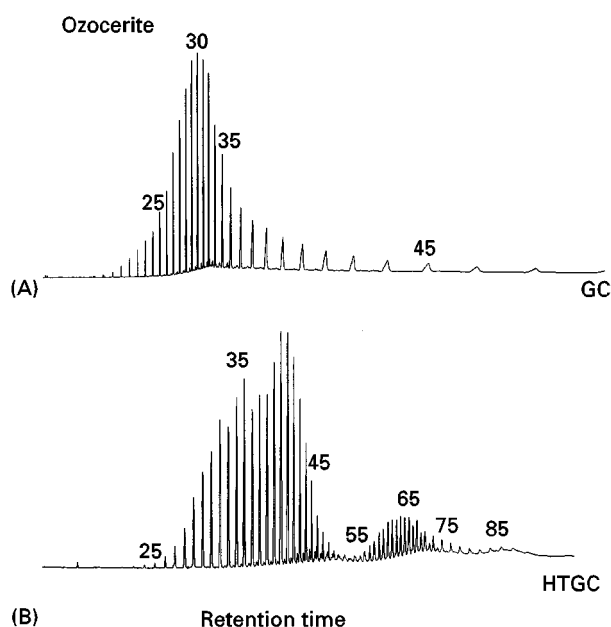

Figure 4 One of the most significant recent developments with-in GC has been the development of high temperature phases for the columns. Before this development it was generally only possible to analyse compounds with up to approximately 40 carbon atoms. The newer HTGC columns permit samples containing up to approximately 120 carbon atoms to be analysed. This figure illustrates the comparison between the analyses of the hydrocarbons in the fossil bitumen ozocerite by (A) conventional GC and (B) HTGC. The difference in distributions is very clear and also demonstrates how the composition of a fraction obtained by conventional GC may not necessarily reflect the true composition of the sample being investigated.

of a wide range of such samples have shown that, in addition to the *n*-alkanes, there is also a wide range of additional compounds in the higher molecular weight fraction including branched alkanes and alkylcyclohexanes. The distribution patterns for these compounds has provided an additional powerful tool for determination of the type of environment from which a sample has been generated. For example **Figure 5A** and **B** show the distributions of high molecular weight fractions from oils whose source materials were known to be deposited in lacustrine and marine depositional environments, respectively. Note the difference in the distributions of these monocyclic hydrocarbons, which are characteristic of the different environments. At present relatively little information is available concerning the origin of these compounds, although their widespread distribution suggests that they are probably related to an algal/phytoplanktonic source, possibly with additional contributions from higher plant waxes. It is known that many marine organisms contain abundant quantities of higher molecular weight esters, alcohols and fatty acids. Relatively simple transformations

could readily convert these compounds to the corresponding hydrocarbon and could easily represent a viable source for such hydrocarbons.

Another area of geochemistry that has become particularly important in the past few years is reservoir geochemistry, and GC has played an extremely important role in its development. Oil and gas reservoirs are very complex geological features with many compartments. A knowledge of the relative position of these compartments is extremely important for reservoir management, determination of where additional production wells should be drilled, and evaluating how a specific reservoir may have been filled. There are a number of ways in which the reservoir compartments may be delineated but one particularly interesting, innovative and relatively cheap method involves the utilization of high resolution GC. As indicated above, crude oils are very complex mixtures of hydrocarbons, but when the chromatograms are expanded the complexity of the mixtures becomes far more apparent and the presence of a large number of minor components is clearly visible. Reservoir geochemistry utilizes these minor components to assist in the delineation of the reservoir compartments. In brief it is first necessary to determine whether all of the oils in the reservoir are derived from the same source materials. Once this has been established, all of the oils need to be analysed by high resolution GC, the early eluting region of the chromatogram expanded and a number of pairs of minor peaks selected as shown in **Figure 6**. Ratios based on pairs of selected peaks are measured and subsequently plotted on a star or polar diagram. This process is then repeated for all the oils to be examined from the reservoir. It is important to ensure that the same pairs of peaks are selected for each oil, even if the identity of these peaks is unknown. Since the differences between the pairs of peaks in individual samples are often quite small it is extremely important to ensure that the GC analyses are highly reproducible for this particular application. However, once all of the oils have been analysed and the data plotted on the star diagram, it will be found that oils that are in the same compartment or in communication will appear virtually on top of each other, whereas those oils in different compartments will be slightly separated (**Figure 7**). These small difference may result from slight differences in oil-rock interactions, slight maturity differences or generation from slightly different sources.

Gas Chromatography-Mass Spectrometry

While GC can provide a great deal of information that is of interest and useful from a geochemical

Figure 5 The availability of HTGC has led to the discovery of numerous new series of compounds present in oils and source rocks above C_{40} . Several of these series, and in particular a series of alkylcyclohexanes, have been shown to be useful in discriminating between oils derived from source materials deposited in lacustrine (A) versus marine settings (B). More subtle variations in these distributions allow the salinity levels of the depositional environments to be distinguished.

perspective, it should also be noted that in most cases GC only provides information on the distribution of the major components in the sample, and for the most part these are generally dominated by the *n*-alkanes. The more useful compounds are the more complex molecules, or biomarkers, which are typically present in relatively low concentrations and which require the use of GC-MS and more specifically single ion or multiple ion detection (MID) in order to determine their distributions. While there are many classes of biomarkers that are commonly used for correlation and other purposes, compounds such as the steranes and terpanes will typically provide the greatest

amounts of useful information for both an environmental and exploration context.

To illustrate the utility of the biomarker fingerprints, the gas chromatograms of three oils are shown in Figure 8. From the gas chromatograms alone it is virtually impossible to determine what relationship, if any, exists between these samples. In other words, are they from the same source rock or can they be correlated with each other? The effects of biodegradation are clearly evident in sample B since all of the *n*-alkanes have been removed, making it appear even more significantly different from the other two samples. Detailed analyses of the same samples by

Figure 6 Reservoir geochemistry has provided an important means of determining continuity and communication within reservoir compartments. Once it has been established that the oil in a reservoir is from a common source, high resolution gas chromatograms are obtained for individual samples and ratios of various pairs of peaks are determined, as shown in the figure. The identity of the components does not have to be known; the important point is that the same pairs of peaks are used for all the samples examined in any particular study. Although the early studies typically used peaks in the early part of the chromatogram, it has been shown that the minor components in the higher regions of the chromatogram can also be used for the same purpose.

GC-MS and MID using the characteristic ions for the sterane and terpane biomarkers at m/z 217 and 191, respectively, produces the additional data shown in **Figure 9**. On the basis of the chromatograms shown in **Figure 9**, samples B and C are in all probability related to each other. It is not necessary to identify each component, rather one should think of the mass chromatograms as fingerprints. If two samples are derived from the same source, then their fingerprints should be the same, or at least very similar; samples from different sources will be different from each other. Hence when the fingerprint for sample A is compared with those for B and C in **Figure 9**, there are a number of significant differences between these samples that permit one to conclude that A is from a different source than B or C. The biomarker fingerprints obtained in this way are very

specific for a variety of applications, in addition to this type of correlation. The presence of individual compounds, for example oleanane and gammacerane, can provide information on the presence of specific types of source materials or the nature of the depositional environment.

To illustrate this type of application, **Figure 10** shows the m/z 191 and 217 mass chromatograms of an oil that is derived from source material dominated by higher plant or terrestrial source material. This evidence is contained in the fact that the predominant component in the m/z 191 mass chromatogram is the terpane called $18\alpha(H)$ -oleanane. It has been established that this compound has its precursor in higher plant material and hence the presence of this compound in an oil will indicate that the sample is derived from such material. In support of such evidence is the

Figure 7 The ratios of the pairs of peaks measured in Figure 6 are plotted on a star or polar diagram. If two oils are in the same compartment, or in communication with each other, then on such a star plot the two oils will have identical plots (i.e. B and C). If they are not in communication with each other, then their plots will show some subtle differences (i.e. oil A).

fact that the sterane chromatogram is dominated by the C_{29} steranes. For oils of this nature it has been clearly established that the C_{29} steranes are also associated with higher plant source materials. In this

Figure 8 Gas chromatograms of three different oils provides limited information concerning the relationship between the samples. In this figure oil B clearly appears to be quite different from oils A and C, but all that can really be said is that oil B has been heavily biodegraded and the n -alkanes have been removed. It is impossible to say what, if any, similarities there may have been between the alkane distribution for this sample and the other two samples.

manner, pieces of evidence can be put together that in many cases will provide a very clear indication as to the origin of the material being analysed.

In the second example, shown in Figure 11, the presence of another very specific compound, gammacerane, can also be very clearly seen in the m/z 191 chromatogram. This compound is a very specific indicator of depositional environments of enhanced salinity. Recent attempts have been made to relate the presence of certain compounds, for example, dinosterane to the age of the source rock from which the sample was generated. Specific ratios of different sterane isomers or terpane isomers are also used extensively for determining the relative maturity of oils or source rocks.

The sterane and methylsterane distributions in crude oils are far more complex than the terpanes and no matter how good the GC resolution, it is impossible to obtain complete separation of all co-eluting isomers, epimers and homologues (Figure 12). In order to optimize this separation it is necessary to utilize GC combined with tandem mass spectrometry, or MS/MS, which provides an additional degree of separation based on the utilization of the MS/MS capability.

Gas Chromatography–Mass Spectrometry/Mass Spectrometry

To demonstrate the utility of the GC-MS/MS approach to the characterization and determination of biomarkers in geochemical samples, the resolution of a complex mixture of sterane isomers and homologues will be described. While this example utilizes the steranes, it should be borne in mind that the same approach can be used to resolve any very complex mixture of organic compounds from geochemical samples.

The mixture of steranes commonly analysed by MS/MS is in the C_{27} – C_{30} carbon number range and each homologue has a molecular mass at m/z 372, 386, 400 and 414, respectively. For each of the steranes the parent ions will undergo a collision-activated decomposition to produce a daughter ion at m/z 217. Hence a series of MS/MS parent–daughter experiments are performed utilizing these parent–daughter transitions in combination with the GC separation. The GC-MS analysis and single ion monitoring of m/z 217 produces the mass chromatogram shown in Figure 12 but with the GC-MS/MS analyses, the results shown in Figure 13 are obtained. It can be seen in Figure 13 that by using the C_{27} parent–daughter ion pair at m/z 372/217, respectively, the result of analysing the sample by MS/MS is to

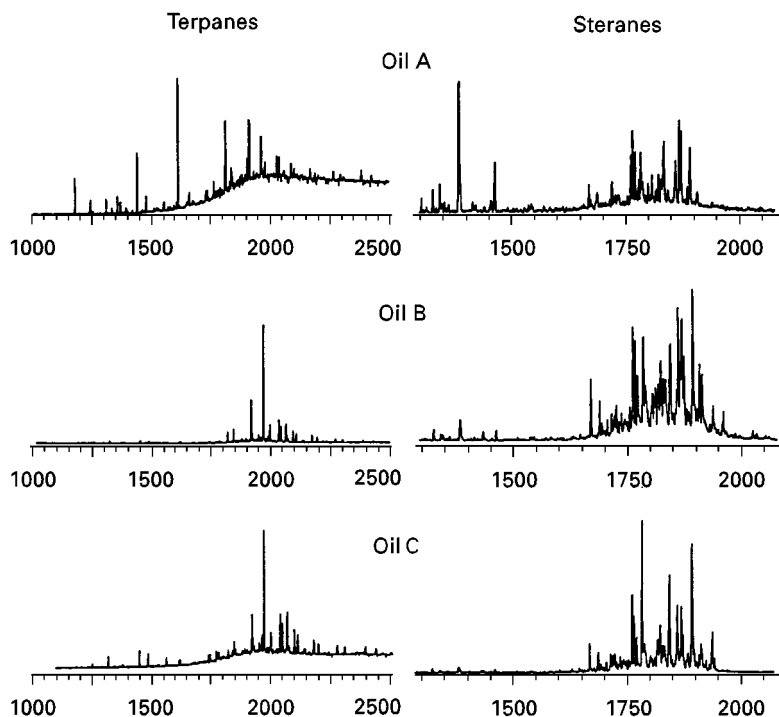

Figure 9 The terpene and sterane distributions for the same three oils as used in Figure 8 provide a more specific indication of the relationship between different samples. It is not necessary to know the identification of all the individual peaks but rather to think of the total chromatogram as a fingerprint. In this case it can be seen that oil A has quite a different set of fingerprints than oils B and C, suggesting it is not related to these other two samples. While the fingerprints of oils B and C may show some differences, these are actually due to small maturity differences in the samples.

totally resolve the C_{27} components from the rest of the complex mixture.

Similar results would be obtained if the parent–daughter pairs for the other members of the series were also illustrated. A similar approach could be applied to the methylsterane mixture using the parent ions and the daughter ion at mass 231 and a similar simplification of the mixture would be obtained. In this particular application the MS/MS serves to introduce an additional element of separation following the initial separation by GC.

Pyrolysis–Gas Chromatography–Mass Spectrometry

While a large proportion of the geochemical samples analysed are soluble in organic solvents and readily amenable to direct analysis by GC or GC-MS, there is another aspect to geochemical samples that is often overlooked. Samples of geochemical interest such as soils, source rocks or coals also have a significant insoluble organic component such as the humic fraction of soils or the kerogen fraction of a source rock. Characterization of these insoluble fractions requires

some type of degradation step prior to analysis. At present for geochemical purposes this degradation step typically consists of some type of pyrolysis reaction with the pyrolyser interfaced to the gas chromatograph or GC-MS system. There are also reports of the use of various NMR techniques to characterize this insoluble fraction, although this is a little less specific than the pyrolysis approach.

An example of the pyrolysis of the insoluble fraction of an organic-rich source rock is shown in Figure 14. This was produced by pyrolysing the sample at a temperature of 600°C for a short period of time and allowing the pyrolysis products to be transferred directly to the GC column. (There are of course a wide variety of pyrolysis conditions that could be used, but those cited here give a general idea of the typical conditions used.) The products of a sample pyrolysed in this manner produce a chromatogram dominated by alkane/alkene doublets plus a wide variety of minor components. From these distributions it is often possible to gain information about the nature of the source materials originally responsible for the formation of the kerogen plus the type of products it will subsequently produce if buried to

Figure 10 GC-MS analysis of crude oils reveals complex fingerprints of biomarkers. In many cases these compounds may be very specific indicators of particular types of source materials responsible for sourcing the oil. In this example the predominant component in the terpane chromatogram is $18\alpha(\text{H})$ -oleanane. Not only is this compound very specific in terms of being derived from higher plant source materials, but it is also more specifically related to the flowering plants or angiosperms that have only evolved since the Late Cretaceous–Early Tertiary periods. The presence of this compound can therefore be used to constrain the age of the source rock from which the oil was generated.

appropriate depths and subjected to thermal degradation.

Another useful application is the pyrolysis of asphaltenes, particularly those isolated from biodegraded crude oil samples. It is often difficult to determine the origin of a biodegraded oil sample. However, if there are a number of possible nondegraded samples with which it can be compared, then the asphaltenes can be isolated from all the samples

Figure 11 Gammacerane is another very specific biomarker that can be readily observed in the m/z 191 chromatogram. The relative concentration of this compound varies with the salinity of the original depositional environment. Hence samples deposited in a very saline lacustrine setting will generally have high gammacerane contents whereas those from freshwater lacustrine environments are generally depleted in gammacerane.

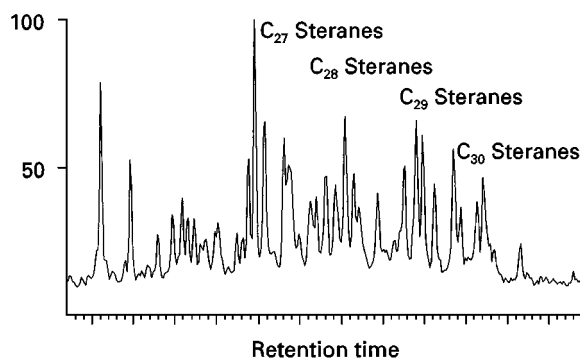

Figure 12 Sterane distributions in crude oils as typically determined by single ion monitoring of m/z 217 reflect the complex nature of the mixture of these components in a crude oil. It is virtually impossible to separate all of the co-eluting isomers, epimers and homologues by GC-MS, no matter how good the chromatography.

by pentane precipitation and pyrolysed. In this way it will be observed that the n -alkane/alkene fingerprints generated from the degraded and nondegraded samples will be virtually identical if the samples are derived from the same source, but quite different if the samples are unrelated.

Gas Chromatography–High Resolution Mass Spectrometry

The majority of geochemical analyses reported in the literature are concerned with the detection and identification of hydrocarbons. However, many

Figure 13 To simplify the sterane fingerprint to some degree GC-MS/MS becomes an important tool. In this diagram the same sterane mixture used for Figure 12 has been analysed in the GC-MS/MS mode. By filtering out the parent–daughter ions for the C_{27} steranes, the top chromatogram shows only the C_{27} compounds. Distributions for the C_{28} – C_{30} steranes could also be obtained using the appropriate parent–daughter ions.

Figure 14 One of the most useful ways for characterizing the insoluble organic matter in a source rock, coal, shale or soil sample is by pyrolysis-GC. This figure illustrates the results obtained from pyrolysis-GC of Messel shale and shows that the major components obtained in the approach are a series of alkane/alkene doublets. Variations in these distributions can be used to characterize the organic matter in terms of whether it is algal or terrestrial as well as provide information on the relative maturity of the samples.

geochemical mixtures contain complex mixtures of compounds in which heteroatoms are mixed with the hydrocarbons in varying amounts. In certain applications knowledge of these components, particularly sulfur-containing compounds, may be extremely important. There are two approaches by which such distributions may be obtained. The first is by the use of element-selective GC detectors, such as the FPD, Hall detector, or one of the more recent types of AED that are selective for sulfur-containing compounds at the exclusion of non-sulfur-containing compounds. The second method combines GC with high resolution MS. Although this approach is not used routinely, it is a very powerful and specific technique for this type of application, as discussed by Tibbetts and Large in 1988. While the use of low resolution GC-MS and ancillary techniques such as single ion monitoring and multiple ion detection have been discussed elsewhere, it needs to be recognized that utilization of nominal masses in MID may lead to ambiguous results. As demonstrated by Tibbetts and Large, while the ion at nominal mass 184 may be used for the determination of dibenzothiophenes (DBT), it is also the nominal mass for the C_4 -substituted naphthalenes, leading to possible misinterpretation of the resulting chromatograms. However, use of the accurate mass at m/z 184.0347 permits detection of only the DBT and no substituted naphthalenes. Several examples have been given by Tibbetts and Large on the use of this approach for the correlation of crude oils or to distinguish oils from different sources or reservoirs.

Used in conjunction with the conventional detection of biomarkers, this method provides a very powerful and additional tool for geochemical analyses.

Gas Chromatography–Isotope Ratio Mass Spectrometry

Carbon naturally exists as a mixture of its two stable isotopes, ^{12}C and ^{13}C , in an approximate $^{12}\text{C}/^{13}\text{C}$ ratio of 99 : 1. The carbon isotopic composition of living organic matter in part depends on the species but is also determined by a number of environmental properties. For example, atmospheric carbon dioxide is assimilated by living plants during photosynthesis and the nature of the plants and whether they assimilate CO_2 via a C3 or C4 photosynthetic cycle will determine the extent of preferential assimilation of the lighter ^{12}C isotope. C3 plants are typically associated with warmer and more arid climates and in general have isotopic values in the -10 to -18‰ range. C4 plants are more typically associated with colder climates and have lighter isotopic values in the -22 to -30‰ range. To determine the ^{13}C composition, the sample is combusted to convert all of the carbon to CO_2 , which is analysed in a stable isotope ratio mass spectrometer and compared with the isotopic composition of a standard material (Pee Dee Belimnite, PDB), whose isotopic composition has been assigned a value of 0.

GC-IRMS and Isotopic Composition of Individual Components

GC-IRMS permits acquisition of $\delta^{13}\text{C}$ values for individual components in complex mixtures. The important part of the system is the interface between the GC and the isotope ratio mass spectrometer. This consists of a reactor tube, generally a narrow-bore ceramic tube, containing a bundle of wires, typically copper, nickel or platinum where complete combustion to CO_2 must occur. After combustion the water and CO_2 pass through a membrane separator to remove the water before the CO_2 enters the mass spectrometer, where the isotopic composition of the gas is determined relative to the standard. The isotopic values of individual components can be interpreted to obtain information on the diagenetic history of an individual component and the nature of the microbial community during deposition.

The isotopic composition of individual compounds is also of importance from an environmental viewpoint. For example, analysis of a whole oil, or the saturate fraction of a whole oil, allows the ready determination of $\delta^{13}\text{C}$ values of the n -alkanes and the

major isoprenoids, pristane and phytane. These values can be used for correlation purposes, to distinguish oils from different sources, to correlate oil spills with their suspected sources, or to determine the source of hydrocarbons that have contaminated wildlife. Examples of this approach are shown in **Figure 15**. Gas chromatograms of oil extracted from the feathers of birds that had been exposed to a crude oil spill and a suspected source are compared with each other and show certain differences, particularly at the lighter end of the chromatograms. Such differences could lead to a dispute as to whether or not this oil was actually the one that was responsible for contaminating the birds. The lower part of the figure shows the carbon isotope data for individual compounds in the two samples. It can be seen

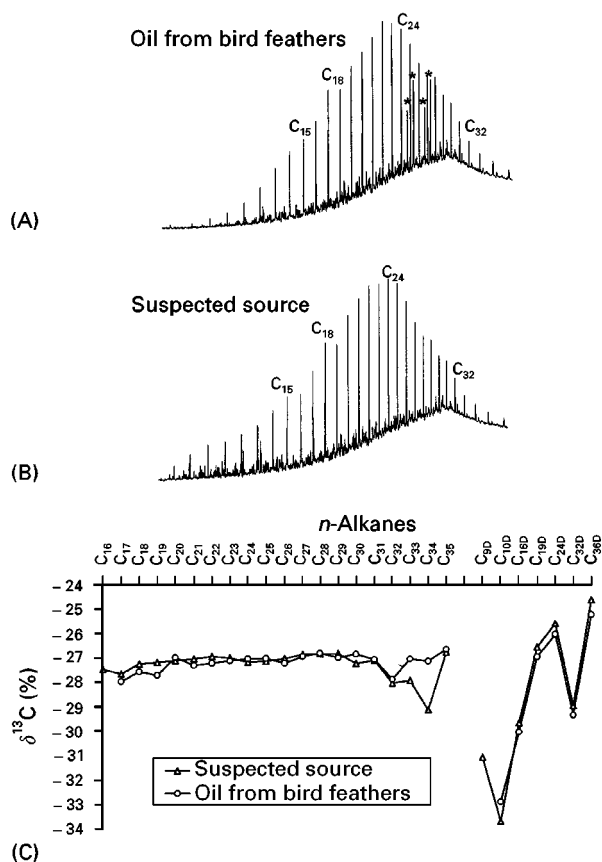

Figure 15 (A) Chromatogram of an extract from bird feathers contaminated by a crude oil; (B) shows the chromatogram for the suspected source of the contamination. The two chromatograms show some significant differences, particularly in the early part of the chromatogram, mainly as a result of weathering. However, in (C) we see that there is a strong relationship between the isotopic compositions for each individual *n*-alkane in the two samples. This isotopic information can be used in conjunction with the biomarker data and other parameters to establish a relationship between the two samples.

that, despite the loss of some of the light ends through evaporation, a good relationship between the two samples can be established. These data could also be used in support of the biomarker and other properties normally used to establish relationships between samples thought to be related. In an additional example, **Figure 16** shows the results from the GC-IRMS analyses of 20 oils from a region in SE Asia. It can be seen that on the basis of these analyses two distinct families of oils are present in the region. One family has isotopic values of around -20‰ for each compound whereas the other family has values around -28‰ . This information can be used in conjunction with the biomarker data to determine the significance of these differences.

While these are just two examples, we have also shown that GC-IRMS can be used in an environmental context to correlate weathered and unweathered oils and refined products and their weathered counterparts. If there are small amounts of the *n*-alkanes remaining it should be possible to obtain their isotopic composition and subsequently use these values to make the correlation. Alternatively if the samples have been so extensively biodegraded that all of the *n*-alkanes have been removed, it is possible to isolate the asphaltenes, pyrolyse them and analyse the pyrolysates by GC-IRMS. Correlations can then be made using these data. This is a particularly valuable approach for the correlation of refined products that only contain lower carbon number compounds and none of the more reliable biomarker compounds that are typically used for correlation purposes.

Summary

This article has attempted to illustrate the importance of GC to geochemical analyses. Geochemical samples from all sources, whether recent or ancient, oils or synthetic chemicals, refined or crude, are incredibly complex mixtures of organic compounds in most cases. To try and analyse such samples, whether simply for correlation purposes or to detect and identify unknown compounds, almost inevitably requires some level of chromatography to facilitate the analytical process. The most common forms of chromatography generally involve some form of liquid chromatography in the initial steps to simplify the mixture into compound classes, followed by GC to separate and resolve as many compounds as possible in the resulting fractions. Chromatography alone simply separates the components, hence it is very common in most geochemical analyses for the chromatographic step to be combined with an identification technique such as MS. The results of such

Figure 16 Analysis of 20 oils by GC-IRMS provides isotopic data for each major compound present in the oils. The oils plotted on this chart can be divided into isotopically heavy and isotopically light groups. Supporting evidence for these groupings can be obtained from the GC-MS data.

analyses generally provide the information necessary to determine the origin of a particular sample and, in the context of crude oil exploration, relate it to possible source rocks and such information as age, maturity, and migration pathways. For environmental samples the information obtained is generally for the purpose of determining the source of a spill and hence a great deal of use is made of these distributions in terms of their fingerprinting capability. As chromatographic and spectroscopic techniques continue to improve, clearly the degree of separation achievable for these complex mixtures will also greatly improve, but mixtures of even greater complexities will always be available to provide that next level of challenge.

Introduction

Many proteins in cells and biological fluids are glycosylated, and these glycoproteins are present in animals, plants, microorganisms and viruses. The most commonly occurring monosaccharides found in oligosaccharide attachments to mammalian proteins are D-mannose (Man), D-galactose (Gal), D-glucose (Glu), L-fucose (Fuc), N-acetylglucosamine (GlcNAc), N-acetylgalactosamine (GalNAc), and N-acetylneuraminic acid (sialic acid or NeuAc).

The primary structure of glycoprotein glycans and their biological functions have been gradually unravelled by the improvements of methods for isolation and structure determination. High performance liquid chromatography (HPLC) is one of the most commonly used methods for the isolation and analysis of both glycoproteins and their derived carbohydrates, mainly due to the excellent resolution, ease of use, the generally high recoveries, the excellent reproducibility of repetitive separations, and the high productivity in terms of cost parameters.

Chemistry and Importance of the Glycan Chain of Glycoproteins

Basic Structure of Glycoprotein

In glycoproteins, glycans are conjugated to peptide chains by two types of primary covalent linkage, N-glycosyl and O-glycosyl. The former is called an N-linked sugar chain and contains a GlcNAc residue that is linked to the amide group of asparagine residues of a polypeptide. As shown in Figure 1, almost all N-linked glycoproteins have a common core of two GlcNAc and three Man residues. N-linked glycoproteins have three types of carbohydrate moieties: complex type (Figure 1), high mannose type and hybrid type. The hybrid type is a mixture of the complex and high mannose types. Complex type structures usually have from two to four branches attached to the two outer core Man residues. The branches are distributed over the two terminating core Man residues. The complex structures are termed diantennary, triantennary and tetraantennary, according to the

number of antennae. The basic branch structures are composed in most instances of one GlcNAc and one Gal residue (Figure 1).

O-Glycosyl glycoproteins contain at their reducing end a GalNAc residue that is linked to the hydroxyl group of either serine or threonine residues of a polypeptide. This linkage is called an O-linked or mucin-type sugar chain. In general, O-linked structures appear to be less complex than N-linkages in terms of the number of antennae and monosaccharides. However, they can be fucosylated and sialylated. Some glycoproteins have both the N-linked and O-linked forms in their molecules (N, O-glycoproteins).

The addition of carbohydrate to a peptide chain changes the shape and size of the protein structure. Several important discoveries have revealed the following biological roles of glycans: (i) protection of polypeptide chains against proteolytic enzymes; (ii) influence on heat stability, solubility, and many physicochemical properties; and (iii) interaction with other proteins or nonprotein components of the cell, including control of the lifetime of circulating glycoproteins and cells.

Microheterogeneity of Glycans

In addition to genetically determined variants expressed as variations in their polypeptide chains, almost all glycoproteins exhibit polymorphism associated with their glycan moieties. This type of diversity is termed microheterogeneity, and these different forms have recently been called glycoforms. These variants were first characterized in the α_1 -acid glycoprotein (AAG) from human serum using electrophoresis. As shown in the structure of major oligosaccharides of AAG (Figure 1), microheterogeneity was found to be due to the occurrence of di-, tri-, and tetraantennary glycans of the N-acetylglucosamine type at the five glycosylation sites.

This feature is widespread and has been observed in natural as well as in recombinant DNA glycoproteins. The existence of microheterogeneity gives rise to many interesting questions regarding the origin of this phenomenon and its relevance to the biological functioning of the glycoproteins that can be distinguished.

Recent interest has been shown in glycoproteins in the industrial field of genetic engineering of human glycoproteins of therapeutic interest. This gives rise to

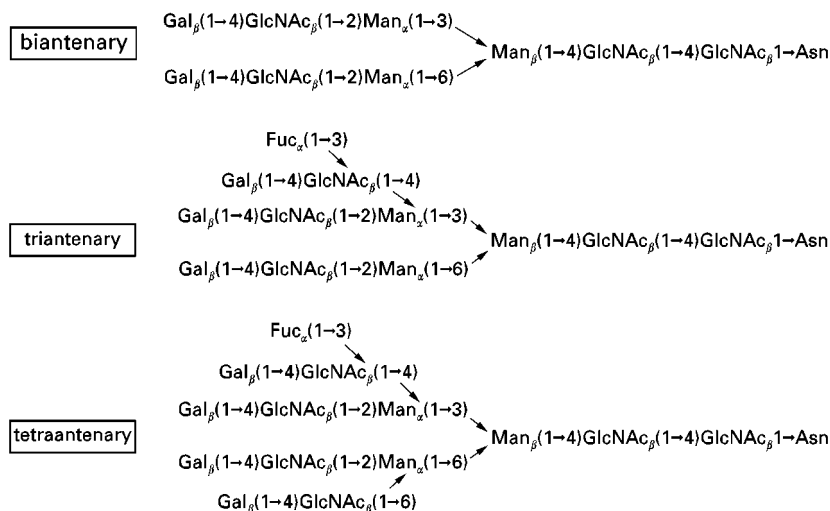

Figure 1 Structure of the major oligosaccharides of α_1 -acid glycoprotein (a complex type of the *N*-linked form). Several NeuAc are linked to Gal residues.

an enormous problem, because the production of recombinant human glycoproteins in nonhuman eukaryotic cells or in prokaryotic cells devoid of glycan biosynthesis machinery leads to the production of incorrectly glycosylated proteins. Incorrectly glycosylated glycoproteins may have an undesirable effect on therapeutic effectiveness and safety due to changes in the properties of the products, including a decrease in the stability against heat or protease, shortening of the *in vivo* life span of the molecules by an increase in clearance, a decrease in the affinity for specific receptors, and an increase in antigenicity.

Isolation and Quantitation of Glycoprotein Molecules and Analysis of Glycan Chains

Determination of the primary structure of glycoproteins necessitates analysis of the protein sequence, identification of the glycosylation sites, unravelling of the glycan structures and determination of the microheterogeneity of the glycans at each glycosylation. For these studies, it is essential that adequate starting materials are available.

For the isolation or purification of glycoproteins, a combination of several complementary separation methods such as gel permeation chromatography, affinity chromatography (lectin or others), anion- or cation-column chromatography, high performance capillary electrophoresis, and HPLC using several sorbents is generally used.

Determination of the carbohydrate composition, type and branching pattern is an important step for understanding the biological function of the native

glycoprotein molecules as well as for the development of a recombinant DNA-derived glycoprotein as a pharmaceutical agent. However, the composition, type and branching pattern of carbohydrates are complex due to the diversity of monosaccharides and the variety of possible linkages. Unlike amino acids, which are linked through an amido bond, monosaccharides are joined through a variety of hydroxyl groups present on the sugar to form glycosidic linkages. For example, two different amino acids can form only two dipeptides, while two different monosaccharides can lead to more than 60 disaccharides. However, the availability of improved and sophisticated methods for the isolation and characterization of glycoproteins and their derived glycans has paved the way for the analysis and characterization of the carbohydrate chains of glycoprotein. These analytical methods include mass spectrometry, enzymatic microsequencing, nuclear magnetic resonance (NMR), capillary electrophoresis, reversed-phase HPLC (RP-HPLC), and high pH anion exchange chromatography with pulsed amperometric detection (HPAEC-PAD), and generally a combination of several complementary analytical methods is needed to determine the carbohydrate structure.

In this section, we give an outline of the recently developed HPLC procedures for the purification, separation, and determination of glycoproteins and their glycoforms.

Examples of Isolation or Purification of Glycoproteins by Using HPLC

α_1 -Acid glycoprotein (AAG) AAG is a characteristic and dominant fraction of human serum sialoglycoproteins with a molecular mass approximately 44 000

Da, an unusually high carbohydrate content (45%) and a large number of sialyl residues. Although its exact biological function is still unknown, AAG is an acute-phase reactant that increases following cancer, myocardial infarction, and congestive heart failure and has also been reported to play an important role in immunoregulation.

Ion exchange chromatography and gel permeation chromatography previously used for purification are time-consuming and require a large volume of plasma or serum because of the low quantities recovered. These methods also lead to a strong possibility of denaturation and desialylation. Moreover, separation of AAG and α_1 -antitrypsin has been difficult, because the chromatographic behaviour of these compounds during anion exchange chromatography is similar. Recently, these problems have been overcome by the introduction of an HPLC system equipped with a hydroxyapatite column as the last step after the clean-up procedures with commercially available cartridge ion exchange columns.

Ceruloplasmin (CP) CP is a serum α_2 -glycoprotein that carries more than 95% of the copper present in plasma and is believed to have an active role in the regulation of copper and iron homeostasis. It has been pointed out that fragmentation of CP during purification and storage has hampered the study of its structure. The rapid degradation of purified CP reported by many laboratories may be largely due to the presence of one or more copurifying or contaminating proteases, at least one of which is a metalloproteinase.

Recently, a highly purified and nonlabile CP has been obtained from human plasma by combining the previously reported chromatographic steps with additional gel permeation and fast protein liquid chromatography (FPLC) steps. In the latter steps, further purification of CP by Sephadex G-50 chromatography and Mono Q FPLC were essential for the removal of plasma metalloproteinase, and this purification procedure yielded a protein that was completely stable even after incubation at 37°C for 4 weeks.

Erythropoietin (EPO) EPO, an acidic glycoprotein hormone, is synthesized in the kidney and circulates in the blood to stimulate red cell proliferation and differentiation in bone marrow. Native human EPO was first purified from the urine of patients suffering from severe aplastic anaemia. Since then, several methods for the purification of urinary human EPO (uHuEPO) have been developed. RP-HPLC has recently been used for the purification of uHuEPO with high *in vivo* activity. This purification

procedure involves two membrane filtration steps, Sephadex G-25, two DEAE-agarose steps, Sephadex G-75, wheat germ agglutinin (WGA)-agarose, and RP-HPLC. The final HPLC step is essential for the removal of nucleic acids.

Chromatographic Determination of AAG

There have been very few reports on chromatographic methods for determining concentrations of glycoproteins other than AAG in biological samples. Radial immunodiffusion (RID) utilizing the antibody against AAG has been widely used to determine AAG in serum because of its strong specificity. This method, however, is time-consuming and is not easily applicable to experimental animals. To overcome these problems, some simple and rapid HPLC methods have been developed.

After pretreatment of human serum with a chloroform/methanol mixture (2:1, v/v), 500 μ L of the upper phase was applied to the anion exchange FPLC system (Mono Q HR 5/5 column), and AAG was eluted with a pH/NaCl gradient elution programme. To measure the serum AAG content, the Mono Q HR column was calibrated with commercial AAG in the range 100–200 μ g/500 μ L of sample volume.

A rapid and sensitive determination method starting from the diluted human serum itself has also been reported. This procedure involves the anion exchange step for cleaning up serum (commercially available cartridge column, DEAE-M) and a hydroxyapatite HPLC system. A linear relationship between standard AAG concentration and peak height was observed over the concentration range 0.5–2.5 mg mL⁻¹ serum. The coefficient of variation at 0.5 mg mL⁻¹ AAG was 3.7% ($n = 8$). A good correlation was observed between this HPLC method (y) and the conventional RID (x) ($y = 1.009x + 0.004$, $r = 0.996$).

Determining the Carbohydrate Composition, Type and Branching Pattern

RP-HPLC has become a commonly used method for the analysis and purification of peptides, proteins and glycoproteins. The RP-HPLC experimental system usually comprises an n-alkylsilica-based sorbent. By using modern instrumentation and columns, complex mixtures of peptides and proteins can be separated and low picomolar amounts of resolved components can be collected. Separation can be easily performed by changing the gradient slope of solvents such as acetonitrile containing an ionic modifier (e.g. trifluoroacetic acid (TFA)); column temperature; or the organic solvent composition. The technique is equally applicable to the analysis of enzymatically derived

mixtures of peptides from proteins and glycoproteins. Separated fractions can be subsequently subjected to further analysis of carbohydrates and amino acids.

A new HPLC method, HPAEC-PAD, which bypasses the derivatization steps by using pulsed electrochemical detection on gold electrodes, has been developed. Monosaccharides and oligosaccharides can be directly resolved by anion exchange chromatography, because the hydroxyl groups of carbohydrates are weakly acidic and reveal anionic forms at pH values greater than pH 12. In addition to high sensitivity in the low picomole range of PAD, a major advantage of HPAEC-PAD is its usefulness in analysing both monosaccharides and all classes of oligosaccharides without derivatization. HPAEC-PAD has therefore been used successfully for resolving and quantitating the constituent monosaccharides released by acidic hydrolysis (e.g. TFA) of glycan chains and for resolving *N*-linked oligosaccharides separated by enzyme digestion (e.g. PNGase F).

Figure 2 shows the HPAEC-PAD chromatograms of fractions 23–27 from the RP-HPLC separation of a tryptic digest of recombinant tissue plasminogen activator (tPA). The peaks from RP-HPLC separation were collected manually, and aliquots of all 62 fractions were analysed for neutral and amino monosaccharides after acid hydrolysis. The chromatograms in

Figure 2 Monosaccharide analysis of fractions 23–27 from RP-HPLC separation of a tryptic digest of recombinant tissue plasminogen activator. Elution positions of monosaccharide standards are indicated on the upper trace. (Reproduced with permission from Townsend *et al.*, 1996.)

Figure 3 Representative chromatograms of monosaccharides after treatment of standard and plasma samples. (A) Standard sample containing $5.0 \mu\text{g mL}^{-1}$ of each monosaccharide; (B) healthy subject; (C) patient with renal insufficiency. Peaks: 1 = mannitol (internal standard); 2 = Fuc; 3 = GlcNAc; 4 = Gal; 5 = Man. (Reproduced with permission from Kishino *et al.*, 1995.)

Figure 2 indicate that fractions 24–26 contain glycopeptides, and the ratio of constituent monosaccharides suggests that their oligosaccharide structures are those of fucosylated *N*-acetylglucosamine-type oligosaccharides. Another *N*-acetylglucosamine-type chain and an oligomannose-type chain were identified similarly by the same analytical procedure.

The HPAEC-PAD method is also applicable to the quantitation of concentrations of monosaccharides after release by acid hydrolysis and following clean-up procedures with commercially available cartridge columns. Figure 3 shows the chromatograms of four monosaccharides in purified serum AAG from healthy subjects and from patients with renal insufficiency. The concentration of NeuAc can also be determined under different solvent conditions. This method enables composition analysis of the carbohydrate moiety of AAG with only 1.0 mL of plasma. Linear relations between the amount of NeuAc or monosaccharides and the peak-height ratio of NeuAc or monosaccharides to the internal standards are observed over the concentration range of 5.0 to $100 \mu\text{g mL}^{-1}$. *N*-Glycolylneuraminic acid and mannitol are used as the internal standard for NeuAc and the four monosaccharides, respectively.

Table 1 Analysis of NeuAc and monosaccharide levels in purified α_1 -acid glycoprotein (AAG) from plasma of healthy subjects, patients with renal insufficiency and patients with myocardial infarction

	Healthy subjects (n = 8)	Renal insufficiency (n = 6)	Myocardial infarction (n = 4)
Age (years)	65.8 ± 12.5	60.2 ± 7.2	69.7 ± 11.7
AAG conc. (mg mL ⁻¹)	0.79 ± 0.14	1.01 ± 0.19 ^a	1.66 ± 0.34 ^b
NeuAc (mg g ⁻¹ ·AAG)	82.77 ± 12.55	89.29 ± 15.55	132.70 ± 6.89 ^b
Fuc (mg g ⁻¹ ·AAG)	9.84 ± 3.08	12.79 ± 3.37	10.40 ± 3.42
GlcNAc (mg g ⁻¹ ·AAG)	113.01 ± 10.07	135.44 ± 10.51 ^b	142.68 ± 12.96 ^b
Gal (mg g ⁻¹ ·AAG)	76.97 ± 4.23	88.78 ± 5.61 ^b	86.92 ± 11.73 ^a
Man (mg g ⁻¹ ·AAG)	49.14 ± 2.57	57.26 ± 3.80 ^b	50.16 ± 1.67
GlcNAc/Man	2.18 ± 0.37	2.50 ± 0.35	2.84 ± 0.21 ^a

Source: Kishino *et al.* (1995).

AAG concentration was determined by the HPLC method with a hydroxyapatite column.

NeuAc and each monosaccharide concentration were determined by HPAEC-PAD.

Values in the table are means ± SD.

^aSignificantly different ($p < 0.05$) from healthy subjects.

^bSignificantly different ($p < 0.01$) from healthy subjects.

The resultant quantitation data (Table 1) for healthy subjects, patients with renal insufficiency and patients with myocardial infarction show that not only AAG levels but also the concentrations of several monosaccharides in patients increased significantly compared to those of healthy subjects, suggesting a change in the carbohydrate branching pattern in such pathologic conditions.

It is well known that the microheterogeneity of AAG is due to the occurrence of di-, tri-, and tetra-antennary glycans of the *N*-acetylglucosamine type at the five glycosylation sites. Moreover, the Man content is constant among the antennary glycans, and the number of branches increases with the addition of GlcNAc to Man residues. A highly branched glycan chain of AAG is constructed by the linkage of Gal to GlcNAc (Figure 1), which results in the formation of an antennary structure (*N*-acetylglucosamine). Therefore, in the case of AAG, determination of the concentration ratio of GlcNAc to Man (GlcNAc/Man) is important for estimating whether the carbohydrate moiety of glycoforms has a highly or less-branched glycan chain. The significantly higher GlcNAc/Man ratio in the patients with myocardial infarction suggests that a highly branched glycan chain was synthesized. Changes in the carbohydrate moiety in the glycoproteins have been reported in patients with various types of disease.

As shown in Figure 4, at least six fractions, which are possibly based on carbohydrate-mediated microheterogeneity, have been obtained from healthy human (Japanese) serum AAG by HPLC using a hydroxyapatite column under a gradient elution programme. From the determination of five monosac-

charides (NeuAc, Fuc, GlcNAc, Gal, Man) in each fraction by HPAEC-PAD, it was found that glycoforms rich in carbohydrates were eluted later (fractions 4, 5, 6) and that NeuAc was relatively abundant in fraction 6. Furthermore, the ratio of GlcNAc/Man in fraction 2 was significantly higher than those in the other fractions, suggesting the presence of a highly branched glycan chain. Interestingly, it has been also shown that fractions 1 and 2, both relatively rich in highly branched glycan chains, showed a significantly lower binding capacity to disopyramide, a drug for the treatment of arrhythmia, than did the other fractions. This result suggests that the binding sites of AAG to disopyramide are hindered by relatively large carbohydrate moieties, such as a tetraantennary structure. These results are consistent with the findings that the binding capacity of purified AAG isolated from patients (with renal insufficiency or myocardial infarction) to disopyramide is significantly lower than that of healthy subjects and that the AAGs of these patients revealed a higher concentration ratio of GlcNAc/Man, an index of the abundance of highly branched glycan chains.

In conclusion, in order to gain further insight into the structure–function relations of the carbohydrate moiety, it is essential that sufficient quantities of glycoprotein variants are available. An effective combination of the sophisticated separation methods for glycoforms, such as the HPLC system using a hydroxyapatite column, and the qualitative and quantitative analytical methods for monosaccharides/oligosaccharides, such as HPAEC-PAD, must be established.

Figure 4 Typical chromatograms of the glycoforms of α_1 -acid glycoprotein (AAG) from the serum of healthy subjects by HPLC. Inlet is the gradient programme for the fractionation of the glycoforms of AAG. (Sampling time of each fraction: fraction 1, 17–22 min; 2, 27–36 min; 3, 43–50 min; 4, 53–57 min; 5, 58–62 min and 6, 65–72 min.) (Reproduced with permission from Kishino *et al.*, 1997.)

GOLD RECOVERY: FLOTATION

S. Bulatovic and D. M. Wyslouzil, Lakefield Research, Lakefield, Ontario, Canada

Copyright © 2000 Academic Press

Introduction

The recovery of gold from gold-bearing ores depends largely on the nature of the deposit, the

mineralogy of the ore and the distribution of gold in the ore. The methods used for the recovery of gold consist of the following unit operations:

- The gravity preconcentration method, which is mainly used for recovery of gold from placer deposits that contain coarse native gold. Gravity is

often used in combination with flotation and/or cyanidation.

- Hydrometallurgical methods are normally employed for recovery of gold from oxidized deposits (heap leach), low grade sulfide ores (cyanidation, carbon-in-pulp (CIP), carbon-in-leach (CIL)) and refractory gold ores (autoclave, biological decomposition followed by cyanidation).
- A combination of pyrometallurgical (roasting) and hydrometallurgical route is used for highly refractory gold ores (carbonaceous sulfides, arsenical gold ores) and the ores that contain impurities that result in a high consumption of cyanide, which have to be removed before cyanidation.
- The flotation method is a widely used technique for the recovery of gold from gold-containing copper ores, base metal ores, copper–nickel ores, platinum group ores and many other ores where other processes are not applicable. Flotation is also used for the removal of interfering impurities before hydrometallurgical treatment (i.e. carbon prefloat), for upgrading of low sulfide and refractory ores for further treatment. Flotation is considered to be the most cost-effective method for concentrating gold.

Significant progress has been made over the past several decades in the recovery of gold using hydrometallurgical methods, including cyanidation (CIL, resin-in-pulp) and bio-oxidation. All of these processes are well documented in the literature and abundantly described. However, very little is known about the flotation properties of gold contained in various ores and the sulfides that carry gold. The sparse distribution of discrete gold minerals, as well as their exceedingly low concentrations in the ore, is one of the principal reasons for the lack of fundamental work on the flotation of gold-bearing ores.

In spite of the lack of basic research on flotation of gold-bearing ores, the flotation technique is used, not only for upgrading of low grade gold ore for further treatment, but also for beneficiation and separation of difficult-to-treat (refractory) gold ores. Flotation is also the best method for recovery of gold from base metal ores and gold-containing platinum group metals (PGM) ores. Excluding gravity preconcentration, flotation remains the most cost-effective beneficiation method.

Gold itself is a rare metal and the average grades for low grade deposits vary between 3 and 6 p.p.m. Gold occurs predominantly in its native form in silicate veins, alluvial and placer deposits or encapsulated in sulfides. Other common occurrences of gold are alloys with copper, tellurium, antimony, selenium, PGMs and silver. In massive sulfide ores,

gold may occur in several of the above forms, which affects flotation recovery.

During flotation of gold-bearing massive sulfide ores, the emphasis is generally placed on the production of base metal concentrates and gold recovery becomes a secondary consideration. In some cases, where significant quantities of gold are contained in base metal ores, the gold is floated from the base metal tailings.

The flotation of gold-bearing ores is classified according to ore type (i.e. gold ore, gold–copper ore, gold–antimony ores), because the flotation methods used for the recovery of gold from different ores is vastly different.

Geology and General Mineralogy of Gold-bearing Ores

The geology of the deposit and the mineralogy of the ore play a decisive role in the selection of the best treatment method for a particular gold ore. Geology of the gold deposits varies considerably, not only from deposit to deposit, but also within the deposit. **Table 1** shows major genetic types of gold ores and their mineral composition. More than 50% of the total world gold production comes from clastic sedimentary deposits.

In many geological ore types, several subtypes can be found, including primary ores, secondary ores and

Table 1 Common genetic types of gold deposits

<i>Ore type</i>	<i>Description</i>
Magmatic	Gold occurs as an alloy with copper, nickel and platinum group metals Typically contains low amount of gold
Ores in clastic sedimentary rock	Placer deposits, in general conglomerates, which contain quartz, sericite, chlorite, tourmaline and sometimes rutile and graphite. Gold can be coarse. Some deposits contain up to 3% pyrite. Size of the gold contained in pyrite ranges from 0.01 to 0.07 μm
Hydrothermal	This type contains a variety of ores, including: Gold–pyrite ores Gold–copper ores Gold–polymetallic ores Gold–oxide ore, usually upper zone of sulfide zones The pyrite content of the ore varies from 3% to 90%. Other common waste minerals are quartz, aluminosilicates, dolomite
Metasomatic or scarn ores	Sometimes very complex and refractory gold ores. Normally the ores are composed of quartz, sericite, chlorites, calcite, magnetite. Sometimes the ore contains wolframite and sheelite

Table 2 Major gold minerals

<i>Group</i>	<i>Mineral</i>	<i>Chemical formula</i>	<i>Impurity content</i>
Native gold and its alloys	Native gold	Au	0–15% Ag
	Electrum	Au/Ag	15–50% Ag
	Cuproauride	Au/Cu	5–10% Cu
	Amalgam	Hg/Au	10–34% Au
	Bismuthauride	Au/Bi	2–4% Bi
Tellurides	Calaverite	AuTe ₂	
	Sylvanite	(Au, Ag)Te ₂	
	Petzite	(Au, Ag)Te	
	Magyazite	Au(Pb, Sb, Fe)(S, Te) ₁₁	Unstable
Gold associated with platinum group metals	Krennerite	AuTe ₂ (Pt, Pl)	
	Platinum gold	AuPt	Up to 10% Pt
	Rhodite	AuRh	30–40% Rh
	Rhodian gold	AuRh	5–11% Rh
	Aurosmiride	Au, Ir, Os	5% Os + 5–7% Ir

oxide ores. Some of the secondary ores belong to a group of highly refractory ores, such as those from Nevada (USA), and El Indio (Chile). The number of gold minerals and their associations are relatively small and can be divided into the following three groups: native gold and its alloys, tellurides and gold associated with PGMs.

Table 2 lists major gold minerals and their associations.

Flotation Properties of Gold Minerals and Factors Affecting Floatability

Native gold and its alloys, which are free from surface contaminants, are readily floatable with xanthate collectors. Very often, however, gold surfaces are contaminated or covered with varieties of impurities. The impurities present on gold surfaces may be argentite, iron oxides, galena, arsenopyrite or copper oxides. The thickness of the layer may be in the order of 1–5 µm. Because of this, the flotation properties of native gold and its alloys vary widely. Gold covered with iron oxides or oxide copper is very difficult to float and requires special treatment to remove the contaminants.

Tellurides on the other hand are readily floatable in the presence of small quantities of collector, and it is believed that tellurides are naturally hydrophobic. Tellurides from Minnesota (USA) were floated using dithiophosphate collectors, with over 95% gold recovery.

Flotation behaviour of gold associated in the platinum group metals is apparently the same as that for the PGMs or other minerals associated with the PGMs (i.e. nickel, pyrrhotite, copper and pyrite). Therefore, the reagent scheme developed for PGMs

also recovers gold. Normally, for the flotation of PGMs and associated gold, a combination of xanthate and dithiophosphate is used, along with gangue depressants guar gum, dextrin or modified cellulose. In the South African PGM operations, gold recovery into the PGM concentrate ranges from 75% to 80%.

Perhaps the most difficult problem in flotation of native gold and its alloys is the tendency of gold to plate, vein, flake and assume many shapes during grinding. Particles with sharp edges tend to detach from the air bubbles, resulting in gold losses. This shape factor also affects gold recovery using a gravity method.

In flotation of gold-containing base metal ores, a number of modifiers normally used for selective flotation of copper–lead, lead–zinc and copper–lead–zinc have a negative effect on the floatability of gold. Such modifiers include ZnSO₄ × 7H₂O, SO₂, Na₂S₂O₅, and cyanide when added in excessive amounts.

The adsorption of collector on gold and its floatability are considerably improved by the presence of oxygen. Figure 1 shows the relationship between collector adsorption, oxygen concentration in the pulp and conditioning time. The type of modifier and the pH are also important parameters in flotation of gold.

Flotation of Low Sulfide-containing Gold Ores

The beneficiation of this ore type usually involves a combination of gravity concentration, cyanidation and flotation. For an ore with coarse gold, gold is often recovered by gravity and flotation, followed by cyanidation of the reground flotation concentrate. In some cases, flotation is also conducted on the cyanidation tailing. The reagent combination used in flotation depends on the nature of gangue present in the ore. The usual collectors are xanthates,

Figure 1 Relationship between adsorption of xanthate on gold and conditioning time in the presence of various concentrations of xanthate. Triangles, O_2 2 mg L⁻¹; circles; O_2 9 mg L⁻¹; squares, O_2 45 mg L⁻¹.

dithiophosphates and mercaptans. In the scavenging section of the flotation circuit, two types of collector are used as secondary collectors. In the case of a partially oxidized ore, auxiliary collectors, such as hydrocarbon oils with sulfidizer, often yield improved results. The preferred pH regulator is soda ash, which acts as a dispersant and also as a complexing reagent for some heavy metal cations that have a negative effect on gold flotation. Use of lime often results in the depression of native gold and gold-bearing sulfides. The optimum flotation pH ranges between 8.5 and 10.0. The type of frother also plays an important role in the flotation of native gold and gold-bearing sulfides. Glycol esters and cyclic alcohols (pine oil) can improve gold recovery significantly.

Amongst the modifying reagents (depressant), sodium silicate starch dextrans and low molecular weight polyacrylamides are often selected as gangue depressants. Fluorosilicic acid and its salts can also have a positive effect on the floatability of gold. The presence of soluble iron in a pulp is highly detrimental to gold flotation. The use of small quantities of iron-complexing agents, such as polyphosphates and organic acids, can eliminate the harmful effect of iron.

Flotation of Gold-containing Mercury/Antimony Ores

In general, these ores belong to a group of difficult-to-treat ores, where cyanidation usually produces poor extraction. Mercury is partially soluble in cyanide, which increases cyanide consumption and reduces extraction. A successful flotation method has been

developed using the flow sheet shown in Figure 2, where the best metallurgical results were obtained using a three-stage grinding and flotation approach. The metallurgical results obtained with different grinding configurations are shown in Table 3.

Flotation was carried out at an alkaline pH, controlled by lime. A xanthate collector with cyclic alcohol frother (pine oil, cresylic acid) was shown to be the most effective. The use of small quantities of a dithiophosphate-type collector, together with xanthate, was beneficial.

Flotation of Carbonaceous Clay-containing Gold Ores

These ores belong to a group of refractory gold ores, where flotation techniques can be used to remove interfering impurities before the hydrometallurgical treatment process of the ore for gold recovery and to preconcentrate the ore for further pyrometallurgical or hydrometallurgical treatment. There are several flotation methods used for beneficiation of this ore type. Some of the most important methods are described as follows:

- Preflotation of carbonaceous gangue and carbon. In this case, only carbonaceous gangue and carbon are recovered by flotation, in preparation for further hydrometallurgical treatment of the float tails for gold recovery. Carbonaceous gangue and carbon are naturally floatable using only a frother, or a combination of a frother and a light hydrocarbon oil (fuel oil, kerosene). When the ore contains clay, regulators for clay dispersion are used. Some of the more effective regulating reagents include sodium silicates and oxidized starch.
- Two-stage flotation method. In this case, carbonaceous gangue is prefloted using the method described above, followed by flotation of gold-containing sulfides using activator-collector combinations. In extensive studies conducted on carbonaceous gold-containing ores, it was established that primary amine-treated copper sulfate improved gold recovery considerably. Ammonium salts and sodium sulfide ($Na_2S \times 9H_2O$) also have a positive effect on gold-bearing sulfide flotation, at a pH between 7.5 and 9.0. The metallurgical results obtained with and without modified copper sulfate are shown in Table 4.
- Nitrogen atmosphere flotation method. This technique uses a nitrogen atmosphere in grinding and flotation to retard oxidation of reactive sulfides, and has been successfully applied on carbonaceous ores from Nevada (USA). The effectiveness of the method depends on the amount of carbonaceous gangue present in the ore, and the amount and type

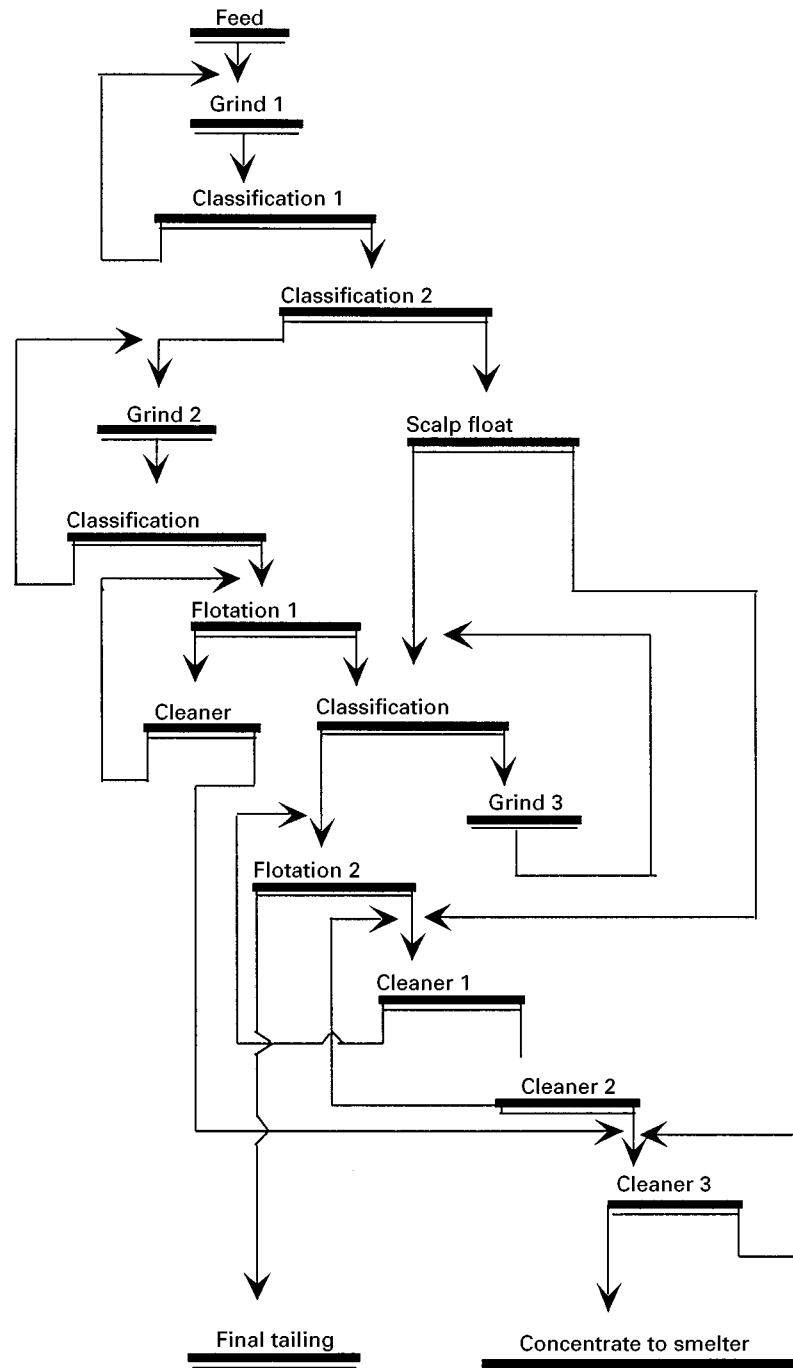

Figure 2 Flotation flow sheet developed for the treatment of gold-containing mercury-antimony ore.

of clay. Ores that are high in carbon or contain high clay content (or both) are not amenable for nitrogen atmosphere flotation.

Flotation of Gold-containing Copper Ores

The floatability of gold from gold-containing copper-gold ores depends on the nature and occurrence of gold in these ores, and its association with iron sulfides.

Gold in the porphyry copper ore may appear as native gold, electrum, cuproaurid and sulfosalts associated with silver. During the flotation of porphyry copper-gold ores, emphasis is usually placed on the production of a marketable copper-gold concentrate and optimization of gold recovery is usually constrained by the marketability of its concentrate.

Table 3 Gold recovery obtained using different flow sheets

Flow sheet	Recovery in concentrate (%)					Tailing Assays (% $g\ t^{-1}$)				
	Au	Ag	Sb	As	S	Au	Ag	Sb	As	S
Single-stage grind flotation	88.1	89.2	72.9	68.4	70.1	1.7	5.0	0.04	0.035	0.38
Two-stage grind flotation	92.2	91.8	93.4	78.7	81.2	1.0	4.1	0.015	0.022	0.27
Three-stage grind flotation	95.3	95.2	95.7	81.2	85.7	0.7	2.2	0.005	0.015	0.19

Reproduced from Sristinov (1964) with permission.

The minerals that influence gold recovery in these ores are iron sulfides (i.e. pyrite, marcasite), in which gold is usually associated as minute inclusions. Thus, the iron sulfide content of the ore determines gold recovery in the final concentrate. **Figure 3** shows the relationship between pyrite content of the ore and gold recovery in the copper concentrate for two different ore types. Most of the gold losses occur in the pyrite.

The reagent schemes used in commercial operations treating porphyry copper-gold ores vary considerably. Some operations, where pyrite rejection is a problem, use a dithiophosphate collector at an alkaline pH between 9.0 and 11.8 (e.g. OK Tedi, PNG Grasberg, Indonesia). When the pyrite content in the ore is low, xanthate and dithiophosphates are used in a lime or soda ash environment.

In more recent years, in the development of commercial processes for the recovery of gold from porphyry copper-gold ores, bulk flotation of all the sulfides has been emphasized, followed by regrinding of the bulk concentrate and sequential flotation of copper-gold from pyrite. Such a flow sheet (**Figure 4**) can also incorporate high intensity conditioning in the cleaner-scavenger stage. Comparison of metallurgical results using the standard sequential flotation flow sheet and the bulk flotation flow sheet is shown in **Table 5**. A considerable improvement in gold recovery was achieved using the bulk flotation flow sheet.

During beneficiation of clay-containing copper-gold ores, the use of small quantities of Na_2S (at natural pH) improves both copper and gold metallurgy considerably.

In the presence of soluble cations (e.g. Fe, Cu), additions of small quantities of organic acid (e.g. oxalic, tartaric) improve gold recovery in the copper concentrate.

Some porphyry copper ores contain naturally floatable gangue minerals, such as chlorites and aluminosilicates, as well as preactivated quartz. Sodium silicate, carboxymethylcellulose and dextrans are common depressants used to control gangue flotation.

Gold recovery from massive sulfide copper-gold ores is usually much lower than that of porphyry copper-gold ores, because very often a large portion of the gold is associated with pyrite. Normally, gold recovery from these ores does not exceed 60%. During the treatment of copper-gold ores containing pyrrhotite and marcasite, the use of $Na_2H_2PO_4$ at alkaline pHs depresses pyrrhotite and marcasite, and also improves copper and gold metallurgy.

Flotation of Oxide Copper-Gold Ores

Oxide copper-gold ores are usually accompanied by iron hydroxide slimes and various clay minerals. There are several deposits of this ore type around the world, some of which are located in Australia (Red Dome), Brazil (Igarape Bahia) and the Soviet Union (Kalima). Treatment of these ores is difficult, and even more complicated in the presence of clay minerals.

Recently, a new class of collectors, based on ester-modified xanthates, has been successfully used to treat gold-containing oxide copper ores, using a sulfidization method. **Table 6** compares the metallurgical results obtained on the Igarape Bahia ore using

Table 4 Effect of amine-modified $CuSO_4$ on gold-bearing sulfide flotation from carbonaceous refractory ore

Reagent used	Product	Weight (%)	Assays (% $g\ t^{-1}$)		Distribution (%)	
			Au	S	Au	S

xanthate and a new collector (PM230, supplied by Senmin in South Africa).

The modifier used in the flotation of these ores included a mixture of sodium silicate and Calgon. Good selectivity was also achieved using boiled starch.

Flotation of Gold-Antimony Ores

Gold-antimony ores usually contain stibnite (1.5-4.0% Sb), pyrite, arsenopyrite gold (1.5-3.0 g t⁻¹) and silver (40-150 g t⁻¹). Several plants in the USA (Stibnite, Minnesota and Bradly) and Russia have been in operation for some time. There are two commercial processes available for treatment of these ores.

- Selective flotation of gold-containing sulfides followed by flotation of stibnite with pH change.

Stibnite floats well in neutral and weak acid pH, while in an alkaline pH (i.e. > 8), it is reduced. Utilizing this phenomenon, gold-bearing sulfides are floated with xanthate and alcohol frother in alkaline medium (pH > 9.3) followed by stibnite flotation at about pH 6.0, after activation with lead nitrate. Typical metallurgical results using this method are shown in Table 7.

- Bulk flotation followed by sequential flotation of gold-bearing sulfides, and depression of stibnite. This method was practised at the Bradly concentrator (USA) and consisted of the following steps: first, bulk flotation of stibnite and gold bearing sulfides at pH 6.5 using lead nitrate (Sb activator) and xanthate; second, the bulk concentrate is reground in the presence of NaOH (pH 10.5) and CuSO₄, and the gold-bearing sulfides are refloatated with additions of small quantities of xanthate; third, cleaning of the gold concentrate in the presence of NaOH and NaHS. The plant metallurgical results employing this method are shown in Table 8.

Recent studies conducted on ore from Kazakhstan have shown that sequential flotation using thionocarbamate collector gave better metallurgical results than those obtained with xanthate.

Flotation of Arsenical Gold Ores

There are two major groups of arsenical gold ores of economic value. These are the massive base metal sulfides with arsenical gold (e.g. the lead-zinc Olympias deposit, Greece) and arsenical gold ores without the presence of base metals. Massive, base metal arsenical gold ores are rare, and there are only a few deposits in the world. A typical arsenical gold ore contains arsenopyrite as the major arsenic mineral. However, some arsenical gold ores, such as those from Nevada in the USA (Getchel deposit), contain realgar and orpiment as the major arsenic-bearing

			Cu	Au	Cu	Au
Conventional (sequential Cu/Au)	Cu/Au conc.	2.28	27.6	32.97	95.4	76.7
	Cu/Au tail	97.72	0.031	0.23	4.6	23.3
	Head	100.00	0.66	0.98	100.0	100.0
Bulk (Figure 4)	Cu/Au conc.	2.32	27.1	36.94	95.2	85.8
	Cu/Au tail	97.68	0.032	0.14	4.8	14.2
	Head	100.00	0.66	0.96	100.0	100.0

minerals. Pyrite, if present in an arsenical gold ore, may contain some gold as minute inclusions.

Flotation of arsenical gold ores associated with base metals is accomplished using a sequential flotation technique, with flotation of base metals followed by flotation of gold-containing pyrite–arsenopyrite. The pyrite–arsenopyrite is floated at a weakly acid pH with a xanthate collector.

Arsenical gold ores that do not contain significant base metals are treated using a bulk flotation method, where all the sulfides are first recovered into a bulk concentrate. In case the gold is contained either in pyrite or arsenopyrite, separation of pyrite and arsenopyrite is practised. There are two commercial methods available. The first method utilizes arsenopyrite depression and pyrite flotation, and consists of the following steps:

- Heat the bulk concentrate to 75°C at a pH of 4.5 (controlled by H₂SO₄) in the presence of small quantities of potassium permanganate or disodium phosphate. The temperature is maintained for about 10 min.
- Flotation of pyrite using either ethylxanthate or potassium butylxanthate as collector. Glycol frother is also usually employed in this separation.

This method is highly sensitive to temperature. Figure 5 shows the effect of temperature on pyrite–

arsenopyrite separation. In this particular case, most of the gold was associated with pyrite. Successful pyrite–arsenopyrite separation can also be achieved with the use of potassium peroxydisulfide as the arsenopyrite depressant.

The second method involves depression of pyrite and flotation of arsenopyrite. In this method, the bulk concentrate is treated with high dosages of lime (pH > 12), followed by a conditioning step with CuSO₄ to activate arsenopyrite. The arsenopyrite is then floated using a thionocarbamate collector.

Separation of arsenopyrite and pyrite is important from the point of view of reducing downstream processing costs. Normally, roasting or pressure oxidation followed by cyanidation is used to recover gold.

Flotation of Gold from Base Metal Sulfide Ores

Very often lead–zinc, copper–zinc, copper–lead–zinc and copper–nickel ores contain significant quantities of gold (i.e. between 1 and 9 g/t). The gold in these ore types is usually found as elemental gold. A large portion of the gold in these ores is finely disseminated in pyrite, which is considered nonrecoverable. Because of the importance of producing commercial-grade copper, lead and zinc concentrates, little or no consideration is given to improvement in gold recovery, although the possibility exists to optimize gold

recovery in many cases. Normally, gold recovery from base metal ores ranges from 30 to 75%.

In the case of a copper-zinc and copper-lead-zinc ore, gold collects in the copper concentrate. During the treatment of lead-zinc ores, the gold tends to report to the lead concentrate. Information regarding gold recovery from base metal ores is sparse.

The most recent studies conducted on various base metal ores revealed some important features of flotation behaviour of gold from these ores. It has been demonstrated that gold recovery to the base metal concentrate can be substantially improved with the proper selection of reagent schemes. Some of these studies are discussed below.

Gold-containing lead-zinc ores Some of these ores contain significant quantities of gold, ranging from 0.9 to 6.0 $g\ t^{-1}$ (e.g. Grum, Yukon, Canada; Greens Creek, Alaska and Milpo, Peru). The gold recovery from these ores ranges from 35 to 75%. Laboratory studies have shown that the use of high dosages of zinc sulfate, which is a common zinc depressant used in lead flotation, reduces gold floatability significantly. The effect of $ZnSO_4 \times 7H_2O$ addition on gold recovery in the lead concentrate is illustrated in Figure 6.

In order to improve gold recovery in the lead concentrate, an alternative depressant to $ZnSO_4 \times 7H_2O$

can be used. Depressant combinations such as $Na_2S + NaCN$, or $Na_2SO_3 + NaCN$, may be used. The type of collector also plays an important role in gold flotation of lead-zinc ores. A phosphine-based collector, in combination with xanthate, gave better gold recovery than dithiophosphates.

Copper-zinc gold-containing ores Gold recovery from copper-zinc ores is usually higher than that obtained from either a lead-zinc or copper-lead-zinc ore. This is attributed to two main factors. When selecting a reagent scheme for treatment of copper-zinc ores, there are more choices than for the other ore types, which can lead to the selection of a reagent scheme which is more favourable for gold flotation. In addition, a noncyanide depressant system can be used for the treatment of these ores, which in turn results in improved gold recovery. This option is not available during treatment of lead-zinc ores. Table 9 shows the effect of different depressant combinations on gold recovery from a copper-zinc ore.

The use of a noncyanide depressant system resulted in a substantial improvement in gold recovery in the copper concentrate.

Gold-containing copper-lead-zinc ores Because of the complex nature of these ores, and the requirement for a relatively complex reagent scheme for treatment of this ore, the gold recovery is generally lower than that achieved from a lead-zinc or copper-zinc ore. One of the major problems associated with the flotation of gold from these ores is related to gold mineralogy. A large portion of the gold is usually contained in pyrite, at sub-micron size. If coarser elemental gold and electrum are present, the gold surfaces are often coated with iron or lead, which can result in a substantial reduction in floatability.

The type of collector and flow sheet configuration play an important role in gold recovery from these ores. With a flow sheet that uses bulk copper-lead flotation followed by copper-lead separation, the gold recovery is higher than that achieved with a

Table 8 Plant metallurgical results obtained using a bulk flotation method

sequential copper-lead flotation flow sheet. In laboratory tests, an aerophine collector type, in combination with xanthate, had a positive effect on gold recovery as compared to either dithiophosphate or thionocarbamate collectors. **Table 10** compares the metallurgical results obtained with an aerophine collector to those obtained with a dithiophosphate collector.

Because of the complex nature of gold-containing copper-lead-zinc ores, the reagent schemes used are also complex. Reagent modifiers such as $ZnSO_4$, NaCN and lime have to be used, all of which have a negative effect on gold flotation.

Conclusions

- The flotation of gold-bearing ores, whether for production of bulk concentrates for further gold

Figure 6 Effect of $ZnSO_4$ additions on gold recovery from lead-zinc ores. Circles, Greens Creek ore (Alaska); triangles, Grum ore Yukon (Canada).

recovery processes (i.e. pyrometallurgy, hydrometallurgy) or for recovery of gold to base metal concentrates, is a very important method for concentrating the gold and reducing downstream costs.

- The flotation of elemental gold, electrum and tellurides is usually very efficient, except when these minerals are floated from base metal massive sulfides.
- Flotation of gold-bearing sulfides from ores containing base metal sulfides presents many challenges and should be viewed as flotation of the particular mineral that contains gold (i.e. pyrite, arsenopyrite, copper), because gold is usually associated with these minerals at micron size.
- Selection of a flotation technique for gold preconcentration depends very much on the ore

mineralogy, gangue composition and gold particle size. There is no universal method for flotation of the gold-bearing minerals, and the process is tailored to the ore characteristics. A specific reagent scheme and flow sheet are required for each ore.

- There are opportunities on most operating plants for improving gold metallurgy. Most of these improvements come from selection of more effective reagent schemes, including collectors and modifiers.
- Perhaps the most difficult ores to treat are the clay-containing carbonaceous sulfides. Significant progress has been made in treatment options for these ores. New sulfide activators (e.g. amine-treated CuSO₄, ammonium salts) and nitrogen gas flotation are amongst the new methods available.

Classical Precipitation Chromatography

Polymer Solubility and Precipitation

Solubility is governed by the general requirement that the change in Gibbs' free energy must be negative.

With low molecular weight substances this condition is easily fulfilled, because the entropy contribution is large owing to the large number of particles involved. But with polymer compounds, the entropy of dissolution is comparatively small and the enthalpy contribution gains in importance. The precept that '*similia similibus solventur*' becomes a stringent requirement; in terms of Hildebrand's solubility concept, this means that a polymer can dissolve only in fluids whose solubility parameters are very closely related

to those of the polymer. Therefore, most liquids are non-solvents and the number of solvents available for a given polymer is far fewer than the number of solvents available for a low molecular weight substance of comparable structure.

The solubility of polymers decreases with increasing molecular weight (MW) and can be measured easily by the controlled addition of a non-solvent to the solution of a polymer. The volume fraction ϕ_{NS} of non-solvent at the cloud point is related to the square root, $M^{0.5}$, of molecular weight by

$$100 \phi_{NS} = C_1 + C_2/M^{0.5}$$

where C_1 and C_2 are constants for the particular system.

This dependence can be used to separate polymers by either fractional precipitation or dissolution. The latter method can also be performed in packed columns by gradients whose solvent power increases in the course of the elution.

The solubility of polymers also depends on temperature. Usually, the temperature coefficient is positive, i.e. fractional dissolution can be carried out with a given solvent (or a non-solvent/solvent mixture at constant composition) by raising the temperature. This procedure can also be performed in columns.

Baker-Williams Fractionation

In 1956, Baker and Williams described 'a new chromatographic procedure and its application to high polymers'. This was column elution combining the effects of solvent strength and temperature. The important innovation was a temperature gradient along the column. The top of the column was heated to a temperature about 50 K higher than that of the cooled bottom. An aluminium jacket ensured a linear temperature profile. The polymer to be investigated was coated onto the part of the inert packing that subsequently was put into the uniformly heated uppermost section of the column. The temperature gradient enabled multistage separation to be performed. Any component dissolved from the sample bed was reprecipitated in a cooler zone of the column. Here it was redissolved later by a non-solvent/solvent mixture of higher solvent strength and transported to the next cooler zone for another reprecipitation. Thus, Baker-Williams fractionation was described as 'a chromatographic method based upon the equilibration of substances between a stationary precipitated phase and a moving solution'. Baker and Williams investigated polystyrene in a glass tube, 350 mm long and 24 mm wide, packed with glass beads of average

size 0.1 mm diameter. The sample size was 300 mg, the gradient ran from ethanol (non-solvent) to methyl ethyl ketone, and the temperature gradient spanned 10–60°C. The multistage mechanism ensured a high separation power, which was confirmed by both theory and experiment. The method became popular in polymer characterization; the second citation in the Bibliography provides a survey of application of the method to about 30 different polymers.

The development of size exclusion chromatography (SEC) made separation according to MW feasible and convenient. SEC allows the investigation of different polymers in a common eluent with very little preliminary work. Dissolved samples can be injected into a running eluent, e.g. tetrahydrofuran, which has sufficient solvent strength for a great many polymers. The elution curve can be monitored with a suitable detector and provides at least a first guess at the MW distribution (MWD). Using MW-sensitive detectors and sophisticated software, reliable MWD curves can be measured within minutes. Interest in the demanding Baker-Williams technique therefore faded away. Although this technique is no longer a competitor in analytical separations according to MW, it should still be considered a powerful tool for separations according to chemical differences and for preparative fractionation. The chemical composition distribution of copolymers, blends or modified polymers can be measured by SEC only in rare cases (if coupled with MWD in a known ratio). This was realized some years ago (see Bibliography).

High Performance Precipitation Liquid Chromatography (HPPLC)

Principle and Instrumentation

The renaissance of precipitation chromatography requires modern equipment, e.g. detectors and programmable gradient devices. The samples to be investigated should be applied in solution and injected into the eluent stream ahead of the column.

About 80% of all high performance liquid chromatography (HPLC) investigations are performed in the reversed-phase mode. Reversed-phase packing materials have a nonpolar surface. They usually consist of particles with a silica core and a bonded layer of alkane chains. Reversed-phase gradients run from a highly polar initial eluent to a final eluent of low polarity. The polar eluent forces nonpolar solutes to be retained by the stationary phase. Retention increases with decreasing polarity of the sample components. The mechanism is understood to be a solvophobic interaction that requires the

mobile phase to be an unfavourable environment for the solute.

The measures taken to force the polymer towards the stationary phase may easily reach or even transgress the limits of solubility. The latter effect has been observed occasionally in reversed-phase chromatography of low molecular weight compounds, but is almost the rule with polymers whose solubility is more restricted.

In normal-phase chromatography, the column is polar and gradient elution is performed with a non-polar starting component A and a polar component B is added during the run. Retention increases with increasing polarity of the sample constituents.

In order to achieve proper retention of a polymer, the starting eluent A must usually be a non-solvent. This means that sample solutions cannot be prepared in a portion of the starting eluent and that the polymer is precipitated at the top of the column. Since proper retention is required, the separation is by this step classified as precipitation chromatography. The precipitation at the top of the column yields preconcentration of the sample. Thus, HPPLC can cope with samples differing widely in concentration, e.g. SEC fractions. The column permeability is not affected. If the sample solvent is a portion of eluent B, the amount of solvent injected will not cause difficulties. The use of another solvent is not recommended because it could overload the column with an additional substance.

The mechanism of separation is, in general, a combination of precipitation and adsorption. The detector must be capable of measuring the eluting sample components without being affected by the solvent gradient. Suitable equipment became available in the late 1970s.

High Performance Precipitation Liquid Chromatography of Styrene-Acrylonitrile Copolymers

Styrene is a polymerizable substance of formula $\text{CH}_2=\text{CH}(\text{C}_6\text{H}_5)$, whose homopolymerization yields polystyrene (PS). It can be polymerized with numerous other monomers to yield copolymers. Styrene units have a strong UV absorption, which means that polystyrene and styrene-containing copolymers can be monitored by UV detectors. Copolymers of styrene and acrylonitrile are of commercial interest. Well-characterized samples graded in composition are available together with a considerable knowledge of styrene-acrylonitrile dissolution/precipitation behaviour. The polarity of acrylonitrile is higher than that of styrene units. Therefore a separation of styrene-acrylonitrile copolymers according to composition is also a separation into constituents dif-

fering in polarity, which is of basic interest in the framework of chromatography. Styrene-acrylonitrile copolymers therefore seemed to be well suited to early studies of high performance precipitation chromatography.

Preliminary studies published in 1982 showed that tetrahydrofuran (THF) has the capacity to separate a mixed styrene-acrylonitrile sample into its constituents, provided that the starting gradient component A enables proper retention of the injected samples. This was achieved by using at least 80% *n*-hexane in THF, i.e. with a non-solvent. The injected polymer was therefore precipitated at the top of the column. The elution characteristic (percentage THF in the eluent versus acrylonitrile content of the sample) was similar to the solubility borderline determined by turbidimetric titration. It was found that equivalent separations could be achieved on a silica column as well as on a nonpolar C_8 column. This surprising result was confirmed in systematic studies performed by Glöckner and van den Berg in 1987 using other polar and nonpolar columns including silica CN bonded phase, small-pore C_{18} , wide-pore C_{18} and μ -Bondagel E1000-10. Thus, the surface of the packings did not actively participate in the separation. It was found that the peak shapes obtained could not be improved further by a temperature gradient along the column (which had been so essential in Baker-Williams fractionation).

Multistage separation without the use of a temperature gradient or interaction with the surface can be achieved on porous packings where the polymer solute is excluded from the pores. The polymer solute then has a higher linear velocity than the eluent, which fills the interstitial volume as well as the pore volume of the column. The polymer bypasses the pores and thus overtakes the eluent which has sufficient solvent strength. The polymer is precipitated and retained until a more powerful eluent reaches its position.

In chromatographic terms, the gradient hexane \rightarrow THF is a normal-phase gradient, i.e. increasing in polarity. In combination with a polar column, e.g. silica or a CN bonded phase, it forms a standard normal-phase system, which should elute more polar sample constituents after less-polar ones. Thus, the observed efficiency of irregular combinations with nonpolar C_8 or C_{18} columns shows that the separation was not governed by the common polarity rules of chromatography. The separation of styrene-acrylonitrile copolymers was, under the conditions of these studies, dominated by a precipitation mechanism. Another example of precipitation mechanism in styrene-acrylonitrile gradient chromatography is given in the next section. However, it should be

firmly stated that styrene–acrylonitrile is an exception rather than the rule. In general, gradient chromatography of synthetic polymers is governed by the combination of precipitation and adsorption. Irregular phase combination will not often work, but they do with styrene–acrylonitrile.

Normal- and reversed-phase chromatography are like mirror images. It was a challenge to find out whether or not a given synthetic copolymer could be separated by both mechanisms. The first positive report appeared in 1987 when copolymers of styrene and ethyl methacrylate were measured by both modes of chromatography. All previous related work was by normal-phase separation. As expected, the elution order achieved by reversed-phase chromatography was the opposite of that in normal-phase chromatography. Since then, several polymer systems have been separated by normal-phase and reversed-phase chromatography with inversion of elution order, e.g. styrene–methyl methacrylate copolymers, styrene–methyl acrylate copolymers or methacrylate homopolymers graded in polarity of the ester group.

High Performance Precipitation Liquid Chromatography of Styrene–Acrylonitrile Copolymers with Inversion of Elution Order

The separation of styrene–acrylonitrile copolymers with an elution order as in reversed-phase chromatography was achieved on a column packed with polystyrene gel. Eluent A was methanol (MeOH), a polar non-solvent for styrene–acrylonitrile samples; the less polar eluent, B, was either THF or dichloromethane. In both cases, the gradient rate was 0–100% B in 25 min. Copolymers with acrylonitrile content between 2.3% and 27.3% were retained longer the less acrylonitrile they contained (see Figure 1). Although the phase system and the elution order conformed to the rules of reversed-phase chromatography, the solubility mechanism prevailed.

The samples were prepared by copolymerization to only about 5% conversion, but they still consisted of macromolecules differing in composition. The chemical composition distributions of the samples are essentially responsible for the shape of the elution curves. The chemical composition distributions of samples with, say, 8.6% or 17.6% average acrylonitrile content are obviously narrower than that of a sample with 12.5% acrylonitrile.

The shape of the elution curve for 36.2% acrylonitrile in Figure 1 looks rather odd. In addition, the position of its maximum is not where it might be expected. According to its high acrylonitrile content, the sample is the most polar of the series investigated. It should therefore be eluted before the copolymer

Figure 1 Merged plot of elution curves of seven styrene–acrylonitrile copolymers on a column (250 mm × 7.1 mm i.d.) packed with polystyrene gel. Gradient: methanol → tetrahydrofuran, 0–100% B in 25 min; UV signal detected at 254 nm. The acrylonitrile (AN) content of the samples is indicated on the curves; the amount of each injected was 30 µg. (Reproduced from Glöckner *et al.*, 1991, by courtesy of Vieweg-Verlag.)

labelled 26.1% acrylonitrile, but it was eluted between the samples 17.6% and 12.5% acrylonitrile. This puzzling observation can be understood with the help of the solubility diagram for styrene–acrylonitrile in THF/MeOH, which is shown in Figure 2. The solubility boundary has a maximum at 20–25% acrylonitrile content, where samples require only about 45 vol% THF in MeOH for dissolution, whereas copolymers with more or less acrylonitrile need up to 12% more THF.

Along the left-hand branch of the solubility boundary (0–20% acrylonitrile), both polarity and solubility decrease with decreasing acrylonitrile content. The sequence of the five late-eluting peaks in Figure 1 is supported by polarity and solubility. Beyond the point of inflection, polarity increases but solubility decreases with increasing acrylonitrile content. A sample with 36.2% acrylonitrile requires about 50% THF for dissolution but should, according to polarity, already be released from the column in a mixture of 35% THF in MeOH. The measured peak position between the peaks for 17.6% and 12.5% acrylonitrile is determined by solubility. This is another indication of precipitation prevailing in the chromatography of styrene–acrylonitrile copolymers.

Along the left-hand branch of the solubility boundary, polarity supports the effect of solubility but beyond the turning point the two effects counteract each other. This is the reason why the elution curve for 36.2% acrylonitrile is much broader than the others. With normal-phase gradients, the 36.2% sample yielded an elution curve of the usual narrow shape, even in irregular phase systems (see Figure 3).

Figure 2 Solubility boundary for styrene-acrylonitrile copolymers in THF/MeOH as measured by turbidimetric titration at 20°C using THF as a sample solvent and methanol as the precipitating non-solvent. Phase separation (precipitation) occurs on crossing the curve from the upper part of the diagram (homogeneous solutions) to the lower part. (Reproduced from Glöckner *et al.*, 1991, by courtesy of Vieweg-Verlag.)

Sudden-Transition Gradient Chromatography of Synthetic Polymers

Interaction of Precipitation and Adsorption in Polymer Gradient Chromatography

Chromatographic retention and elution of synthetic polymers is generally governed by precipitation/dissolution and adsorption/desorption. The contribution of adsorption can be judged by comparing the solubility and elution characteristics of the sample

Figure 3 Merged plot of elution curves of six styrene-acrylonitrile copolymers on a reversed-phase column (250 mm \times 4.3 mm i.d.) packed with C_{18} bonded phase; in irregular combination with a normal-phase gradient *n*-heptane \rightarrow (THF + 20% methanol), 0–100% B in 25 min. Detection by signal from an evaporative light-scattering detector. The acrylonitrile (AN) content of the samples is indicated on the curves; the amount of each injected was 30 μ g. (Reproduced from Glöckner *et al.*, 1991, by courtesy of Vieweg-Verlag.)

system. If solubility prevails (and both temperature and concentration are suitable), both curves coincide. Noticeable adsorption shifts the elution characteristic above the solubility boundary, i.e. a higher concentration of solvent B is necessary for *eluting* a given sample than for *dissolving* it. The least adsorption was observed in reversed-phase systems with polystyrene samples. The predominance of an adsorption mechanism causes a retention behaviour different from (or even opposite to) that observed with a precipitation mechanism (see **Table 1**).

Baker and Williams reported that classical precipitation chromatography can be performed with ‘a column of inert material... providing that the polymer gel does not flow through the column’. This type of flow can also occur in high performance precipitation chromatography in which case an optical detector may register the strong signal characteristic of a turbid liquid. Such a signal is affected by many parameters including time and is therefore poorly reproducible. Gel breakthrough can be avoided if there is some contribution of adsorption to retention. Separation according to composition with the least superimposition of molecular weight effects requires adsorption to dominate, i.e. elution by changing polarity of the eluent rather than by solvent strength. On the other hand, the unfavourable effect of sample size owing to strong adsorption can be compensated by increasing the contribution of precipitation to retention.

Independent Control of Adsorption and Precipitation

In common binary gradients, the solvent power and polarity of the mobile phase change simultaneously in the course of the run. An optimum can be sought by using a variety of different eluents A and B and their combinations. However, this is a cumbersome procedure requiring an adequate supply of chemicals and a prolonged time. In addition, it may not be successful because thermodynamic reasons restrict the number of possible solvents for a given polymer, and several of these may be further ruled out by physical, physiological, or financial reasons. More promising and efficient is the use of ternary systems consisting of two non-solvents (A and B) and one solvent (C) for the polymers under investigation. A and B must be opposite in polarity, i.e. if A is a polar non-solvent, B is a nonpolar one. The polarity of solvent C is in between those of A and B. Solvent C must be miscible with A and B and must have sufficient strength to dissolve samples in the whole range of molecular weight and composition under investigation.

Table 1 Features of polymer gradient chromatography with predominance of either precipitation/dissolution or adsorption/desorption

Dominating mechanism	Elution characteristic	Irregular phase combinations	Increasing temperature	Increasing sample size (overload)	Increasing molecular weight ^a
Precipitation	Coincident with the solubility boundary	Separating like standard ones	Decreases retention	Increases retention	Increases, retention, $C_2 = 2-4 \times 10^3$
Adsorption	Above the solubility boundary	Ineffective in separation	Increases the retention of polymers	Decreases retention	Increases retention slightly, $C_2 = 2-5 \times 10^2$

^aFor C_2 factors see the equation in the text. Values of C_2 are compiled in Glöckner G (1991) *Gradient HPLC of Copolymers and Chromatographic Cross-Fractionation*, p. 107. New York: Springer-Verlag.

Since with gradients of this kind the chromatographically significant process is the result of interactions between non-solvents there is, owing to the large variety of the latter, more freedom in adjusting optimum conditions than with binary non-solvent/solvent gradients.

The samples to be investigated are dissolved in solvent C and injected into a starting eluent (e.g. A), whose polarity and precipitating power ensure proper retention at the top of the column. Solvent C is then added to the eluent at a concentration that in itself does not suffice for elution. In order to achieve short chromatograms, the concentration of C is changed as rapidly as the apparatus allows. No unfavourable side effects of the shock caused by the sudden transition from injection to elution conditions have ever been observed. The disturbance is visible with the help of optical detectors. With cyanopropyl or C_{18} packings, it is swept through by the approximately three-fold volume of mobile phase in the column. The elution of the sample is then triggered by a gradient $A \rightarrow B$ at a constant level of solvent C.

The first results of gradient elution with sudden transition of solvent concentration were achieved in the normal-phase mode of chromatography. The column packing was polar (CN-modified silica), A was iso-octane (with addition of 2% MeOH to the starting eluent), B was MeOH and C was THF. The gradient $A \rightarrow B$ was performed at $5\% \text{ min}^{-1}$ and applied to copolymers of styrene and ethyl methacrylate (EMA), methyl methacrylate (MMA), or 2-methoxyethyl methacrylate.

Figure 4 is the merged plot of UV signals measured on the elution of a mixture of five styrene-EMA copolymers through a gradient iso-octane \rightarrow MeOH after sudden transition to 20, 25, 30 or 35% THF solvent. Both iso-octane and MeOH are non-solvents for styrene-EMA. The addition of 35% THF yielded too high a solubility: the sample with 4.7% EMA was swept through the column by the sample solvent. A proportion of 20 or 25% THF did not suffice

for baseline separation. The best result was obtained after addition of 30% THF.

The advantage of this technique in comparison with binary gradient elution is obvious (see Figure 5). The chromatogram in Figure 5 was obtained in the same laboratory as those of Figure 4 with the same instrument and identical solvents. The baseline shift in Figure 5 is due to the UV absorption of THF which, at 259 nm, is slightly higher than that of iso-octane. This causes the baseline rise with

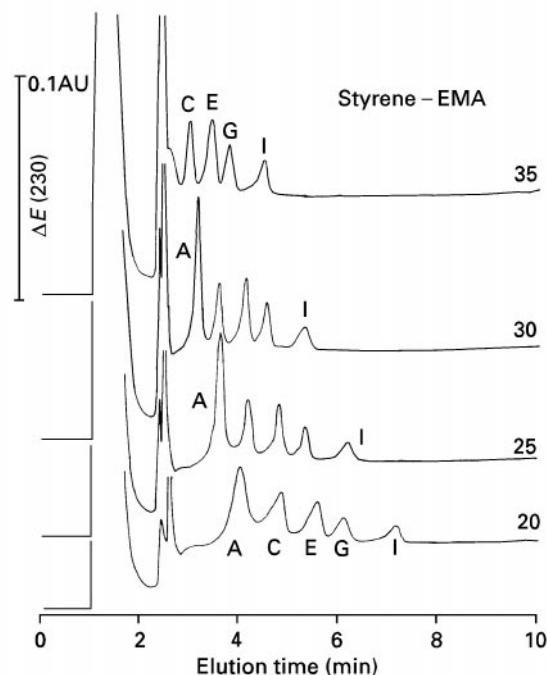

Figure 4 Separation of the mixture of five styrene-EMA copolymers at 50°C on a column (60 mm \times 4 mm i.d.) packed with cyanopropyl bonded phase. Gradient: iso-octane \rightarrow methanol ($5\% \text{ min}^{-1}$) after increase of THF concentration from zero to the percentage indicated at the curves; flow rate 0.5 mL min^{-1} . Sample: 1.8 μg copolymer A (4.7% EMA) + 1.2 μg C (32.2% EMA) + 2.0 μg E (54.6% EMA) + 1.2 μg G (68.0% EMA) + 2.0 μg I (92.5% EMA); UV signal detected at 230 nm. (Reproduced from Glöckner, 1991, by courtesy of Springer-Verlag.)

Figure 5 Separation of the mixture of four styrene-EMA copolymers at 50°C on a column (60 mm × 4 mm i.d.) packed with silica. Gradient: iso-octane → methanol (5% min⁻¹); flow rate 0.5 mL min⁻¹. Samples A to G as in Figure 4, 2.5 µg each; UV signal detected at 259 nm. (Reproduced from Glöckner, 1987a, by courtesy of Elsevier Science Publishers.)

increasing THF content of the eluent. The effect would be still more dramatic at a shorter wavelength, e.g. at 230 nm. Figure 4 presents horizontal baselines although the chromatograms were monitored at 230 nm. This is due to the constant concentration of THF throughout the elution, which disturbs the traces much less than a changing amount of THF does. The higher the THF addition, the higher the level of the baseline at the end of the chromatogram in comparison to the starting position in Figure 4.

The poor separation in Figure 5 is explained by the comparatively low molecular weight of these samples (50–80 × 10³) and the superimposition of separation by molecular weight and by composition. The peaks are indeed quite well separated when SEC fractions of the copolymer mixture are injected. Figure 4 indicates that the molecular weight effect in the investigation of the raw copolymers can be suppressed by the sudden-transition technique. **Table 2**

Table 2 Characteristics of polymer separation with separate control of solubility and adsorption^a

Factor	Details
Sample	20–100 µg polymer per injection, dissolved in about 50 µL solvent
Solvent	C, capable of dissolving samples of the system under investigation in the whole range of composition and molecular weight, used also for sample solutions (recommended: tetrahydrofuran, dichloromethane)
Non-solvents	A and B, opposite in polarity, both miscible with solvent C, e.g. A, acetonitrile, methanol; B, <i>n</i> -heptane. In general, the variety of non-solvents for a given polymer system is much broader than the list of suitable solvents
Interactions of eluents and detector	Eluents must not impede the monitoring of the eluting sample components, they must be transparent if optical detection is employed. This demand is more stringent for the gradient components A and B than for solvent C, whose concentration is not changed during the elution of sample components. For instance, separations at constant concentration of THF can be monitored at 230 nm or at constant DCM concentration with an evaporative light scattering detector without disturbance
Reversed-phase separation	Non-polar column, e.g. reversed-phase C ₁₈ bonded phase, injection into polar non-solvent A, gradient A → B after adjusting the solvent concentration to a suitable constant value
Normal-phase separation	Polar column, e.g. cyanopropyl bonded phase, injection into non-polar non-solvent B, gradient B → A after adjusting the solvent concentration to a suitable constant value
Reversed-phase and normal-phase separations	Can be performed with a common set of three eluents
Automated search for optimum separation method	Possible with programmable apparatus equipped with three storage bottles and a device for column switching
Balance between solubility and adsorption	Can be adjusted by the solvent concentration, which remains constant during the elution
Length of chromatograms	Can be optimized by sudden transition ^a of solvent concentration from zero to the selected level

^aInformation on how to perform sudden-transition gradients is available in Glöckner G, Wolf D and Engelhardt H (1994) *Chromatographia* 39: 557–563.

summarizes the characteristics of sudden-transition gradient elution.

Chromatography in Normal-Phase and Reversed-Phase Modes Using a Solvent and Two Non-Solvents

Independent control of adsorption and solubility enables normal-phase *and* reversed-phase separations to be performed with a common set of three liquids. This was first demonstrated with styrene-MMA copolymers in the system A (acetonitrile), B (*n*-heptane) and C (dichloromethane, DCM) on either CN or C₁₈ bonded phases.

Figure 6 shows chromatograms measured under reversed-phase and normal-phase conditions. Both modes yielded good separations. The elution order is inverted in the reversed-phase mode, as expected. The elution of styrene-MMA copolymers by the strong precipitant heptane (Figure 6A) is rather surprising.

Figure 7 shows the composition triangle of the eluent system used in Figure 6 with dichloromethane at the top, the polar non-solvent acetonitrile at the bottom left and the non-polar precipitant heptane at the bottom right. Acetonitrile and heptane have a miscibility gap that diminishes as dichloromethane is added. Eluent mixtures containing 25% or more dichloromethane are homogeneous. The elution characteristics of the styrene-MMA copolymers investigated in reversed-phase mode with 25–50% DCM or

in normal-phase mode with 25–40% dichloromethane are indicated. The characteristics of reversed-phase elutions form a group in the left-hand area of the triangle. The proportion of acetonitrile present means that eluent systems in this region have a higher polarity than those in the right-hand region. Reversed-phase chromatography starts with retention in a strongly polar medium. Sample components are released when the polarity of the eluent is no longer sufficient for retention. Thus, the characteristics of reversed-phase elution are to be expected on the polar side of the composition diagram. On the other hand, normal-phase elution characteristics are located in the right-hand part of the triangle. This can be understood by complementary reasoning because normal-phase chromatography starts with retention in a nonpolar medium.

The characteristics in Figure 7 are due to samples containing methyl methacrylate in the proportions (from left to right) 83.7%, 62.2%, 48.1%, 34.1%, 14.1% or 0% (polystyrene homopolymer). This sequence holds true with reversed-phase as well as with normal-phase elutions. In both modes, the copolymer with the highest content in polar methyl methacrylate units yields characteristics nearer to the polar (left) side of the diagram than the other samples. As expected, the least polar sample (polystyrene) marks the right border of the elution area in each mode.

All polymers considered here are soluble in the region beneath the solvent apex. The addition of

Figure 6 Separation of the mixture of five styrene-MMA copolymers at 35°C and flow rate 1 mL min⁻¹ by gradient elution in reversed-phase (A) or normal-phase mode (B) after a sudden increase of dichloromethane concentration from zero to 30%, monitored by an evaporative light-scattering detector. Sample in each mode: 6.76 μg copolymer A (14.1% MMA) + 5.54 μg C (34.1% MMA) + 5.28 μg E (48.1% MMA) + 5.48 μg G (62.2% MMA) + 5.02 μg I (83.7% MMA), dissolved in 10 μL DCM. (A) Column (250 mm × 4.1 mm i.d.) packed with reversed-phase C₁₈ bonded phase. Gradient: acetonitrile → *n*-heptane (4.99 min⁻¹). (B) Column (250 mm × 4.1 mm i.d.) packed with cyanopropyl bonded phase. Gradient: *n*-heptane → acetonitrile (4.99 min⁻¹). (Reproduced from Glöckner *et al.*, 1994, by courtesy of Vieweg-Verlag.)

Figure 7 Composition triangle for acetonitrile/*n*-heptane/dichloromethane with elution characteristics of styrene-MMA copolymers in normal-phase and reversed-phase sudden-transition gradients. Samples: ●, 83.7% MMA; ○, 62.2% MMA; +, 48.1% MMA; ◇, 34.1% MMA; *, 14.1% MMA; □, polystyrene. (Reproduced from Glöckner, 1996, by courtesy of Gordon & Breach.)

small quantities of heptane or acetonitrile to dichloromethane will impair solubility but will not immediately cause precipitation. The polymers are still soluble in mixtures of dichloromethane with about 40% acetonitrile or 40% heptane. Thus, the upper sections of the solubility boundary follow the left and right sides of the eluent triangle. With increasing concentration of nonsolvent, a precipitation threshold is reached on each side. From these points, both branches of the solubility boundary bend towards each other. These sections may be determined experimentally by turbidimetric titration. For example, the elution characteristics of the copolymer containing 48.1% MMA run almost parallel to the corresponding sections of the solubility boundary. In both reversed-phase and normal-phase modes, the elution characteristics are shifted from the solubility boundary towards the centre of the solubility window. This shift indicates the contribution of adsorption to retention, which is well known in gradient HPLC of styrene-methyl methacrylate copolymers. Finally, both branches of the boundary will merge inside the triangle (above the miscibility gap). For details, see Glöckner G (1996).

Solubility windows of similar shape can be expected with many polymers in mixtures of a solvent with two non-solvents differing in polarity. Hence, HPLC separation generally should be possible in normal-phase as well as in reversed-phase mode with a suitable ternary eluent system. These separations should be achievable near the respective side of the solubility boundary. Thus, the use of ternary gradients consisting of a solvent and two non-sol-

vents and control of solubility by a sudden increase of solvent concentration to a constant level will not only offer the opportunity to improve separations with small additional effort, but will also contribute to a better understanding of the mechanisms of polymer chromatography.

Herbicide Formulations

Weeds have been controlled by humans since the beginning of agriculture by means of mechanical tools or by hand. It was early in the 20th century that some inorganic compounds were first used with this aim. The discovery of the herbicidal properties of 2,4-D (2,4-dichlorophenoxyacetic acid) in 1945 can be considered the initiation of use of organic herbicides in agriculture. Since then, more than 130 different active compounds have been synthesized for their application as herbicides. These compounds can be grouped, according to their chemical structures, into different herbicide classes (Table 1).

Compounds belonging to the principal herbicide groups will be considered in this study. These compounds control weeds in a variety of ways, showing different modes of action, selectivity and application characteristics. Soil-applied herbicides are absorbed by roots or emerging shoots and foliage-applied herbicides are absorbed into the leaves, where they may be translocated to other parts of the plant.

The active ingredient of a herbicide is a compound, usually obtained by synthesis, which is formulated by a manufacturer in soil particles or liquid concentrates. These commercial formulations of herbicides are diluted with water before application in agriculture at the recommended doses. Herbicide formulations generally contain other materials to improve the efficiency of application.

Analysis of herbicide formulations was initially carried out by wet chemical procedures, such as determination of total chlorine, nitrogen or phosphorus, or by spectrometric procedures like ultraviolet absorption. The development of gas

chromatography (GC) allowed the analysis of these compounds in commercial formulations with high selectivity and sensitivity. The analytical procedure is commonly based on the dissolution of a known amount of the formulation in an organic solvent, which often contains an internal standard to improve the precision and accuracy of the determination. An aliquot of this solution is analysed by GC. Packed columns were used initially, but have now been replaced by capillary columns of low or medium polarity and flame ionization is the detection technique more widely used. When herbicides are not volatile or thermally stable, high performance liquid chromatography (HPLC) is the preferred technique for their determination in commercial formulations. Figure 1 shows the gas chromatographic separation of a mixture of phenoxy esters.

Herbicide Residue Analysis

Residues of herbicides will persist in the plant or in the soil for a variable time, depending on their physicochemical properties and on the environmental conditions. Analysis of herbicide residues in these matrices is important, not only from the point of view of the efficacy of application, but also to know the distribution and persistence of these compounds in food and in the environment. Therefore, herbicides of a wide range of polarities have to be determined in complex environmental matrices at very low levels.

Initially, herbicide residues were analysed by colorimetric methods. These procedures were generally based on acidic or basic hydrolysis followed by formation of derivatives. These methods are time-consuming and do not usually distinguish between the parent herbicide and metabolites.

Since the development of GC, this technique has been widely used in the analysis of these compounds. Table 2 summarizes the preparation of different types of samples for residue determination. These samples are generally analysed by a procedure with the following main steps: sample extraction, clean-up of extracts, then GC determination and identification. Some compounds are not volatile or thermally stable

and need to be derivatized before being analysed by GC.

Currently capillary columns are most commonly used for residue analysis. **Table 3** shows some representative examples of different packed and capillary columns used in the determination of herbicides.

In trace analysis, blank samples are commonly processed through the analytical method to identify the possibility of interferences in the herbicide determination from other sample or reagent components. In addition, recoveries of the analysed compound are also carried out through the extraction and clean-up procedures. The accepted normal range of these re-

coveries is 70–120%, with a standard deviation of 20%.

Several injection techniques are used in herbicide residue analysis. The techniques most often employed are splitless, on-column and programmed-temperature vaporizer injection and the volume normally injected is 1–2 μ L.

Various selective detectors are used in trace analysis of herbicides. The electron-capture detector (ECD) was first used for the determination of halogen-containing compounds or halogenated derivatives, due to its high sensitivity for these compounds. The nitrogen-phosphorus detector (NPD), also known as thermionic or alkali flame detector, is commonly used in the analysis of nitrogen-containing herbicides. Both detectors are highly sensitive and can detect herbicide concentrations lower than 1 pg. The flame photometric detector (FPD) has sometimes been used in the determination of sulfur-containing herbicides. The limit of detection (LOD) reflects the sensitivity of a detector for a given compound and it is defined as the amount producing a signal-to-noise ratio equal to 3. When this ratio is determined with extracts of real samples, processed through the whole analytical procedure, this parameter is known as the limit of quantification (LOQ), which depends on the efficacy of the extraction and clean-up procedures and on the selectivity and sensitivity of the detector. The coupling of mass spectrometry (MS) with GC allows the determination of herbicide residues with high selectivity and sensitivity and, in addition, the identification of residues by means of their mass spectra obtained at trace levels. The atomic emission detector allows monitoring characteristic wavelengths for carbon and hydrogen atoms, as well as the more specific emission lines for phosphorus, nitrogen and sulfur. **Table 4** summarizes the detection techniques for herbicide residue determination by GC.

The analysis of herbicides, grouped into various chemical classes, is considered in more detail below.

Benzonitriles and Phenoxy Acids

Benzonitriles and phenoxy acids are widely applied as salts or esters, but they are hydrolysed to their

Table 2 Procedures used in sample preparation for herbicide residue determination

Matrix	Amount sampled	Sample preparation	Amount extracted	Extraction procedure
Soil	1 kg	Sieving (< 2 mm)	10–20 g	Shaking, Soxhlet, SFE

Table 3 Chromatographic columns used in herbicide residue analysis

Column (length/diameter)	Stationary phase	Applications
Packed (1–3 m/2–4 mm)	Dimethylpolysiloxane (SE-30, DC-200)	Carbamates, ureas, dinitroanilines, triazines
	Phenylmethylpolysiloxane (OV-17, OV-25)	Benzonitriles, phenoxy acids
	Trifluoropropylpolysiloxane (QF-1, OV-210)	Carbamates, chloroacetamides, phenoxy acids
	Polyethyleneglycol (Carbowax)	Triazines
	Cyanoethylpolysiloxane (XE-60)	Triazines
	Cyanopropylpolysiloxane (OV-225)	Ureas
Capillary (10–30 m/0.2–0.5 mm)	Dimethylpolysiloxane	Nitrogen-containing herbicides
	Phenylmethylpolysiloxane	Triazines
	Polyethylene glycol	Triazines, phenoxy acids, benzonitriles
	Cyanopropylphenylmethylpolysiloxane	Multiresidue

respective phenols or acids in the matrix. Extraction of residues from soil and water is commonly performed at acidic pH with organic solvents of medium polarity. The extraction of these herbicides from vegetable matter is often done with aqueous solutions at basic pH, followed by extraction with organic solvents.

Purification of extracts is required in most cases and this step is accomplished by liquid–liquid partition at basic pH or by chromatography on silica columns.

Analysis of these compounds in air is carried out by trapping herbicides in ethylene glycol or in various adsorbents, like polyurethane or amberlite resins.

Derivatization of phenoxy acids, before GC determination, is necessary to make them volatile. Various alkyl, silyl or pentafluorobenzyl derivatives are obtained with this aim. Methyl esters have been commonly prepared for the determination of phenoxy acids and the reagents most often used are diazomethane and boron trifluoride–methanol. Benzo-

nitriles can be determined directly by GC, but the sensitivity and reproducibility achieved are poor. Various derivatives overcome these problems and diazomethane and heptafluorobutyric anhydride are the reagents most often used.

The determination of herbicides is widely carried out by GC with ECD, if the compound has halogen substituents or halogenated derivatives are obtained. MS detection has the advantage of being more selective and requiring less clean-up of extracts.

Carbamates

Carbamates are a wide group of pesticides and some of them have herbicide properties, like the thiocarbamates S-ethyl dipropylthiocarbamate (EPTC) and triallate. These compounds are extracted from soil with methanol or acetone and from water by means of hexane or dichloromethane. The extraction from plants is commonly accomplished with acetonitrile or by steam distillation. Clean-up of extracts is often

done by chromatography on silica columns. Most carbamates are thermally unstable and are usually analysed by HPLC. Some carbamates, such as the thiocarbamates considered above, can be determined by GC and their residues are determined by this technique using different detectors, like ECD, NPD, FPD and MS.

Chloroacetamides

These compounds, also known as anilides, are very often used for weed control in maize, in combination with triazines. Chloroacetamides are extracted from soil by polar and medium polarity solvents and their determination is generally carried out without further purification. Extraction from water is performed by reversed-phase solid-phase extraction (SPE) or by liquid-liquid extraction with low polarity solvents and clean-up of extracts on silica columns is necessary in some cases.

Analysis of these herbicides in plants is done by extraction with polar solvents, followed by purification by liquid-liquid partition or column chromatography on silica or alumina adsorbents.

Analytical methods for the determination of these herbicides in air have been reported, using several adsorbents or an ethylene glycol phase for their extraction from air. NPD and MS are the detectors most widely used in the determination of chloroacetamides; the ECD is also sometimes used.

Dinitroanilines

Dinitroaniline herbicides are highly lipophilic with a low solubility in water and some compounds have a remarkable volatility. Extraction of these compounds from soil is carried out by polar as well as by low polarity solvents. Dinitroanilines are extracted from water by SPE or by liquid-liquid extraction with low polarity solvents, such as dichloromethane. Clean-up of water and soil extracts on silica columns is sometimes needed.

Extraction with polar solvents, like methanol, is the method often used for the determination of dinitroanilines in plants, followed by liquid-liquid partition or Florisil column clean-up of extracts.

Analysis of these herbicides in air is performed by means of several adsorbents or organic solvents as trapping phases to remove these compounds from air.

ECD is often used in the determination of these compounds due to the large response obtained, particularly with some halogen-containing dinitroanilines. NPD and MS are also used in the gas chromatographic analysis of these herbicides.

Triazines

These compounds form a wide group of herbicides often employed in fruit trees and cereals; in particular, simazine and atrazine are the most widely used triazines.

Triazine herbicides are extracted from soil by polar or medium polarity organic solvents, followed by liquid-liquid partition or column chromatography clean-up if necessary. Supercritical fluid extraction is also used in the analysis of triazines in soil.

These herbicides are extracted from water by reversed-phase SPE, by anion exchange columns or by liquid-liquid extraction with low polarity solvents, followed in some cases by Florisil column clean-up.

Analysis of these compounds in plants is performed by sample homogenization with polar organic solvents and column chromatography or liquid-liquid partition clean-up. Triazines are sometimes analysed in air and plugs of polyurethane foam have been used to extract these compounds from air.

The gas chromatographic determination of triazines is commonly performed with NPD, due to the high response obtained with this detector because of the number of nitrogen atoms in their molecules. ECD is also employed but its sensitivity and selectivity for these compounds are lower. GC-MS is used for confirmation of residues as well as for routine determination, due to the good sensitivity obtained with selected ion monitoring. **Figure 2** shows some chromatograms of the determination of various triazines, together with other herbicides, by GC with NPD and MS detection.

Uracils

These compounds, also named pyrimidines, are used to control weeds in some fruit trees, vegetables and sugar beet. Extraction of these herbicides from soil is carried out with polar organic solvents or with basic aqueous solutions. Extraction from water is performed by SPE or by liquid-liquid extraction with low polarity solvents. Uracils are extracted from plants by homogenization with basic aqueous solutions or with mixtures of polar solvents with water. Clean-up of extracts is commonly carried out by liquid-liquid partition at different pHs. The gas chromatographic determination of these herbicides is performed using ECD and NPD detectors, and also by MS and atomic emission detection.

Ureas

Substituted ureas constitute one important group of herbicides formed by two different classes of compounds: phenylureas, one of the first used herbicides, and sulfonylureas, introduced later and applied

Figure 2 Gas chromatograms of herbicide residues in soil, fortified at $0.01 \mu\text{g g}^{-1}$, separated on an HP-1 capillary column, $12.5 \text{ m} \times 0.20 \text{ mm i.d.}$, with helium as carrier gas at 1 mL min^{-1} and detected (A) by GC-MS with selected ion monitoring or (B) by GC-NPD. Oven temperature was maintained at 100°C for 1 min, programmed at $15^\circ\text{C min}^{-1}$ to 250°C and held for 1 min. Sim, simazine; Th, thiazopyr; Pen, pendimethalin; Hex, hexazinone. Adapted with permission from Pérez RA, Sanchez-Brunet C, Miguel E and Tadeo JL (1998) Analytical methods for the determination in soil of herbicides used in forestry by GC-NPD and GC-MS. *Journal of Agriculture and Food Chemistry* 46: 1864.

at lower doses due to their high herbicidal activity. Both types of compounds suffer from thermal instability and their decomposition products, rather than the parent compounds, have been determined in some cases. To overcome this problem, various derivatives amenable to GC have been obtained, mainly their methyl, heptafluorobutyl or perfluorobenzyl derivatives.

Substituted ureas are extracted from soil by shaking with organic solvents of medium or high polarity, like methanol or acetone, sometimes followed by silica column or liquid-liquid partitioning clean-up. These herbicides are extracted from water by reversed-phase SPE or by liquid-liquid extraction with dichloromethane.

Urea herbicides are generally extracted from plants by homogenization with polar organic solvents. Supercritical fluid extraction of these compounds

from plants has also been reported. Clean-up of extracts through column chromatography or liquid-liquid partition is necessary before GC determination.

Detection of these herbicides is performed by NPD or by ECD, mainly when halogenated derivatives are obtained. MS is also used in the determination of substituted ureas in environmental matrices.

Multiresidue Analysis

The wide range of polarities and physico-chemical properties of herbicides does not allow the determination of the more than 130 available herbicides in one analytical method. Nevertheless, it is advisable to use analytical procedures that allow the determination of as many herbicides as possible in one method. These multiresidue methods permit reduction in time and cost of analysis as well as detection of the possible

presence of herbicide residues in samples with unknown origin or contamination. A multiresidue method is able to determine all the herbicides that can be extracted, cleaned up, separated and detected in the conditions used in the analytical procedure. In some cases, two detectors – generally ECD and NPD – are connected at the end of the same chromatographic column to allow the detection of a wider type of compounds. MS is used as a universal detector and also for residue identification purposes. Atomic emission detection is a more recent detection technique which is increasingly used in trace analysis.

Herbicide residues are extracted from soil and plants with medium or high polarity solvents, like

methanol, ethyl acetate and acetone. Vegetable samples are generally homogenized with organic solvent and soil samples are normally shaken and filtered. Matrix solid-phase dispersion (MSPD) is a technique which has recently been employed for pesticide residue determination in food samples: it performs sample extraction and purification at the same time. A simple multiresidue method, based on soil extraction in small columns, has been reported. **Figure 3** shows representative chromatograms of the analysis of various nitrogen-containing herbicides by this method.

Analysis of herbicides in water is generally based on liquid-liquid extraction with dichloromethane or on SPE using reversed phase columns, mainly C₁₈. Determination of herbicide residues in air is

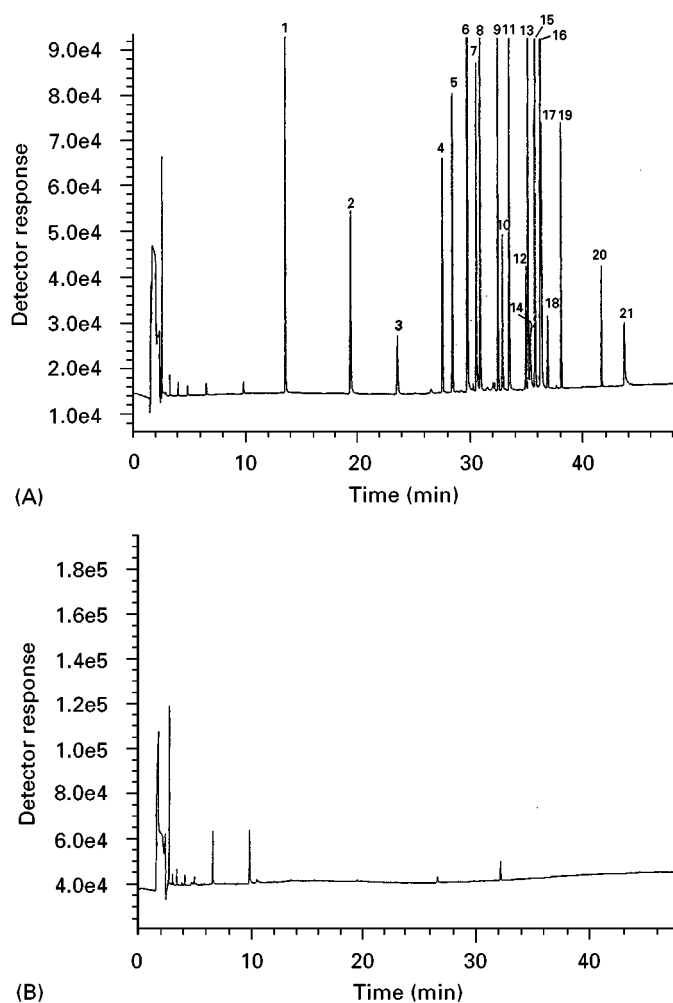

Figure 3 Multiresidue analysis of soil extracts separated on an HP-1 column, 30 m × 0.25 mm i.d., with helium as carrier gas at 1 mL min⁻¹ and detected by GC-NPD. accomplished by trapping these compounds on adsorbents, followed by extraction with organic solvents.

Future Developments

GC will continue to be the main chromatographic technique used in herbicide residue analysis in the near future, due to the high sensitivity and selectivity given by the detectors that can be coupled with this technique. In particular, the use of less expensive and more robust and sensitive GC-MS equipment will keep growing in the routine determination and confirmation of herbicide residues.

The time needed for sample processing is expected to be reduced as a consequence of the continuation in the development of automatic processes for sample preparation, extraction and clean-up. These processes will use less sample and lower volumes of organic solvents in the analytical procedure.

New improvements in the gas chromatographic equipment to allow higher injection volumes of less purified extracts can also be expected.

Solid-Phase Extraction

Y. Picó, Universitat de València, València, Spain

Copyright © 2000 Academic Press

Solid-phase extraction (SPE) methods, using bonded-silicas, were first introduced in 1971 as an alternative to liquid partitioning. The method combines extraction and preconcentration of organic compounds in water by adsorption on proper solid material followed by desorption with a small quantity of an organic solvent. In comparison with liquid-liquid extraction, the following advantages are offered: the amount of solvent required for the clean up is greatly reduced, thus saving time for the evaporative concentration step and minimizing exposure of the analyst to the toxic solvent; the final eluate has less interfering material, and it could be analysed using any of a variety of detection, separation and identification techniques, including high performance

liquid chromatography (HPLC) or gas chromatography (GC); accuracy and precision are improved; and it is rapid and easily automated.

Another impressive feature of SPE is the commercial availability of sorbents in small and inexpensive cartridges. C₁₈-bonded silica cartridges, styrene-divinylbenzene Empore® extraction discs and Carbo-pack® cartridges have been extensively used for the extraction of organic molecules from water samples. Automated column switching systems and on-line SPE coupled to determination devices have also been often reported for determination of pollutants in drinking and surface water.

Because of the reasons given above, in recent years much analysis of herbicides in fruit, vegetable and water has been conducted using SPE. Phenoxy acids, phenylureas, aryloxyphenoxypropionic acids, triazines, sulfonyleureas, imidazolinones, glyphosate, phenoxyacetic acids, bipyridinium compounds,

chloroacetamides, dinitroanilines and substituted phenols are examples of herbicides usually extracted and isolated by this technique.

It is undeniable that SPE is gaining in importance and, today, is a well-established and validated method, since the Environmental Protection Agency (EPA) in the United States currently offers one SPE procedure for the analysis of organic compounds (including neutral herbicides) and two for the analysis of acid herbicides.

Solid-Phase Extraction

Analyte Characteristics

The determination of herbicide residues is an intricate problem because of the large number of chemicals involved. As a general rule, to classify them into a wide variety of classes depending on their chemical structure results in a lot of groups that barely provide enough information in order to select the best SPE procedure.

In this way, the most practical approach is to organize the herbicides according to their acid/base character or other properties that condition the protocol following by SPE. Table 1 shows these characteristics for the major classes of herbicides and some examples of the structures included in each group.

Disposable Solid Phases

The modern SPE technique began in 1978 with the introduction of Sep-Pack cartridges, the first compact silica-based solid-phase extraction device for sample preparation on the market. Present-day, disposable prepacked columns or cartridges are available from more than 30 manufacturers, who offer phases such as C₁₈, C₈, cyano and amino. The containers are generally made of polypropylene. The sorbent bed varies from 100 to 1000 mg and is retained between two porous frits.

The use of Empore® discs are described in more recent studies. These devices include flat discs with large cross-sectional areas that provide advantages for preconcentration and clean-up methods with respect to the sorption, capacity, back pressure and stability after repeated use.

Reversed-phase silica-based sorbents, especially C₈ and C₁₈ bonded-silicas, are the most widely used packings for SPE. A typical SPE requires a previous sorbent activation step (wetting), usually with methanol, and removal of activation solvent excess (conditioning), usually with water.

Neutral herbicides can be extracted from 1 L samples with an average amount of sorbent (500 mg).

The sample is extracted under neutral or slightly alkaline conditions, and the pH is adjusted before the extraction to between 6 and 8. Under these conditions, salts of humic acids, which generally cause considerable interference in herbicide determination, are unlikely to be adsorbed during enrichment. As acid herbicides are highly polar, they are soluble in water and in aqueous solutions and are less soluble (in their dissociated form) in apolar sorbents. To overcome this difficulty, the aqueous phase has to be acidified before extraction to suppress the dissociation of this class of herbicides and to facilitate the transfer of the undissociated molecular species to the solid phase.

The recoveries and the relative standard deviation of the performance of different devices and solid phases are compared in Tables 2 and 3 for basic/neutral and acid/phenolic herbicides, respectively. The C₁₈ cartridges showed good recoveries with most of the basic/neutral and acidic/phenolic herbicides. Compounds having a small (deisopropylatrazine, tribensulfuron-methyl) or a very high (beta-cyfluthrine) affinity to the C₁₈ material gave the worst recoveries. In comparison with Empore® discs a lower breakthrough of polar metabolites of atrazine was reported, possibly due to the fact that Empore® discs contain only half the quantity of C₁₈ material. However, lower recoveries were achieved for medium polar and non-polar pesticides except trifluralin and triallate.

As reported in the literature on the subject, the bonded-silicas, in cartridge or in disc configuration, are the most commonly used supports, but they also have some limitations:

- For polar analytes, the retention is weak and often results in breakthrough during the loading step.
- Basic analytes interact strongly with the residual silanols, which in turn cause low recovery.
- The sorbent must remain wet prior to sample loading. (If one accidentally lets the cartridges run dry, the recovery is low and variable.)
- Poor stability in very acidic and basic media, which limits their use to the pH range of between 2 and 8.

These limitations have led to a search for new materials with improved characteristics. For example, the styrene-divinylbenzene resins have been extensively checked for their use in the extraction of pesticides. These polymers show higher retention of analytes and a wider pH range than C₁₈ silicas. The LC-grade polymers used as stationary phases have more commonly been used in precolumns (mainly PRP-1 and PLRP-S) for on-line purposes, because

Table 1 Chemical structure of major classes of herbicides according to the character that determines the SPE procedure used

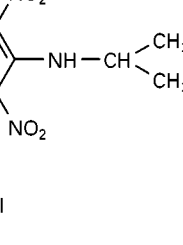

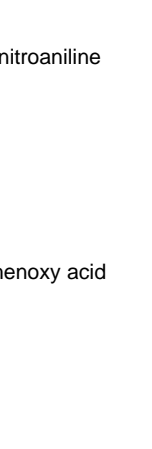

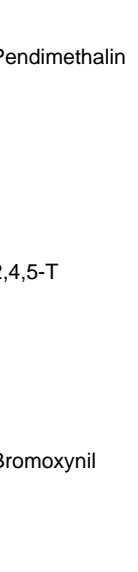

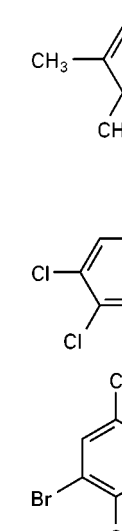

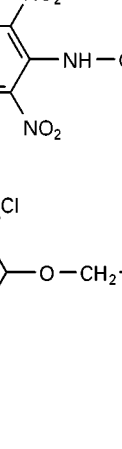

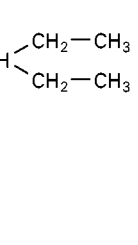

Character	Class	Typical herbicide	Chemical structure
Basic/neutral	Triazine	Atrazine	$\text{CH}_3\text{—CH}_2\text{—NH—}$ 
	Chloroacetamide	Metolachlor

they are too expensive for use in disposable SPE cartridges. Empore® extraction discs have recently become available, with styrene divinylbenzene (SDB) copolymer sorbents enmeshed in the matrix.

Recoveries of acid herbicides from water samples have been compared by using C₁₈ and SDB discs; the results of this comparison are controversial. Some authors documented an improvement in the recoveries of phenoxy-carboxylic acid and phenols on SDB discs for the enrichment of samples down to 500 mL (see Table 4). The addition of salt considerably enhances the recovery and decreases the differences between the extraction efficiency of C₁₈ and resin discs. However, other authors reported that SDB discs showed worse recovery rates under acidic conditions, in comparison with C₁₈ when preconcentrations were carried out with 1-L samples (see Table 3). In any case, salting out the water sample enhances the retention of substances on both materials; this increases recovery rates for hydrophilic substances. However, salting out is avoided as it may introduce impurities into the samples. The addition of a small quantity of methanol or other organic solvent also enhances the recovery by the so-called 'dynamic solvation'. However, it is not recommended, as it produces a relatively early breakthrough of hydrophilic substances.

Graphitized carbon black (GCB) has been confirmed to be a valuable adsorbing material for SPE of pesticides in aqueous environmental samples. GCB cartridges proved to be more efficient than the more commonly used C₁₈ bonded-silica cartridges for the SPE of polar herbicides, whereas the extraction of non-polar compounds showed inferior results (see Table 3). Although GCB is known to behave as a natural reversed phase, it contains chemical heterogeneities on its surface, which are able to bind anions via electrostatic forces. GCB can behave as both a reversed-phase sorbent and an anion exchanger, retaining the acidic pesticides in their ionic form under acidic conditions. In this situation, the base-neutral/acid fractionation can be achieved by using solvent mixtures at different pHs.

Silica-based ion exchangers are found in disposable SPE cartridges. They are not widely used for the preconcentration of environmental samples owing to their low capacity. Strong anion exchanger discs have been used for the analysis of chlorinated acid and phenoxy acid herbicides. The main problem with these comes from the fact that environmental waters contain high amounts of inorganic ions, which overload the capacity of the sorbent.

Selective SPE from environmental waters has been accomplished by using different sorbents coupled in the same or in different cartridges.

One of the sorbents is non-specific, such as GCB, which traps the analytes of interest and many other compounds, while the other is more specific, such as a cation or anion exchanger, which retains and reconcentrates the analytes of interest. **Table 5** shows the recoveries of nine phenoxy acid herbicides extracted by one miniaturized cartridge containing 50 mg of GCB at the top and 70 mg of a silica-based strong anion exchanger (SAX) at the bottom, compared with C₁₈ and anion exchanger extraction. A large loss of dicamba and incomplete recovery of phenoxyacids were obtained by using the resin-based exchanger material.

Ammonium quaternary compounds and glyphosate constitute a special and complicated case. Their determination is very important because they are among the top herbicides used in the world. An important drawback in the preconcentration of such compounds from water is their high polarity. Several efforts have been made to analyse them in environmental samples.

SPE of ammonium quaternary herbicides has been mainly performed with silica, which is a well-known example of the solid phase using adsorption and ionic interaction mechanisms with the silanol groups. Recoveries are rather acceptable in the pH range 7.5-9. Taking into account that at pH values higher than 7 the silanol groups of the stationary phase are ionized, at these pH values the cation-exchange capacity of the solid-phase will be increased.

Glyphosate, due to its ionic form, can be preconcentrated using anionic and cationic resins. Derivatization of the analyte, prior to SPE of the water sample, seems to help the concentration from water samples.

Table 5 Recovery of herbicides from 200-mL groundwater samples by using one cartridge containing GCB and anion exchanger compared with that from two other extraction methods

It can be concluded that C₁₈ material is inappropriate for some herbicides, especially more polar and very non-polar herbicides. In these cases, the SDB polymers and GCB offer a valuable alternative. The appropriate choice of solid phase for application to a separation problem will vary from case to case and must be adapted accordingly.

Elution of the Target Analytes

Desorption of the compounds from the concentration columns is mainly performed with a small volume of liquid. The partition coefficient in a given solid-phase eluent system should favour the shift of the studied herbicides. On the other hand, SPE is not a separate step, but it is part of a process that includes subsequent determination and so it should be taken into account that some determination systems, such as GC, are incompatible with the presence of water. In this way, the selection of the eluting solvent depends on the selected sorbent, the analytes and the detection method. Air-drying is often applied before analyte elution in order to remove residual water.

Methanol and acetonitrile are recommended solvents for the elution of herbicides adsorbed to C₈ or C₁₈ silicas. Dichloromethane and ethyl acetate have also been extensively used, especially when the presence of water is undesirable. Table 6 presents the

results obtained when herbicides were eluted from a cartridge using different solvents, such as methanol, ethyl acetate, acetone, hexane and dichloromethane following acetone.

Desorption of acid herbicides from the sorbents can also be performed using a solution adjusted to a pH where the analytes are in their ionic form (two units below or above the pK_a). The uniqueness of GCB is that acid compounds are retained in their ionic forms and neutral compounds are adsorbed by unspecific mechanisms. In this situation, base-neutral/acid fractionation can be easily achieved by first eluting base-neutral species with a neutral organic solvent mixture and then passing a basified or acidified solvent system to desorb acidic compounds. Table 7 reports the results obtained using base-neutral/acid fractionation in three kinds of GCB. In all cases, there was some carryover of 2,4-DB, which is the weakest compound included in this table.

With ion exchange sorbents, the analytes can be eluted from the SPE column by either adjusting the pH in order to neutralize the charge on the analyte or by using a buffer of high ionic strength.

Sample Requirements

Samples undergoing SPE need to be filtered to separate suspended matter. Filtration is especially necessary before extraction of surface water, but is also

often advisable for extraction of ground water to avoid blocking up the cartridge material. However, waters from different sources are very different in chemical composition. Matrix effects from the water itself can cause errors in quantitation and determination. The presence in waters of common contaminants (natural or xenobiotics), such as

humic acids, surfactants, inorganic salts, phenols, polycyclic aromatic hydrocarbons (PAH), other pesticides and related compounds, can negatively affect the analysis, significantly diminishing the recovery efficacy or interfering with the posterior determination. **Figure 1** shows that when natural samples are acidified, humic and fulvic acids are

¹Average recovery calculated from four determinations.

(Reproduced with permission from Ibáñez M, Picó Y and Mañes J (1996) Influence of organic matter and surfactants on solid-phase extraction of diqua, paraquat and difenzoquat from waters. *Journal of Chromatography A* 727: 245–252.)

co-extracted and co-eluted, which generates a large, unresolved peak in the chromatogram when HPLC with UV detection is used (chromatogram A). At pH 7, humic and fulvic acids are not co-extracted, as can be seen by the flat baseline from the beginning to the end of chromatogram (B).

Organic matter and anionic or non-ionic surfactants have demonstrated negative effect on the recovery of any class of herbicides. Although these undesirable effects are well known, only a few analytical studies have focused on ways in which to avoid them. The proposed methods for removing interferences are based on the use of chemical reagents, such as sulfite or cationic surfactants. In these cases, the recovery values after chemical treatment were similar to those when a Milli-Q-quality water standard was analysed. The recoveries reported in Table 8 show that the quantitative SPE of diquat, paraquat and difenzoquat is affected by the presence of anionic, zwitterionic and non-ionic surfactants when they are present in water at a level of up to $50 \mu\text{g L}^{-1}$.

Although some common contaminants of natural waters have a negative effect on the recoveries, SPE is useful for analysing herbicides in drinking and surface water because only in very extreme conditions does the concentration of these contaminants reach levels at which recoveries are significantly decreased.

The application of SPE to the isolation of herbicide residues from other matrices presents difficulties that must be overcome, which have, up to now, discouraged investigation into the use of other matrices. For liquid matrices (plasma, urine, blood or milk), acceptable recoveries have been obtained using protein precipitation prior to SPE but the impurities present can accumulate in the analytical columns and affect the chromatogram. The recoveries obtained by SPE for determining triazines from milk are compared with those obtained by liquid-liquid extraction (Hajšlova *et al.*) in Table 9. SPE was performed using a double trap: first, a non-specific adsorbent (GCB), and then a cation exchanger. The liquid-liquid extraction method, after an initial double protein precipitation using methanol in

basic and acid environments, used a partition with chloroform followed by a sample clean up using a silica cartridge. There were no significant differences in the triazine recovery using the two methods.

Solid matrices can also be extracted by SPE with cartridge or disc devices but require a separate homogenization step and other laborious processes. The reported recoveries are lower than those obtained with water, and the addition of methanol or acetonitrile as organic modifier is necessary. However, these recoveries are comparable to those obtained by other well known extraction methods for solid matrices. **Table 10** gives a comparison of the features of three extraction procedures for tribenuron methyl analysis in soil. Solid-phase and supercritical fluid extractions are the most adequate in terms of recovery percentage and precision, with acceptable detection limits; nevertheless, the recovery is affected by the amount of herbicide present in soil. SPE can also be performed by blending directly a homogenized sample with C₁₈ sorbent, transferring the mixture to a glass chromatography column and eluting the analytes with appropriate solvent.

The SPE of matrices other than water requires further investigation.

On-line and Off-line Procedures

Nowadays, SPE methods using off-line procedures can be converted into on-line SPE methods by direct connection of the precolumn to the analytical column via switching valves. The concentrated analytes are then directly desorbed and transferred to the analytical system. Such systems often involve microprocessor control of the stages for sample switching and flushing of solvents and eluents through the concentration and chromatographic columns.

On-line procedures have gained popularity since European Union (EU) guidelines were introduced which limited the maximum amount allowed for a single pesticide in drinking water to 0.1 $\mu\text{g L}^{-1}$ and for several pesticides to 0.5 $\mu\text{g L}^{-1}$, including toxic transformation products. Very sensitive methods are required for monitoring herbicide residues in drinking water at such low concentrations. Furthermore the recent commercialization of automatic devices has certainly helped in the development of on-line trace enrichment methods in environmental analysis, because the sequence can be totally automated using systems such as the Prospect module (Spark Holland) or the OSP-2 system (Merck).

On-line SPE-LC is the most common procedure used because it is easily performed in any laboratory. The extracted compounds are eluted directly from the precolumn to the analytical column by a suitable mobile phase, which permits the separation of the trapped compounds. It is well established that on-line procedures enable lower concentrations of pesticides to be determined, and most compounds can be kept within EU limits. **Table 11** illustrates the improvement in detection limits obtained for triazine and phenylurea herbicides using on-line procedures when compared with off-line ones.

Breakthrough is the key parameter in on-line SPE because it indicates the sample volume and the amount of analyte that can be preconcentrated. Two factors can be responsible for breakthrough: insufficient retention of the analytes by the sorbent and overloading of the sorbent. One important factor of the concentration procedure is the selection of the

Table 10 Comparison of the extraction procedures for tribenuron methyl analysis

sorbent, which must allow a convenient breakthrough of the analytes. Table 12 shows a comparison of SPE sorbents for analysis of phenyl carbamate herbicides. The results were unsatisfactory with some herbicides. GCB is not used much in online SPE because it is not sufficiently pressureresistant.

Another factor in the procedure is to evaluate the maximum sample volume that can be preconcentrated without breakthrough of analytes, thus avoiding peak broadening. Generally, 50 mL was considered as optimum, but it could be increased for a particular kind of herbicide.

It should be taken into account that sorbents used in on-line SPE are not selective and numerous compounds from the matrix of natural samples are preconcentrated and can be eluted with the analytes of interest. Interferences depend on the nature of the water. They have an effect on both detection

limits and quantification. Figure 2 shows some chromatograms obtained with different waters. In spite of the presence of interference peaks, it can be seen that making a good choice of preconcentration parameter and analytical conditions, allows low levels of many pesticides to be determined, even in highly contaminated surface waters.

In this way, the EPA in the United States currently offers an on-line SPE procedure followed by HPLC for the analysis of acidic herbicides in drinking water. The sample is first adjusted to pH 12 to hydrolyse esterified analytes, then it is acidified to a pH of 1 and a 20-mL aliquot is pumped through a reversed-phase concentration column. By use of a switching valve, the concentration column is then pumped in line with the analytical column and the sample constituents are then passed to the analytical column for separation and detection.

On-line SPE-GC is another interesting approach that has gained popularity over the last few years. The SPE-GC coupled techniques generally use an

uncoated, deactivated capillary precolumn, also known as a retention gap, which accommodates the liquid SPE eluent while it vaporizes, thereby providing

Figure 3 SPE-GC-NPD chromatograms obtained after pre-concentration of 10 mL of (A) HPLC grade water, (B) Amsterdam drinking water, and drinking water spiked with (C) triazines ($0.1 \mu\text{g L}^{-1}$) and (D) OPPs ($0.03 \mu\text{g L}^{-1}$). Peak assignment for the herbicides: S, simazine; A, atrazine; P, propazine; SB, sebumeton; T, trietazine; and TB, terbutylazine. (Reproduced with permission from Picó Y, Louter AJH, Vreuls JJ and Brinkman UATH (1994) On-line trace-level enrichment gas chromatography of triazine herbicides, organophosphorus pesticides, and organosulfur compounds from drinking and surface waters. *Analyst* 119: 2025–2031.)

solute pre-concentration. **Figure 3** shows typical results for the SPE-GC-nitrogen phosphorus detector (NPD) analysis of triazines. The most striking observation is the good baseline stability, because NPD is a very selective detector. The drawback of this technique is the high cost involved, which makes it unaffordable by most of the laboratories involved in herbicide analysis.

The analysis of herbicides, using an automated on-line solid-phase extraction device results in:

- a reduction in error
- a more efficient use of time

- savings in amount of solvent used
- an improved chromatographic separation
- a reduction of sample volume needed to achieve good results (up to 200 mL)
- a ten-fold improvement detection limit over that required by EPA and EU regulations (limit values)

The advantages cited for on-line procedures are convenient for some analysts, but many prefer the off-line approach, which gives a convenient extract in an organic solvent suitable for multiple analyses. Moreover, such an extract is generally much more stable than the aqueous sample from which it

was derived, and is therefore more suitable for long-term storage. Also, the off-line approach allows the processing of many samples at one time, an approach which is generally more productive in laboratories that are not fully automated.

Both off-line and on-line techniques are not mutually exclusive. The possibility of employing both methods gives the analyst more tools at his/her disposal for performing the analysis adequately.

Future Developments

Today, SPE has become generally accepted as the analytical method of choice for determination of all major herbicide groups in water. It is suitable for detecting approximately 300 pesticides and pesticide-related compounds and has undergone rigorous multi-laboratory calibration studies. SPE is also the backbone of residue analysis protocols for government agencies such as the EPA in the US. However, there is still much to be done. The development of new, more selective supports for SPE, its coupling with high separation power techniques, such as capillary electrophoresis (CE), and its application to extract herbicide residues from solid samples, may further reduce the detection limit and will represent an exciting challenge for researchers working in the area of herbicide residue analysis.

Looking to the future, it is interesting to note that new SPE sorbents involving antigen-antibody interaction, so-called immunosorbents, have been described. Due to their high affinity and high selectivity for these interactions, extraction and clean up of complex aqueous environmental samples is achieved in the same step. Their application to extracts from solid samples is solvent-free and simpler than any other clean-up procedure. Two class-selective immunosorbents have been optimized up to now that enable the trapping of two groups of widely used herbicides, phenyl urea and triazines.

Experiments have been recently designed to explore the possibility of recovering herbicide residues from food, soil, biological liquid and tissue samples by SPE. For liquid matrices, such as plasma, urine, fruit juice or milk, acceptable residue recovery may be obtained almost without clean up. Before SPE can be used with solid matrices (e.g. muscle, vegetables or soil) a separate homogenization step and often multiple filtration, sonication and centrifugation are required. Despite these drawbacks, SPE has been used a few times to extract residues of triazines, carbamates, ureas and other herbicides. More work is needed to further develop SPE for use with the many different types of matrices that may contain herbicide residues.

Capillary electrophoresis (CE) is very much suited for those analytes that are not amenable to GC or when existing LC methods do not offer sufficient separation power. Many impressive CE separations, including the separation of triazines and sulfonylureas, have been demonstrated in the last few years. The main disadvantages of these techniques are its inadequate detection limits and lack of selective detectors for the determination of residues in environmental matrices. As a result of coupling with SPE, use of CE has become competitive in trace analysis, and the door has been opened to environmental applications in real matrices. Thus, the potential of CE is very good indeed.

Introduction

Modern agricultural production in major agriculture countries depends heavily on the use of pesticides. Herbicides represent more than 50% of all pesticides used (in the USA and Germany the figure is about 60%) and are found in soil, ground and surface water and food. Triazines are the most common herbicides, and they represent *c.* 30% of all herbicides used. As they are relatively stable they are also the ones most commonly found in the environment. Triazine toxicity is low and they do not usually present a risk to humans. However, as they are extensively used, their presence in the environment and in food must be monitored (triazine residues, especially those of atrazine, can be found, in milk, butter and sugar). Phenylureas are replacing triazines as they are easily degraded, but this fact makes their analysis more difficult. Phenoxyacids are the oldest synthetic herbicides. Other herbicides include triazines, carbamates, uracils, pyridazines, substituted ureas and anilines (Figure 1).

Methods used to analyse herbicides and their residues are similar to those used for other pesticides. The methods applied should be able to determine multicomponent pesticide mixtures simultaneously, have a good reproducibility and a high recovery and a low limit of determination (the maximum permissible concentration in drinking water is as low as $0.1 \mu\text{g L}^{-1}$).

Principles of Thin Layer Chromatography and High Performance TLC (HPTLC)

Thin-layer chromatography (TLC) remains an important practical analytical method for the analysis of herbicides with well-developed standard procedures. Its main advantages for this type of analysis are simple equipment, the possibility of varying a large number of the experimental parameters, high throughput (up to 36 samples can be analysed simul-

taneously), fast analyses, economy and low solvent consumption. Sample clean-up is either simple or not required at all.

TLC thus provides a simple and inexpensive screening method for the analysis of herbicides.

In classical TLC the samples are applied to the thin layer and then the layer is developed by a mobile phase (a solvent or a solvent mixture). After the mobile phase is evaporated, the separated zones are evaluated. As capillary forces govern the migration of the solute through the stationary phase, the mobile-phase velocity is less than optimal. Higher velocity can be obtained by forced-flow development.

High performance TLC (HPTLC), which has developed from classical TLC, offers greater separation efficiency, greater sensitivity and reproducibility, accurate quantification and automation.

Modern instrumental HPTLC is thus a complementary technique to high performance liquid chromatography (HPLC) in the analysis of herbicides and is increasingly used in this application.

Chromatographic Systems

Silica gel is the most common stationary phase in TLC and HPTLC of herbicides but reversed-phases (silica gel modified with C_8 , C_{18} , e.g., RP-18 W, Nano-Sil C_{18} -100, silica gel impregnated with paraffin oil) can also be used. Silica gel impregnated with diethylene glycol is suitable for triazine herbicides. Good separation of herbicides can also be obtained on alumina. TLC layers covered with a transparent polymer film have been recommended to prevent evaporation of the mobile phase and volatile herbicide samples and to suppress the adsorption of environmental impurities.

Mobile phases frequently used in the TLC of herbicides in combination with silica gel include dichloromethane, hexane–acetone and hexane–butyl acetate mixtures. Methanol or acetonitrile with water is recommended when reversed-phase stationary phases are employed. Hexane–dioxane mixtures are used with alumina layers. The hydrophobicity of herbicides can be modified by the addition of cyclodextrins.

For the TLC systems commonly used in the analysis of herbicides, see Table 1.

Figure 1 Structure of common herbicides.

Multiple Development

In multiple development the sample spots are re-concentrated whenever the solvent front contacts the chromatographic zone and the spots are re-focused to narrow bands. This results in increased separation efficiency and improved detection limits.

Automated multiple development (AMD) HPTLC has been applied to the screening of pesticides (including triazine, phenylurea, carbamate, phenoxy-carboxylic acids and other herbicides) in environmental samples. Herbicides from different classes can be resolved by a universal gradient, based on dichloromethane. Positive results are confirmed by a second analysis using special gradients optimized for indi-

vidual classes. Separated pesticides can be evaluated by densitometric detection and characterized by their UV spectra and migration distance. Most pesticides have detection limits in the range from 5 to 60 ng and their analysis does not require preconcentration methods. Only a few pesticides have higher detection limits and require preconcentration, e.g. by solid-phase extraction. An AMD-HPTLC method, DIN 38407, part 11, has been included in Germany's official methods for water analysis. An example of the AMD-HPTLC analysis of drinking water spiked with herbicides is shown in **Figure 2**; multi-wavelength detection was used. The optimized 20-step gradient for this separation is shown in **Figure 3**. Analysis takes 90 min (12 samples are analysed on one plate)

Table 1 Examples of TLC systems for the analysis of herbicides

Stationary phase	Mobile phase	Detection
Silica gel (60 or G)	Dichloromethane	Hill's reaction, sprayed with silver nitrate, <i>o</i> -toluidine 4,4'-tetramethyldiaminodiphenylmethane, 1% ferric chloride in butanol
	Ethyl acetate	
	Hexane-acetone (8 : 2)	
	Toluene-acetone (85 : 15)	
	Benzene-chloroform-methanol (9 : 3 : 2)	
PR-18W, PR-18, Nano-Sil C ₁₈ -100	Chloroform-methanol (3 : 1)	Sprayed with silver nitrate or <i>o</i> -toluidine
	Methanol-water (7 : 3)	
	Acetonitrile-water (7 : 3)	

Figure 2 Multi-wavelength scan of drinking water spiked with 1, 2,4-dichlorophenoxyacetic acid; 2, mecoprop; 3, simazine. The optimized gradient is given in Figure 3. Reproduced with permission from Morlock (1996).

and peak capacity (separation number) is more than 40. This method was shown to be suitable for 283 pesticides, including herbicides.

Detection

Various agents have been used to visualize herbicide spots. They include silver nitrate, Gibbs reagent, diphenylamine and ninhydrin. The commonest detection method in TLC of herbicides is densitometry. Pre- and post-column derivatization can be carried out if the substances do not absorb visible or UV light. Simultaneous use of densitometry and fluorescence quenching is advantageous in the analysis of herbicides in multicomponent formulation, e.g. bromacil and diuron, chlortoluron and terbutryn.

Biochemical detection based on Hill's reaction is a very sensitive and selective method for herbicide residues that inhibit the enzyme system of isolated chloroplast. The concentration of the herbicide residues can also be determined from the lifetime of the spot. This method can be used for triazines, phenylureas, carbamates, uracils and pyridazone. Detection limits for herbicide residues in water, agriculture crops, foods and soil are in the range $1-10 \mu\text{g kg}^{-1}$.

TLC with radioactive detection is useful in environmental studies, for example, in studies on the degradation of herbicides, formation of residues and their uptake and metabolism by plants.

Combination of TLC with mass spectrometry, recommended for the identification of herbicide metabolites, is less frequently used because of its high price.

Figure 3 Optimized 20-step gradient for the determination of 2,4-dichlorophenoxyacetic acid, 4-chloro-2-methylphenoxyacetic acid (isooctyl ester) and atrazine. Reproduced with permission from Morlock (1996).

Selected Applications

TLC analysis of herbicides present in various matrices is usually preceded by isolation and/or preconcentration methods, e.g. solid-phase extraction (SPE) for water samples and supercritical fluid extraction (SFE) for solid samples, e.g. soils and plants; sample clean-up is usually not required. Some typical examples of the application of TLC in herbicide analysis are given below.

TLC can be used to determine triazine herbicides and their metabolites in drinking and surface water. Preconcentration by SPE is followed by chromatography on C_{18} plates with hexane–ethyl acetate–acetone (4 : 4 : 1 v/v) or silica gel with nitromethane–tetrachloromethane (1 : 1 v/v) and densitometric detection. The same chromatographic system can be used to determine triazine and triazone herbicides in soil after SFE. Detection limits range from 30 to 60 ng L⁻¹. A simple TLC method to determine atrazine in drinking and ground water is based on its extraction with chloroform, followed by separation on silica gel with toluene–acetone (85 : 15) as mobile phase and detection by spraying with 4,4'-tetramethyldiaminodiphenylmethane. The detection limit is 20 ng L⁻¹.

Phenoxyacetic acid herbicides can be analysed on silica gel with acidified mobile phases, e.g. ethyl acetate–acetic acid (49 : 1 v/v) or toluene–acetone–acetic acid (2 : 2 : 1 v/v) and detected by spraying with a solution of 3,5-dichloro-*p*-benzoquinonechlorimine.

Residue analysis of phenylurea herbicides in water, potatoes and soil is based on extraction with acetone or dichloromethane, clean-up on silica gel, hydrolysis to anilines and derivatization to fluorescent dansyl derivatives *in situ* on plate. This is followed by separation on silica gel with dichloromethane–methanol (99 : 1 v/v) as mobile phase and fluorescence detection. Detection limits of *ca.* 1, 20 and 200 mg kg⁻¹ can be attained for water, potato and soil samples.

Pre-coated silica gel plates impregnated either with a 20% solution of formamide (A) or diethylene glycol (B), with hexane–chloroform–diethyl ether (2 : 1 : 1 v/v) as a mobile phase for system A and hexane–benzene–acetone (1 : 1 : 1) for system B gave satisfactory separation of 12 substituted urea herbicides (Table 2).

The screening of drinking water (about 300 compounds, including herbicides) is based on SPE followed by AMD. Identification is by analysing the sample under different separation conditions, together with reference compounds, measurement of the UV spectra *in situ* and by the use of post-chromatographic detection with various reagents. Both SPE and HPTLC can be automated.

Table 2 R_F values of substituted urea herbicides

Herbicide	A	B
<i>N'</i> -(3-chloro-4-methoxyphenyl)- <i>N,N</i> -dimethylurea	0.16	0.36
<i>N'</i> -Phenyl- <i>N,N</i> -dimethylurea	0.20	0.40
<i>N'</i> -(4-Chlorophenyl)- <i>N,N</i> -dimethylurea	0.26	0.47
<i>N'</i> -(3,4-Dichlorophenyl)- <i>N,N</i> -dimethylurea	0.35	0.54
<i>N'</i> -(3-Chloro-4-methylphenyl)- <i>N,N</i> -dimethylurea	0.39	0.58
<i>N'</i> -[4-(4'-Chlorophenoxyphenyl)]- <i>N,N</i> -dimethylurea	0.45	0.62
<i>N'</i> -(4-Isopropylphenyl)- <i>N,N</i> -dimethylurea	0.46	0.64
<i>N'</i> -(4-Chlorophenyl)- <i>N,N</i> -methoxyphenylurea	0.70	0.77
<i>N'</i> -(4-Bromophenyl)- <i>N,N</i> -methoxyphenylurea	0.74	0.80
<i>N'</i> -(3,4-Dichlorophenyl)- <i>N,N</i> -methoxyphenylurea	0.78	0.83
<i>N'</i> -(4-Chlorophenyl)- <i>N,N</i> -methylisobutyl-2-urea	0.56	0.70
<i>N'</i> -(3,4-Dichlorophenyl)- <i>N,N</i> -methylbutylurea	0.72	0.79

HPTLC can be used for the optimization of HPLC conditions where direct method development is more time-consuming and expensive. The herbicide migration data obtained in HPTLC on silica gel, RP-18, RP-8 and CN chemically bonded phases correlate well with HPLC.

Conclusions and Future Trends

TLC is useful in herbicide analysis when many samples have to be analysed. It requires minimal sample pretreatment and reduces the number of separation steps. The reason for using HPTLC for herbicide residue is that it can analyse samples in complex matrices with minimal matrix modification. The ability to separate a number of samples simultaneously is important in screening studies. HPLC should be applied in cases of complicated samples when TLC fails and when full automation is required.

It is expected that TLC will keep its place as a simple and rapid method for qualitative and semiquantitative analysis of herbicides. HPTLC will find increasing use in herbicide residue determinations due to its main advantages of increased separation efficiency, decreased detection limit, more accurate quantitative analysis and automation. There will be developments in mobile-phase optimization. Greater use of combined TLC-spectroscopic methods can be expected.

A growing demand for method validation can be expected.

HEROIN: LIQUID CHROMATOGRAPHY AND CAPILLARY ELECTROPHORESIS

R. B. Taylor, A. S. Low and R. G. Reid,

Copyright © 2000 Academic Press

Introduction

The separation and quantitative determination of opiates is required for a wide variety of purposes and applications. These include therapeutic drug monitoring, metabolism and pharmacokinetic studies and forensic investigations, as well as the detection and control of drug abuse. The determination of opiates in human urine is of considerable analytical interest, particularly in the context of detecting the consumption of heroin; it is in this context that the present article is written.

The first step in the establishment of such presumptive consumption of heroin is usually by enzyme immunoassay. This has the merit of low detection limit and large sample throughput, making it very suitable for large screening programmes. The immunoassay technique, however, is nonselective with respect to individual opiates and a positive result in such a screen for legal purposes must be followed by identification of individual opiates present. The purpose

of this is usually to confirm or refute the hypothesis that heroin has been consumed. The short metabolic half-life of heroin complicates its confirmation, so that its consumption is inferred by detection of its metabolites. One generally sought metabolite is morphine owing to its relatively long half-life. This approach has the disadvantage that morphine is also produced as a metabolite of codeine, so that heroin consumption is presumed or not on the basis of notional codeine-to-morphine ratios. The detection of the first metabolite of morphine, 6-monoacetylmorphine, is now taken as an unequivocal indicator of heroin consumption.

The detection of heroin consumption is further complicated by the quite general inclusion of legal opiates such as codeine, pholcodine and dihydrocodeine in commonly available medicines. This results in numbers of subjects being screened as positive for opiate consumption who are not confirmed by alternative methods as having consumed heroin or morphine.

To confirm the presence of individual opiates, techniques are required that are more selective than immunoassay. These are usually based on established chromatographic techniques. Several thin-layer systems have been used but in general these have

insufficiently low limits of detection to confirm adequately results obtained by immunoassay. This is a particular problem since immunoassay detects total opiates and, following separation, individual concentrations may be much lower. The most generally accepted confirmation is by combined gas chromatography-mass spectrometry (GC-MS), owing to the selectivity of the capillary gas chromatography separation coupled with the unequivocal identification by electron impact ionization mass spectrometry. The technique of high performance liquid chromatography (HPLC) has been extensively applied to heroin and some of its metabolites as well as individual related opiates for a variety of purposes associated with drug abuse. No liquid chromatography (LC) method has specifically addressed the problem of confirmation of results obtained from immunoassay. Work in this area has concentrated on developing LC methods capable of quantifying morphine and codeine individually since, as indicated above, the codeine-to-morphine ratio has been a major criterion in establishing heroin consumption. The emerging technique of capillary electrophoresis (CE) is potentially attractive as a separation technique because of its capability for high resolution and peak capacity. As yet little has appeared in the literature concerned with the capability of this technique to determine low concentrations of opiates in biological matrices.

The literature on the determination of drugs of abuse and screening procedures using GC-MS is extensive and will not be discussed here. The present article describes both normal and reversed phase LC systems for the separation and quantification of a set of opiates comprising heroin, 6-monoacetylmorphine, morphine, codeine, dihydrocodeine and pholcodine, and discusses their potential in acting as an intermediate test in determining opiate abuse. Such a test may eliminate so-called false positives arising from urine samples screened as containing opiate that is subsequently found not to originate from consumption of heroin. A method based on CE is also described and its potential in relation to the LC methods discussed. Heroin is rapidly metabolized and cannot be detected in urine. This drug is included in this set, however, as the separation with respect to legal opiates may be of relevance in forensic applications.

Reversed-Phase LC System

Several reversed-phase separations of selected groups of opiates have been reported in the literature using column switching, gradient elution and ion pairing techniques. From our experience in the analysis of

basic drugs in biological fluids, the most general approach to ion pairing is the use of mobile-phase additives. An anionic surfactant such as sodium dodecyl sulfate (SDS) or alkylsulfonic acid, which is adsorbed onto a C_{18} surface, is incorporated in the mobile phase to increase retention and thus separation. The inclusion, in addition, of a less hydrophobic species of similar charge to the analyte, such as a tetraalkylammonium bromide, has been found to reduce tailing of such basic compounds and also in some cases to alter selectivity. In using such systems the pH of the mobile phase is made acid, thus protonating the basic analytes.

For the opiates morphine, pholcodine, dihydrocodeine and codeine the best anionic mobile phase additive is pentanesulfonic acid used in conjunction with tetraethylammonium bromide. At concentrations of 1 mmol L^{-1} and 100 mmol L^{-1} , respectively, these additives in methanol/aqueous buffer (10:90 by vol.) containing disodium hydrogen phosphate at pH 2.5 give excellent separation of these four opiates in 15 min when dissolved in water. This system allows the inclusion of nalorphine as an internal standard, which elutes between pholcodine and dihydrocodeine. This optimum separation is shown in Figure 1. Both heroin and 6-monoacetylmorphine elute much later than codeine and therefore cannot be determined at sensitivities comparable with the other compounds. The separation of these four opiates is accompanied by excellent individual linearity of response of peak height ratios versus concentration over the range $1\text{--}5 \mu\text{g cm}^{-3}$ using UV detection at 285 nm.

A standard solid-phase extraction procedure was applied to urine spiked with the four opiates and the internal standard. Bond-Elut Certify extraction cartridges containing a mixed stationary phase of non-polar C8 and strong cation exchanger (SCX) were used. The extraction consisted of cartridge conditioning with methanol, water and acetate buffer followed by sample addition and washing with acetate buffer, water and methanol. After drying, the analytes were eluted with dichloromethane/isopropyl alcohol (80:20 by vol.) mixture containing 2% (v/v) ammonia. The resultant solution was dried at 40°C under nitrogen, reconstituted in 250 μL of ethyl acetate, and again dried under nitrogen. Immediately prior to injection, the sample was redissolved in 500 μL of mobile phase. This procedure gave percentage recoveries in excess of 80% for all the compounds other than morphine, for which the recovery was 71%, presumably as a result of its known propensity for being adsorbed onto glass surfaces.

This extraction procedure gives a large solvent peak in this reversed-phase solvent system. At the

Figure 1 Representative reversed-phase separation of morphine (M), pholcodine (P), dihydrocodeine (DHC), codeine (C) and nalorphine (IS) using 10% methanol/90% water, containing 50 mmol L^{-1} disodium hydrogen orthophosphate, 1 mmol L^{-1} pentanesulfonic acid and 100 mmol L^{-1} tetraethylammonium bromide as mobile phase at a flow rate of 0.4 mL min^{-1} , column $100 \times 2 \text{ mm}$ i.d. packed with $3 \mu\text{m}$ microporous octadecylsilica, detection by UV at 280 nm .

detector sensitivity required for 500 ng cm^{-3} opiate concentrations, it is not possible to quantify morphine or pholcodine since they are not separated from the solvent front. A specimen chromatogram of urine spiked (500 ng cm^{-3}) with the four opiates and nalorphine is shown in Figure 2.

It appears that for such a set of opiates, which vary widely in hydrophobicity, the reversed-phase system is of minimal use for the purpose of detecting heroin consumption by urine analysis when coupled with UV detection. Neither heroin nor 6-monoacetylmorphine interfere with the quantification of the legal opiates. However, the retention time of the 6-monoacetyl metabolite is excessive for quantification and

the codeine-to-morphine ratio cannot be established because of the masking of the morphine peak at levels below 500 ng cm^{-3} by endogenous compounds in the solvent front when using UV detection. The inherent high resolution of reversed-phase chromatography is not helpful in the quantification of this widely differing range of analytes. The obvious choice of gradient elution, by analogy with GC, would result in compression of the timescale for elution of the complete range of compounds. However, the potential improvement in detection limits may not be wholly achievable owing to increased baseline noise. The use

Figure 2 Representative chromatogram of a urine sample spiked with morphine (M), pholcodine (P), dihydrocodeine (DHC) and codeine (C) at a concentration of 500 ng cm^{-3} and incorporating nalorphine (IS) as internal standard after solid-phase extraction using 10% methanol/90% water containing 50 mmol L^{-1} disodium hydrogen orthophosphate, 1 mmol L^{-1} pentanesulfonic acid and 100 mmol L^{-1} tetraethylammonium bromide as mobile phase at a flow rate of 0.4 mL min^{-1} , column $100 \times 2 \text{ mm}$ i.d. packed with $3 \mu\text{m}$ microporous octadecylsilica, detection by UV at 280 nm .

of electrochemical detection, while it has been shown to be highly sensitive in the detection of opiates, would not overcome the long retention time required to elute 6-monoacetylmorphine. Its characteristics were not examined using this separation system.

Normal-Phase LC System

In common with most drug separations by LC, reversed-phase methods predominate in the literature for the separation and quantification of opiates. Normal-phase solvent systems have been reported for the quantitative determination of selected groups of opiates. None of these, however, is suitable for the purpose of determining heroin consumption, either by identification of 6-monoacetylmorphine or by quantitative estimation of the concentration of morphine relation to other legal opiates present.

Using a 200 mm × 2.1 mm column packed with 3 μm Hypersil it has been found possible to resolve completely morphine, dihydrocodeine, pholcodine, codeine, 6-monoacetylmorphine, nalorphine (as internal standard) and heroin. The optimized mobile phase consists of dichloromethane/pentane/methanol (29.8 : 65 : 5.2 by vol.) containing 0.026% (v/v) diethylamine. Figure 3 shows a representative chromatogram of this set of opiates. The resolutions between individual pairs of opiates are less than in the reversed-phase system, although still in excess of one. This system results in complete elution of all components of interest in approximately 16 min. This separation appears to be more advantageous for the detection of heroin consumption than the reversed-phase system in that the order of elution is reversed and heroin and 6-monoacetylmorphine are eluted fairly early in the chromatogram, thus allowing maximum sensitivity of detection of the latter.

When a solid-phase extraction procedure identical to that described above is used, it is found that the choice of solvent is critical to redissolve the dried analytes completely while preserving peak shape on injection. The final injection solvent consists of dichloromethane/pentane (10 : 90 by vol.). This ensures complete solution of the extracted analytes and allows injection in a solvent chromatographically weaker than the mobile phase, which maintains peak sharpness. Figure 4 shows a chromatogram of the six opiates together with the internal standard, nalorphine, after extraction from a spiked urine sample. In contrast to the reversed-phase system, all the analytes of interest are completely resolved from the solvent front and can thus be readily quantified using UV absorption at 280 nm. The main quantitative characteristics of analysis for these six opiates are shown in Table 1. The separation is adequately rugged with

Figure 3 Representative chromatogram showing the separation of a pentane solution of morphine (M), dihydrocodeine (DHC), pholcodine (P), codeine (C), 6-monoacetylmorphine (6-MAM), nalorphine (IS) and heroin (H) (column 200 × 2 mm i.d. packed with 3 μm microporous silica mobile phase—dichloromethane/pentane/methanol 29.8 : 65 : 5.2 by volume containing 0.026% v/v diethylamine at a volumetric flow rate of 0.4 mL min⁻¹, detection by UV at 280 nm).

respect to the retention times as a result of the inclusion of nalorphine as an internal standard, even allowing for the relatively volatile solvents used in the mobile phase. The selectivity aspect of the separation is excellent with respect to both endogenous materials and the opiates of interest. The retention times of commonly ingested drugs, opiate metabolites and other compounds relative to nalorphine are listed in Table 2.

Table 2 shows that the selectivity with respect to the more commonly ingested drugs such as aspirin and caffeine, and also to several of the established opiate metabolites, is good in that retention times are appreciably different from the compounds of interest. Paracetamol, however, elutes between codeine and pholcodine and is incompletely resolved from the latter. At the wavelength of 280 nm used, the sensitivity for paracetamol is very low and

Figure 4 Representative chromatogram of a urine sample spiked with 500 ng cm^{-3} morphine (M), dihydrocodeine (DHC), pholcodine (P), codeine (C), 6-monoacetylmorphine (6-MAM), nalorphine (IS) and heroin (H) following solid-phase extraction on subsequent reconstitution in 10% dichloromethane/90% pentane and injected (column $200 \times 2 \text{ mm}$ i.d. packed with $3 \mu\text{m}$ microporous silica mobile phase dichloromethane/pentane/methanol 29.8:65:5.2 by volume containing 0.026% v/v diethylamine at a volumetric flow rate of 0.4 mL min^{-1} , detection by UV at 280 nm).

there would be minimal interference from paracetamol in the determination of any pholcodine present. The linearity and limits of quantification show that quantification after extraction and separation is adequate to confirm the presence of 6-monoacetylmorphine. The relative amounts of legal opiates as well as morphine detectable in urine are at levels corresponding to those that would result in the detection of opiate by immunoassay; the cutoff value generally used is 300 ng mL^{-1} .

An advantage of the normal-phase separation is the facility of coupling this with MS detection via an appropriate interface. The system described has been successfully linked via a particle beam interface with

some loss of resolution. Electron impact ionization allows unequivocal identification of all of the opiates.

Capillary Electrophoresis

Separation of charged analytes by utilizing their differential migration rates in an electric field has been achievable for many decades. The high theoretical plate numbers readily realized by using narrow capillaries, and the relatively recent (compared to LC) availability of reliable microprocessor-controlled equipment, have resulted in increased interest in the theory and application of this technique. The high efficiency can potentially be exploited to achieve resolution and also to accommodate higher peak capacity than is readily or conveniently achieved in LC. Both of these aspects are relevant to the identification and quantification of this group of opiates. However, because only a small sample volume can be injected onto a capillary and only a short pathlength is available when direct UV detection is used, the concentration sensitivity of capillary electrophoresis with UV detection suffers in comparison with LC methods when hydrodynamic injection is used. Within the extensive literature that now exists on CE methods, there are relatively few reports on applications concerning the determination of drugs in biological fluids such as plasma or urine, in which the analyte is generally at low concentration levels. Most applications in the literature reporting quantification of drugs at the ng mL^{-1} concentration level in biological fluids have used sample pretreatment methods that involve a preconcentration step in order to reach the required limits of detection, and thus exploit the undoubted separational advantages of the technique.

Samples can also be introduced into the capillary electrokinetically, i.e. by application of a relatively low voltage with the capillary end immersed in the solution of analyte. It has been established both theoretically and practically that the amount of analyte of a particular charge introduced electrokinetically can be dramatically increased if the solution from which the sample is injected is of low ionic strength compared with that of the buffer used for the electrophoretic separation. While this injection method is subject to bias (not all analytes will be introduced into the capillary in this way), this can be a positive advantage when quantifying particular analytes in a given matrix.

An optimized separation of the six opiates and levallorphan (as internal standard) by CE is shown in **Figure 5**. The parameters affecting separation are buffer concentration and pH. As is general, increase of buffer ionic strength over the range 20 to 140 mmol L^{-1} increases retention and resolu-

tion. Increase of buffer pH from 4 to 8 decreases the retention as a consequence of increased electroosmotic flow. Figure 5 shows that all the opiates of interest are eluted in 12 min with resolution between individual pairs well in excess of that achieved by normal-phase LC. What is equally significant is that all seven compounds are eluted within a narrow time-scale of 9–12 min, so that there is much less disparity between the relative amounts of peak broadening than is the case in either of the LC methods described earlier.

A urine extraction procedure based on the method developed for LC has been developed in which a 0.5 cm^3 urine sample is extracted as previously but reconstituted in 1 cm^3 of a solvent consisting of water/methanol (9 : 1). The resultant electropherogram obtained from urine spiked at approximately 300 ng cm^{-3} subsequent to extraction and elec-

trokinetic injection is shown in Figure 6A. Figure 6B shows the corresponding electropherogram of a blank urine sample. In contrast to the LC methods there are very few endogenous compounds brought through the extraction and electrokinetic injection procedures. Only one of these is a potential interference as it elutes close to pholcodine.

The separational abilities of the CE method are clearly superior to those of either of the liquid LC methods, taking into account both the selectivity with respect to individual opiates and also the separation from endogenous urine components. The quantitative aspects of the CE method are also significant. It has been found that reconstitution of extracted and dried

analytes in aqueous methanol allows the field-amplified sample injection technique to be applied extremely effectively. Indeed, in the method development it was found that the increase of peak areas when comparing electrokinetic injection from water with hydrodynamic injection ranged from 90 in the case of heroin to 160 for 6-monoacetylmorphine and pholcodine. This, coupled with the use of 200 nm as the wavelength of detection, allows limits of detection well below the cutoff level for immunoassay to be achieved. The electrokinetic injection technique for the enhancement of concentration sensitivity applied to this assay procedure is capable of overcoming the perceived limitation of CE as technique for determining these compounds in urine. Table 3 summarizes the main validation parameters of the assay of these drugs based on the CE procedure described.

The validation parameters in Table 3 show that the quantitative aspects are very comparable with those quoted for LC. The electrokinetic introduction of sample is in general more variable than hydrodynamic introduction but incorporation of an internal standard, which is required to accommodate variable extraction efficiencies, results in within day and day to day precision better than that achieved by normal-phase LC. The limits of quantification quoted are indicative only, since time of sampling could be considerably increased over the 10 s at 5 kV used. The significance is that there is more than adequate sensitivity to allow detection of these particular opiates at the required levels for elimination of common opiates that have resulted in so-called false positives during immunoassay screening. The elec-

trokinetic method of sample introduction, however, does require that the solution for injection into the capillary be of low ionic strength. Consideration must be given to the overall sample matrix pretreatment to ensure this. In addition, at very low concentrations, there is considerable sample depletion from the small sample volumes used and care has to be taken to limit the number of successive injections from a given sample vial.

Conclusions

There are many opiates for which a multitude of assays have been determined in a variety of matrices for often very widely different purposes. In screening for drugs of abuse, chromatographic methods are extensively used to increase the information gained by rapid immunoassay. The method of choice for unequivocal identification of particular opiates is likely to continue to be GC-MS on the basis of the mass spectral information obtainable. The present article indicates that, at least for the specified relevant group of opiates chosen, separations in the liquid phase are capable of achieving adequate separations and that these can be applied with variable success to the determination of the specified compounds in urine. The results quoted for the reversed-phase LC method show an inherent limitation of this approach when determining a number of compounds differing widely in hydrophobicity. Such methods, however, can usually be manipulated to allow good resolution and quantification for more restricted mixtures of compounds. The widely

differing retention times for codeine and morphine tends to make reliable quantification of the ratio of these compounds difficult. The normal-phase method offers a viable alternative to GC as a separation procedure and is capable of quantifying the codeine-to-morphine ratio and of detecting 6-monoacetylmorphine at useful concentration levels. More importantly, the normal-phase method is capable of detecting and quantifying the commonly ingested legal opiates that can obscure or delay the final results of an immunoassay opiate screen. The separation achieved by CE arguably offers the most realistic alternative to GC. Method development is rapid and the plate numbers are comparable with those achievable by capillary GC. The underlying difficulty of lack of concentration sensitivity can be overcome by electrokinetic injection techniques if suitable sample pretreatment methods are developed with appropriate sample solvent composition. The eventual linking of CE with MS on a commercial basis should result in a combined technique capable of challenging GC-MS in this area of drug analysis.

Humic substances (HS) which are widespread in the soil, present structural complexity and polyelectrolyte properties. Many techniques and methods have been used to obtain more information about them, as reviewed by Davies and Ghabbour in 1999. The characterization of HS has been the focus of intense research for many years because the organic matter in soil contributes to the quality of the soil more than the other constituents. Nowadays, one of the main goals is the separation of HS into fractions which can then be studied independently. The aim is to determine HS structure, which remains unknown, despite the enormous efforts and remarkable progress in this field. HS exhibit properties similar to weak acid polyelectrolytes, presenting a wide range in molecular weights, solubilities and acid strength. They are sparingly soluble in acid and slightly acidic solutions, but solubility increases with pH and they are only fully soluble alkaline solutions. Many general hypothetical models of HS structure have been proposed, and most of these have been discussed by Shevchenko and Bailey.

As HS play an important role in environmental chemistry, it is important to know their properties. HS are very important as regards the quality and productivity of a soil and in retention of metal ions and pollutants by the environment. Dissolved humic material has a tendency to interact with these compounds, complexing metal ions or pollutants, which may alter their fate and transfer in the soil. The mechanisms involved in the interaction of these compounds with HS are not clear and may vary depending on the physicochemical properties of the compounds, soil pH, redox status and the heterogeneous structure of HS. The effect of pH, for example, is related to the degree of humic R-COOH and R-OH dissociation; deprotonation increases the polarity of the humic material and altering its structure.

Electrophoretic methods have been applied for the purpose of HS studies since the 1960s. The first work on the separation of HS by a capillary technique was

performed in 1991 using capillary isotachopheresis. However, few really suitable methods for the separation of HS exist.

Nevertheless, to understand HS behaviour, it is useful to perform separation into fractions and determine the structure of each fraction. Capillary zone electrophoresis (CZE) has been applied by Rigol *et al.* in 1994 for this purpose.

HS Properties Studied by CZE

A short overview will be given here because the understanding of the properties of HS is the key to their successful separation.

Adsorption of HS

In the literature, most of authors have used high HS concentrations in order to reach or observe CZE separation patterns; however, no explanation was given (Table 1). In fact, it has been observed that when using a background electrolyte that did not interact with HS (rimantadine, for example), high adsorption of HS on bare fused silica capillary wall occurs. This explains why previous authors used rather high concentrations of HS solutions for analysis, because a considerable part of the HS was lost from the solution during the separation process. This observation is in agreement with the fact that HS are highly adsorbed on to silica rocks and silicates or induce interactions with metal ions on clay surface. Such adsorption processes of HS have already been studied on different silica-based materials with other methods. Adsorption on the surface of the silica capillary complicates CZE separation. It was demonstrated recently that the adsorption can be reduced using additives such as magnesium(II) ($>14 \text{ mmol L}^{-1}$) in the background electrolyte (BGE). In such magnesium-doped electrolytes, more fractions of HS can be observed, but also a secondary hump pattern. Via study of HS adsorption, a new method of CZE separation has been developed, which allows the concentration of HS in solution needed for CZE separation to be lowered to around $35\text{--}50 \text{ mg L}^{-1}$.

Oligomerization of HS

It has long been known that HS aggregate in solution. Various authors describe this property differently. Von Wandruszka *et al.* described the

[HS], concentration of humic substances; + hump present; – no hump.

aggregates as pseudomicelles, whereas Wershaw and Chien *et al.* used humic membrane-micelle, Dachs *et al.* introduced the term fractal aggregates,

Shevchenko *et al.* used polymers and finally, the formation of oligomers was proposed by Havel *et al.* in 1997.

The most interesting theory from the last decade is that of Wershaw, who introduced a model for humic materials which provides a mean of understanding the interactions of hydrophobic compounds and HS. This model considers humic material to be constituted of a number of different oligomers and simple compounds. The resulting structures are similar to micelles or membranes in which the interiors are hydrophobic and exterior surfaces hydrophilic. Thus, the enhancement in the solubility of DDT was observed by Wershaw in concentrated HS solutions which implies the formation of HS micelles. According to Karckhoff *et al.* and Wang *et al.*, the adsorption of hydrophobic organic compounds by organic matter involves weak mechanisms of adsorption such as hydrogen bonding. Few papers concerning aggregation of HS have been published as yet. Schmitt *et al.*, using micellar electrokinetic chromatography (MECK), observed that some HS behave like ionic micelles and defined a humic initial micellar concentration (CMC) around 30 mg L^{-1} . The micellar properties of HS are due to both hydrophilic and hydrophobic sites which are responsible for the enhancement of the solubility of organic compounds in aqueous media or the lowering of the surface tension of water.

In 1998, the aggregation properties of HS were studied by CZE. Oligomerization of HS was observed during CZE when the effect of HS concentration on CZE separation patterns was studied. The phenomenon was described for several BGE: DL-alanine, phosphate and rimantadine systems. When either concentration or sample injection time were increased, significant changes in HS separation patterns were observed. The CMC of humic acid was estimated to be around 35 mg L^{-1} .

Interaction of HS with Metal Ions and Organic Compounds

Metal Ions

The interaction of metal ions with natural soil particles is complex, involving various mechanisms. Binding between trace metals and dissolved HS is important in controlling the chemical speciation, toxicity and bioavailability of trace metals. For example, it has been observed that, in the presence of HS dissolved in seawater, the accumulation rates of cadmium in organisms were faster in comparison to accumulation rates of cadmium from seawater without HS.

Different models of metal-HS interactions have been described. Due to the broad spectrum of binding sites reported by Ephraim, HS can interact

with metal ions by adsorption, ion exchange, precipitation and/or surface complexation. Specific adsorption involves several heavy metal ions such as Cd^{2+} , Ni^{2+} , Co^{2+} , Zn^{2+} , Cu^{2+} , Pb^{2+} and Hg^{2+} . Coprecipitation of trace metals with carbonates is very important for semi-arid soils and in soils formed from limestone. Techniques like synchronous and time-resolved fluorescence, luminescence, anodic stripping voltammetry and modified carbon paste electrodes have been used in the study of the fate and distribution of inorganic pollutants in the environment. Many papers concerning the binding of metal ions to HS have been published.

In 1997, Nordén and Dabek-Zlotorzynska applied CZE to study Sr^{2+} , Pb^{2+} , Cu^{2+} , Hg^{2+} and Al^{3+} . Their interactions with HS were confirmed. Study of the influence of pH on the complexation showed that complexation can be better followed by direct rather than indirect detection. The following order of complexation was obtained by CZE: $\text{Al}^{3+} > \text{Hg}^{2+} > \text{Cu}^{2+} > \text{Pb}^{2+} > \text{Sr}^{2+}$. This result is in agreement with other work on metal ion-HS interaction strengths. Furthermore, when pH is increased, complexes are more stable and, ageing of HS solutions showed an increase of more than 25% in the amount Hg^{2+} bound to HS after 5 months. This increase is supposed to be connected to the possible time dependence of the reduction process, and/or to be related to the macromolecule nature of HS. Changes in HS separation pattern were also observed when adding iron(III) to HS and forming Fe^{3+} -HS complexes, when the study was performed at pH 12.

Radionuclides

The other important interactions which have been studied and are highly important with respect to environmental protection policies are those between HS and radionuclides like ^{60}Co , ^{85}Sr , ^{137}Cs , ^{237}Np , ^{241}Am , etc. For example, it has been shown that samarium(III) (10^{-10} to $10^{-5} \text{ mol L}^{-1}$) and americium(III) ($10^{-11} \text{ mol L}^{-1}$) form 1 : 1 complexes with HS; their pH-independent complexation constants, $\log \beta$, are respectively 7.1 ± 0.2 and 6.6 ± 0.2 . Spiking actinide elements (Th, U, Np, Pu, Am) in HS fractions, it has been shown that these fractions vary greatly in their effectiveness and selectivity as ligands for early actinides.

Rigol *et al.* used CZE to study humic fractions in organic soil and their relationship with radiocaesium mobility. The quantification of the radiocaesium confirmed that there may be some organic matter-radionuclide interactions other than those originated by HS and which may govern radionuclides

retention in soils with a high content of organic matter.

Organic Compounds

It has been known for many years that organic compounds interact with HS. There have been studies on the interaction of pesticides (chlorodimeform and lindane) and herbicides (paraquat, 2,4-dichlorophenoxyacetic acid and atrazine) with HS. Later, the effect of HS was studied on solute transport in clays and it was suggested that humic and fulvic acids facilitate the transport of small organic molecules by encapsulation. Over the last 5 years, the effects of dissolved HS on the bioconcentration of xenobiotics have been studied by several authors. It was observed that dissolved HS can change the physicochemical properties of these pollutants in aqueous environments by modifying the hydrolysis kinetics, enhancing their water solubility or decreasing the toxicity of the organic chemicals. The binding of hydrophobic organic compounds to humic polymers has been studied, using a predictive thermodynamic HS–organic solute interaction model. A distributed reactivity model was studied for phenanthrene sorption and desorption equilibria by soils and sediments. Relationships were observed between the chemical and structural characteristics of associated organic matter and it was noted that hysteresis is important to the fate and transport of organic contaminants in environmental systems.

It was proposed to use the potential of dissolved HS to enhance the desorption of hydrophilic pollutants in remediation processes for soils and waters. Following this idea, some authors used a complexation–flocculation method to determine binding coefficients of phenanthrene, anthracene, pyrene and fluoranthene to dissolved HS. In some cases, pH dependence of the sorption was observed. While naphthalene binding to dissolved HS was not decreased at lower pH, dichlorodiphenyl trichloroethane (DDT) and polyaromatic hydrocarbons (PAHs) showed the opposite effect.

As reviewed in Table 1, the effect of organic solvents on the migration behaviour of HS in CZE

was also studied. Migration time values are usually shifted to longer values compared to aqueous BGE. This effect is attributed to either a decrease in electroosmotic flow (EOF) or an increase in the electrophoretic mobility of HS compounds, or even to both effects together. Furthermore, some additional fractions were distinguished when applying mixed solvents. They are attributed to the formation of supramolecules between the organic solvent and HS.

Paramagnetic studies have been carried out in the study of atrazine solubilized by humic micellar solutions. This work suggests that atrazine is preferably present in the hydrophobic interior of HS micelles. Other techniques, such as light and X-ray scattering also give evidence of molecular aggregation in humic solutions. Using ultraviolet-visible (UV/Vis), Fourier transform infrared and electron spin resonance spectroscopy, a group of authors studied the mechanism of atrazine sorption on HS and confirmed that hydrogen bonding is responsible for the interaction. Proton transfer and possibly also hydrophobic bonding are involved in the interactions between atrazines, and HS and CZE studies of the binding between S-triazines and HS confirmed that interactions between ionizable pesticides and HS occur: differences in the electropherograms were observed.

Capillary Electrophoretic Separation of HS

The major advances in the separation of HS are listed in Table 2.

CZE separations of HS have been performed using UV/Vis, diode array or laser-induced fluorescence detection. In Table 1, the BGE used for this purpose are listed; mainly borates, amines and amino acids have been applied. Nevertheless, even if a large variety of BGE were used, four main types of electropherogram separation patterns can be observed and the three most important types of HS separation are shown in Figure 1. The first type is obtained in a tetraborate BGE and represents separation patterns with one or more broad peaks, called usually the humic hump.

Table 2 Important advances in HS separation

1960–70	First applications of electrophoretic methods to HS
1980–90	Application of size exclusion chromatography to HS
1991	First HS separation by capillary technique (Kopáček <i>et al.</i>)
1994	First application of capillary zone electrophoresis (CZE) to HS separation (Rigol <i>et al.</i>)
1996–1997	CZE study of HS interactions with some metal ions and organic compounds
1998	First separation of HS on to 15–30 peaks or fractions (Fetsch and Havel)
	Study of HS properties by CZE as adsorption on capillary wall and oligomerization process (Fetsch <i>et al.</i>)
	Combination of ultrafiltration and CZE (Rigol <i>et al.</i>)

Figure 1 Three BGEs for coal-derived humic substances. Humic acid: Fluka no. 53680 (analysis number 38537/1 293) supplied by Fluka Chemika (Switzerland). Fused silica capillary: $L = 43.5$ cm ($l = 35.5$ cm) \times 75 μ m i.d. (A) BGE 1 and conditions: 60 mmol L^{-1} DL-alanine adjusted by HCl at pH 3.20; 15 kV, 20 s hydrodynamic injection, 40°C , 220 nm and $C_{\text{HA}} = 100$ mg L^{-1} . (B) BGE 2 and conditions: 50 mmol L^{-1} phosphate adjusted by NaOH at pH 9.20; 20 kV, 15 s hydrodynamic injection, 40°C , 220 nm and $C_{\text{HA}} = 100$ mg L^{-1} . (C) BGE 3 and conditions: 350 mmol L^{-1} boric acid adjusted by HCl at pH 3.20; 20 kV, 15 s hydrodynamic injection, 40°C , 220 nm and $C_{\text{HA}} = 530$ mg L^{-1} .

Sometimes, these humps do show shoulders and some resolution. It is usually suggested that the hump corresponds to the average electrophoretic mobility of the HS polymeric mixture.

The second type of electropherograms in L- or DL-alanine BGE consists of three fractions. These elec-

tropherograms can distinguish between HS of different origin via changes in migration times of the fractions and in the number of peaks. It was shown in these studies that temperature plays an important role in the patterns obtained. The best separation is obtained for temperatures in the range 30 – 40°C and the highest peak area and peak height are obtained at $\approx 40^\circ\text{C}$. An example of separation under optimized conditions is shown in Figure 1A. Three main fractions were found and, for the wavelength lower than 220 nm, a negative peak was observed. Separation also depends on pH and buffer concentration. As the EOF changes with pH, the migration times of the separated components are directly affected and generally decrease as pH increases. In the pH range 5.0 – 9.5 , HS constituents are moving as anions. In the case of alanine-based BGE, it appears that one fraction is moving as a neutral molecule, while the others are moving as anions. Under the presence of HS, it is difficult to determine the EOF simultaneously with HS separation because common neutral markers used (mesityl oxide, methanol, acetone and water) interact with HS. Independent determination of the EOF is necessary.

In the case of borate BGE, when increasing BGE concentration, migration times increase but no important changes in separation patterns are observed.

The next type of HS separation gives a humic hump with small peaks on it. This effect is generally observed with dihydrogen phosphate BGE (Figure 1C) or dihydrogenphosphate combined with borate BGE.

On the other hand, quite important changes in the separation patterns and number of peaks, were observed using slightly acid BGE, which consists of a high concentration of boric acid. This gives the best HS separation resolving from 10 to 30 peaks depending on the type of humic acid sample. In this case, highly concentrated (100 – 350 mmol L^{-1}) boric acid BGE is used as a complexing BGE (Figure 1C). The possible explanation for this excellent separation pattern is as follows: functional groups of hydroxycarboxylic acids, oxalic acid and oligoalcohols are present in the HS structure. Boric acid interacts with phenolic and carboxylic groups and therefore also reacts in a similar way with HS. This reaction was also proved by spectrophotometric and potentiometric studies. It was suggested that the large number of peaks observed in highly concentrated boric acid BGE is due to the breaking of HS oligomers into real fractions of humic substances (Figure 2). Humic substances contain a limited number of chemical entities (even as low as perhaps only 3 – 7). However, when the concentration of HS is increased, these species

do oligomerize. Complexation of boric acid with phenolic or carboxylic groups prevents the formation of oligomers and thus the individual chemical compounds can be separated by CZE. The species formed must be kinetically robust, which is the condition to observe separated peaks. If just three fractions, HA₁, HA₂ and HA₃, are considered, oligomerization might take place according to eqns [1-3]:

In addition, mixed oligomers can be formed according to the general reaction:

If reaction [4] is quantitative, instead of the peaks of HA₁, HA₂, HA₃ species, just one peak (one hump) of the oligomer will be observed.

This oligomer will be broken down by reaction with boric acid

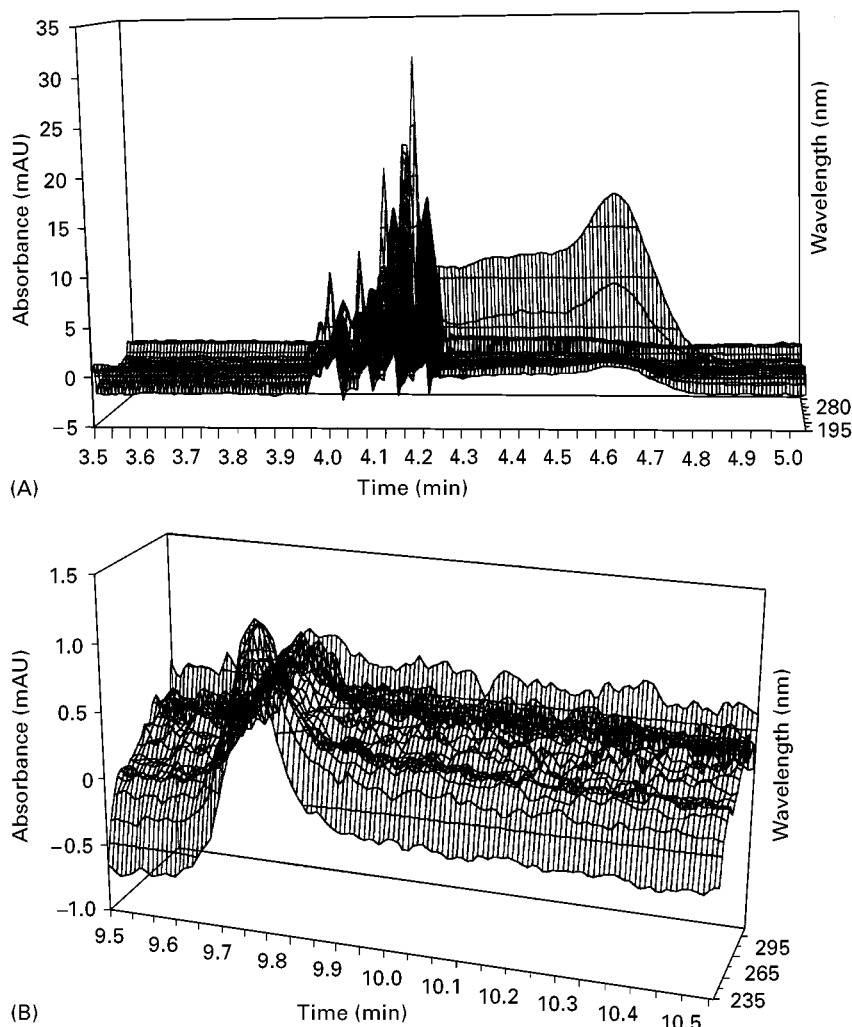

Figure 2 Fluka humic acid three-dimensional electropherogram at higher HS concentration in boric acid BGE. Humic acid: Fluka no. 53680 (analysis number 38537/1 594) supplied by Fluka Chemika (Switzerland). Fused silica capillary: L = 43.5 cm (l = 35.5 cm) × 75 μm i.d. BGE: 350 mmol L⁻¹ H₃BO₃ adjusted by HCl at pH 3.15. Conditions. 20 kV, 40°C, 15 s hydrodynamic injection and C_{HA} = 533 mg L⁻¹. Figure 2 Continued

Oligomers are broken down and three monomers will be observed in this theoretical case. Thus, it seems that for the first time separation of HS into the real fractions, real chemical entities forming the humic substances mixture, has been achieved in highly concentrated boric acid BGE. Some other examples of fingerprints are presented in Figure 3, showing the separation of humic acids of peat, soil, oxyhumolite and tschernozem origin.

In conclusion, different CZE separations have been presented with very different results; the most interesting and efficient were the results of Fetsch and Havel in highly concentrated boric acid solution.

Future Developments

CZE has been shown to be the most powerful tool for the separation and characterization of HS due

to their ionic and/or polyelectrolyte properties. The CZE separation patterns of HS obtained may, in the future, find a direct application in forensic science.

Nevertheless, even if several different models of HS are proposed and various properties of HS intensively studied, the real structure of humic, fulvic, humin and hmatomelanic acids is still unknown. The latest results obtained by CZE showing separation into 10–30 fractions present an optimistic insight into the humic substances puzzle. On the basis of recent results, fraction collection in order to perform studies on individual fractions by gas chromatography–mass spectrometry, matrix assisted laser desorption–time of flight (MALDI-TOF) mass spectrometry and nuclear magnetic resonance is beginning to appear feasible. It is possible that the problem of HS structure is at last on the way to being resolved.

The main mass of organic carbon in the aquatic environment and in soils/sediments is located in humic organic matter (HOM). A typical agricultural soil contains about 2–7% HOM in the upper level. Depending on the type of water (freshwater lake, marine origin, bog water, etc.), the content of aquatic HOM may range from 50 to almost 100% of the dissolved organic carbon. Terrestrial HOM acts mainly as a pollutant sink; aquatic HOM has a distinctive vehicle function. Thus, HOM influences fate, bioavailability and transport behaviour of organic and inorganic pollutants.

The detailed structural characterization of the ubiquitous HOM is an ambitious task because these polymers do not possess the uniform structure observed with other natural polymers. The extreme heterogeneity of both soil-derived and aquatic HOM in terms of chemical composition, monomer unit sequence, molar mass and functionality is associated with their genesis: for example, soil organic matter is composed of a variety of plant and animal residues in different stages of decomposition, of (radical) metabolites possessing mesomeric forms, and of products formed from these breakdown products. During the genesis, the chemical identity of the precursors is lost by abiotic and/or biotic condensation reactions.

The combined application of powerful analytical techniques may reveal some basic principles in HOM structure, but will probably never give a complete structure. Therefore, HOM analysis should not be targeted at the elucidation of discrete HOM structure but to recognizing substructures and functional groups (including their linkages), on the basis of which the fundamental interactions of HOM with environmental contaminants of organic and inorganic origin may be better understood. Nondestructive nuclear magnetic resonance (NMR) and Fourier transform infrared spectroscopy (FTIR) have proved to be very useful in providing information on functional groups and on the neighbourhood of substructures. Small scale analytical pyrolysis and controlled wet chemical degradation, in which the polymeric network is broken down to smaller subunits, constitute efficient supplements to non-destructive spectroscopic methods, in which an averaged structure is studied. Thermal and wet chemical degradation can give volatile products amenable

to gas chromatography (GC) analysis, including hyphenated techniques, such as gas chromatography–mass spectrometry (GC-MS) and gas chromatography–atomic emission detection (GC-AED). The combination of data obtained from the structure-related mass spectrum and the element-related atomic spectrum is especially useful for the detection of heterocyclic compounds as well as chlorinated structures in humic-like chlorolignins. The basic assumption in this strategy is to correlate the destructive products with original moieties present in the starting HOM network.

In addition to structure-related analytical investigations, destructive methods can also be applied for elucidation of the carbon cycle in soils and water, for solving geochemical problems (such as the diagenesis of HOM), in recognizing pathways of emissions from biomass combustion, in revealing pesticide contamination of soils, in studying humification processes taking place in landfills, in studying chlorinated aqueous HOM, in screening residues in bioremediated soils, and for other applications.

Conventional Analytical Pyrolysis

The traditional analytical pyrolysis, which can easily be performed using a flash pyrolyser or ferromagnetic wires with defined Curie temperatures, is useful in detecting certain building blocks, including polysaccharide-like substances, aromatic units, cyclopentenone units, *N*-containing units and aliphatic units in the HOM network, thus giving some evidence of the structure, origin, genesis, degree of decomposition and humification (condensation) of the polymer under study. As an example, pyrograms of marine samples are rich in protein products derived from phytoplankton, but are free from the lignin-derived guaiacyl (4-hydroxy-3-methoxyphenol) and syringyl (4-hydroxy-3,5-dimethoxyphenyl) compounds which are common in terrestrial and freshwater samples. Although there are many sources of typical fragments in the pyrolysate, it is generally accepted that furfural, levoglucosan (and other anhydrosugars), pyranones and acetic acid originate from carbohydrates, methoxyphenols from wood and lignin, ammonia, acetonitrile and pyrrole from proteins, while alkanes, alkylbenzenes (-naphthalenes, -phenanthrenes, etc.) and fatty acids originate from fossil fuels and biomass. Pyrograms of soil- and sediment-derived HOM are mainly characterized by the classical *n*-alkane/*n*-alk-1-ene/*n*- α,ω -alkadiene triplet series.

They may originate from esters, the saturated alkanes originating from decarboxylation of the fatty acid moiety, and the olefins from the alcohol moiety as a result of β -scission. Another source may be alkyl-benzenes with long side chains.

Generally, pyrograms are very complex, composed of several hundreds of compounds. Figure 1 shows two extracted ion chromatograms used to trace thiophenes and benzenediols in the complex pyrogram. The (anthropogenic) fulvic acid under study was isolated from a coal wastewater pond, where it was formed spontaneously from coal wastewater components. High concentrations of phenols and benzenediols as well as of heterocyclic compounds are striking in comparison with pyrograms of HOM isolated from natural sources. The comparison between these patterns in the fulvic acid isolated from the coal wastewater, in the HOM of the associated sediment on the bottom of the pond, in the organic solvent extract of the sediment (obtained by means of accelerated solvent extraction or ASE) and the pollutant pattern in the wastewater allows conclusions to be drawn on the humification process and on the

pathways of contaminants present in the coal wastewater.

Reproducibility of the pyrograms is mainly determined by the steps in sample preparation, pyrolysis and pyrolysate transfer to the GC column rather than by the pyrolysate analysis by GC-MS (AED). Prior to pyrolysis, the HOM sample is usually subjected to an intense degreasing procedure, e.g. by Folch's chloroform-methanol (2:1) mixture to avoid ambiguous results with regard to the source of the pyrolysate. The extract from exhaustive solvent extraction contains the same compounds which are released during thermal desorption at subpyrolysis temperatures (e.g. 300°C). Both methods reveal contaminants attached to the HOM rather than covalently bound. To obtain a more homogeneous material and to simplify the pyrogram, a combination of pyrolysis and chemical modifications may be used: for example, acid hydrolysis removes carbohydrates and proteins/peptides, whereas the more resistant hydrocarbon fraction remains unchanged.

In general, pyrograms of HOM reveal overwhelmingly nonpolar hydrocarbons and less polar

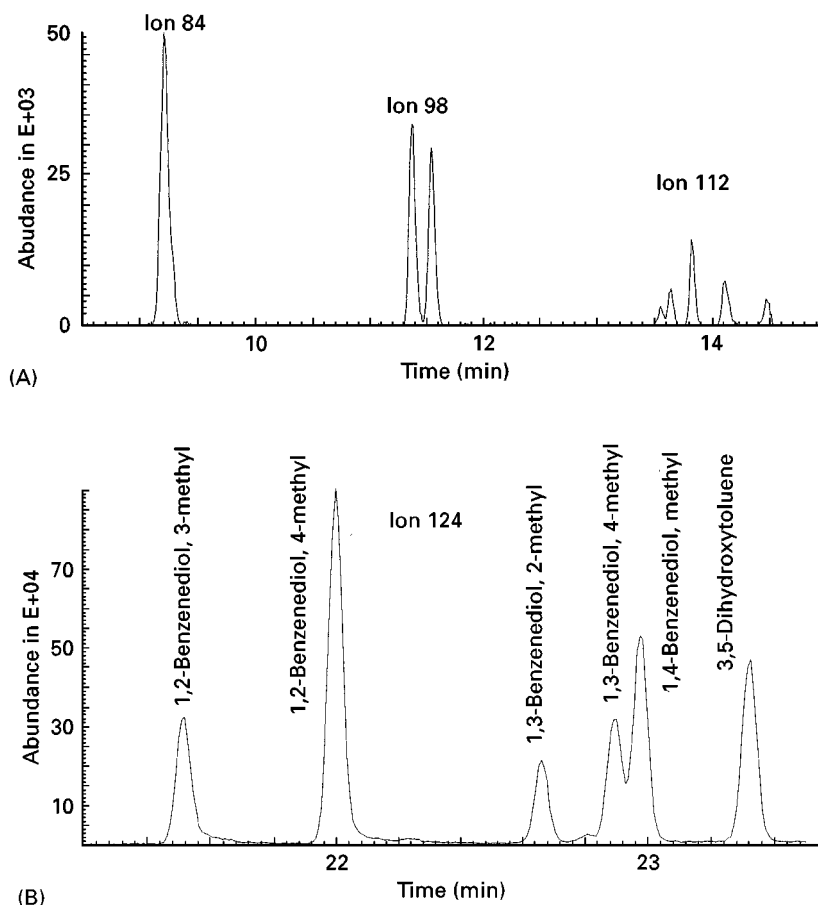

Figure 1 (A) Thiophene and (B) benzenediol pattern of an aquatic humic acid isolated from coal wastewater on an inert HP-5 capillary column.

Figure 2 Aromatic methyl esters (ME) obtained in TMAH-assisted *in situ* methylation of a humic acid isolated from peat. Selected ion traces are given in parentheses.

heterocyclic compounds (e.g. benzofuranes, chinolines, benzothiophenes, etc.). Evidently, there are large discrepancies between NMR results and common titration results on the one hand, which indicate high carboxyl and hydroxyl group contents, and the basically nonpolar pyrolysates on the other hand. This finding is due to pitfalls occurring during pyrolysis, like the decarboxylation of fatty acids to give alkanes and the formation of polar, less volatile products inaccessible to GC (see below). Some efforts have been made to overcome these drawbacks. The coupling of pyrolysis with the 'soft' field ionization MS to give overwhelmingly molecular ions of thermal degradation products, including polar and higher molecular ones, turned out to be very useful in rapid profiling of HOM. The significance of this strategy can be further enhanced by using high resolution MS. The hyphenated technique thermogravimetry-MS, which allows running experiments in a time-resolved manner, can give further information on the binding state of the compounds released from the matrix. Another approach is to produce appropriate derivatives to preserve the analytical integrity of HOM in a better way.

Thermochemolysis with TMAH

Challinor was the first to introduce *in situ* methylation using a methanolic solution of tetramethylammonium hydroxide (TMAH) with biopolymers to convert polar carboxylic and hydroxyl groups to less polar and GC-accessible methyl derivatives so as

to avoid decarboxylation and dehydration. Methodological studies revealed that simultaneous pyrolysis/methylation (SPM) is not a pyrolysis but a thermally assisted chemolysis. This saponification/esterification reaction can be performed at subpyrolysis temperatures in both an online and offline (batch) approach, the latter including flushing of the thermochemolysis products into an organic solvent spiked with internal standards.

In contrast to conventional pyrolysis, some compound classes of diagnostic value can be detected by means of the SPM approach:

1. Aromatic acids, including mono-, di- and trimethoxybenzenecarboxylic acid methyl esters, benzenedicarboxylic acid dimethyl esters, mono- and dimethoxybenzenepropenoic acid methyl esters (Figure 2). The presence of trimethylgallic acid (3,4,5-trimethoxybenzoic acid) is of special diagnostic value, because it indicates the final step in the oxidation of side chains in lignin units¹. To verify the ambiguous origin of methoxy compounds (real methoxy moieties or resulting from originally free hydroxyls), deuterated TMAH can be used². Another approach is the application of

¹ The 3,4,5-trimethoxybenzoic acid methyl ester may also be derived from syringic acid (4-hydroxy-3,5-dimethoxybenzoic acid).

² Analogously, to investigate the role of methanolysis, the reagent TMAH/CD₃OH may be used.

tetrabutylammonium hydroxide, giving rise to *O*-butyl ethers only from phenolic groups, whereas aliphatic hydroxyls do not undergo a reaction with the weaker acidic reagent.

2. Long chain fatty acid methyl esters (FAMES). A pronounced even-over-odd discrimination constitutes a strong evidence of biogenic input, while uniform FAME patterns indicate anthropogenic origins. Iso- and anteiso FAMES (frequently C₁₅ and C₁₇) are related to Gram-positive bacterial activities, whereas *cis*-vaccenic acid (C_{18:1}, double bond in Δ11 position) is related to Gram-negative bacteria.
3. The homologous series of α,ω -dicarboxylic acid methyl esters (DME). The α,ω -alkanedioic acids are of distinctive diagnostic value because they are thought to act as bridges in the HOM network and thus are considered to be markers for the cross-linking ratio. However, other pathways cannot be ruled out: the C₉-DME is widely distributed in both aquatic and terrestrial HOM of natural origin. It may originate from fatty acids with double bonds in Δ9 position, e.g. oleic acid, which have undergone oxidation. Analogously, the C₁₁-DME is common in pyrolysates of bacteria, the lipids of which contain distinctive *cis*-vaccenic acid moieties.
4. The pristenes refer to chemically bound phytol and tocopherols.
5. 1-Methoxyalkanes formed by thermochemolysis represent mainly alkanols bound by ester groups.

SPM at 'mild' temperatures followed immediately by thermal treatment under more severe conditions can be used to estimate the share of ester, ether and C-C bonds in the HOM polymeric network. Pyrograms of HOM of both aquatic and terrestrial origin reveal a pronounced FAME pattern under mild conditions at 500°C, but do not reveal any alkanes. SPM at 750°C after the treatment at 500°C gives typical *n*-alkane patterns originating either from ether linkages or from alkylbenzenes. These findings may be attributed to the fact that ester bonds are cleaved at 500°C, whereas the more stable C-O-C and C-C bonds are resistant to decomposition at this 'mild' temperature.

Limitations of Pyrolysis in Structure Elucidation of HOM

Generally, pyrolysis work is aimed at obtaining a maximum yield of pyrolysis products to be analysed by means of GC and at ensuring that these volatile products reflect the structure of the polymer

from which they are generated as truly as possible³.

It was not until the mid 1990s that *Kopinke* carried out the first quantification experiments with HOM pyrolysis using a two-detector technique (MS to identify the pyrolysate, flame ionization detector (FID) to quantify organic carbon). Before that time, quantification was done in a semiquantitative way at best (+++ most abundant, ++ less abundant, etc.). Calibration can be done offline using on-column injection of calibration mixtures, or can be performed by vaporizing internal standards in the hot pyrolysis interface during equilibration just before the beginning of the pyrolysis process. Three fractions can be distinguished in the pyrolysate, the sum of which amounts to almost 100% of the original HOM organic carbon:

1. A solid residue, which consists almost exclusively of carbon, due to charring reactions resulting from the elimination of functional groups and additional cross-linking. This residue is about 30% of the original organic carbon content, largely independent of the kind of HOM studied. Thus, considering the fact that HOM consists of about 40–50% organic carbon, over 50% of the HOM's carbon, which is expected to carry substantial structural information, is lost on pyrolysis. Unfortunately, this residue cannot be significantly reduced by increasing the pyrolysis temperature, and it is also in the same order of magnitude when pyrolysing under in-source vacuum conditions. The latter finding indicates that the 'coke' formation is a solid-phase reaction rather than a transport-limited step. When pyrolysing soils, the tendency to form solid carbonaceous residue is correlated to organic carbon content.
2. Compounds in the pyrolysate with little structural significance. The remaining carbon is detected mainly as nonspecific light gases, including carbon dioxide, carbon monoxide and methane eluting at the beginning of the chromatogram. Although carbon dioxide is assumed to be a rough measure of decarboxylation and methane a rough measure of methyl substitution, etc., all these light gases are of minor diagnostic relevance to the HOM structure.
3. Compounds with supposed structural significance (C > 4, assumed arbitrarily), comprising about

³Losses due to the limitations of the analytical system are outside this consideration. They may be circumvented by pyrolysis inside a GC precolumn; all volatile pyrolysates are completely transferred to the column.

6–10% of the organic carbon. A slight increase in the yield of structure-related compounds can be observed when turning from the conventional pyrolysis to SPM (15% at best).

However, the situation gets even worse when considering the real significance of the compounds in group 3 above. Whereas long aliphatic chains definitely originate from the HOM skeleton, aromatic and cyclic compounds may undergo unwanted thermal modifications, resulting in their misinterpretation, as already discussed above with alkanes/fatty acids. Further, the occurrence of furanes in the pyrolysate does not necessarily mean that furane moieties are present in the HOM backbone. It can also be related to thermal rearrangements and reactions originating from polysaccharide-related units (e.g. xylans, cellulose from terrestrial plants) or OH-substituted carbon chains with at least four carbons. Hence, if pyrolysis products are considered to be building blocks, cellulose should be made up of furans, pyranones, anhydrosugars, etc. Similar pitfalls occur with alkylbenzenes. They can be formed in the cracking of triglycerides and fatty acids (catalytically stimulated, e.g. by elemental sulfur). Most recent findings also indicate the formation of alkylbenzenes via a metal-catalysed alkylation of aromatic hydrocarbons, the cations being complexed in the HOM network. Therefore, structural models based on conventional pyrolysis studies are largely biased.

SPM is considered to be less error-prone. However, this approach has not been scrutinized as closely as conventional approach up until now. Saiz-Jimenez, who pioneered the SPM approach, found that model phenolic acids underwent decarboxylation reactions. Most recent results indicate that the occurrence of benzene carboxylic acids in the pyrogram does not necessarily indicate their presence in the HOM backbone: lignin models free of carboxylic groups may yield MEs of benzenecarboxylic acids during SPM. On the other hand, decarboxylation reactions and isomerization of unsaturated fatty acids have not been under intense study yet, but presumably they cannot be completely excluded. Hydroxyl- and carbonyl-containing resin acid MEs have been shown to undergo side reactions with the reagent, resulting in the formation of nitrogen-containing derivatives. Likewise, aldehydes have been recently shown to undergo a Cannizzaro-like reaction, in which the products are methylated to esters and ethers. In addition to that, the quantity of FAMEs released in 500°C thermochemolysis surpasses by far the quantity of hydrocarbons (including alkanes, alkenes and alkylbenzenes) released in conventional pyrolysis, pointing to further aliphatic precursors. Moreover,

the FAME pattern does not necessarily coincide with the alkane pattern.

Apart from the ambiguous origin of markers in the pyrograms of HOM, these markers cannot be assigned to defined biological precursors by themselves. As an example, *n*-alkanes can be derived from anthropogenic sources (fuels), from direct input of biosynthesis (higher plants), from reduction of fatty alcohols (bacteria, higher plants), from decarboxylation of almost ubiquitous fatty acids and from depolymerization of aliphatic biopolymers. To assign these sources, isotope ratio GC-MS is very useful.

Controlled Wet Chemical Degradation

The ultimate aim of this approach (mostly conducted in an offline mode), elucidation of the HOM structure on the basis of degradation products, is similar to that of pyrolysis. As with HOM pyrolysis, large quantities of nondiscriminated building blocks are expected from an ideal chemical degradation method in a mechanistically predictable manner⁴. Common methods to obtain defined degradation products include mainly traditional approaches, such as:

1. Reductive degradation, e.g. using catalytic hydrogenation or alkali metals such as sodium or sodium amalgam in liquid ammonia, or lithium in liquid ethylamine. (The free or solvated electrons are provided in metallic reductions by the conversion of metal atoms to their cations.) In all cases, the carbon skeleton of aliphatic substructures is claimed to remain intact, whereas bonds between carbon and heteroatoms (in particular oxygen) are cleaved. A reagent with reactivity slightly higher than that in catalytic hydrogenolysis is iodotrimethylsilane, capable of cleaving ether and ester bonds. **Figure 3** shows the fatty acid pattern of a terrestrial HOM isolated from the sediment at the bottom of a coal wastewater pond after this treatment followed by methylation. The fatty acid pattern reflects both natural sources, expressed by the even-over-odd discrimination in the C₁₄–C₁₈ range, and the presence of bacterial iso- and ante-iso-acids and anthropogenic sources, expressed by very long chain acids and a less pronounced even-over-odd discrimination at higher carbon numbers.
2. Oxidative and hydrolytic degradation. Common oxidative reagents include cupric oxide, ruthenium tetroxide and potassium permanganate. The

⁴The derivatization of HOM has also been used for subsequent analysis by NMR or infrared spectroscopy to obtain well-resolved spectra, e.g. by silylation of groups with acidic protons.

Figure 3 Fatty acid pattern (as methyl esters) of an HOM isolated from a sediment associated with coal wastewater, obtained after iodotrimethylsilane cleavage (using chlorotrimethylsilane–sodium iodide) and boron trifluoride catalysed methylation. Numbers indicate the carbon chain length of the homomorphic fatty acid.

hydrolysis is mainly catalysed either by sodium hydroxide or sulfuric/hydrochloric acid⁵. Another direction includes mild and selective enzymatic hydrolysis. As with thermochemolysis with TMAH, these approaches revealed products, including benzene mono-, di-, tri- and tetracarboxylic acids, furane di- and tricarboxylic acids, aliphatic mono-, di- and tribasic acids and (di-, tri- and tetracarboxyphenyl) glyoxylic acids, all of them preferably subjected to GC as MEs or trimethylsilyl ethers. CuO is known to oxidize the lignin macromolecule (cleavage of the β O-4 ether bond, as with TMAH thermochemolysis) and produces a series of *p*-hydroxyphenyl, guaiacyl and syringyl compounds.

3. Transesterification, e.g. using boron trifluoride–methanol. The yields from this milder approach are quite low, but the formation of by-products and the destruction of labile structures are minimized.

As with pyrolysis, chemical degradation may be full of pitfalls. Hexose sugars are known to dehydrate to hydroxymethylfurfural; pentoses give furfural in strong acids at elevated temperatures. Moreover, melanoidins may be formed from sugars in the presence of amino acids leading to enhanced (apparent)

aromaticity. Diols can be oxidized, including ring rupture, to form low molecular weight aliphatic acids. Gallic acid can be decarboxylated on heating in water, and so forth. Although the loss in weight of the HOM on chemical degradation gives yields between 3 and 30%⁶ of the mass of the starting polymer, the yields of products accessible to GC are significantly lower, in the range of 0.5–3%. A large percentage (about 25%) of the total organic carbon is lost as CO₂ by KMnO₄ oxidation. FTIR spectra give strong evidence that permethylation cannot remove all acidic protons. Thus, extrapolation to the macromolecular skeleton is quite biased.

Selective chemical degradation has also been used in a more restricted way to elucidate the fate of organic pollutants and metabolites in soils/sediments, which cannot be released by means of organic solvent extraction. This results in a better understanding of their incorporation into the macromolecular HOM and their remobilization potential. Pioneering work has been done by *Michaelis*, who cleaved bound polycyclic aromatic hydrocarbon (PAH) metabolites such as hydroxynaphthoic acids from the macromolecular HOM network using boron trichloride (capable of degrading ester and ether bonds) as well as by alkaline hydrolysis, and degraded phenolic entities from the HOM matrix by rhodium on charcoal

⁵Hydrolysis proceeds faster and more efficiently if the HOM is dissolved in the hydrolytic reagent; thus, alkaline hydrolysis should be used with humic acids, which by definition are insoluble in acids.

⁶Empirical findings suggest that a methylation procedure prior to degradation is beneficial towards yields of oxidative products of HOM.

hydrogenolysis. The type of bonding and linkage of pollutants/metabolites can be better elucidated using isotope-labelled Na^{18}OH , because only the carboxylic entity of the ester carries the heavier oxygen isotope, thus referring to products attached to the HOM matrix by ester bonds.

Although wet chemical degradation techniques as well as pyrolysis techniques involve some pitfalls and limitations, they can contribute to elucidation of the fundamentals of the diagenesis of organic compounds in soil and water. ^{13}C NMR results yield strong evidence that a large percentage (in general, about 60% in case of the HOM under study) of methyl groups is attached to hydrogen-free paraffinic carbon. These findings cannot be explained by building blocks consisting of alkanes or alkylbenzenes. Steranes and hopanes, considered to be the end products of a complex web of diagenetic reactions starting from functionalized bacteriohopanepolyols and serving as biomarkers in ancient sediments and petroleum, are assumed to account for that. Indeed, pentacyclic terpanes with 32–35 carbon atoms, confirmed by tracing $m/z = 191$ in the GC-MS mode, can be detected using both chemical and thermal degradation.

Future Developments

Conventional and TMAH pyrolysis, as well as controlled chemical degradation methods, applied together in combination with highly efficient GC-MS can give insight to the building blocks and the linkages between them in the polymeric HOM network. However, analytical pyrolysis has a significantly higher potential in revealing the chemical nature of simpler polymers, e.g. polyethylene and polystyrene, which give no or minor solid residue. Traditionally performed pyrolysis work with HOM conceals much significant information on the chemical nature of HOM by thermal degradation of functional groups and thermal rearrangements. Thermochemolysis with TMAH gives rise to complementary and more independent reactions in comparison

with conventional pyrolysis. Not much attention has been paid to improved specificity of bond cleavage in the structures. It will be important to understand the mechanisms of the cleavages, and to be able to relate the products identified to possible structures in the parent macromolecule.

Liquid Chromatography

D. K. Ryan, University of Lowell, Lowell, MA, USA

Copyright © 2000 Academic Press

Humic substances are complex mixtures of compounds and in order adequately to elucidate and

characterize the properties and reactions of humic substances, separation techniques are an absolute requirement. Initial work in this area employed low pressure liquid chromatography (LC) with extensive use of size exclusion chromatography (SEC). The advent and acceptance of high performance liquid

chromatography (HPLC) as well as its miniaturization and the development of column technologies, throughout the 1970s, has resulted in HPLC becoming the most widely used chromatographic technique for the separation of humic substances. The focus here will be on the HPLC of humic materials with only a passing reference to low pressure chromatographic methods.

The physical and chemical properties of humic substances are of obvious importance in their interaction with column materials and subsequent separation in chromatography. A brief description of germane humic characteristics will be presented first, followed by a discussion of the various chromatographic modes of separation, the important detectors employed and new horizons in the LC of humic substances.

Humic Properties

Humic substances are known by many names and can be found in measurable concentrations in almost every soil, water or sediment system on earth. Carbon-containing compounds are the common denominator from both plant and animal sources which break down under the normal sequence of death and microbial decomposition in the environment. All forms of organic carbon (OC) or organic matter (OM) that are dissolved and of natural origin are of interest here and form the broadest category, of which humic substances (HS) or the synonymous humic materials (HM) are the largest part. Nonhumic compounds under the OC classification include identifiable species such as amino acids, sugars, fatty acids and the like. Humic acids (HA) and fulvic acids (FA) are the two subunits of humic substances making up all water-soluble material in this class. The relationship between all of these categories is depicted in Figure 1.

Humic substances are macromolecular species ranging in molecular weight from about 1 to 100 kDa. They have historically not been considered polymeric in nature, lacking any confirmed monomeric unit, although this view has been challenged in recent years with the proposal of an approximately 700 Da monomer. Figure 2 shows a molecular model of the lowest energy building block conformation computed for a humic acid hexamer. Humic substances exhibit significant polydispersity and are polyelectrolytic, containing numerous carboxylic acid and ionizable phenolic groups. Very small amounts of amine functionality are sometimes present; however, essentially no sulfur groups are found associated with humic samples. Properties of humic substances that are relevant to chromatographic sep-

Figure 1 Terminology, acronyms and relationship for soluble organic carbon (OC) of natural origin. Humic and fulvic acid are the two categories of soluble humic substances or humic materials which are a subset of all organic materials in the environment.

arations are summarized in Table 1. Significant among these are the hydrophobicity or surface activity of humic substances causing them to adsorb and partition with appropriate materials, their acidity and polyelectrolytic character imparting water solubility and charge to the molecules allowing for ion exchange, and their range of molecular sizes and possibly shapes that makes feasible separations based on size.

Figure 2 (See Colour Plate 87). Molecular model of the lowest energy conformations of humic acid building blocks linked to form a hexamer. Carbon atoms are green, oxygen atoms are red, nitrogen atoms are blue and hydrogen atoms are not shown. Reproduced with permission from Davies and Ghabbour (1999).

Table 1 Summary of characteristics for typical humic substances

Elemental composition	Approximately 50% C, 5% H, 45% O; very little N, no S
Ash content	Typically less than 0.5%
Molecular weight range	1–100 kDa
Purity	Complex mixture
Structure	Difficult to specify exactly
Functional groups	Aromatic and aliphatic carboxylic acids Phenolic OH and aliphatic OH Carbonyl groups Numerous aromatic rings Aliphatic chains Quinone/hydroquinone present Traces of bound metals, particularly Fe and Al
Acidity	Approximately 6 mmol g ⁻¹ from carboxyl groups
Solubility	Very soluble in water; generally, solubility increases with pH Poor solubility in most organic solvents
Other characteristics	Polydisperse Polyelectrolytic Surface active: hydrophobic portion with hydrophilic groups Metal complexation: binding of numerous metal ions Binding of organic molecules

Chromatographic Modes

Size Exclusion Chromatography

Some of the earliest LC separations of humic substances were based on the size exclusion mode of separation using distilled water, salt solutions or aqueous buffers as mobile phases. SEC studies showed that size separations were possible but, unfortunately, most attempts at SEC of humic substances gave poor resolution and marginal results. Chromatograms typically exhibited only one or two broad peaks with an occasional shoulder. Experiments resulting in several peaks by SEC have often been found by subsequent analysis to be the result of a mixed-mode separation. This comes about in low ionic strength mobile phases because of the repulsive forces between negatively charged humic substance molecules and negative charges on the surface of the column-packing materials. The actual separation is based partially on size and partially on charge, resulting in poor reproducibility and dramatic changes in the chromatography with slight changes in ionic strength, pH or solution composition. This complication completely eliminates the possibility of obtaining any molecular weight information from size exclusion – something that is normally a strong point of the method.

Once the problems with SEC of humic substances were better understood, improved packing materials such as the TSK gels (Toyo Soda, Tokyo, Japan) provided somewhat better resolution and reduced surface charge. However, the SEC of humic substances did not improve dramatically with these materials, primarily because of the nature of the humic substances themselves. Although humic substances have a seemingly broad size range, most samples have been preselected for size because of environmental conditions or by a particular isolation procedure, i.e. the method by which the sample was extracted from soil, sediment or water. In addition, each humic sample may contain a fairly uniform distribution of molecules over that range. These factors result in simple one- or two-peak chromatograms consisting of broad or poorly resolved peaks, such as those shown in **Figure 3**. The recent literature on humic substances has revealed little application of the SEC technique.

Ion Exchange

Ion exchange chromatography has found fairly limited application in the separation of humic

Figure 3 Size exclusion chromatograms of a humic acid sample on a TSK G3000SW (600 × 7.5 mm i.d.) with UV detection at 280 nm. Mobile-phase conditions are as follows: A, 0.05 mol L⁻¹ NaNO₃, pH 7; B, same as A with 4.6 × 10⁻⁷ mol L⁻¹, pH 6.97; C, same as A with pH adjusted to 5.54 with HCl; D, same as A with 4.6 × 10⁻⁷ mol L⁻¹ acetic acid, pH 5.69. Reproduced with permission from Conte and Piccolo (1999).

substances, possibly because of the very strong retention of humic molecules for most ion exchange packings. Early work with diethylaminoethyl (DEAE) functionalized supports demonstrated that ion exchange of humic substances is feasible, but rather harsh conditions must be used to approach quantitative elution of the retained material from the column. Some researchers advocated the use of 0.5 mol L^{-1} NaOH to obtain the best recoveries of humic substances from DEAE columns. Concern about the possible alteration of the humic substance molecules (hydrolysis, etc.) under these conditions has restricted its use. Ion exchange separations have been used extensively in the past for isolation and purification of humic substances from the environment. However, strongly basic conditions are also required for elution in this application and there has been a concerted effort in the area of humic substance isolation and purification to move towards less severe methods.

Reversed-phase HPLC

The general popularity of the reversed-phase mode for HPLC (RP-HPLC) separations in analytical chemistry is paralleled by its prominence as the chromatographic mode most applied to humic separations. One important reason for the development of this situation is the availability of several variables that can be adjusted to influence the separation. The percentage of organic modifier such as methanol, 2-propanol or acetonitrile can be regulated and held constant in isocratic separations or varied (either stepwise or continuously) in gradient elution. Ionic strength and buffer pH are commonly adjusted to improve resolution and even the length (C_1 to C_{18}) or type of stationary phase can be changed from alkyl to phenyl, diol or other types of functionality.

With all the flexibility available in RP-HPLC separations, it is often unclear upon initial examination why essentially all of the published chromatograms of humic substances exhibit broad, poorly resolved peaks that by some chromatographic standards would be unacceptable. The reason for this dilemma once again is linked to the nature of the mixture of molecules in humic substances. One view suggests that, although varied in properties, the molecules form a near continuum of species with characteristics so similar to one another that they are difficult to separate. The appearance of isolated peaks in the chromatogram is a function of greater numbers of molecules of certain types (in the continuum) over other molecules which elute in the valleys between peaks.

Since RP-HPLC separates on the basis of polarity, most chromatograms show two or three distinct re-

gions of peaks. Early in the chromatogram the most polar compounds elute, often as a jumble of sharp, but unresolved bands. Late in the chromatogram, the nonpolar species appear usually as very broad peaks with unresolved shoulders or side bands. Sometimes, a band of intermediate polarity is present midway through the chromatogram.

An important consideration in selecting a column for separating humic substances by RP-HPLC is the pore diameter of the packing material. Reversed-phase supports are available with a variety of pore sizes; however, larger pore diameters are more suitable for larger molecules such as humic substances. A common choice is a 30 nm pore diameter sold as a reversed-phase column for protein separations.

Ion Pair Reversed-phase Chromatography

Improvements in the RP-HPLC separation of many charged species can be realized by adding an ion-pairing reagent to the mobile phase. The ion-pairing reagent is commonly a tetrabutylammonium salt (in the cationic case) which can form an ion pair with the species of interest. Humic substances contain many ionizable carboxylic acid and phenolic groups, making them very suitable for this mode of chromatographic separation. **Figure 4** shows a representative ion pair reversed-phase (IP-RP-HPLC) chromatogram for the fulvic acid fraction of humic substances derived from soil. Although IP-RP-HPLC represents some improvement over RP-HPLC, the nature of the humic substances still gives rise to broad peaks that are less than completely resolved.

With regard to the exact mechanism of the separation in IP-RP-HPLC, at least two models exist. One perspective is that the ion pairing alters the polarity of the humic substance molecules, dramatically changing their retention characteristics on the reversed-phase column. A second theory supposes that the ion-pairing reagent partitions into the column leaving charged sites that allow for an ion exchange process with the humic substances as a means of separation. Reality is most probably somewhere between these two viewpoints. It should be noted that, once a RP-HPLC column has been subjected to an ion-pairing reagent, it is always an ion-pairing column.

Table 2 gives an overview of the HPLC modes discussed above. Representative publications are included for further reading in this area.

Detectors

Humic substances absorb UV and visible radiation at essentially all wavelengths and can therefore be readily monitored by absorbance detectors in HPLC. The

Figure 4 Ion pair reversed-phase chromatogram of Swanee Stream reference fulvic acid (SSRFA) separated on an SEG C₁₈ column using gradient elution beginning with 37% CH₃CN for 8 min followed by a linear gradient to 68.5% CH₃CN over 8 min at a flow rate of 1 mL min⁻¹. Tetrabutylammonium perchlorate was used as the ion-pairing reagent at a concentration of 50 mmol L⁻¹. UV absorbance at 254 nm was monitored for an 8 μL injection of 0.048% (w/v) SSRFA.

absorbance spectrum of a typical humic substance sample is essentially featureless, looking somewhat like an exponential curve. Absorbance is high in the short wavelength region of the UV spectrum and drops quickly with increasing wavelength, tailing off into the red region of the visible spectrum. Therefore, almost any wavelength can be used to detect humic substances, but shorter wavelengths are more sensitive. Fixed wavelength measurements at 254 nm are the most common; however, variable wavelength detectors have been used at a variety of wavelengths with good success.

Photodiode array (PDA) monitoring of the complete UV-visible spectrum of the column effluent adds an additional dimension to HPLC, providing several advantages over conventional single wavelength detectors. PDA systems repeatedly collect spectra at a specified time interval (often once every second) throughout the life of the chromatogram. This spectral information is invaluable in method development, particularly when many unknown

compounds are present. Once the data are collected, several chromatograms can be generated, each with a different monitoring wavelength revealing features not visible in a single wavelength chromatogram. For example, a single well resolved peak at one wavelength may show a poorly resolved doublet at another wavelength. Similarly, peak purity can be determined by examining the spectra at several time intervals across a peak.

Finally, PDA detection can aid in the qualitative identification of the separated components by comparison of a peak's spectrum with the spectrum of known compounds. This approach has been used in some applications to elucidate certain structural features in separated fractions of humic substances. The general drawback with this application is that UV-Vis absorbance spectra are not conclusive evidence of a compound's identity and can only provide possible structural clues. When applied to the complex mixture of humic substances, only vague inferences can be made about possible structural components in

Table 2 Modes of liquid chromatography employed for separations of humic substances (HS)

Mode	Mechanism of separation	Reference
Size exclusion	Exclusion of larger HS molecules from certain pores based on size	Chin <i>et al.</i> (1994) Huber and Frimmel (1994)
Reversed-phase	Partitioning of hydrophobic portion of HS molecules into nonpolar stationary phase	Saleh <i>et al.</i> (1989)
Ion exchange	Exchange of anionic HS on cationic stationary phase	Andres <i>et al.</i> (1987)
Ion pair reversed-phase	Retention of ion-paired HS on nonpolar phase or ion exchange of HS on ion-pairing reagent-loaded phase	Butler and Ryan (1996)

the macromolecules that are contained within a peak. This type of data gives further evidence that moieties such as vanillic acid, catechol or other substituted aromatics are part of the structure of humic substances, but cannot provide unequivocal results.

The second and only other major detection method used for the HPLC of humic substances is fluorescence. Humic substances emit a broad fluorescence peak centred around 450 nm when excited by radiation in the 330–350 nm range. This fluorescence is not considered to be a very strong signal (high quantum yield) in comparison to other fluorescent species; however, sufficient sensitivity can be obtained with standard commercial fluorescence detectors to measure easily humic substances down to the low part-per-million level sufficient for most environmental measurements. Fluorescence is a selective means of detection because not all molecules fluoresce – a situation that is clearly true of the mixture of molecules in humic substances. HPLC experiments with both absorbance and fluorescence detection have shown that some components of humic substances absorb but do not fluoresce. This lack of fluorescence may result from one of at least two possibilities. The absence of the appropriate structural features (usually extended π electron system) in certain fractions of humic substances will render them non-fluorescent or the presence of fluorescence-quenching agents in a normally fluorescent fraction will likewise remove fluorescence. The most common fluorescence quenchers for humic substances are the paramagnetic metal ions, such as Cu^{2+} , Fe^{3+} , Ni^{2+} , Co^{2+} , Mn^{2+} , which form complexes at appropriate binding sites on the molecule. Recent studies have also shown that certain organic molecules can bind to humic substances either electrostatically or through hydrophobic interactions and also quench fluorescence.

Other Considerations

Humic substances are a fairly difficult class of compounds to work with because they are poorly characterized with respect to their chemical structure and many of their properties are not yet fully understood. Intra- and intermolecular hydrogen bonding, hydrophobic interactions and electrostatic effects surely play a role in what can be called the tertiary structure or shape of humic substance molecules. The variables of pH and ionic strength clearly play a role in determining molecular shape, which is very important with respect to HPLC separations; however, an understanding of the factors influencing shape is only now yielding to analysis through the use of molecular modelling.

Irreversible adsorption, concentration effects and solubility problems also plague the analysis of humic substances by HPLC. Although the fulvic acid fraction of humic substances is soluble at any pH, humic acid is not soluble at low pH and may have varying solubility depending on the exact solution conditions. Samples of isolated humic substances must be carefully dissolved and filtered before HPLC analysis and even then may not remain soluble throughout the separation because of changing gradient conditions.

Concentration effects are a related problem since high concentrations tend to favour aggregation and coagulation of humic substances, resulting in precipitation of the most nonpolar components in the sample. An important consideration when examining the published results in chromatographic studies of humic substances is the concentration of the solution injected into the chromatographic system. Many studies are conducted using as much as 500–1000 mg L^{-1} of humic substances – a concentration level that is orders of magnitude higher than typical environmental levels in most cases. The results obtained in these instances may be influenced by concentration artifacts and are not likely to be representative of environmental conditions.

Irreversible adsorption is another difficulty that frequently occurs at the top of guard or analytical columns because of a high affinity of the column packing material for the humic substances. This mechanism may result in significant losses of sample material to the column and may skew results by selectively removing some compounds while not affecting others. The presence of bare silica for silica-based packings or other active sites can influence adsorption. In addition, the presence of sample components or impurities such as metal ions can facilitate interactions between humic substances and active sites on a column.

New Horizons

Although HPLC may be considered a mature technique, many advances have been made in recent years, primarily in the area of detectors, that have an impact on the chromatography of humic substances. One example is the use of carbon analysers as detectors for HPLC. Instruments that measure organic carbon in solution have long been used for the measurement of humic substances and other natural organics in nonchromatographic applications. It is only in the last decade that these instruments have been modified for use in HPLC. The advantages of dissolved organic carbon (DOC) detectors include their universal detection of all organic compounds

and their specificity for only carbon-containing species.

Two new approaches in the area of fluorescence detection of humic substances are the coupling of a fluorescence lifetime instrument to HPLC and post-column fluorescence quenching titrations as a means of measuring metal complex equilibria. Fluorescence lifetime measurements add yet another means of increasing the specificity of analysis, allowing improved qualitative determinations and generally increasing the amount of information obtained from fluorescence analysis of a sample. The coupling of phase modulation spectrofluorometry to HPLC results in a powerful method for measuring and resolving overlapping peaks as well as adding a dimension for identifying unknowns in a chromatogram. Although this type of detector is inherently expensive and will not see routine use, its application to humic substances, which have been shown to have three distinct fluorescence lifetimes, seems logical.

Post-column fluorescence quenching titration experiments have recently been employed in metal complexation studies to elucidate binding of metals to fractions of humic substances separated by HPLC. Quenching of the natural fluorescence by certain metal ions has become an accepted method for measuring equilibrium constants and other binding parameters for complexation of the metal by sites on humic substance molecules. Studying these equilibrium processes by HPLC has heretofore been very difficult because the chromatographic separation of the humic-metal complexes is adversely influenced by the presence of the metal ion. By separating the humic substances first without metal present, then adding metal ion via a post-column inline mixing tee, the complexes are formed just prior to their measurement by a conventional fluorescence detector. This approach alleviates any chromatographic problems associated with the presence of metal ions and allows valuable binding studies of metal ions with separated fractions of humic substances in a time-saving online mode.

Two of the most powerful instruments for measuring chemical structures of organic molecules are Fourier transform infrared spectroscopy (FTIR) and mass spectrometry (MS). A relatively new form of MS that has a major advantage in its application to macromolecules such as proteins is matrix-assisted laser desorption and ionization (MALDI) MS. The immense benefit of coupling a powerful separation technique such as HPLC with the unparalleled structural capabilities of FTIR and MS is obvious, particularly when applied to complex mixtures. However, there are significant difficulties encountered in the interfacing of these techniques which have hindered

advances in this area. A novel approach has been developed to meet this challenge which centres on the inherent ability of FTIR and MS to analyse solid samples. Column effluent which exits from the chromatograph is sprayed on to a slowly moving solid substrate under controlled conditions. Solvent is evaporated and the sample dried as the separated components are deposited sequentially. Once the chromatographic run is complete, the solid substrate with the deposited sample components is placed in a modified FTIR or MALDI MS unit for analysis. Sequential analysis along the track of deposited sample components yields a series of spectra similar in concept to PDA detection in HPLC, but this approach is far more useful in elucidating structural features and providing absolute qualitative confirmation of component's identity. The application of this technology to the analysis of humic substances with RP-HPLC has been pioneered.

Conclusion

The use of HPLC for separation of humic substances has been, and will continue to be, a challenging area in separation science. Additional information about the nature of humic substances will aid in the fine-tuning of this application of HPLC, as will improvements in column technology. Probably the most significant advances in the HPLC of humic substances will come with the utilization and development of more powerful detectors, particularly spectroscopic detectors. No doubt the complex, heterogeneous nature of humic substance samples will require a host of separation and detection strategies to be applied in the years to come before their analysis is considered in any way routine.

HYDRODYNAMIC CHROMATOGRAPHY: PRACTICAL APPLICATIONS

A. Revillon, Centre National de la Recherche Scientifique, Vernaison, France

Copyright © 2000 Academic Press

Introduction

Either in research, the control or the production of chemicals, or during general observations in biochemistry, characterization is a primary necessity. Depending on the product, the nature, structure, size, shape, and molecular weight are some of the important parameters to be measured. For instance, the molecular weight distribution of polymers and particle size of latex/colloids (MWD and PSD, respectively) have to be known so that they can be correlated with properties. The data may be obtained using many techniques. These techniques are governed according to the various properties of a material and depend on the size range of the investigated material. Hydrodynamic chromatography (HDC) is one of these techniques and has found applications for sizing soluble or dispersed solid components. This article will discuss the size distribution of organic latex particles from the theoretical and practical points of view. Progress in packing columns with fine materials or in the use of fine capillary tubes has allowed rapid separation of species with high resolution. A second field of interest is polymers in solution. The combined effects of hydrodynamic and exclusion chromatography have extended possibilities for the separation of high-molecular-weight materials.

Hydrodynamic chromatography is used for diameter determination in the micron range (some nm to some μm). It will work for both solid and soluble samples, which are eluted according to their decreasing size. This leads to a visual picture of the size distribution. The main interest of HDC lies in the rapid separation (fractionation, which is an alternative name for this method: HDF) of the liquid or solid components present in the sample. Often low peak capacity and poor resolution are its limitations and involve the necessity for peak dispersion correction. Moreover, a quantitative study requires a double calibration. The first relates to elution volume and diameter of the analysed particles; the second gives a correspondence between the signal intensity and size of particles. This intensity depends on the nature of the detector and the operating conditions, for instance the choice of wavelength in UV. As an example, **Figure 1** shows the different absorbance curves of polystyrene (PS) latexes of different sizes. **Figure 2** shows the change in absorbance and scattering with wavelength and illustrates different peak contributions of PS particles to the chromatogram.

HDC operates similarly to size exclusion chromatography (SEC) and field flow fractionation (FFF), but needs one (inert) mobile phase and one (hydrodynamic) field only. The interesting principle of particles separation is the difference in their transport rates in a capillary, related to their location in the eluent. Large particles are preferentially in the centre of the capillary, where the flow rate is max-

Figure 1 UV absorbance curves for polystyrene latex particles. (Reprinted from Nagasaki S, Tanaka S and Suzuki A (1993) Fast transport of colloidal particles through quartz-packed columns. *Journal of Nuclear Science and Technology* 30(11): 1136-1144.)

imum, so they are eluted faster than small ones, which are closer to the wall of the capillary, where the flow rate is zero. The ratio of the highest elution volume for a small molecule – called a marker – to that of a given particle is the separation factor (R_f). Besides the simplicity of the process, secondary advantages are the rapidity of measurement performed directly on the untreated medium and ease of operation of the equipment. Variation of operating parameters (flow rate, nature of eluent and additives, size of the capillary, etc.) allows a considerable range of possible applications. Chromatography is performed

Figure 2 Effect of wavelength (—, 220 nm; ----, 254 nm) on the chromatogram of a trimodal mixture of polystyrene latexes (357, 176, 109 nm) on a capillary column $2\text{ m} \times 4\ \mu\text{m}$, ionic strength 1 mM. (Reprinted from Dos Ramos JG and Silebi CA (1990) The determination of particle size distribution of submicrometer particles by capillary hydrodynamic fractionation. *Journal of Colloid and Interface Science* 135(1): 165-177.)

on two types of columns, open capillary or packed, where the interstitial space defines the channels. The use of very small particles (diameter $2\ \mu\text{m}$) or fine capillaries (diameter $4\ \mu\text{m}$) allows a high resolution. Relatively short capillary columns (3 m) lead to a rapid and efficient separation (5 min), as shown in Figure 3 for monodisperse polystyrene latexes.

This article focuses on the main applications of HDC and which are under constant evaluation. There is no effect of density and no limitation on the nature of the sample, but most studies are related to the field of polymers. Since there is no solvent limitation (soluble samples) or no solubility condition (solid samples), all polymer families have been examined. Most of the applications are relative to synthetic organic colloid separation in latex production and diameter measurements for quality control. As mentioned above, interesting perspectives are apparent by combining HDC and SEC with porous packings.

Figure 3 Fractogram of a mixture of four samples of Dow polystyrene latex of diameters 357, 234, 176 and 109 nm. 0.1 mM SLS, capillary $3\text{ m} \times 4\ \mu\text{m}$. Applications in Polymer Chemistry

Colloids/Latex

Some methods of polymer synthesis offer the possibility of preparing polymers with a defined average molecular weight with a narrow distribution (anionic initiation or modern controlled free-radical polymerization). This is important since some polymer properties are dependent on molecular weight and its distribution.

For certain applications it is the size which is the key parameter. For instance, it is the particle size which is important for rheological properties, film formation or protecting ability in relatively low-cost industrial coatings such as aqueous-phase paints and inks. Latexes of small particles have a lower viscosity than those of larger particles with the same percentage solids. They also have a better storage stability against sedimentation and further aggregation. In other applications, these 'water-borne' particles may also be high-value colloids for model compounds and reference materials. For instance, they are used as standards for calibration (membranes) or for packing chromatography columns. Surface modification allows many applications in biochemistry for diagnostic aids and purification. It is thus evident that accurate monitoring of diameter is important.

These particles are obtained in the free-radical emulsion polymerization heterogeneous process. Their diameter is around 100 nm, which can be dealt with in HDC. This process tends to be substituted by bulk and organic solvents processes, in order to reduce the use of solvents in the production of polymers. General interest in these particles is 'triple' fold: their regular and spherical shape, and the possibility of obtaining a predetermined diameter of a given value. This diameter does not depend on mechanical treatment, such as milling and sieving, but depends on the chemical and thermodynamic values of the process: size measurement is a way to determine the polymerization mechanism in relation to these parameters.

Polymerization kinetics As has been mentioned, a major use of HDC is related to colloids obtained by emulsion polymerization, a process which allows simultaneous high-polymerization rates and high-molecular weights. The rapidity of the HDC measurement is compatible with kinetic studies and monitoring during the polymerization. Eluted fractions may be characterized further by transmission electron microscopy (TEM) and analytical centrifugation to verify the effective existence of detected particles and to obtain a calibration curve. Photon correlation

spectroscopy (PCS) may be used for a simultaneous rapid analysis.

A normal emulsion system can be depicted as follows: a large fraction of the monomer is in large droplets (diameter around 1 μm); a small part of the monomer is dispersed in the aqueous phase either as an individual soluble molecule or as small aggregates stabilized by the surfactant, and called micelles (diameter around 5 nm). Various ionic and nonionic surfactants are used, besides steric ones, which are not as sensitive to electrolyte and pH effects. The initiator is in the aqueous phase: it is decomposed to active radicals by thermal activation or redox reaction. The primary radicals may add to soluble monomers molecules to form oligoradicals and/or enter into the micelle to give active particles. This is the first step of the polymerization up to a conversion of 5–10%: initiation or nucleation. The second step is the growth of these particles by consumption of the monomer contained in the large droplets. The number of particles remains constant up to 90% conversion, but their size increases. The rate of polymerization is constant during this second step. This rate (R_p) and number of particles (N) are governed by the concentration of monomer (M), initiator (I) and surfactant (S):

$$R_p = k_p [M] N/2 \quad \text{and} \quad N[I]^{0.4}[S]^{0.6}$$

k_p is the propagation rate constant.

Measurement of conversion and of particle size allows determination of the number of particles. A constant number of particles and an increase in their size are observed. The values may be correlated to concentration. Exponents may differ to those expected in the classical scheme, where particles are spherical and uniform in size. Some deviations may occur, such as additional nucleation by coagulation of precursor particles generating new particles and a second size distribution. They are of lower stability and have a slower rate of polymerization. Large aggregates may be formed by association of particles, as a result of insufficient stabilization. This leads to a broad or multimodal size distribution.

When industrial processes are discontinuous, the particles size of successive batches may differ. In order to correct this and obtain a constant quality, several batches are blended to deliver a uniform size distribution, corresponding to specific properties. Instead of performing physico-chemical measurements (rheology, surface tension) and end use tests, HDC is a rapid means of diagnosis.

Most of the literature on HDC is related to the separation of latexes. Conditions of elution – particularly the ionic strength – affect the separation,

but the surface charge density of the particles does not affect the separation factor. In contrast with polymers, the shear rate has little or no effect on particle size characterization. No deformation occurs when the particle is relatively rigid.

Modification of latexes To obtain large size latex, colloids obtained in a first step are polymerized further: successful results have been obtained with the method of Ugelstad.

Latexes are reactive to an extent depending on their stability. For instance, changes in size by the swelling of carboxylated styrene-butadiene latexes has been measured, according to changes in pH.

Flocculation of colloids in the presence of water-soluble ionic polymers or inorganic oxides has been observed by HDC in relation to other methods. Association of particulates under the effect of a thickener has been clearly demonstrated, though this association can be broken by intensive shear, and the same applies to aggregates.

Mini-emulsions

Mini-emulsions are oil droplets (50–500 nm) in water, stabilized by a surfactant (such as sodium lauryl sulfate) and a co-surfactant, which may be a long-chain alkane or a fatty alcohol with low water solubility. Their action is to reduce the oil diffusion from smaller to larger droplets. These mini-emulsions may also constitute an interesting polymerization system. Their stability depends on the relative concentration of components. An exponential decrease of droplet size has been observed when the concentration of cetyl alcohol is increased. The effect of the nature of the co-surfactant and ageing time has been studied. **Figure 4** shows chromatograms of a mini-emulsion at different times, corresponding to size differences: increase of diameter and decrease of dispersity occurs when cetyl alcohol is used. This is not observed when hexadecane is the co-surfactant.

Polymers

Dimensions of soluble polymers depend on molecular weight, nature of polymer, solvent type and temperature. A linear polymer is represented by an ideal random coil of a flexible chain, the radius of gyration being r_g . For actual polymers, requirements mean taking account of bond angles, hindered rotations and short-range intrachain interactions. Since polymer segments occupy space, this generates an 'exclusion volume', corresponding to an increase of dimensions; however 'unperturbed' dimensions, $\langle r_g^2 \rangle_0$, do not take solvent into account. Both interactions between

Figure 4 Fractograms at three different times for a toluene mini-emulsion prepared from a gel phase consisting of 10 mM SLS and 30 mM cetyl alcohol. (Reprinted from Miller CM, Venkatesan J, Silebi CA, Sudol ED and El-Aasser MS (1994) Characterisation of miniemulsion droplet size and stability using capillary hydrodynamic fractionation. *Journal of Colloid and Interface Science* 162: 11–18.)

the chains and between chain and solvent modify r_g . In a 'poor' solvent, these unperturbed dimensions mean that square of the radius of gyration $\langle r_g^2 \rangle_0$ is valid, since the polymer sphere is poor in the solvent. But in a 'good' solvent, it becomes $\langle r_g^2 \rangle = \alpha^2 \langle r_g^2 \rangle_0$, due to the expansion of the coil by the internal solvent molecules. For a given polymer, the unperturbed dimensions depend on solvent and temperature, corresponding to the θ conditions of Flory, with $\alpha = 1$. In these conditions, the a exponent of the Mark-Houwink viscosity law $[\eta] = KM^a$ is 0.5. Finally, applying classical theories of polymers in solution allows a relationship between size and molecular weight to be obtained. But the question is: what radius is to be considered in a chromatography experiment? In other words, is the apparent radius obtained in HDC a useful answer? Viscometric measurements show that polymer chains behave rather as non-free-draining (solvent immobilized in the interior of the chain) rather than a permeable coil. This means that the hard-sphere model is a reasonable approach. It may be represented by the hydrodynamic radius r_h , the value of which is about $0.7 r_g$.

Polymer molecules which are in a laminar flow near the wall in a tube are in a high stress domain and can be elongated and oriented. Those in the centre of the tube are in a low stress region, so that they differ in entropy. The entropy gradient in the tube leads to a migration of the molecules away from the wall, called 'stress-induced diffusion'. This is favoured by a high flow rate, small tube diameter and high

molecular weight. A second feature is a result of elongation: the cross-section of the chain is decreased and the molecule is eluted later. A third factor may affect the elution time: the fluid inertia induces a radial migration of the molecules towards an annular region of equilibrium, which is about at $0.6R$ (R is the capillary radius) of the centre of the tube (also called the 'tubular pinch effect'). This is more effective in capillary tubes than in packed columns.

Excellent results have been obtained for the separation of numerous polymers in solution, on columns packed with very small non-porous silica particles. As an example, a set of four polystyrenes (molecular weight differing by a ratio of 2) in THF was fully separated in less than 2 min (Figure 5). Two sets of polybutadienes (PB) and polyisoprenes (PIP) in THF at a lower flow rate were completely separated in 11 min. The maximum separation factor was about 1.3. An experimental calibration curve (molecular weight as a function of R_i) may be obtained for each polymer and fits theoretical predictions. A universal calibration curve is obtained when plotting relative size (chain radius r_p/R) as a function of $1/R_i$ (Figure 6). Alternatively, this means that different polymers of similar molecular weight may be separated, as shown in Figure 7. Other solvents of different thermodynamic properties are dioxane (PS, PB, PIP), toluene, methanol, ethyl methyl ketone and acetonitrile (PMMA), used in θ conditions (minimum interactions between chain and solvent, for a min-

imum coil size). The polymer size is effectively decreased, and the elution time is very sensitive to small changes in temperature around θ .

Combined HDC and SEC fractionation has been shown to expand the elution scale and allow complete separation of a wide range of polystyrenes, using porous silica (Figure 8) and polymeric packings. This offers interesting possibilities for elution of very high-molecular-weight materials. The

calibration curve on silica (Figure 9) clearly shows HDC and SEC domains (higher molecular weight and steeper slope for HDC). With narrow-pore cross-linked polystyrene, only one classical sigmoidal SEC curve is obtained.

Some authors have attempted to determine molecular weight or size for very large polymers, for instance water-soluble ones, which are used as viscosifiers in

Figure 9 HDC-SEC calibration graph (molecular weight as a function of the ratio of the solvent to polymer migration velocity) with polystyrene on three columns of 15-cm each, packed with Hypersil 3- μm porous particles. oil-recovery wells. The porous structure induces converging and diverging flow channels, where polymer solutions have non-Newtonian behaviour. At high flow rate, under pressure and passing through small pores, polymer coils may undergo chain extension and orientation which modify their size and viscosity.

Flow and dynamic behaviour of flexible and rigid macromolecules in a packed bed has been studied comparatively. Partially hydrolysed (10%) polyacrylamide (molecular weight higher than 12 million) was a flexible model of a random coil, xanthan polysaccharide (molecular weight over 2 million) a model for a rigid backbone and tobacco mosaic virus as a rodlike structure (length 0.7 μm , diameter 15 nm). They have been eluted on a column packed with an ion exchange resin (diameter 11 μm). Deformation of the initial flexible linear polymers occurs, since their apparent size changes with flow rate, at a value corresponding to unity for De , the Deborah number, defined as the ratio of hydrodynamic forces to Brownian forces. The polymers which have been strongly sheared or sonicated before the chromatographic analysis do not show this change in size, since the chain has been extensively broken. The effective size of rodlike polymers decreases when the flow rate increases: this is accounted for by orientation. For xanthans, two domains are observed when the flow rate increases: constant size, then a decrease after a flow value corresponding to the chain elongation (Figure 10). The slope (-0.5) of the high flow rate region fits that of the dumbbell model. Xanthan

polysaccharide behaviour has also been studied on nonporous SiC particles.

Biomaterials

Biomembranes are efficient separating materials. They are found in cells and are an excellent model for synthetic chemistry. They have many applications such as the separation of enantiomers, isotope enrichment, photosynthesis, and catalysis. Liposomes are used as drug-delivery systems and membranes, so their size and the amount of the transported material are important factors. Elution of liposomes from egg yolk lecithin has been performed on a column packed with porous inert glass, at different ionic strengths. An equivalent capillary radius R is given by the formula $R = d/[2 - 2(2 - R_t)^{1/2}]$, where d is the diameter of a colloidal particle, known from calibration with polystyrene standards. Recycling of the sample improves the separation (Figure 11).

Separation of natural products such as milk or globular proteins is also of interest. Preliminary results have been obtained for very large proteins on small nonporous glass spheres (Figure 12). Decreasing the ionic strength improves the separation. For common proteins, which require smaller particle sizes, the difficulty lies in the affinity of silica to proteins. The alternatives are to modify chemically the OH groups by grafting an inert moiety, or using an aqueous buffer, to repel proteins from the surface.

Inorganic Compounds

Silica or carbon black are widely used in various industries as fillers, the effect of which depends on the size. A variety of other compounds has

Figure 11 HDC of liposomes from egg yolk lecithin on inert glass particles (125–180 μm) in a 300 \times 15-mm column, eluent with 0.02 mM NaCl; filtration on 0.3- μm pore size, four recycles. Figure 12 Separation of proteins on nonporous silica gel 2.1 μm particles, column 250 \times 4.6 mm, sodium borate 5 mM, pH = 9. 1: thyroglobulin; 2: γ -globulin; 3: glycine. (Reprinted from Kraak JC, Oostervink R, Poppe H, Esser U and Unger KK (1989) Hydrodynamic chromatography of macromolecules on 2 μm nonporous spherical silica gel packings. *Chromatographia* 27(11/12): 585–590.)

been examined: paper fibres, cement, clay, metals and metal oxides of Fe, Ti, Al, silver halides. It has been found that a difference in density does not alter the elution order. The calibration based on polystyrene latexes remains valid for carbon black particles of density 1.86, and the results agree with those obtained by photon correlation spectroscopy.

Applications are also found in geology.

Conclusion

Despite its ability to provide useful results in size separations and determination, HDC is still only infrequently used. However, efforts are being made to improve its resolution and ease of use. Progress in synthesizing small size particles for packings and in narrow capillaries effectively allows rapid and excellent separation. Combined HDC and SEC offers new possibilities for determination of size and molecular weight of polymers in solution. HDC is also of interest in fundamental studies of flow behaviour in tubing or pores which are encountered in 'transport technology of materials': various fluids, solid particles, waste in rocks and soils, as well as in factories or pipes. In such work silica has the interesting advantage of being a hard spherical model for HDC mechanism studies.

HYDROGEN RECOVERY USING INORGANIC MEMBRANES

R. Hughes, University of Salford, Salford, UK

Copyright © 2000 Academic Press

Introduction

Global annual production and utilization of hydrogen now total some $6 \times 10^{11} \text{ Nm}^3$. Of this amount, approximately 50% is produced by steam reforming or partial oxidation of natural gas. Other sources include electrolysis of water and recovery from refinery off-gases. The main use of bulk hydrogen includes synthesis of ammonia, hydrotreating of heavy petroleum feedstocks, hydrogenation of vegetable oils and manufacture of transformer steels and other metallurgical heat treatment operations. More recent applications where high purity hydrogen is required include semiconductor processing and fuel cells. To obtain high purity several methods may be adopted, such as pressure swing adsorption and cryogenic technology. However, both these methods have disadvantages, including cost and degree of purity obtained; the cryogenic method gives purities ranging from 90 to 98% only.

Membranes can provide an efficient low cost means of separation and purification for hydrogen. Although polymeric membranes are well proven for gas separation, they are limited to temperatures not much greater than 250°C whereas, in many applications, high temperature processing is required. Inorganic membranes have shown considerable develop-

ment in recent years and, apart from their high temperature stability, they have in general much higher fluxes than polymeric membranes.

Inorganic membranes suitable for the recovery and purification of hydrogen may be divided into two classes, namely, porous and dense membranes. The former includes materials such as alumina, silica, zirconia and porous metals, for example, stainless steel. The dense membranes include palladium and its alloys, in which the unique permeation properties of palladium to hydrogen are utilized.

Porous Membranes

To achieve appropriate separations with this type of membrane, the pore size needs to be small. However, to achieve a suitable gas permeation rate through the membrane, the membrane should be as thin as possible. To meet this requirement, a composite structure is usually adopted in which a thin finely microporous separation layer is supported on a thicker more open microporous material. Such structures have now been developed by a number of procedures.

The various possible gas permeation mechanisms applicable to porous membranes are illustrated in **Figure 1**.

In this figure, the progression from Knudsen diffusion to molecular sieving is in parallel with increasing permselectivities (it should be noted that viscous flow gives no separation). The separation factor for all the processes depends strongly on the pore size and its distribution, the temperature, pressure and the

Figure 1 Transport mechanism in porous membranes. (A) Viscous flow. Pore diameter is greater than gas mean free path – no separation. (B) Knudsen flow. Pore diameter is smaller than gas mean free path – separation is proportional to the square root of M_a/m_B . (C) Surface diffusion. Adsorbed gas on the pore water contributes to total gas flow. Transport of condensable vapour is enhanced. (D) Multilayer diffusion. Transport of adsorbed gases is dominant and so condensable vapours have high transport rates. (E) Capillary condensation. Adsorbed gas completely blocks pores. There is no transport of nonadsorbed gas. (F) Molecular sieving. Pores are so small that they begin to filter small molecules from large ones. Transport of small molecules is preferred. Modified with permission from Saracco G and Specchia V (1994) Catalytic inorganic membrane reactors: present experience and future opportunities. *Catalysis Review, Science and Engineering* 36: 305.

nature of the membrane and the permeating molecules. Because of these factors, porous membranes are more versatile in their applications compared with dense metal membranes, because they can be used for

separation of gases other than just hydrogen and oxygen only. Conversely, porous membranes show significantly lower selectivities compared with dense membranes.

Viscous flow occurs when the mean free path of the gaseous molecules is much less than the pore diameter. Under these conditions, molecule–molecule collisions are much more frequent than collisions between the molecules and the walls of the pores. The mean free path, λ , of a gas molecule is given by:

$$\lambda = kT/(2\sigma p) \quad [1]$$

where k is the Boltzmann constant, T the absolute temperature, p the absolute pressure and σ the collision diameter of the molecule. Thus, λ will increase with increase in temperature and with decrease in pressure. Calculated values of λ are shown in **Table 1** for a number of gases. Since the pore diameter of many separation membranes is of the order of 1–4 nm it can be seen that mean free paths under conditions often encountered in many catalytic processes are greater than the pore diameter and therefore Knudsen diffusion can be the operating mechanism for many current membranes.

In Knudsen flow, as shown in **Figure 1B**, the molecules collide on average more frequently with the pore walls than with one another when the mean free path becomes much greater than the pore diameter and absolute pressure does not affect the flux if this flow is fully developed. With a binary mixture, the highest separation factor achievable is given by the ratio of the inverse of the square roots of the molecular weights. Hence, small molecules are preferentially transported across the membrane and the greatest potential is for separation of hydrogen from other gases. Even in this case, however, separation is limited: that for a hydrogen–nitrogen mixture is only 3.74 at best.

Table 1 Mean free paths for representative gases (nm)

Gas	Gas diameter (nm) σ	Temperature 500 K		Temperature 800 K	
		0.1 MPa	1.0 MPa	0.1 MPa	1.0 MPa
H ₂	0.29	183	18.3	293	2.9
CO	0.37	113	11.3	181	18.1
N ₂	0.37	111	11.1	177	17.7
CO ₂	0.39	102	10.2	164	16.4
C ₄ H ₁₀	0.50	62	6.2	100	10.0
C ₆ H ₁₂	0.61	42	4.2	67	6.7

Surface flow occurs (Figure 1C) when one of the permeating molecules can be preferentially physisorbed or chemisorbed on the pore walls and migrates along the surface. Surface diffusion increases the flux of the more strongly adsorbed components while reducing the contribution of the gas phase diffusion to total gas transport by decreasing pore diameter. Surface flow becomes more important as the pore size is reduced. Also, the effective pore diameter is further decreased by adsorption of the relevant species on the walls of the pores and thus obstructing the transfer of the other species through the free volume of the pores. As the temperature increases, most species will desorb from the surface and surface diffusion becomes less important.

Multilayer diffusion has been postulated to occur when molecule-surface interactions are very strong. The process is shown diagrammatically in Figure 1D. It may be regarded as an intermediate flow regime between surface flow and capillary condensation.

When the pores are small enough and one of the components of the gaseous mixture to be separated is a condensable vapour, adsorbed vapour on the surface of the pore walls may be sufficient for the condensate to block gas-phase diffusion through the pore (Figure 1E). The condensate fills the pores and then evaporates at the permeate side, which has to be maintained at low pressure. In this case, only the condensed vapour permeates the membrane and nonabsorbed gases are almost totally retained by the membrane.

Molecular sieve transport occurs when pore diameters are small enough to permit only smaller molecules to permeate, while larger ones are excluded from entering these molecular-sized pores (Figure 1F). This type of process is frequently referred to as shape-selective diffusion. A necessary condition for effective separation by this means is that the pore size distribution is monodisperse and that the pores are very small – of the order of 0.5–1.0 nm.

From the above considerations it can be seen that a small pore size is necessary to obtain adequate separations. Since very finely porous membranes must necessarily have low permeabilities, useful fluxes are only obtained if the separating layer is made very thin. This has led to the evolution of asymmetric membranes in which the thin separation layer is supported on a wide pore matrix of similar material. Composite membranes have been developed in which different materials are used for the separation and support layers of the membrane. Molecular sieve membranes have been produced in this manner. An interesting development is the use of nanoporous carbon membranes for gas separation.

These membranes, which are produced by carbonization of polymers, have pore sizes in the molecular sieve range (0.5–0.6 nm) and operate by a combination of selective adsorption and surface flow. Rao and Sircar have shown that these nanoporous membranes can separate hydrogen from carbon dioxide and hydrocarbons with high selectivity. Experiments with silicalite zeolite for the separation of hydrogen and butane mixtures by Moulijn's group at Delft have shown that butane excludes hydrogen from the pores of the silicalite at room temperature by butane adsorption. However, at high temperature where adsorption effects are reduced, hydrogen permeation now predominates. These examples show that there is considerable scope for hydrogen separation from gas mixtures by using membranes with very small pore sizes and utilizing the adsorption and surface diffusion behaviour of the species involved.

Dense Membranes

A second type of hydrogen-separating membrane is the dense membranes made from various metals, metal alloys and metal oxides. Hydrogen permeates a number of metals at high temperatures, including tantalum, niobium, vanadium nickel, iron, copper, cobalt and platinum. Alloys of these and other metals also possess high permeation rates for hydrogen together with certain metal oxides such as perovskites, which permeate hydrogen ions at temperatures in excess of 700°C. However, the main materials developed for hydrogen permeation are palladium and its alloys. This is because of the very high level of hydrogen absorption possible with these materials. Pure palladium absorbs 600 times its volume of hydrogen at room temperature, with the various palladium alloys absorbing comparable quantities. Although metals such as niobium and tantalum, also possess the ability to absorb large quantities of hydrogen, the formation of surface oxide films inhibits the ingress of hydrogen into the bulk metal and consequently these metals cannot be used to permeate hydrogen as such. Attempts have been made to overcome this problem by deposition of thin layers of platinum or palladium but the results have not been entirely successful, due in part of the formation of intermetallic compounds.

Consequently, palladium and/or palladium alloys represent the main dense metals currently favoured for membranes for selective permeation of hydrogen because of the high hydrogen permeation rates achievable at temperatures less than 500°C. However, below a critical temperature of 300°C and a critical pressure of 20 bars, the hydrogen-palladium system exhibits two-phase behaviour. Early experiments with palladium membranes resulted in

mechanical failure due to the expansion and contraction of the metal lattice as hydrogen was absorbed and released. Alloying palladium with other elements such as silver, yttrium or cerium enables this difficulty to be overcome and an alloy of palladium with, for example, about 23% silver has been shown to be stable and have the optimum permeation rate for hydrogen.

Hydrogen Transport in Metal Membranes

Hydrogen transport through metal membranes is a multi-step process, as illustrated in **Figure 2**. Hydrogen molecules in the feed gas are adsorbed on to the metal surface where they dissociate into atoms. These atoms then diffuse through the metal to the downstream (permeate) side of the membrane where they recombine to form hydrogen molecules on the surface. These molecules are finally desorbed into the permeate gas stream. The process is selective, in that only hydrogen is transported through the membrane; other gases are excluded, so that in theory the membranes should have infinite selectivity. However, due to a number of factors, this does not occur, although very high selectivities can be attained.

Depending on which of the above steps is controlling, the exponent of the pressure driving force for the overall permeation will change. For diffusion control by hydrogen atoms, which process is normally attained at high temperatures, the overall hydrogen flux (J) will be given by:

$$J = K(p_h^{0.5} - p_l^{0.5}) \quad [2]$$

where p_h and p_l are the feed and permeate side pressures of hydrogen respectively.

However, if adsorption and/or dissociation of hydrogen into atoms is the controlling step then

the pressure exponents will tend to a value close to unity.

Metal Composite Membranes

Palladium-silver alloys have been used for a number of years for preparation of ultra-pure hydrogen for laboratory use. In recent years larger units have been made for the electronics industry. These membrane modules typically contain a number of small diameter alloy tubes with a metal wall thickness of about 50 μm . Sheet palladium alloys have also been used successfully for separation of hydrogen in reaction systems by Gryaznov and co-workers in Russia. However, the use of metal membranes alone has two serious disadvantages. If the permeation rate of hydrogen through the metal is diffusion-controlled, then the hydrogen flux is inversely proportional to metal thickness; most pure metal-alloy systems require a finite thickness to withstand the necessary pressure differential inherent in the separation process. Associated with this increased metal thickness is the material cost of palladium and its alloys.

Because of these factors, a number of methods have been proposed to overcome this problem, but essentially the common feature is to deposit the palladium on to a porous support material. The aim has been to obtain thin films of thickness ranging from 1 to 10 μm , but much thinner films have been produced by some investigators. The danger is that, with very thin films, the likelihood of pinholes being present increases considerably. Thin films in the micron range will give greatly increased fluxes, but the main difficulty is to produce films without cracks and to have good adherence to the support material. Substrates which have been used include porous glass, aluminas, silica, zirconia and stainless steel, although other porous materials have also been tried. The main

Figure 2 Permeation of hydrogen through metal membranes. 1, Sorption; 2, dissociation; 3, diffusion; 4, reassociation; 5, desorption.

techniques which have been developed for the deposition of thin films of palladium and palladium alloys on to porous substrates include:

1. magnetron sputtering
2. electroless plating
3. chemical vapour deposition
4. physical vapour deposition (thermal evaporation)
5. flame pyrolysis

There is some distinction in the way which palladium is deposited by these methods. The magnetron sputtering and vapour deposition methods tend to produce surface films whereas the chemical process of electroless plating can also act as a pore-plugging process. It has been found by a number of investigators, including the present author, that in comparing the suitability of α - and γ -alumina substrates for electroless plating, the wider pore α -alumina gives a more pinhole-free deposition. This has been attributed to the tendency of the electroless plating process to plug the pores; the more accessible wider pore mouths of the α -alumina facilitate entry of the depositing palladium.

In recent years the use of porous stainless steel as a support medium has been investigated since, although the pore sizes of stainless steel are currently larger than those of ceramic materials, this is compensated for by the robustness of the stainless steel and its potentially easier fabrication into an appropriate membrane module.

Use of composite membranes based on either ceramic or stainless steel supports is able to provide hydrogen permeation fluxes of $10^{-6} \text{ mol m}^{-2} \text{ s}^{-1} \text{ Pa}^{-1}$ or better with hydrogen-nitrogen selectivities in the range of 1000–5000. These results are suitable for a number of processes for hydrogen recovery, which are currently under evaluation.

Technical Challenges to the Use of Membranes for Hydrogen Recovery

Membranes used for separation of hydrogen from other gases at high temperature should possess the following features:

1. thermal and chemical resistance
2. crack-free
3. small pore diameters (porous membranes)
4. large surface areas for membrane modules
5. require high temperature seals
6. composite membranes must retain adherence of the separation layer under thermal cycling
7. fouling of the membranes must be avoided

Some of these problems are being overcome currently. A major problem is that of sealing the individual membrane units into a module. If cylindrical tubes

are to be used as membranes, then a shell-and-tube configuration as in conventional heat exchangers would seem to be the most favourable configuration, with the individual membrane tubes sealed into the end-plates of the shell. A stainless steel supported membrane tube would clearly have advantages in this case and would be preferable in terms of robustness compared to ceramic tubes.

Cost is a further factor. Although palladium is frequently cited as a major cost, it should be pointed out that, at present, the costs of porous ceramic or stainless steel support tubes are significant. No doubt these costs will decrease with increased production, but these represent a current constraint on applications.

Present Status and Potential Developments

Because of the increased demand for hydrogen as a clean fuel and for newer applications where very high purity is required (current semiconductor processing requires hydrogen with impurities of 10 p.p.b. or less), there will be a continued demand for processes to fill this need. Membrane technology can provide a significant input into this demand. Both porous and dense membranes can be utilized to provide recovery of hydrogen from process streams, but dense membranes are necessary at present to provide hydrogen of high purity. Although palladium and palladium alloys have been used almost entirely for production of pure hydrogen, other metals such as niobium, tantalum and vanadium possess, in theory, good permeating properties and are less expensive than palladium. The problem of the surface oxide layer inhibiting permeation of hydrogen is being tackled with some success and further efforts will undoubtedly lead to better performance from these materials.

With porous membranes, perhaps the most important developments are likely to occur with zeolite membranes. The development of these, either as individual membranes or in composite form on another support material, will undoubtedly open up a new area of application for inorganic membranes for hydrogen recovery and purification.

IMMOBILIZED BORONIC ACIDS: EXTRACTION

P. Martin and I. D. Wilson,
AstraZeneca Pharmaceuticals,
Macclesfield, Cheshire, UK

Copyright © 2000 Academic Press

Introduction

With the exceptions of antibody and molecular imprint-based methods, most solid-phase extractions rely on relatively nonspecific nonpolar van der Waals or ionic interactions. Another exception to the use of nonspecific interactions involves the use of reversible covalent bond formation with vicinal diols, or similar structures, in the target analyte with immobilized boronic acids. Clearly, the potential to exploit this type of interaction is limited but, where it can be exploited, highly specific solid-phase extraction (SPE) methods can result. Such methods, based on the use of boronic acids immobilized on materials, such as sepharose gels or phenylboronic acid (PBA) covalently linked to silica gel, have provided the basis for a number of SPE methods, as described below.

Mechanism of Interaction of Analytes with Immobilized PBA

The extraction mechanism that results in the formation of cyclic boronates is illustrated in **Figure 1**. In order for the reaction to proceed, the boronate must be in the reactive $-B(OH)_3^-$ form, which is readily obtained by equilibrating the phase with an alkaline buffer. When the sample is applied, the covalent bond forms only with analytes possessing suitable

functional groups, e.g. vicinal diols, found in sugars or catechols. Other functional groups which can form covalent bonds with boronic acids include α -hydroxy acids, aromatic O-hydroxyacids and amides, 1,3-dihydroxy-, diketo-, triketo- and aminoalcohol-containing compounds. With formation of the covalent bond, the analyte is strongly bound to the phase, which may then be washed with strongly eluotropic solvents to remove nonspecifically retained contaminants (an alkaline pH must be maintained). Analytes can then be recovered using an acidic buffer/solvent, which hydrolyses the covalent bonds to liberate retained compounds and return the PBA to the $-B(OH)_2$ form.

As well as these specific interactions with PBA, a number of nonspecific interactions can also occur with residual silanols, the aminopropyl group via which the PBA is attached to the silica, and the phenyl ring itself, which offers the opportunity for π - π interactions. In addition, the boronic acid can act as a hydrogen bond donor, cations can also bind to the boronic acid, and there is the potential for the formation of charge-transfer complexes with unprotonated amines. All of these interactions may happen when performing an extraction, and care must be taken to ensure that the extraction scheme is optimized to the required boronate retention mechanism if the maximum specificity is to be obtained.

Buffer Selection

The first criterion to ensure a good extraction efficiency is to select a buffer for extraction on to

Figure 1 Mechanism of boronic acid extraction. (A) Activation of boronic acid in the presence of alkali; (B) formation of a covalent bond with a vicinal diol; (C) the use of acid to break the covalent bond and regenerate the boronic acid and the free diol.

PBA with an alkaline pH for the conditioning and sample application steps. Equilibration can be performed with, e.g. $0.1\text{--}1.5\text{ mol L}^{-1}$ buffer at pH 10–12 and then $0.01\text{--}0.05\text{ mol L}^{-1}$ buffer at pH 8–8.5. Zwitterionic buffers such as HEPES, glycine, diglycine and morpholine offer advantages and all have been used in this type of application. Clearly, buffers which can form covalent adducts with PBA are to be avoided, for the obvious reason that they eliminate covalent bond formation with the analyte. Such buffers include bicine, tricine, tris and 1',2',3'-ethanolamine.

Having obtained retention, analytes can be recovered by reducing the pH of the eluent to 5 or below. Typically acetic, trifluoroacetic and phosphoric acids may be used, with the addition of an organic modifier to help overcome nonpolar or silanophilic secondary interactions. Occasionally, the covalent adduct is sufficiently stable to require the addition of lactic or salicylic acid to the eluting buffer. Alternatively, elution with borate-containing buffers can be employed when acid-labile analytes are present.

Applications

Endogenous Biochemicals

Adenosine, catecholamines, dopamine, DOPA and related substances A major field of application in

the use of SPE with immobilized boronates (both gels and silica-based materials) is the extraction of various endogenous substances, especially catecholamines, l-dihydroxyphenylalanine (DOPA) and related materials, from biofluids. However, here we have concentrated on descriptions of the more recent procedures, generally involving the use of silica-based materials.

PBA gels have been employed in the extraction of nucleosides from biological samples for several studies, including the isolation of inosine and adenosine from human plasma. Methods have also been described for the simultaneous extraction of the adenosine and dopamine from human urine using a silica-based PBA phase. In this case extraction was performed using 100 mg PBA, activated by washing first with 5 mL of 0.1 mol L^{-1} formic acid followed by 5 mL pH 8.8 ammonium acetate buffer (0.25 mol L^{-1}). Urine (0.5 mL, pH 8.8) containing (\pm)-isoproterenol and 2-chloroadenosine, was allowed to flow through the sorbent bed until the liquid meniscus just reached the top of the layer, at which point 1 mL of pH 8.8 ammonium acetate (0.25 mol L^{-1}) was also applied to the cartridge. Elution was achieved with 1 mL of 0.1 mol L^{-1} HCl-methanol (4 : 1 v/v). This methodology allowed recoveries of 88–104% to be attained with good coefficients of variation (less than 5%).

An interesting two-stage SPE method has been devised for the isolation of DOPA from plasma and

urine using [^{14}C]-DOPA as an internal standard. Interfering urinary pigments (urochromes) were eliminated via an initial extraction on to a dual-layer cartridge consisting of an upper layer of strong cation exchanger (SCX) and a lower layer of Cl silica. After this cartridge had been conditioned with 5 mL methanol and HCl (0.2 mol L^{-1}) the urine sample (2.8 mL) was applied followed by a further two bed volumes of 0.2 mol L^{-1} HCl. The eluate was taken to pH 7.5–7.7 (1.5 mL of 2 mol L^{-1} Tris buffer), after which an aliquot was passed through 200 mg of PBA SPE column (conditioned with 1 mL of methanol and 1 mL of 0.2 mol L^{-1} Tris buffer). After removing of interferences with methanol (2 mL) and 0.1 mol L^{-1} Tris (1 mL), the analyte was eluted in 0.3 mL of 0.1 mol L^{-1} HCl. For plasma samples, it was necessary to remove plasma proteins prior to extraction. This was done via precipitation using ice-cold perchloric acid. The supernatant obtained after centrifugation was then passed through the PBA cartridge (at pH 7.5–7.7 with 2 mol L^{-1} Tris) and the analyte subsequently eluted, as described above. Overall recoveries of 80% for urine and 84% for plasma (SD 2–3%) were obtained (allowing 10–15 pg to be detected with high performance liquid chromatography (HPLC) electrochemical detection).

As well as DOPA itself, several methods have used PBA for extracting 5-*S-L*-cysteinyl-*L*-dopa (5-SCD) from urine. These methods have included a dual extraction, first on to a cation exchanger and then a PBA gel with 5-*S-D*-diastereoisomer as an internal standard. A more recent method using PBA on silica was also based on dual extraction with SCX and PBA. The urine samples, to which 5-*S-D*-cysteinyl-*L*-dopa (D-CD) had been added as an internal standard, were applied to an SCX column that had been washed sequentially with methanol (1.0 mL) and HCl (0.1 mol L^{-1} , 1 mL). After washing with HCl (0.1 mol L^{-1}) the SCX cartridges were placed in series with a PBA column (pretreated with methanol and then 1 mol L^{-1} dipotassium phosphate buffer). The target compounds were eluted from the SCX using the dipotassium hydrogen phosphate buffer. Compounds retained on the PBA cartridge were then eluted with 0.5 mL of 0.1 mol L^{-1} HCl (containing 10 mg L^{-1} of ascorbic acid), following a water wash step. Aliquots of the eluate were then analysed by HPLC.

More recently a new, fully automated method for 5-*S*-cysteinyl-dopa in plasma and urine has been proposed. In this method, the PBA cartridges were treated sequentially with heptane and acetone (1 mL of each) to remove impurities and were then conditioned with methanol (1 mL), HCl (0.3 mol L^{-1} ,

1 mL) and Tris buffer (10 mmol L^{-1} , 2 mL) followed by application of the appropriately buffered sample (1 mL of plasma or 1:100 diluted urine). The cartridges were then washed with 4 mL of 10 mmol L^{-1} Tris buffer prior to elution of the analyte with HCl (1 mL of 0.3 mol L^{-1}). Typical chromatograms from this work are illustrated in Figure 2.

Boric acid gels and silica-PBA have both been used to extract catecholamines from biological samples. The silica-based material has also been employed for the determination of noradrenaline and adrenaline in urine and found to be superior to conventional methods. In this method two SPE cartridges, a pentanesulfonic acid phase (PSA) and PBA were connected in series (the PBA cartridge had previously been washed with methanol (1 mL) and then HCl (0.1 mol L^{-1} , 1 mL)). Both cartridges were then washed sequentially with methanol (2 mL) and then aqueous ammonia (4 mL) and finally phosphate buffer (4 mL, 5 mmol L^{-1} pH 8.5). The urine sample (1 mL, pH 5 using ammonia) plus internal standard (dihydroxybenzylamine) were then applied followed by a wash with phosphate buffer (4 mL of pH 8.5 phosphate). After washing with a further 2 mL of the alkaline phosphate buffer, the PSA column was removed and the PBA cartridge was washed first with methanol (1 mL) and then acetonitrile-phosphate buffer (1 mL, 1:1 v/v). Recovery of the analytes was achieved using HCl (1 mL, 0.1 mol L^{-1}) and these were then analysed by HPLC with electrochemical detection.

In a similar method, urine (1 mL, diluted to 5 mL with water, pH 6.5–7.0) being assayed for dopamine, adrenaline and noradrenaline with 3,4-dihydroxybenzylamine added as internal standard was extracted using a combination of SCX and PBA. The SCX and PBA cartridges were initially treated with 1 mol L^{-1} HCl followed by methanol and 0.01 mol L^{-1} ammonium acetate buffer (pH 7.3), following which the sample was applied to the SCX column. This was washed with methanol and then ammonium acetate (0.01 mol L^{-1}): recovery of the analytes from this phase was achieved with $3 \times 500\text{ }\mu\text{L}$ of perchloric acid. This eluate was neutralized using a saturated solution of sodium carbonate and was then loaded on to the PBA cartridge which was first washed with methanol and then water. Finally the analyte was recovered for analysis, by HPLC with electrochemical detection, by elution with $2 \times 500\text{ }\mu\text{L}$ of 0.1 mol L^{-1} perchloric acid. Limits of detection of $1\text{ }\mu\text{g L}^{-1}$ for noradrenaline and $2\text{ }\mu\text{g L}^{-1}$ for dopamine were claimed.

Glycosylated amino acids In diabetes the glycosylated amino acid glucitolysine is formed when the

Reproduced with permission from Hartleb *et al.* (1999).

amino acid lysine in proteins reacts with glucose. An online extraction method for glucitolysine in protein hydrolysates with 'on-column' reaction with *o*-phthaldialdehyde (OPA) to allow HPLC with fluorescence detection has been described.

Glucitolysine extraction was achieved by washing the PBA phase with 0.1 mol L^{-1} HCl to remove

contaminants, followed by 0.1 mol L^{-1} NaOH, equilibration with pH 8.5 phosphate buffer (0.1 mol L^{-1}) and then application of the sample, also at pH 8.5. With the protein hydrolysates, interfering co-extracted amino acids were removed by washing with water or methanol. Recovery of glucitolysine was achieved by lowering the pH of the mobile phase.

Reduced oligosaccharides PBA has also been applied to the separation of oligosaccharides from their alditols and interfering amino acids and glycopeptides. The purification of an oligosaccharide–lipid conjugate (neoglycolipid) formed by the reductive amination of the sugar lactose with phosphatidylethanolamine dipalmitoyl (PPEADP) has also been demonstrated.

The columns were activated by treatment with methanol, HCl (0.1 mol L^{-1}), water and then NaOH (0.2 mol L^{-1}). Following washing with water ($2 \times 1 \text{ mL}$) samples were applied as aqueous solutions. Elution was performed by washing with water, acetic acid (0.1 mol L^{-1}) and finally HCl (0.1 mol L^{-1}) with the fractions eluted from the PBA analysed by thin-layer chromatography on silica. Under these conditions, oligosaccharides with glucose at the reducing end were not retained by the PBA columns, but the corresponding alditols were retained. Similar results were obtained for glycoprotein-derived octasaccharides and their corresponding alditols. The application of samples under alkaline conditions enabled the separation of the analytes from amino acids, peptides and glycopeptides, although there was some retention of nonreducing oligosaccharides.

In addition, methods were also provided that enabled the purification of oligosaccharide derivatives formed by reductive amination (resulting in the ring-opened sugars giving acyclic vicinal hydroxyl groups). Column activation in this example was performed using water, methanol and a 1 : 1 (v/v) mixture of methanol–chloroform to wash the column.

Reaction mixtures obtained after reductive amination were applied in methanol–chloroform (1 : 1 v/v), with subsequent elution (after various washes) in chloroform–methanol– 0.1 mol L^{-1} acetic acid (30 : 70 : 30 v/v).

Natural Products

Polyhydroxyflavones HPLC with sample preparation via extraction on to PBA cartridges has recently been applied to the analysis of a variety of dietary polyhydroxyflavones (quercetin, kaempferol, fisetin, rutin, myricetin and morin; see **Figure 3** for structures) present in vegetables, red wine and human blood plasma. The extraction involved conditioning the cartridges with aqueous acetonitrile (1 mL, 28% v/v) containing 1% trifluoroacetic acid followed by 1 mL water and 1 mL of phosphate buffer (0.5 mol L^{-1} , pH 8.5). The samples were then loaded on to the cartridge in phosphate buffer (pH 8.5). Following a wash step (1 mL of 10 mmol L^{-1} phosphate buffer, pH 8.5) the analytes were recovered in 2 mL of the aqueous acetonitrile solution used in the first step of the cartridge conditioning process (applied in four 0.5 mL aliquots). In general, good recoveries of the target compounds were obtained from matrices such as red wine and onions; recovery of, for example, quercetin was always greater than 90%. From human plasma the recovery of this compound was reduced to *c.* 80%, but with quite acceptable inter- and intraassay coefficients of variation. In **Figure 4** chromatograms for a variety of sample types are illustrated following sample preparation on PBA.

Figure 3 Structures of the dietary polyhydroxyflavones.

Figure 4 Chromatograms for a variety of sample types containing dietary polyhydroxyflavones following sample preparation on PBA. (A) Standard polyhydroxyflavones; (B) onion skin extract; (C) wine; (D) plasma spiked with quercetin. Peaks: 1, rutin; 2, myricetin; 3, fisetin; 4, morin; 5, quercetin; 6, kaempferol. Structures given in Figure 3. Reproduced with permission from Tsuchiya (1998).

It was noted that the absolute recoveries of quercetin, fisetin and rutin were better than those for the other compounds, and it was suggested that this could be explained by differences in the boronate complexes formed by 1,2 as opposed to 1,3 diols.

Ecdysteroids The ecdysteroids are the moulting hormones of insects and crustaceans. They are relatively polar polyhydroxy steroids (the structure of 20-hydroxyecdysone is given in Figure 5) which are widely distributed in nature. Indeed, over 250 ecdysteroids have been isolated from various sources, particularly plants, where they probably function as chemical defences against predatory insects. Many of the ecdysteroids contain one or more vicinal diols, most often encountered at C-2 and C-3 of the A ring of the steroid nucleus, and in the side chain at C-20 and C-22. PBA has been found to provide the basis for the selective extraction of those compounds in possession of a C-20,22 diol group, but not ecdysteroids containing only a C-2,3 structure.

In this instance the extraction of the C-20,22 diol-containing compounds involved activation of the PBA with ethanol (5 mL) and then an alkaline buffer (5 mL, *c.* pH 8). Borate (100 mmol L⁻¹ pH 8.0 or pH 8.2) or phosphate (100 mmol L⁻¹, pH 8.0) buffers gave essentially the same result. Under these conditions compounds such as ecdysone and 2-deoxyecdysone, which lack the C-20,22-diol, were extracted from the matrix but were readily recovered using alkaline methanol (70% methanol). The C-20,22-containing compounds were, in contrast, surprisingly well retained and even eluents composed of 90% methanol–1% trifluoroacetyl failed to recover more than 20% of these substances. Quantitative

recoveries of these strongly adsorbed ecdysteroids required buffers that contained either salicylic acid (25 mmol L⁻¹) or lactic acid (3% w/v) in 50–70% methanol. A typical chromatogram for 20-hydroxyecdysone from a plant extract is shown in Figure 5.

These differences in the extraction properties of the C-20,22-diol and the C-2,3-diol-containing ecdysteroids is interesting and may well result from the difference in the O–O atomic distances in the two structures. Thus, with the C-2,3 compounds, this distance is 28 pm but with the C-20,22 structures this narrows to 25.2 pm. It is thus possible therefore that a rigid 2,3-diol would be unable to form a cyclic boronate whereas with the less rigid C-20,22 a cyclic boronate is possible.

Drugs and Metabolites

β-Blockers

PBA has been used to extract β-blockers (a class of aminoalcohol-containing drugs) from aqueous solution, rat, and human plasma. The analytes included propranolol, epanolol, ICI 118551 and practolol (see structures in inset to Figure 6). The cartridges (100 mg PBA) were first conditioned with 1 mL methanol followed by 5 mL of glycine buffer, following which SPE was performed using 0.1 mol L⁻¹ glycine buffer at pH 8.2. Following sample application, nonspecifically retained substances were removed by washing with 1 mL of deionized water followed by 3 mL of methanol–water (40 : 60 v/v). The analytes were then recovered in 3 mL methanol–water trifluoroacetyl (50 : 50 : 1 v/v). The extraction was pH-dependent, with the greatest

Figure 5 A typical chromatogram obtained for a PBA extract of a plant sample containing 20-hydroxycyclopentanone (see inset for structure).

extraction efficiency observed at pH 8 (Figure 6) but, in addition, structural features were also important. The extraction was most efficient for propranolol and ICI 118,551 (greater than 90%) with

only small losses at the application and wash steps. With practolol, losses at the application step were high (>7%), and both practolol and epanolol showed losses at the wash step (8.8 and 16.5% re-

Figure 6 The effect of pH on the extraction of the β -blockers, propranolol, epanolol, ICI 118,551 and practolol on to PBA.

spectively). The latter could be reduced by decreasing the proportion of methanol in the solvent used for elution.

Some matrix effects were also noted for ep-anolol (but not propranolol, practolol and ICI118,551) when extraction was performed from rat plasma where losses at the application and wash steps were greater than from buffer. This effect, which probably resulted from protein binding, was reduced by diluting the sample with glycine buffer prior to extraction.

Glucuronides

Glucuronides are an important class of metabolites for xenobiotics such as drugs. In many analytical methods these conjugates are hydrolysed back to the aglycone followed by extraction. However, the glucuronides have the potential for SPE on PBA, enabling glucuronide-specific assays to be developed. A limited number of studies into the potential of this type of SPE using a range of model phenolic glucuronides, spiked into urine, have been performed.

The test analytes in these studies were phenolphthalien glucuronide, *p*-nitrophenylglucuronide, α -naphthylglucuronide and 6-bromo-2-naphthylglucuronide present in human urine at a concentration of 5 mmol L⁻¹. The extraction protocol developed for these compounds involved mixing 500 μ L urine with 1.5 mL of 100 mmol L⁻¹ 8.5 glycine buffer (pH 8.5) which was then applied to a PBA column that had been conditioned first with pH 10 glycine buffer (5 mL, 100 mmol L⁻¹) and then equilibrated with a further 5 mL glycine buffer at pH 5. Glucuronides that were retained on the PBA were then eluted with 5 mL of methanol-1% HCl (90:10 v/v). With this protocol the selective retention of some of the test compounds was demonstrated depending upon the structure of the analyte and the amount of PBA employed. With phenolphthalien glucuronide, good extraction was obtained with 300 mg PBA and complete extraction was demonstrated with cartridges containing 400 mg. Extraction on 100 and 200 mg cartridges was, however, incomplete. Good recoveries were seen in the methanol-HCl elution step. Phenolphthalien glucuronide and phenolphthalien sulfate were readily separated from each other using PBA. Good results for the extraction of 6-bromo-2-naphthyl- β -D-glucuronide were also obtained on 600 mg cartridges.

However, with both *p*-nitrophenol glucuronide and α -naphthylglucuronide extraction efficiency was not as good (20 and 50% respectively with 500 mg PBA cartridges).

Thus, whilst it was possible for certain structures to extract phenolic glucuronides on to PBA, and selectively to fractionate sulfates and glucuronides, the presence of glucuronic acid is not of itself sufficient to ensure extraction. Indeed, glucuronic acid itself was not retained under the extraction conditions used for the conjugates. Clearly the structure of the aglycone on to which the glucuronic acid is attached is also important. The exact structural features that would ensure good extraction of glucuronides have still to be elucidated, but π - π interactions may be important. It should also be noted that, whilst glucuronides possess vicinal diol groups with which to form boronate esters, it is also possible that the carboxylic acid and its adjacent hydroxyl group are responsible for the observed extraction.

Miscellaneous

Alizarin The tricyclic anthraquinone dye alizarin contains a *cis*-diol and has been used as a model compound for studying SPE with PBA. The cartridges were conditioned with methanol and then pH 8.6 HEPES buffer (0.1 mol L⁻¹). An aqueous solution of the dye (0.1%) was quantitatively retained, as a sharp band on the cartridge with elution subsequently achieved with methanol-HCl (0.1 mol L⁻¹) (3:1). Efficient extraction was only achieved at pH 7-10; however it was also shown that good extractions were also possible from solutions containing up to 70% of an organic solvent as long as they were alkaline. Indeed, as long as wash solvents were alkaline, it was possible to use solvents such as methanol, ethanol or acetonitrile without loss of the dye from the cartridge. The extraction of the analyte from plasma was only efficient if the sample was first extracted on to a C₁₈ phase. Elution from C₁₈ with an alkaline methanol buffer on to the PBA then resulted in good recoveries. Presumably protein binding was responsible for the poor result (see the β -blockers above).

Conclusions

For those compounds with the structural features that permit it, the possibility of selective extraction using immobilized phenylboronic acid may have potential benefits. Such a sorbent clearly has the potential to result in a relatively specific clean-up and it is perhaps surprising that there are relatively few published applications. However, it is evident from some of the examples provided above that the suitability of a particular analyte for extraction on to PBA can only be determined by experiment as the apparent possession of a suitable structure for cyclic boronate formation (e.g. a *cis*-diol) is no guarantee of success.

IMMUNOAFFINITY EXTRACTION

D. Stevenson, University of Surrey, Guildford, UK
Copyright © 2000 Academic Press

Introduction

The mechanisms of separation in liquid chromatography are often classified as adsorption, partition, ion exchange and size exclusion. A further category could be included—affinity separations. Affinity chromatography uses very specific interactions between the compound of interest and a ligand bound to a chromatographic support to obtain separations. An early example of affinity separations was the use of an enzyme and its substrate. One particular type of affinity separation is immunoaffinity chromatography. In this case antibody–antigen interactions are used to obtain the separation. Either the antibody or the antigen can be bound to a support (immobilized). The current use of immunoaffinity extraction usually has the antibody immobilized (Figure 1). Immunoaffinity chromatography has often been used in the preparative mode where molecules of biological interest, which are difficult to recover by other methods, have been purified. Exam-

ples include enzymes, hormones, vaccines, interferons and antibodies.

Many modern analytical methods involve at least two distinct stages: preparation of a sample in a relatively clean form followed by instrumental analysis. This is particularly the case for the measurement of low concentrations of organic compounds in complex biological matrices such as blood, plasma, serum, urine, tissues and environmental matrices such as water, air, soil, foods, etc. One reason for the current interest in immunoaffinity extraction is its potential use as a highly specific variant of traditional solid-phase extraction in such analyses. In an ideal immunoextraction the sample is added to the column and only the target analyte is retained on the column. A wash step is then incorporated and potentially interfering material in the sample is washed from the column and discarded. The solvent is then changed and the elution solvent removes the target analyte from the column. The clean eluent is then analysed, usually by a modern instrumental method such as high performance liquid chromatography (HPLC) or gas chromatography (GC). This principle is shown in Figure 2. Immunoaffinity extraction is thus an attempt to combine the specificity of antibody-based methods with the separation and selective detection that can be obtained from instrumental chromatographic methods.

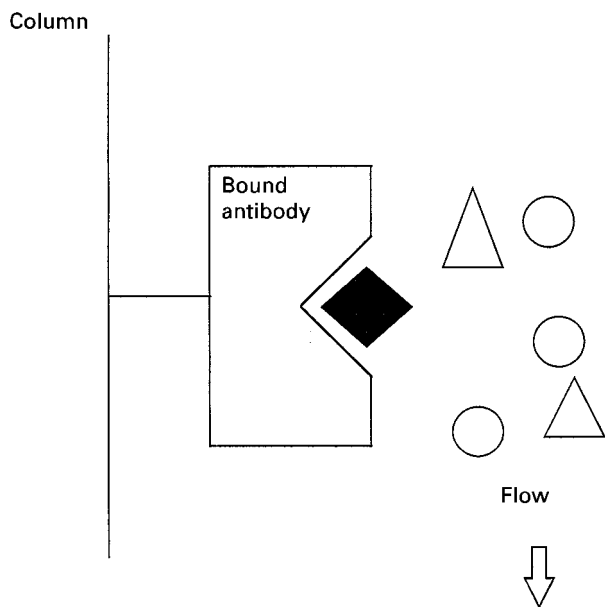

Figure 1 Principle of affinity extraction. Only analyte binds to the antibody. ♦, analyte; △, ○, unrelated compounds.

Solid-Phase Extraction

Solid-phase extraction is one of the most common forms of sample preparation in current use. In its usual format, it involves introducing a liquid sample to an extraction cartridge in a small syringe-shaped container. The cartridge contains a solid phase capable of extracting the analytes of interest and retaining them on the solid phase. The analyte is thus removed from a 'dirty' matrix. It is then eluted from the solid phase and injected into a GC or an HPLC. Such a procedure produces a cleaner sample and therefore less likelihood of peaks co-eluting with the analyte. The liquids are normally drawn through the cartridge under vacuum using a purpose-designed vacuum box, or using positive pressure at the head of the column. Solid-phase extraction is a simple form of liquid chromatography. A range of phases is commercially available, such as silica, C₁₈, C₈, C₅, C₂, phenyl, diol, amino bonded silica, ion exchange phases and polymer phases. Conventional solid-phase extraction

Figure 2 Idealized immunoextraction. Only analyte (◆) is retained through the wash step. This is then eluted and subsequently injected onto HPLC, GC, etc.

is easy to automate both online and offline. Commercially available phases have been used to analyse thousands of different compounds, but generally they are nonselective about which analytes they extract. A range of tailor-made phases have been developed, designed to extract only one or a few closely related analytes. Immunoaffinity extraction is an example of an attempt to develop highly specific solid-phase extraction procedures.

Antibodies

The key reagent for immunoextraction is the antibody which is immobilized on to a support. Antibodies are large biological molecules present in the serum of animals. They are produced by the immune system in response to foreign compounds, the so-called antibody-antigen response. Antibodies belong to a group of proteins called the immunoglobulins and have a relative molecular mass of about 150 000–900 000. Antibodies are normally only produced in response to compounds with a molecular mass of 1000 or above. As many of the compounds of interest in analytical chemistry are much smaller than this, they are chemically bonded to a carrier protein in order to elicit the immune response. For the antibody to be useful it must respond to the analyte, not

to the analyte-protein complex alone. In cases where the analyte does not contain a functional group suitable for bonding to a carrier protein, a structural analogue to the analyte is sometimes evaluated. As serum containing the antibodies is collected, it is referred to as antiserum. It will contain a number of different antibodies and is known as a polyclonal antibody.

In practice these antibodies will bind compounds bearing a close structural relationship to the compound of interest. This is known as cross-reactivity, and can be useful in immunoextraction as a group of compounds, such as phenylurea pesticides, can be extracted and then subsequently separated by HPLC. The forces involved in the antibody-antigen interaction are a mixture of ionic attraction, hydrogen bonding, hydrophobic attractions and van der Waals forces. Although individually they are relatively weak forces, in combination a relatively strong attraction is achieved. As a chemical reagent, antibodies are not very stable. They are easily denatured by extremes of pH and by organic solvents. They are much more stable under physiological conditions (i.e. close to pH 7 and in saline at about 1%). The main attraction of biological antibodies in analytical chemistry is their specificity, which arises due to biological recognition at the molecular level.

Immobilization of Antibody

Immunoextraction columns require the bonding of an antibody on to a suitable support while retaining the maximum amount of antibody activity. Some of the support materials used are shown in **Table 1** (for their particular characteristics, see Godfrey in Further Reading). Ideally, supports should show good flow characteristics, good chemical and mechanical stability, low nonspecific adsorption, low cost and suitable functional groups for bonding the antibody. As with conventional HPLC and solid-phase extraction, silica-based sorbents are the most popular for immunoextraction.

The methods used to couple antibodies to sorbents usually involve reaction with the carboxyl or amino groups on the antibodies. A range of different reagents is used to activate the sorbent on to which the antibody is bound. These include cyanogen bromide, carbonyl diimidazole, 1,4-butanediol diglycidioxy ether, divinyl sulfone, tresyl chloride and glutaraldehyde. Sorbents need to be thoroughly washed after bonding to remove residual reagents.

Optimization of Immunoextraction

Once an immunosorbent has been prepared, a known amount (by weight or volume) is added to a plastic or glass column with a retaining frit. As immunosorbents are relatively expensive to prepare (compared with commercially available solid-phase extraction columns), the minimum amount needed for a particular assay is used. Conditions are also chosen to allow the columns to be used many times. This means that gentle extraction conditions are favoured, otherwise the antibody will be denatured. However, when using immunoaffinity extraction as a clean-up method for chromatography, it is also desirable to elute the analyte in as small a volume as possible so that further preconcentration is unnecessary. A further consideration is the nature of the desorbing eluent with respect to the possibility of direct injection into an HPLC or GC. In principle there are many different variables requiring optimization for a successful immunoextraction (**Table 2**).

As the actual column preparation follows established protocols, much of the effort of developing a successful extraction protocol concentrates on the solvents used for conditioning and washing the column and on the solvent used for elution of analyte. Columns typically contain between 50 and 500 μL of antiserum. As antibodies originate from animal serum, physiological conditions are favourable for column washing.

A typical protocol would prime the column with phosphate-buffered saline at neutral pH. The sample would be loaded at a pH adjusted to fall in the range pH 5–9. Large sample volumes can be added and this allows concentration of the analyte on the column. The capacity of immunocolumns is usually dictated by the mass of analyte rather than the volume of sample. Biological samples such as plasma or serum often cause column blockage unless proteins are precipitated before the sample is added to the column. Flow rates up to about 5 mL min^{-1} are acceptable; otherwise, with higher flow rates the antibody–antigen interaction does not have sufficient time to ensure binding.

Once the analyte is bound on to the column it can be washed with phosphate-buffered saline at neutral pH. In order to elute the analyte in as small a volume as possible, without damaging the antibody, elution solvents are typically composed of phosphate-buffered saline at a low pH (down to pH 2) with the addition of a water-miscible solvent such as methanol or ethanol at a concentration of up to about 50%. At higher pH or lower concentration of organic modifier, the analyte elutes in a larger volume of elution solvent, which necessitates further concentration. This type of desorption is known as nonselective desorption. An alternative approach is to try selective desorption by adding a compound very similar in structure to the analyte in the elution solvent. This

approach has generally necessitated larger desorption volumes to obtain quantitative recovery than non-selective desorption and hence is not common.

One of the advantages of immunoaffinity extraction is that these procedures are usually carried out under aqueous conditions. As reversed-phase HPLC is often the favoured technique for subsequent analysis, the introduction of analyte dissolved in an aqueous medium is compatible with the mobile phase. Most applications of the technique involve extraction of drugs, endogenous compounds and pesticides. Examples of compounds for which immunoaffinity extraction has been reported are shown in **Table 3**.

One of the most successful applications of immunoaffinity has been the extraction of pesticides from water. Immunoextraction columns have been shown to be capable of preconcentrating up to 1 L of water containing the herbicides chlortoluron and isoproturon, yet still capable of desorption into low volumes (even as low as 1 mL) of elution solvent. Although lower sample volumes (such as 50–100 mL) are more likely to be used in practice, this feature of immunocolumns offers the possibility of large concentration factors and low overall detection limits. The cross-reactivity of antibodies to triazines and phenylureas has been used to immunoextract several compounds which were then subsequently separated and measured by HPLC.

The capacity of the immunocolumns is governed by the mass of analyte that can be retained before the column is overloaded rather than the volume of water passed through. The mass capacity of the column can be assessed by loading 1 mL aliquots of a standard solution of analyte and analysing fractions eluting from the column until the presence of analyte is detected. A simple calculation of the number of addi-

tions to the column times the amount added each time gives the mass breakthrough of analyte. An alternative approach involves overloading the column but then washing out excess analyte in solution, leaving bound analyte on the column. This is then eluted with the desorbing solution and the concentration and volume measured. A simple calculation gives the amount of analyte required to saturate the column.

The major advantage of immunoaffinity columns is the specificity that can be obtained. This is utilized to give cleaner chromatographic traces than using nonselective extraction such as liquid–liquid extraction or solid-phase extraction on silica or non-polar bonded silica.

Other Formats of Immunoaffinity Extraction

Immunoaffinity extraction has been carried out in formats other than solid-phase extraction. This has included high performance immunoaffinity chromatography and online HPLC column switching. In the former, immunosorbents are used as HPLC columns whereas in the latter, samples are extracted on an HPLC immunosorbent, preconcentrated and the flow then switched to a conventional HPLC column for analysis. Both methods attempt to base the separation on antibody–antigen interactions. In the case of column switching, complete automation can be achieved.

Molecular Imprinted Polymers

The major disadvantage with immunoaffinity extraction is the difficulty and expense in obtaining biological antibodies. An alternative approach is the use of molecular imprinted polymers as antibody mimics. These are synthesized in the chemistry laboratory and are consequently easier and less expensive to obtain. The target analyte (template) is mixed with a monomer such as methyl acrylic acid and a cross-linking agent such as ethylene glycol dimethacrylate. They are dissolved in a suitable solvent such as acetonitrile along with an initiator such as 2,2'-azobis-(2-methylpropionitrile) and heated or subjected to UV radiation. The polymer forms around the template within about 16 h. The polymer is ground into fine particles and then washed to remove the analyte template, thereby leaving cavities where the analyte can subsequently be bound. This polymer can then behave as an affinity column, mimicking the biologically derived immunoaffinity solid-phase extraction columns.

Table 3 Examples of immunoaffinity extraction

Zeranol

Columns derived from molecular imprinted polymers often show secondary interactions arising from the monomer, e.g. with methyl acrylic acid, cation exchange can occur. They show best specificity in the solvent in which they were originally dissolved, hence they are used with organic rather than aqueous solvents. Although easy to obtain and more stable to extremes of pH and organic solvents, they are not as specific as columns utilizing biologically derived antibodies. One problem with molecular imprinted polymers is the difficulty in washing out all traces of the analyte template. Remaining template leaches out when the columns are used for analysis, giving falsely high results. This problem is partially overcome by using a structural analogue to the analyte as the template. Provided the template can be separated from the analyte by HPLC, GC, etc. it will not interfere with the analysis. This approach does require cross-reactivity of the polymer, i.e. it must retain the analyte as well as the template.

The use of molecular imprinted polymers is an emerging field and new synthetic methods may improve the performance of these columns as well as other uses of the polymers. Examples of solid-phase extraction using molecular imprinted polymers include atrazine, pentamidine, propranolol, sameridine and tamoxifen.

Future Developments

Immunoaffinity extraction has been demonstrated as being capable of selectively capturing analytes from complex matrices using antibody-antigen interactions. Techniques for preparing the columns and procedures for optimizing the retention and desorption of analyte are now well established. The availability of antisera to more compounds will expand the use of immunoextraction. As better procedures to produce antibodies or antibody fragments become available, the cost of antisera should come down. Although much of the work to date uses low molecular weight compounds as target analytes, immunoextraction might be even more valuable for the new products emerging from biotechnology which may present different problems with extraction using conventional liquid-liquid or solid-phase extraction methods. Better specificity from synthetic polymer antibody mimics should also see a growth in their utility in immunoaffinity-type extractions. Polymers that show specificity for analyte under aqueous conditions would be an advantage. Selective extraction at present comes at an extra cost in the production of the columns and is not yet available 'off the shelf'. It is likely to prove most useful

where simpler procedures cannot be used due to analyte instability or where particularly low detection levels are required. It should also be remembered that immunoaffinity extraction need not only be used with HPLC, GC or capillary electrophoresis.

IMPREGNATION TECHNIQUES: THIN-LAYER (PLANAR) CHROMATOGRAPHY

I. D. Wilson, AstraZeneca Pharmaceuticals,
Macclesfield, Cheshire, UK

Copyright © 2000 Academic Press

Introduction

The use of impregnated phases in thin-layer chromatography (TLC) has a long history, beginning in the very earliest days of the technique. As a consequence, much of the key literature in this field dates back to the 1960s and 1970s. The literature also contains a considerable number of examples of impregnation reagents where subsequently the methods have received little attention except in reviews of the subject.

The impregnation of the stationary phase in thin-layer, or planar, chromatography can be used to achieve a number of ends. These include changing the mode or selectivity of the chromatographic system, improving chromatographic performance and enhancing detectability. An example of the use of impregnation to change the type of chromatography would be the use of a nonpolar, water-immiscible material such as paraffin oil which can be used to enable reversed-phase separations to be performed on silica-gel TLC plates. Alternatively, plates impregnated with silver nitrate can be used to improve the separation of compounds containing double bonds (argentation chromatography). Similarly, boric acids or boronates are useful for compounds such as carbohydrates and sugars containing vicinal diols, and ion pair reagents provide a means for successfully separating polar ionic species. Although the use of impregnation techniques for enhancing detectability will not be considered in depth here, examples would include the incorporation of ammonium acetate followed by heating, which can result in the formation of intensely fluorescent derivatives, whilst paraffin oil impregnation can stabilize or enhance fluorescence and the radiolabelled substances can be detected using impregnation with a scintillant.

There are a variety of methods for obtaining impregnated layers, including the preparation of the TLC plate with slurries containing both the stationary phase and the impregnating reagent, pre- or post-chromatographic dipping, pre- or post-chromatographic development of the plate in a solvent containing the impregnating agent or spraying, and these are described below.

Impregnation Techniques

All of the techniques for impregnating TLC plates described below have been used at one time or another and are illustrated with examples in the subsequent sections on applications.

Spraying

Spraying the TLC plate is a simple and convenient method for applying the reagents used for detection in TLC and indeed is widely used for this type of application. It is, however, much less well suited to the impregnation of TLC plates in order to modify chromatography because of the difficulty of ensuring uniform coverage. It also requires much skill and expertise in order to ensure reproducible results from day to day. Both of these technical difficulties are clearly disadvantages, and spraying is therefore not recommended for routine applications in this area. Spraying is therefore probably best used, if at all, for one-off applications or for screening phases and impregnating reagents for a particular property during method development.

Dipping

Dipping plates in solutions of the impregnating reagent in a suitable (usually volatile) solvent is probably the simplest and most efficient method of ensuring even coverage of the stationary phase with the reagent of choice. Suitable dipping chambers, of the type used for immersing plates in solutions of chromogenic visualization reagents, are available from a number of manufacturers at modest cost. These chambers have relatively small volumes and so are not expensive in reagent. Some automated devices are also available that can be used to control the impregnation time accurately. Dipping, in general, because of the ease of control over parameters such as reagent concentration and impregnation time, should be considered to be the preferred method for impregnating TLC and HPTLC plates.

Pre-development

It is also a relatively easy matter to prepare TLC plates impregnated with the desired reagent by pre-development in a solution of reagent in a suitable solvent. This technique is also referred to as irrigation of the plates. The solvent used for this purpose needs to be sufficiently eluotropic to ensure that any

affinity of the reagent for the stationary phase is overcome or else, at worst, the plate will not be impregnated with the reagent which will stay at or near the origin (or else be distributed as a gradient of decreasing concentration up the plate). Nonmigration of the impregnating reagent is seen with, for example, the ion pair reagent cetrимide if dissolved in water and then used to coat reversed-phase TLC plates in the pre-development method. Because the reagent is relatively nonpolar it has a strong affinity for the stationary phase and remains at the origin. In such cases dipping is to be preferred.

Mixed Phases

Although with the advent of good quality commercial TLC and high performance TLC (HPTLC) products the preparation of TLC plates in the laboratory is no longer widely practised, one method of producing impregnated plates was to produce mixed phases. Thus, the bulk stationary phase (generally silica gel) was mixed with an appropriate amount of the impregnating reagent, a binding agent, slurried in a suitable solvent and spread as a layer on glass plates. After drying and activating (if necessary), the plates were then used as required. Some manufacturers provide a range of mixed phases (e.g. silver nitrate-impregnated plates, buffered layers, ammonium acetate-impregnated layers, etc.).

Specific Examples of Impregnation in TLC

Impregnation to Form Lipophilic Stationary Phases for Reversed-phase Separations

Before the introduction of good-quality bonded phases, the preparation of suitably hydrophobic stationary phases used to be a very popular method for obtaining layers with which to perform reversed-phase separations, and still has many advantages. This is readily achieved using liquid paraffin oil, undecane, *n*-decane, nitromethane, propylene glycol, silicone oil, decalin, Carbowax 400, formamide, 2-phenoxy- and 2-methoxyethanol, various mineral oils, and substances such as ethyl oleate and similar materials. In addition to modifying chromatography, impregnation with these materials can also be used to enhance or stabilize the fluorescence of suitable analytes, thus improving detection and quantification. However, it is the use of these materials to provide reversed-phase separations that is of interest here.

A typical example of the use of paraffin oil is provided by work on the reversed-phase separation of ecdysteroids (polar, polyhydroxylated steroids found in plants and arthropods). Here silica-gel TLC and

HPTLC plates were impregnated with a solution of 7.5% paraffin oil in dichloromethane (v/v) by dipping. The plates were air-dried and chromatography was performed using methanol-water mixtures. In an interesting variation on this general technique of impregnation, a variety of normal-phase separations, for nonsteroidal anti-inflammatory drugs, ecdysteroids, antipyrine and aminophenols, on silica gel were performed with the paraffin added to the mobile phase. Addition of 7.5% (v/v) of paraffin to the normal-phase solvent system did not affect chromatography but did enable the plate to be impregnated so that a subsequent reversed-phase separation in a second dimension could be undertaken immediately that the solvent from the normal-phase separation had evaporated. An example of this for the nonsteroidal anti-inflammatory compounds is shown in Figure 1. It should be noted that, with this type of impregnated plate it is also possible to perform the reversed-phase separation first, remove the nonpolar impregnating reagent with a suitable solvent (i.e. one that does not affect the analytes but does remove the impregnating reagent) and then perform a normal-phase separation in the second dimension. Alternatively, a similar outcome can be achieved by impregnation of that portion of the plate not used for

Figure 1 Two-dimensional separation of nonsteroidal drugs with paraffin impregnation during normal-phase (NP) separation in the first dimension to enable reversed-phase (RP)-TLC to be carried out in the second. 1, Ibuprofen; 2, ibufenac; 3, methyl analogue of isoxepac; 4, indomethacin; 5, isoxepac; 6, salicylic acid; 7, 5-methoxysalicylic acid. Details in Wilson ID (1984) Normal-phase thin-layer chromatography on silica gel with simultaneous paraffin impregnation for subsequent reversed-phase thin-layer chromatography in a second dimension. *Journal of Chromatography* 287: 183-188.

the separation in the first dimension, and examples of a normal-phase separation followed by impregnation with 2-phenoxyethanol or undecane for reversed-phase chromatography in the second dimension have been described.

Impregnation with Silver Nitrate

Argentation TLC also represents an important methodology and is considered in detail elsewhere in this work and so will only be briefly described here. The impregnation of TLC plates with silver nitrate has been used for many years as a means of improving the separation of unsaturated compounds, particularly certain lipids, based on the ability of silver ions to form charge transfer complexes with the π electrons of the carbon-carbon double bonds. In general, silica gel is used: the amount of silver nitrate used varies from as little as 2% up to 20 or 30% w/w depending upon the author and application. With silica gel, impregnation by both spraying (with a 10–20% solution in either water or methanol) and the preparation of mixed phases have been described. Following preparation it seems to be good practice either to use the plates the same day or else to store them in a sealed container in the dark until required. In general, non-polar solvent systems are employed (e.g. pentane, hexane-diethyl ether, chloroform-methanol, diethyl ether, light petroleum, etc.).

Whilst the use of silver nitrate-impregnated plates has generally been with normal-phase separations on silica gel, there has been recent work using reversed-phase (C_8 -bonded) layers dipped in solutions containing between 0.5 and 4% silver nitrate for 10 s. These plates were investigated for their ability to separate the *cis/trans* isomers of capsaicin, and comparison was made simply using the silver nitrate in the mobile phase (60 : 40 methanol-water v/v). With impregnation no effects were observed until the 2% (w/v) impregnating solvent was used, and even with 4% this was insufficient to provide the required resolution. In contrast, when present as a mobile-phase additive, even as low a concentration as 0.5% w/v was sufficient to give baseline resolution. It appears likely from this result that the high solubility of the silver nitrate in the mobile phase led to its rapid elution from the impregnated plate, with consequent loss of effect. Thus, interestingly, it seems from this work that the use of the silver nitrate in reversed-phase systems is only practicable when it is present as a mobile-phase additive.

Impregnation with Polyol and Sugar Complexing Reagents

The ability of borate ions to complex with suitable polyhydroxylated compounds such as carbohydrates

is well known and has provided the basis of a number of methods for their separation. TLC with layers impregnated with sodium arsenite, phosphotungstic, tungstoarsenate and molybdic acids have also been shown to have useful properties for the resolution of mixtures of oligo and monosaccharides.

Various methods have been used to prepare such layers, including both spraying and the preparation of mixed layers. Thus, in an early example of the use of boric acid, sodium borate and sodium arsenite plates were either sprayed with methanolic or aqueous solutions containing 10–20% of the impregnating reagent or plates were prepared by mixing 2.8 g of the reagent in 50 mL of water with 25 g of silica gel G to give a 10% (w/w) mixed layer. These layers were then used to separate the *erythro* and *threo* isomers of a variety of di- and trihydroxy long chain fatty acid esters.

Similar work on phosphotungstic and molybdic acid impregnated silica gel TLC plates showed them to be particularly useful for the separation of oligosaccharides giving complexes with higher R_f values than the corresponding boric acid complexes under similar conditions. In this case the plates were made by mixing 35 g of the chromatographic stationary phase (e.g. silica gel-alumina 1 : 1 or 3 : 1 or alumina) with 70 mL of an aqueous solution containing an appropriate amount of the impregnating reagent and spreading the plates as a 0.4 mm layer on to glass. The resulting plates were then dried at room temperature for 24 h, and heated for 1 h at 110°C before use. In general, the best results were obtained with TLC plates treated with phosphoric acid-sodium tungstate or saturated molybdic acid as impregnating reagents.

Impregnation with Liquid Ion Exchangers and Neutral Organophosphorous Compounds for Metal Ion Separations

The separation of inorganic ions has been an important application of TLC. Another area that has proved to be of some interest for the use of the impregnation technique as a means of improving analyte resolution in TLC has been the employment of the so-called liquid ion exchangers. This developed from the widespread use of this type of reagent in paper and column chromatography. A range of these liquid ion exchangers were used in early examples of this type of application. However, extensive experimentation suggested that adogen 464, alamine 336, amberlite LA1 and primene JM-T were suitable for this type of application. In these early studies a 0.1 mol L⁻¹ solution in chloroform was used for impregnation of the silica gel, with plates prepared from a suspension of the silica gel in this solution. Metal ions on TLC have also been resolved on layers

impregnated with neutral organophosphorous compounds such as tri-*n*-butyl phosphate and tri-*n*-octylphosphine oxide. The bulk of the early literature in this area was collated by Brinkman *et al.* (see Further Reading).

More recent examples of the use of impregnation for metal ion separations have included further examples of the use of primene JM-T, amberlite LA-1 and LA-2, alamine 336 and aliquat 336, tri-*n*-octylamine, tri-*n*-butyl phosphate and tri-*n*-butyl amine-impregnated silica gel TLC plates.

Impregnation with Ion Pair Reagents

The use of ion pair reagents is also discussed in detail elsewhere in this work and will therefore only be briefly described here. A number of workers have shown that ion pair reagents can be used as mobile-phase additives or following impregnation in the stationary phase for the subsequent chromatography of polar organic compounds. The methodology used depends to a large extent on the nature of the reagent, but also to some degree on the stationary phase. So, whilst both silica gel and alkyl-bonded layers can be treated with these reagents, the results are generally better with the bonded phases. In addition, it should be noted that low molecular mass ion pair reagents such as tetramethylammonium salts are so soluble that simply impregnating the stationary phase is generally ineffective as, with aqueous solvents, the reagent rapidly dissolves in the mobile phase when chromatography is initiated. This rapidly depletes the amount of reagent available for ion-pairing and results in a generally unsatisfactory chromatographic result. Other reagents, however, typically long chain sulfonic acids or quaternary ammonium compounds (e.g. sodium dodecyl sulfate or cetrимide) are only effective when the plate has been impregnated with the reagent (as a solution in a volatile organic solvent such as chloroform or ethanol) prior to chromatography. We have found that dipping is the most effective means of ensuring an even coating of the layer with these substances.

Impregnation with Chiral Selectors

Chiral separations in TLC have been accomplished using chiral stationary phases, chiral mobile-phase additives and by impregnating suitable TLC phases with chiral selectors. Probably the best characterized separation of this type is based on chiral ligand exchange where the chiral selector (2*S*, 4*R*, 2'*RS*)-4-hydroxy-1-(2'-hydroxydodecyl)proline/copper [II] acetate impregnated into C₁₈-bonded TLC or HPTLC plates. These plates are excellent for the separation of chiral amino acids and related compounds, and sub-

stances such as α -hydroxycarboxylic acids. Plates of this type are commercially available from several manufacturers (as the CHIR and Chiral Plate from Merck and Macherey Nagel, respectively). A typical series of separations on the CHIR HPTLC plate is shown in Figure 2. Alternative systems based on a similar mechanism involve the use of *N,N*-di-*n*-propyl-*L*-alanine or poly-1-phenylalaninamide copper complexes.

Another example of the impregnation approach to the chiral TLC separations involves the impregnation of diol-bonded HPTLC plates with the chiral ion pair reagent *N*-benzoxycarbonyl-glycyl-*L*-proline (ZGP). These plates are prepared by first washing with dichloromethane, then dipping in a 4 mmol L⁻¹ solution of ZGP and 0.4 mmol L⁻¹ ethanolamine. Following drying these plates can be used to separate the enantiomers of β -blockers such as popranolol using chloroform-ethanol solvent systems.

It is also possible to prepare a Pirkle-type stationary phase for chiral separations by dipping amino-propyl-bonded silica gel HPTLC plates into solutions of substances such as (*R*)-*N*-(3,5-dinitrobenzoyl)-phenylglycine or (*L*)-*N*-(3,5-dinitrobenzoyl)leucine

Figure 2 Separation of the enantiomers of (A) isoleucine and (B) leucine on the CHIR HPTLC plate (detection using ninhydrin) with a water-methanol-acetonitrile mobile phase (50:50:200 v/v). Details in Wilson ID, Spurway TD, Witherow L, Ruane RJ and Longden K (1990) Chiral separations by thin-layer chromatography. *Recent Advances in Chiral Separations*, pp. 159-168. New York: Plenum.

Figure 3 Separation of the enantiomers of 2,2,2-trifluoro-(9-anthryl)ethanol on aminopropyl bonded HPTLC plates modified by impregnation with *N*-(3,5-dinitrobenzoyl)-L-leucine to form an ionically bonded Pirkle-phase. Details in Witherow L, Spurway TD, Ruane RJ and Wilson ID (1991) Problems and solutions in chiral thin-layer chromatography: a two-phase 'Pirkle' modified amino-bonded plate. *Journal of Chromatography* 553: 479–501.

(0.5 mol L^{-1}). Since what is being formed is essentially an ionically bonded stationary phase, it is arguable that the plate is not being impregnated. However, the process that is performed, and the overall effects, are indistinguishable from conventional impregnation and the methodology is included for completeness. An example of a typical separation on such a modified plate is shown in Figure 3.

Impregnation with Oxalic Acid

The modification of TLC plates with oxalic acid has been performed to good effect for a range of solutes, including fatty acids, insecticides, nonionic detergents, azulenes and amines. In the example of the azulenes, the TLC plates were prepared by spreading the silica gel in a aqueous solution of 0.19 mol L^{-1} oxalic acid, as immersion was found to give less satisfactory results. The plates were then

activated by allowing them to dry for several hours over desiccant silica gel (activation using heating in an oven gave similar but irreproducible results). This activation was quite critical for the achievement of a good separation, as plates that were too damp gave no resolution. For the TLC of certain acidic mycotoxins, the use of silica gel TLC plates that had been immersed in a 10% solution of oxalic acid in methanol for 2 min and then activated by heating at 110°C for 2 min enabled tailing to be eliminated and resulted in well-defined spots.

Impregnation with Inorganic Buffer Salts

The use of phases impregnated with sodium or potassium salts has been described for a number of solutes. Thus, conjugated dihydroxy bile acids were separated on silica gel plates that had been impregnated by dipping in a solution of potassium dihydrogen phosphate. However, a major application of this type of impregnation has been for carbohydrates. As examples, glucose, fructose and sucrose in molasses were resolved on silica gel HPTLC plates dipped in 0.2 mol L^{-1} aqueous solution of monobasic potassium phosphate. In contrast, when this separation was attempted on nonimpregnated plates it failed. Similar results have been observed by other workers with this type of sample and in addition to potassium-based buffers, plates buffered with 0.15 mol L^{-1} sodium dihydrogen phosphate (prepared by mixing Kieselghur with the buffer prior to spreading the plates) have also been used to separate sugars (fucose, xylose, ribose, etc). Other workers have also examined impregnation of silica gel, prepared by spreading the adsorbent in a solution of the appropriate salt, with a range of sodium salts (phosphates, acetate, sulfate, phenyl phosphate) for a wide range of carbohydrates, including mono- and oligosaccharides and uronic acids. From these studies the best separations of monosaccharides and uronic acids were obtained with plates impregnated with $0.2\text{--}0.3 \text{ mol L}^{-1}$ salt concentrations, whilst oligosaccharides gave the best results with $0.05\text{--}0.1 \text{ mol L}^{-1}$ salt solutions. Overall, from the published examples, it seems clear that the TLC separation of carbohydrates does benefit from the use of this type of impregnating reagent.

Charge Transfer Complexes for the Resolution of Polynuclear Aromatic Hydrocarbons

A range of compounds have been used to impregnate silica gel TLC plates in order to improve the

resolution of compounds such as the polynuclear aromatic compounds (fluoranthene, benzopyrene, etc.) based on the formation of charge transfer complexes with different electron acceptors. These reagents have included caffeine, tetracyanoethylene, 1,3,5-trinitrobenzene, picric acid, chloranil, bromanil, benzoquinone and similar compounds, 2,4,7-trinitrofluorenone, teramethyluric acid, urea, pyromellitic dianhydride, 9-dicyanomethylene-2,4,7-trinitrofluorenone, sodium desoxycholate, dimethylformamide, styphnic acid and various amino acids and nucleic acid bases. However, although a wide range of reagents have been impregnated into TLC plates in an attempt to enhance the separation of polynuclear aromatic hydrocarbons, not all have been equally effective: in one study picric acid was described as values, whilst styphnic acid showed some effect and trinitrofluorenone (on alumina) proved to be excellent. Some of the reagents listed above also proved to be heat- or light-sensitive further restricting their utility.

A recent example of the use of caffeine, shown by several groups to have a profound effect on the TLC of polynuclear aromatic hydrocarbons, as

Figure 4 Fluorescence scan of a separation of polynuclear aromatic hydrocarbons (2 ng per spot, except 6 which was 10 ng per spot) on a caffeine-impregnated silica gel layer with chromatography performed at -20°C . 1, Benzo (ghi) perylene; 2, benzo (a) pyrene; 3, benzo (b) fluoranthene; 4, benzo(k)fluoranthene; 6, fluoranthene. Reproduced with permission from Funk W, Gluck V, Schuch B and Donnevert G (1989) Polynuclear aromatic hydrocarbons (PAHs): charge transfer chromatography and fluorimetric determination. *Journal of Planar Chromatography* 2: 28-32.

a means of improving the HPTLC resolution of the polynuclear aromatic hydrocarbons, by charge transfer complex formation, involved preparing a solution of 4 g of the reagent in 96 mL of dichloromethane. Silica gel plates (with a preconcentration zone) were then dipped in this solution for 4 s and dried at 110°C for 30 min. Then, before sample application, the plates were pre-washed by running a blank chromatogram with dichloromethane as the mobile phase with subsequent reactivation at 110°C and then preconditioning the impregnated plate for 30 min at 100% relative humidity prior to sample application and chromatography. Following sample application, development was performed with diisopropyl ether-*n*-hexane (4:1) as the solvent in an unsaturated TLC tank. Although chromatography could be performed at room temperature, the best results (especially where quantification was to be performed) were obtained when the plates were developed at 22°C . The results of this type of separation, at room temperature and -22°C , are illustrated in Figure 4.

An added benefit of this type of system is that some of the reagents used for charge transfer chromatography also result in enhanced detection of the compounds of interest because of the highly coloured or even fluorescent complexes that are formed with reagents such as chloranil or pyromellitic dianhydride.

Miscellaneous Impregnation Reagents

As well as the areas described above, there are a large number of other applications of impregnation to modify the properties of the stationary phase in TLC. Some of these are briefly outlined below in order to give an indication of the extent of this type of work, but the list is by no means exhaustive.

Plates impregnated with ethylenediaminetetraacetic acid have been employed for the chromatography of certain antibiotics (e.g anthracyclines and tetracycline), mycotoxins, citrinin and 8-hydroxyquinolone derivatives, and may confer benefits when the TLC of metal chelating compounds is performed.

TLC plates have also been impregnated with a variety of metal salts for particular compounds or classes of compounds. These include ferric chloride on Kieselguhr (oxine derivatives), zinc salts on silica gel and silanized silica gel (chlorinated anilines, carbamates), cadmium salts on silica gel (aromatic amines), manganese salts on silica gel (aromatic amines), copper sulfate on silica gel (hexosamines, glycosamines, barbiturates), thallium nitrate on silica gel (monoterpene hydrocarbons) and lithium

chloride-impregnated silica gel (pyrrolizidine alkaloids). Magnesium acetate has been used for phospholipids. In addition, lead salts have been employed as impregnating reagents to modify the separations of sugars and polyols. Recently, ammonium cerium (IV) nitrate was used for the separation of aromatic amines.

Other types of impregnation include the use of silica gel with phenol for aliphatic and aromatic amines following impregnation with 2% aqueous solution of the reagent. For the aromatic amines, phenol itself was found to be the most useful reagent, providing a significant improvement in spot shape was noted for a wide range of anilines compared to chromatography on the untreated stationary phase. In the case of aliphatic amines *o*-chlorophenol gave the best result. For both classes of compound this improvement in chromatography was assumed to be due to hydrogen bond formation between the reagent and the solutes. The chromatography of phenols on cellulose has also been modified by impregnation with 10% polyamide, and on silica gel with 20% polyamide. In addition, aniline-impregnated layers have been used for phenol derivatives whilst sodium nitrite-impregnated silica gel has also been shown to provide separations that could not be achieved on native silica gel. Carbonyl compounds were modified by derivatization to 2,4-dinitrophenylhydrazones on alumina TLC plates impregnated with silver nitrate (44%, w/w). Urea impregnation, described above for polynuclear aromatic hydrocarbons and related compounds, has also been used for the separation of lipid classes on silica gel plates.

Concluding Comments

As indicated in the introduction, impregnation techniques have been employed since the earliest days of TLC and their use greatly extends the versatility of TLC by enabling more selective separations or detec-

tion. To some extent the increasing availability of bonded layers has reduced the need for the preparation of silica gel layers impregnated with nonpolar materials such as paraffin oil in order to perform reversed-phase separations. However the usefulness of silver nitrate-impregnated phases for the separation of compounds containing double bonds remains undiminished, and similar observations could be made for many of the impregnation reagents described above. A continued role for impregnated stationary phases in TLC therefore seems likely.

IN-BORN METABOLIC DISORDERS: THIN-LAYER (PLANAR) CHROMATOGRAPHY

E. Marklová, Charles University, Hradec Králové,
Czech Republic

Copyright © 2000 Academic Press

The term inborn errors of metabolism or, more precisely, inherited metabolic diseases (IMD), is usually applied to a large group of relatively rare genetic disorders in the process of intermediary metabolism, transport defects or impaired receptors. The diagnostic procedure is complicated; the difficulty is the lack of sharp criteria for differential diagnosis, since the attendant symptoms are usually nonspecific. Comprehensive and specialized biochemical investigations therefore are the basis for the diagnosis of IMD. Using this approach, selective laboratory screening programmes can be prepared. The analytical programme includes a three-stage systematic procedure. Qualitative or semiquantitative procedures for urine metabolites are used when starting the investigation, the second step includes quantitative methods, while enzyme analysis or DNA testing belongs to the third stage, and completes the process of examination.

Multicomponent analysis of body fluids using gas and liquid chromatography combined with mass spectroscopy is the most important procedure used in the screening of IMD. However, at first one cannot do without simple and inexpensive methods like colour tests and thin-layer chromatography (TLC), which may give rapid qualitative information on metabolic conditions.

Selective laboratory screening concerns the analysis of individual groups of metabolites, usually those of amino acids and small peptides, catabolites of tryptophan, sugars, oligosaccharides, glycosaminoglycans, organic acids, purines and pyrimidines.

Separations are performed on pre-coated cellulose or silica gel high performance TLC (HPTLC) plastic or glass plates with or without fluorescent indicator F₂₅₄. The plates lay on a temperature-controlled surface (110–115°C), rapidly evaporating the elution solvent in the process of sample spotting. A volume, equivalent to a chosen amount of creatinine is used, when urine is applied.

Plates are developed with a mobile phase in either a horizontal DS chamber (Chromdes, Poland) or in a vertical pre-saturated glass tank. Chromatograms are dried and visualized under ultraviolet (UV) light of

$\lambda = 254$ and 366 nm and/or by spraying with a detection reagent. Reference standards are used for metabolite identification. Quantification is carried out by linear scanning with a TLC scanner, operated with a PC software package. Interpretation of results is made according to age, diet, therapy, clinical symptoms and elementary biochemical results.

Amino Acids

Two-dimensional ascending TLC on cellulose with ninhydrin detection is used as the first approach in the screening for amino acid metabolic disorders. As a rule, 10 μ L of plasma, serum, cerebrospinal or amniotic fluids (previously deproteinized with solid sulfosalicylic acid, 50 mg mL⁻¹) and a volume of urine, equivalent to 20 nmol of creatinine (previously desalted on Dowex-50WX8 in H⁺ form, eluted with 2 mol L⁻¹ ammonia) are applied to the 50 × 50 mm HPTLC cellulose layer. The plate is then developed in the solvent systems 2-propanol–formic acid–water, 80 : 4 : 20, in the first dimension and *tert*-butanol–acetone–25% ammonia–water, 50 : 30 : 10 : 10, in the second dimension. Chromatograms are sprayed with ninhydrin reagent, observed within 1 h and the next day, then heated for 3 min at 80°C (Figure 1). Aspartylglycosamine (in patients with lysosomal storage disease) can be detected as a blue-green spot when lightly overstained with a mixture of concentrated acetic and hydrochloride acids, 4 : 1 and heated at 60°C for 5 min. For detection of proline and hydroxyproline isatin (0.2 g in 100 mL acetone + 5 mL acetic acid) is recommended. When abnormalities are suspected, multiple spraying, in addition to ninhydrin, can be used: Ehrlich reagent (for tryptophan, hydroxyproline, citrulline and homocitrulline), Pauly reagent (for histidine and tyrosine metabolites), Sakaguchi reagent (for arginine) or platinum iodide (for sulfur amino acids).

Mono- and Disaccharides

The best results of screening for sugar defects have been achieved using two-dimensional vertical TLC on silica gel glass plates with orcinol detection.

Filtered urine is diluted with 2-propanol, 1 : 1, and an aliquot, equivalent to 5 nmol of creatinine (or alternatively 5 μ L equivalent of plasma, serum or cerebrospinal fluid, deproteinized with solid sulfo-

Figure 1 TLC of amino acids. The original 100×100 mm glass plate was divided into four by scraping off material. (A) Normal plasma; (B) normal urine (infant); (C) nonketotic hyperglycinaemia (urine, neonate); (D) leucinosi (urine, neonate). 1, Cys; 2, His + MeHis; 3, Lys; 4, Gln; 5, Ser; 6, Gly; 7, Tau; 8, Glu; 9, Ala; 10, Thr; 11, Tyr; 12, Phe; 13, Val; 14, Leu.

salicylic acid, 50 mg mL^{-1}) applied on the 50×50 mm layer. The plate is consecutively developed, with 0.5% boric acid in water-*n*-butanol-2-propanol, 20:30:50 (w/v) in the first direction and ethylacetate-acetic acid-water, 60:20:20 in the second direction. A freshly prepared mixture of orcinol (0.4% in ethanol, w/v) and concentrated sulfuric acid, 19:1, is used for detection. The plate is examined by transmitted light after 10 min warming at 100°C . Identification is made by comparison with standards, separated on the same plate (Figure 2).

Oligosaccharides

One-dimensional horizontal TLC on silica gel glass plates with fluorescent indicator F_{254} combined with orcinol or resorcinol detection is used for screening of certain lysosomal storage diseases and adenylosuccinate lyase deficiency. A supernatant of centrifuged native urine is applied in an amount, derived from urinary creatinine and the age (μL of sample = $40 \times F$ per concentration of creatinine in mmol L^{-1} ; $F = 0.75, 1, 1.5$ and 2 for the ages $< 1, 1-2, 2-8$ and > 8 years, respectively). The plate is developed twice under saturated conditions with a freshly prepared mixture of *n*-butanol-acetic acid-water, 4.5:2:2, with drying in between. The chromatogram is observed under UV 254 nm light to look for two dark bands of succinyl purines (absorbing at 254 nm)

below raffinose. The oligosaccharides are then visualized by spraying with orcinol in the same way as described for mono- and disaccharides (Figure 3). Positive finding in UV light leads to rechromatography and detection with Pauly reagent and naphthoresorcinol, warmed for 10 min at 100°C . The same chromatographic procedure is convenient for screening of sialurias if using resorcinol reagent. For this a mixture of 1% resorcinol in 95% ethanol, w/v, and 2 mol L^{-1} HCl, 1:9, with the addition of 0.1 mol L^{-1} $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ in water (0.025 mL per 10 mL of the mixture) is used. After spraying, the chromatograms are covered with glass and warmed at 120°C for 30 min. Pathological glycopeptides in urine (on α -*N*-acetylgalactosaminidase deficiency, aspartylglycosaminuria and fucosidosis) should first be detected by ninhydrin (see section on amino acids, above), then overstained with orcinol.

Glycosaminoglycans

One-dimensional multisolvent TLC on cellulose plastic sheet is one of the methods used for qualitative analysis of urinary glycosaminoglycans (GAGs, acid mucopolysaccharides), whenever the photometric screening test with azure A + B is repeatedly positive. GAGs are isolated from the sediment of centrifuged urine (10 mL aliquots of 24 h urine, adjusted to

pH 5.5) by precipitation with 0.2 mL 5% aqueous cetylpyridinium chloride for 4 h in an iced-water bath. The dry precipitate is washed using 10 mL of 95% ethanol (saturated with sodium chloride) then diethyl ether, with centrifugation, decantation and drying in between. The precipitate is dissolved in 0.6 mol L^{-1} sodium chloride (100 μL) and 10 μL aliquots are spotted on the layer. GAGs are successively separated (incremental distances of 2 cm for each run without intermediate drying) according to the solubility of their calcium salts in six solvents of decreasing ethanol concentration (1 mol L^{-1} acetic acid–calcium acetate (g)–95% ethanol, v/w/v; I, 30 : 1 : 70; II, 40 : 2.5 : 60; III, 50 : 2.5 : 50; IV, 60 : 2.5 : 40; V, 70 : 2.5 : 30; VI, 100 : 5 : 0). After the sixth run, the plate is dried and immediately stained by immersing in toluidine blue in ethanol–acetic acid for 3 min. Excess stain is removed by rinsing in 10% acetic acid and the air-dried plate is evaluated by comparing with standards and using a densitometer (Figure 4).

Organic Acids

One-dimensional sequential TLC on cellulose glass plates in a horizontal arrangement with aniline–xylose detection is used in the screening for pathological organic acidurias.

Plasma, cerebrospinal fluid or vitreous humour is deproteinized with 95% ethanol, the supernatant is evaporated at 25°C under nitrogen, dissolved in water and the equivalent of 1 mL of the native material is further processed. A volume of urine, equivalent to 2.2 μmol of creatinine, is made up to 1 mL with deionized water. All samples are then spiked with phenylbutyric acid as an internal standard, acidified to pH 1 with concentrated HCl and saturated with NaCl. Organic acids are extracted with 6 mL of diethyl ether–ethyl acetate mixture, 1 : 1 (vortexed, three times for 30 s). The supernatant is mixed with 100 μL of 1 mol L^{-1} ammonia solution in ethanol (to protect the volatile organic acids), concentrated under nitrogen at 25°C to 1 mL, and 20 μL aliquots applied on the plate. Development is performed under saturated conditions in four consecutive steps (development distances increased in 1 cm steps in each run with intermediate drying), using the mobile-phase *n*-propanol– 2 mol L^{-1} ammonia, 7 : 3. The plate is sprayed with aniline–xylose reagent (xylose and aniline in methanol) and evaluated with a densitometer (Figure 5).

Purines and Pyrimidines

Two-dimensional TLC on cellulose glass plates in the horizontal arrangement with UV detection at

Figure 4 (A) TLC of glycosaminoglycans, multiple development. A, standards; B, control urine; C, mucopolysaccharidosis I-H. 1, dermatan-; 2, chondroitin-4-; 3, heparan-; 4, chondroitin-6-; and 5, keratan sulfates. (B) Densitogram of lane A; (C) densitogram of lane C.

254 nm is used to screen purine and pyrimidine defects. After 3 days on a low purine diet, 24 h urine is collected, warmed for 30 min at 50°C to dissolve precipitates and a filtered sample, equivalent to 50 μmol creatinine, spotted on the layer. The mobile phase is *n*-butanol-methanol-water-25% ammonia, 40:20:20:1, developed twice with 15 min drying between each run for the first direction and 2 mol L⁻¹ ammonium sulfate in water for the second direction. Chromatograms are evaluated under UV light and by comparison with an age-control urine and the nucleoside and base standards, separated in parallel (Figure 6). For further identification, chromatograms are sprayed with mercuric acetate in 95% ethanol, then immediately with diphenylcarbazone in 95% ethanol and heated at 120°C for 10 min.

Tryptophan and its Metabolites

Screening method for both indolic and kynurenine metabolites of tryptophan (Trp) in urine is based on

Sep-Pak C₁₈ pretreatment, two-dimensional TLC on cellulose and detection at 254 and 366 nm, followed by staining with Ehrlich reagent. A volume of urine, equivalent to 2 μmol of creatinine, is acidified to pH 3.5 and the clear supernatant applied on the Sep-Pak cartridge. Impurities from the sample are washed out, successively with sodium dodecyl sulfate (SDS) and SDS-methanol. The Trp metabolites are eluted with a mixture of 1 mol L⁻¹ ammonia and methanol (8:2). After evaporating the solvent under nitrogen the residue is dissolved in 250 μL methanol. An aliquot of 20 μL is applied on the dry cellulose layer, previously washed with deionized water. The plate is subjected to ascending development under saturated conditions at 4°C with two 0.2 mol L⁻¹ sodium acetate buffers: pH 6 for the first and pH 3.3 for the second direction. The air-dried plate is examined under UV light (Figure 7) and then sprayed with Ehrlich reagent. Comparing the urine sample with a mixture of standards, identification of 13 metabolites of tryptophan is possible.

Discussion

The protein-free filtrate from plasma and other material must be prepared rapidly to avoid binding of sulfur-containing amino acids to proteins. Some

changes occur rapidly at room temperature or even when stored at -20°C for a week (glutamine and asparagine, in particular, disappear).

There are several amino acid metabolic disorders which can easily be detected solely by TLC screening

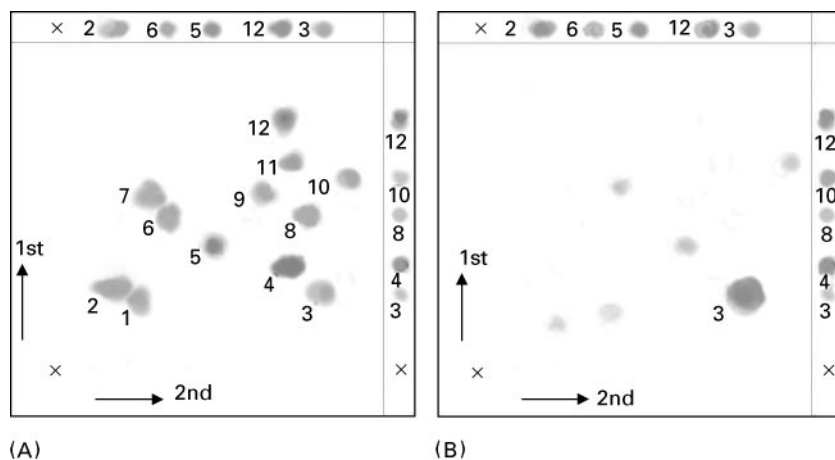

Figure 6 TLC of purines and pyrimidines. (A) Standards; (B) uric aciduria (adult). 1, xanthine; 2, guanine; 3, uric acid; 4, xantnosine; 5, hypoxanthine; 6, adenosine; 7, adenine; 8, orotic acid; 9, uracil; 10, cytosine; 11, inosine; 12, thymine.

Figure 7 Separation of some indolic and kynurenine metabolites of tryptophan, UV 254 nm detection. (A) Standards, (B) xanthurenic aciduria (urine, child). 1, indolylacryloylglycine; 2, xanthurenic acid; 3, kynurenine; 4, kynurenic acid; 5, 5-hydroxyindolic acid; 6, 3-hydroxyanthranilic acid; 7, anthranilic acid; 8, indoxyl sulfate.

of urine, plasma or cerebrospinal fluid, such as leucinosis, phenylketonuria (where infants have not had newborn mass screening), hypermethioninaemic or -uric conditions, iminoglycinuria or cystinuria. An increase of glycine indicates primary nonketotic hyperglycinaemia or can be a secondary indication of an organic acid disease. Plasma glutamine is an important indicator of disorders of ammonia removal. Amniotic fluid is useful for prenatal detection of citrullinaemia, argininosuccinic aciduria or homocystinuria. High glycine in urine during therapy with valproate or ninhydrin-positive metabolites of antibiotics may confuse the interpretation of results.

On other occasions TLC only leads to a suspicion of IMD and a more precise method (amino acid analysis or HPLC) must be used for final diagnosis.

TLC is a simple screening technique for sugars, provided that their precursors are present in food. Under normal conditions no melituria is detectable. In neonates, traces of lactose and galactose appear in urine. Malabsorption, sugar intolerance, type I tyrosinosis and liver diseases, besides the genetic defects in metabolism of sugars, are the conditions related to pathological melituria. Two ribose-containing succinylpurines appear as blue-grey spots close to saccharose and galactose on chromatograms from urine and cerebrospinal fluid of patients with adenylosuccinase deficiency (IMD of purines).

Further investigation of sugar defects can be performed by specific enzyme assays, GC and HPLC.

Only slight banding with the most prominent glucose below raffinose-tetrasaccharide is detectable in normal urine when analysing oligosaccharides. Diagnosis may be difficult in neonates, where physiological lilac bands should be differentiated from the brownish ones excreted in mannosidosis, or from the pink-brown stripes seen under fucosidosis.

It is possible to combine a successive detection in UV light and spraying by ninhydrin, orcinol and resorcinol without losing sensitivity substantially. Some authors emphasize the importance of sample desalting; we have not found this necessary, desalting may lose some metabolites.

The final diagnosis can be achieved by enzyme activity assessment or structural analysis of the excreted oligosaccharides by gas chromatography-mass spectrometry (GC-MS) or nuclear magnetic resonance spectroscopy.

Most of the mucopolysaccharidoses (MPS) known so far present patterns of urinary GAGs which are clearly different from normal, even if the total urinary GAGs are not always present in excess (some cases of type III MPS), or the typical component does not react (keratan sulfate in MPS type IV). On the other hand, some pathological chromatograms may not reliably differentiate between MPS types I and VI, for example, without enzyme analysis. The main advantage of TLC of GAGs is to facilitate selection of the probable defective enzyme to be analysed for the definite diagnosis.

Urinary organic acid analysis is a vital diagnostic tool in the investigation of patients with suspected IMD, although not many laboratories perform TLC of organic acids. We consider this approach to be an important and convenient way of getting prompt orientation, allowing exclusion of negative samples in the first place. In healthy controls, organic acids are present at trace levels, the most prominent being hippuric acid. Pathological specimens are conspicuous by either unusual or very dark bands. Unclear or suspicious results are further checked by GC-MS, employing the remaining sample which is immediately lyophilized after an aliquot has been applied on the TLC layer.

Organic acid analysis may help in the diagnosis of saccharides, amino acids, fatty acids and respiratory chain defects.

Using two-dimensional TLC, some purine and pyrimidine defects can be revealed. Unfortunately, specific and sensitive visualization agents of these strongly UV-absorbing substances are not available. Large unusual spots in urine are easily detectable, but some false positives, due to other metabolites, drugs or food additives, should be carefully interpreted and verified by HPLC. HPLC-MS combined with an ion exchange pretreatment of urine is a promising method for the final diagnosis of these defects.

Metabolites of Trp are difficult to analyse because of their instability and low concentration in urine. To minimize losses, bright light should be avoided throughout the procedure. The method used is simple and reliable enough to detect increased excretion of Trp metabolites. In the case of any abnormality observed, the same pretreated urine sample is further processed by HPLC.

Conclusion

TLC might seem to be slightly overshadowed since the introduction of more sophisticated methods in the screening of IMD. However, these methods are not available everywhere and their cost may discourage their use for screening, so that they are only applied in rather advanced cases. Using TLC, more samples can be separated simultaneously on one plate under identical conditions, which decreases the price per analysis. Horizontal arrangement of plates can be economically employed for routine use because mobile-phase consumption is very low. Availability of pre-scored layers makes analyses more flexible, more rational and economical. Advantages of HPTLC pre-coated layers, compared to the standard ones which were previously used, consist in sharper separation, shorter migration distance, minimal diffusion and increased detection sensitivity.

Various TLC techniques in screening for IMD have been described. In general, we prefer such procedures, when the sample, analysed by TLC, may be subject to more detailed analysis by HPLC or GC-MS, if necessary. Using creatinine concentration as a basis for the volume option of the urine processed, misinterpretation of results can be minimized.

In children with unexplained neurological disease it is highly recommended that amino acid and sugar analysis of cerebrospinal fluid and urine before and after acid hydrolysis is performed systematically. In this way defects of purines or (*N*-acetylated) amino acids and peptides can be detected by virtue

of a large increase in aspartate, glycine or ribose levels.

TLC represents only one part of the whole IMD screening procedure and it is necessary to emphasize that negative TLC results do not prevent more detailed investigation if the patient shows continuous signs of an acute disease or progression of neurological symptoms.

It should be emphasized that negative findings are also important, because metabolic disease can be excluded.

INCLUSION COMPLEXATION: LIQUID CHROMATOGRAPHY

Introduction

Liquid chromatography (LC) may be simply described as an analytical technique used to separate the individual components of a solution based on their relative affinities for a liquid mobile phase and a stationary phase. There are numerous modes of LC (i.e. reversed-phase, normal-phase, ion exchange) that are commonly classified according to the mechanism by which separation occurs. One such mechanism involves the formation of inclusion complexes. An inclusion complex can be defined as an entity, consisting of two or more molecules, in which one molecule, the 'host', noncovalently encapsulates or includes a 'guest' molecule. In chromatography, differences in the strength of binding between guest molecules or analytes and a specific host allow for separation. The purpose of this article is to review recent applications of inclusion complexation in liquid chromatography. Although a variety of small molecule interactions with macromolecules or polymers have been ascribed to inclusion complexation, the focus of this article is on well-defined host molecules.

Host Molecules

Currently, there is a variety of compounds that can serve as a host molecule in an inclusion complex, most of which may be grouped into one of four classes. These classes include cyclodextrins, crown ethers, calix[n]arenes and macrocyclic antibiotics. A representative structure from each class of hosts is shown in Figure 1. One characteristic shared by each class of host molecules is the ability to include selectively compounds on the basis of size and shape.

It is important to point out that many inclusion host molecules possess at least one chiral centre (e.g. macrocyclic antibiotics and cyclodextrins) and that the vast majority of applications lie in the area of chiral separations. Chiral molecules are those that can exist as nonsuperimposable mirror images, or enantiomers. It has been demonstrated that the enan-

tiomers of many chiral compounds exhibit different bioactivities and/or biotoxicities. It has also been demonstrated that enantiomers may exhibit different complex stabilities when included in a given chiral host. This fact, combined with an increased awareness of the implications of chirality, has led to the exploitation of inclusion complexation for chromatographic chiral separations. For this reason the emphasis of this article is placed on chiral applications, but some achiral applications are also presented.

Briefly, cyclodextrins (CDs), which are natural products, are cyclic oligosaccharides consisting of D-glucose rings linked through α -(1,4)-bonds. The glucose units are arranged in a toroidal structure best described as a truncated cone. The most common cyclodextrins are α -, β - and γ -CD which consist of six, seven and eight glucose rings, respectively. The interior of the cyclodextrin molecule is hydrophobic while the exterior is hydrophilic. Because a cyclodextrin consists of chiral D-glucose units, it constitutes a chiral host.

Crown ethers are perhaps best described as synthetic, heterocyclic macrocycles with repeating units of $(-X-C_2H_4-)$ where X is the heteroatom. In contrast to cyclodextrins, crown ethers are characterized by a hydrophobic exterior and a hydrophilic cavity. The cavity typically has a strong affinity for cationic species owing to electrostatic interactions between the cation and the heteroatoms of the crown ether. These characteristics of crown ethers have led to their use as phase transfer catalysts in organic synthesis.

Calix[n]arenes are synthetic, cyclic oligomers composed of phenolic units linked by methylene bridges. They may contain four to eight aryl moieties forming a macrocyclic structure with a central cavity. The inclusion interaction between calixarenes and various guest molecules is determined both by the cavity size and by the nature of the functional groups that act as binding sites. Although still relatively unexplored, the ability to functionalize calixarenes offers yet another method for the tailoring of chromatographic selectivity.

Finally, macrocyclic antibiotics typically possess numerous chiral centres that surround several pockets or cavities bridged by a series of aromatic rings. Like cyclodextrins, the macrocyclic antibiotics are also natural products. In contrast to other host molecules, native macrocyclic antibiotics incorporate ionizable moieties.

Figure 1 Representative structures of inclusion complex host molecules: [I], γ -CD; [II], a chiral crown ether; [III], a calix[4]arene; and [IV], vancomycin.

Currently there are two primary methods for exploiting inclusion complexation in LC. One method is the use of an inclusion host molecule as an immobilized ligand on a chromatographic sorbent. Stationary phases modified by cyclodextrin, crown ether, calixarene and macrocyclic antibiotic have all been reported. Alternatively, inclusion complex host molecules may be employed as mobile phase additives.

Historically, many of the hosts used to modify stationary phases originated as mobile phase additives, and thus will be considered first. Some advant-

ages and disadvantages of each method are outlined in Table 1.

Inclusion Complexation in the Mobile Phase

One approach to exploiting inclusion complexation in chromatography involves dissolving the host in the mobile phase. As indicated in Table 1, use of the host as a mobile-phase additive (MPA) instead of the cor-

Table 1 Advantages and disadvantages of using inclusion complex host molecules as mobile phase additives

<i>Advantages</i>	<i>Disadvantages/limitations</i>
Less expensive, conventional packed columns can be used	Possible interference with detection of analyte
Type and concentration of host are easily changed	Potential solubility problems
Wider variety of additives compared with stationary phases	Effect on mobile phase viscosity
Different selectivities relative to corresponding stationary phase	Impact on analyte recovery
	Large amounts of additive needed for column pre-equilibration

responding bonded stationary phase has a number of advantages and disadvantages, depending on the application. One of the primary reasons for utilizing the host as a MPA is that it offers more flexibility for the application, both in the type of host used and the concentration of the host. Unfortunately, the amount of additive needed to equilibrate chromatographic columns and to separate the samples can be very large, making this approach very costly. This is not a problem in thin-layer chromatography, since TLC plates do not require equilibration with the mobile phase. In either case, the presence of the additive in the mobile phase can complicate detection and analyte recovery.

Both cyclodextrins and macrocyclic antibiotics have been used extensively as MPAs, with cyclodextrins being the most widely used. Calixarenes and crown ethers have found more limited use as MPAs. The large absorption of the phenyl groups in the calixarene molecule makes it very difficult to detect the analyte by UV spectrophotometry owing to the high background. Crown ethers have been used to aid in the dissolution of buffers in strong organic systems and to assist in the partitioning of analytes

into the mobile phase. In one study, 18-crown-6 was used in the separation of carboxylated porphyrins. It was suggested that the crown ether could facilitate the partition of the porphyrins into the mobile phase through hydrophobic and polar interactions.

Cyclodextrins

Cyclodextrins are commonly used for the separation of enantiomers (chiral applications), but have also found use in the separation of geometric and structural isomers (e.g. α -pinene and β -pinene). Cyclodextrins can be used in their native form or as chemically modified additives. By derivatizing the outer rim hydroxyls of the cyclodextrin with various functional groups, the properties of the native cyclodextrins can be changed. Several representative examples of native and derivatized cyclodextrins, together with the types of molecules separated, are outlined in **Table 2**.

One of the main advantages to derivatization is the change in the solubility properties of cyclodextrins. Native β -CD, which is one of the most commonly used inclusion-type additives, has a very low solubility in aqueous-organic systems (solubility = 1.85 g

Table 2 Typical applications of native and derivatized cyclodextrins in liquid chromatography

<i>Cyclodextrin</i>	<i>Abbreviation</i>	<i>Applications</i>
Hydroxypropyl β -CD	HPBCD	Barbiturates, chlorophenols, amino acids, laser dyes, chlorophenols, hydantoins
Carboxymethyl β/γ -CD	CMCD	Steroidal drugs, amino acids
Water-soluble β -CD polymer	SCDP	Pesticides, barbiturates, chlorophenols, nitrostyrenes, tensides, cyclic hydrocarbons
Dimethyl carbamate β -CD	DMP	Radioligands
2,6-di- <i>O</i> -methyl β -CD	DIMEB	Barbiturates
Heptakis(2,3,6-tri- <i>O</i> -methyl) β -CD	TRIMEB	Tensides
Naphthylethyl carbamate β -CD	NEC-CD	Benzodiazepines, anesthetics, amines, amino acid esters, diuretics
Cationic β -CD		Amino acids, hydantoins
Acetyl β -CD		Anticancer drugs, aminoalkyl phosphonic acids, bronchodilators
Permethylated β -CD		Amino acids
Maltosyl β -CD		Amino acids, alkaloids
Sulfated β -CD		Anesthetics, antiarrhythmics, antimalarials, catecholamines, antidepressants, anticonvulsants, antihistamines
Native α -CD		Barbiturates, ArOH, tensides, terpenes
Native β -CD		Barbiturates, amino acids, PAHs, ArOH, aflatoxins, hydantoins, antiepileptic drugs, tensides, terpenes, alkaloids
Native γ -CD		Barbiturates, tensides, porphyrins, β -blockers

ArOH, aromatic alcohol.

per 100 mL of water, $\approx 16 \text{ mmol L}^{-1}$ solution). Solutions of derivatized cyclodextrins, however, can be made at concentrations as high as 400 mmol L^{-1} . It is important to note that these functionalized cyclodextrins are complex mixtures of reaction products. The increased solubility is a direct consequence of this product impurity. Unfortunately, the more concentrated cyclodextrin solutions have increased viscosity. Derivatization of cyclodextrins also affects its chromatographic selectivity, as a result of additional interactions made possible by the presence of various functional groups.

Liquid chromatography Thus far, of all the potential host molecules, cyclodextrins are the most extensively used MPAs in liquid chromatography. Most commonly, cyclodextrins are used as MPAs in the reversed-phase mode. The mobile phase typically consists of an aqueous buffer and an organic modifier. The cyclodextrin additive is included in the buffer component at concentrations appropriate to the application. In general, as the concentration of the cyclodextrin is increased, the enantioselectivity increases until an upper limit is reached. This is illustrated in Figure 2 for the separation of (\pm) - α -pinene. The organic component of the mobile phase should not form strong inclusion complexes with cyclodextrin as this will limit the interactions with the analyte(s) of interest. Large, bulky organic solvents should be avoided for this reason. Solvents typically used are methanol and acetonitrile, both of which form relatively weak inclusion complexes with cyclodextrins. Percentages of organic solvent used can be as low as 3% and as high as 45% in an isocratic mixture where gradients are not used. Typically, octadecylsilane (ODS) columns are used but other

Figure 2 Separation of α -pinene enantiomers using α -CD as a mobile phase additive: (A) 16 mmol α -CD; (B) 8 mmol α -CD; (C) No α -CD. (Adapted from Moeder C, O'Brien T, Thompson R and Bicker G (1996) Determination of stoichiometric coefficients and apparent formation constants for α - and β -CD complexes of terpenes using reversed-phase liquid chromatography. *Journal of Chromatography A* 736: 1–9).

bonded phases can be employed, depending on the application.

As mentioned, the use of cyclodextrins as MPAs allows the separation of enantiomers (e.g. (\pm) - α -pinene) and structural isomers. This allows the application of this method to many pharmaceuticals, pesticides and natural products. By varying the experimental parameters (type and concentration of cyclodextrin, percent organic solvent, etc.), information about the strength and stability of the complex can be obtained.

Mechanistic information about complex formation can also be obtained from the data. Frequently, a 1 : 1 host-guest complex is formed, but 2 : 1 complexes have been reported in the separation of terpenes and polycyclic aromatic hydrocarbons (PAHs).

Thin-layer chromatography Cyclodextrins can also be used as complex hosts in TLC. They are almost exclusively employed as MPAs rather than as bonded phases because there are no commercially available cyclodextrin bonded-phase TLC plates. The success of cyclodextrins may be partially attributed to their UV transparency.

Commercially available, reversed-phase plates are typically used. However, a 5% paraffin-hexane solution can be used to impregnate standard TLC plates for use as reversed-phase plates. The mobile phase is usually a water/organic solvent mixture with occasional use of buffers in the aqueous portion. As in column chromatography, the organic component is typically methanol or acetonitrile, and in some cases ethanol. The concentration of cyclodextrin in the mobile phase is usually less than 30 mmol L^{-1} and the choice of cyclodextrin concentration is governed by the same factors as discussed above for liquid chromatography. In general, as the concentration of the cyclodextrin is increased, the development time will increase due to the increased viscosity of the resulting solution.

The use of MPAs in TLC is often used to study the binding characteristics of various compounds to inclusion complex host molecules. This is typically accomplished using the following general equation (eqn [1]):

$$R_M = R_{M0} + bC \quad [1]$$

where R_M is the actual R_M value of an analyte determined at C (mmol L^{-1}) additive concentration; R_{M0} is the R_M value of an analyte extrapolated to zero additive concentration; b is the decrease in the R_M value caused by a 1 mmol L^{-1} increase of the additive concentration in the eluent (indicator of the complexing capacity); and C is the additive concentration in the eluent (mmol L^{-1}).

The slope value, b , is linearly related to the stability of the host-guest complex. For example, a wide variety of pharmaceuticals, nonionic surfactants (tensides) and substituted aromatics have been investigated by this method. Frequently, information is needed about the steric and hydrophobic character of various analytes. Host-guest binding constants can provide information about inclusion within the cyclodextrin cavity. Cyclodextrins have also been used to study the effects of inclusion on the stability and transport of drugs. It is known that cyclodextrins can influence many of the biological properties of drugs when a host-guest complex is formed. The uptake, adsorption properties and degradation of the drug can be modified by complex formation.

Cserhádi and Forgács recently studied complex formation between carboxymethyl- γ -cyclodextrin and steroidal drugs. They found that the cyclodextrin mediated the hydrophobicity of the drugs suggesting that the complexed drug may have a modified efficacy.

Macrocyclic Antibiotics

In contrast to cyclodextrins, which have been used for chiral as well as achiral applications, macrocyclic antibiotic MPAs have been applied exclusively to enantiomeric separations. Macrocyclic antibiotics such as vancomycin and erythromycin have been used to resolve enantiomers by TLC. The first macrocyclic antibiotic to be used as a MPA was vancomycin by Armstrong and Zhou in 1994. It was used as a chiral selector in the TLC resolution of dansyl-amino acids, 6-aminoquinolyl- N -hydroxysuccinimidyl carbamate (AQC)-derivatized amino acids, and several pharmaceutical compounds. The composition of the mobile phase as well as the nature of the stationary phase were found to affect chiral resolution for these compounds. The mobile phase consisted of 0.6 mol L^{-1} NaCl with acetonitrile concentration between 17 and 40 vol%. The purpose of NaCl was to stabilize the binder on the TLC plates. For some of the derivatives, a 1% triethylammonium acetate buffer (pH 4.1) was also needed. It was found that diphenyl-type bonded phases provided the best resolution of the compounds studied. For all the amino acid derivatives, the D-enantiomer had a larger R_F value than the L-enantiomer.

Inclusion Complexation in the Stationary Phase

As mentioned previously, no commercially available TLC plates incorporate inclusion complexation ligands. However, conventional TLC plates have

been coated with various inclusion host molecules. For example, erythromycin was used to resolve a variety of dansyl-DL-amino acids. By impregnating the plate with 0.05% erythromycin, resolution of the enantiomers of the amino acids was achieved in a relatively short time (20–25 min). A mobile phase consisting of 0.5 mol L^{-1} NaCl, acetonitrile and methanol was used for the separation with one amino acid requiring the presence of acetic acid for separation. The amount of NaCl solution used was generally 7–25 times the amount of acetonitrile used. Methanol was required in very small amounts in some cases. The resolution of the enantiomers was affected by small changes in the mobile phase composition, as is the case with most chiral separations.

Cyclodextrin Phases

Among the inclusion-type stationary phases, the cyclodextrin phases have been the most widely used and the most successful, specifically in the area of chiral separations. Most chiral separations reported on native CD phases (α, β, γ) have been accomplished in the reversed-phase mode using aqueous buffers with small amounts of organic modifier. β -CD is the most commonly used of the native cyclodextrins. The applicability of CD phases has increased with the development of strategies for derivatizing these compounds. Functionalized cyclodextrins have also been used in the reversed-phase, normal-phase, and nonaqueous reversed-phase modes.

The functional groups on derivatized CDs can play a variety of roles in enhancing enantioselectivity. In some cases the substituent provides additional sites for interaction or may enlarge the CD cavity, allowing inclusion of larger analytes. Reported applications of the cyclodextrin phases are seemingly endless. However, several general conclusions can be drawn based on applications along with the theoretical work done in this area. First of all, inclusion complexation is believed to be a significant interaction only when CD-bonded phases, native or derivatized, are used in the reversed-phase mode. Next, inclusion complexation requires that at least some portion of the analyte fits structurally into the CD cavity. Typically, the presence of an aromatic ring in the analyte molecule satisfies this condition. Results indicate that chiral recognition is enhanced if the stereogenic centre lies between two π -systems or is incorporated in a ring. The presence of secondary hydroxyl groups at the rim of the CD cavity allows for hydrogen bonding with polar molecules. Amine and carboxyl functional groups have been shown to interact strongly with those hydroxyl groups on na-

tive CD phases, while nitrate, sulfate, phosphate and hydroxyl functional groups seem to prefer inclusion. Finally, both flow rate and temperature are known to affect CD-based chiral recognition in the reversed-phase mode. The enantioselective inclusion properties of native CDs have rendered them quite useful as chromatographic substrates, and the ability to derivatize these macrocyclic compounds has made them extremely versatile as inclusion complex host molecules.

Crown Ether Phases

The use of crown ethers as inclusion complexation stationary phases for LC originated with the work of Cram and co-workers during the mid-1970s. They observed that these compounds, specifically tetra-naphthylated 18-crown-6-ethers, could form inclusion complexes with alkylammonium compounds and used this idea to develop a chiral stationary phase for the separation of enantiomeric amines. Initially, crown ethers were covalently attached to a silica gel or polystyrene matrix until it was realized that they could be dynamically coated onto reversed-phase packing materials. Eventually, this chiral crown ether stationary phase was made commercially available. Numerous applications have demonstrated the ability of this phase to resolve most primary amino acids, amines, amino esters and amino alcohols. **Figure 3** shows a chromatogram in which a series of three racemic amino acids are separated using an ODS column coated with the chiral crown ether, compound [II]. With respect to enantiomeric separations, the crown ether phase is unique in that it does not require that analytes possess an aromatic ring for the achievement of chiral separation. Optimum performance of the crown ether is observed in acidic mobile phases that ensure protonation of the primary amine

Figure 3 Enantiomeric separation of racemic amino acids: 1, D-arginine; 1a, L-arginine; 2, D-methionine; 2a, L-methionine; 3, D-tyrosine; and 3a, L-tyrosine. (Adapted from Shinbo *et al.*, 1987.)

functionality, which is included in the crown ether cavity. Typically, perchloric acid ($\cong 0.01 \text{ mol L}^{-1}$) with small amounts of acetonitrile or methanol is recommended as it provides better resolution and exhibits low UV absorption. A notable advantage of the crown ether phases is the commercial availability of both chiral configurations, so that the enantiomeric elution order can be readily changed.

Calix[n]arene Phases

Much like cyclodextrins, calixarenes are macrocyclic compounds that may be easily functionalized, which gives them great potential as stationary phase material. Unlike CDs, however, calixarenes have not yet been extensively employed in liquid chromatography, and therefore only a limited number of applications have been reported. The most successful applications have come with the calixarene chemically immobilized onto a silica gel matrix using a short hydrophilic spacer.

Successful separations of several classes of compounds including amino acids, polyaromatics, nucleosides and nucleobases using a *p*-tertbutyl calixarene-bonded phase indicated that this phase behaves primarily as a reverse-phase material. A typical chromatogram illustrating the separation of nucleosides on this phase is shown in **Figure 4**. In the same study, calixarene phases were reported to form strong inclusion complexes with sodium ions. The complexation with sodium presumably induces a conformational reorientation of the calixarene that increases its hydrophobic surface area, allowing for stronger interaction with hydrophobic analytes.

In another study using a calix[4]arene tetra-diethylamide phase, selective retention of Na^+ over other alkali metals and Ca^{2+} over Mg^{2+} was observed using only water as the mobile phase. Furthermore, addition of methanol to the mobile phase resulted in increased retention of NaCl while the retention of LiCl, KCl and CsCl was unaffected by methanol.

Macrocyclic Antibiotic Phases

Stationary phases based on macrocyclic antibiotics (MAs) such as vancomycin and teicoplanin were introduced by Armstrong in 1994. Now commercially available, and used almost exclusively for enantiomeric separations, these phases are typically referred to as the ChirobioticTM phases. **Figure 5** illustrates a chiral separation of bromocil, devrinol and coumachlor on a vancomycin stationary phase. Chiral selectivity with these phases is demonstrated in

Figure 4 Separation of four nucleosides using a calixarene-bonded phase: cytidine (C), uridine (U), guanosine (G) and adenosine (A). (Adapted from Friebe *et al.*, 1995.)

the normal, polar organic and reversed-phase modes, allowing for the separation of a large variety of chiral analytes. The complexity of the antibiotic structures provides a number of potential interactions that may assist in separation, only one of which is inclusion complexation. Furthermore, an inclusion mechanism is likely to play a role only in the reversed-phase

Figure 5 Enantiomeric separation of (1) bromocil, (2) devrinol and (3) coumachlor using a vancomycin stationary phase. (Adapted from Armstrong *et al.*, 1994.)

mode, hence this discussion will be limited to the reversed-phase characteristics of these phases.

A great deal of success has been attained with MA phases for the chiral separations of neutral molecules as well as amides and esters. Table 3 lists the conditions for several representative examples of chiral separations accomplished on a vancomycin-bonded phase.

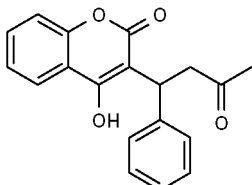

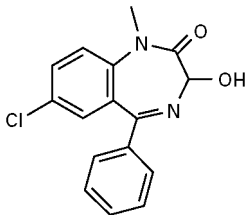

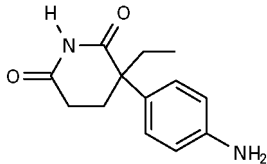

In terms of optimization and method development, retention can be controlled by adjusting the amount of organic modifier in the mobile phase. Selectivity is controlled by the type of buffer, the type of organic modifier and the pH. Both efficiency and selectivity are affected by the buffer type, ionic strength, flow rate and temperature. Tetrahydrofuran is reported to be the best overall starting organic modifier for efficiency and selectivity, but acetonitrile, methanol and ethanol have also been used with success.

It is important to note that these MAs can also be derivatized to alter enantioselectivity, which will undoubtedly increase the number of potential applications. Furthermore, the relatively small size of these molecules together with the fact that their structures are known increases the feasibility of performing mechanistic studies on chiral recognition.

Conclusions and the Future of Inclusion Complexation in Liquid Chromatography

The inclusion properties of several macrocyclic compounds with guest molecules have been extensively utilized in liquid chromatography. This has been accomplished by employing potential inclusion hosts as mobile-phase additives or as immobilized ligands on the chromatographic stationary phase. The presence of these macrocyclic host molecules in the mobile phase can interfere with analyte detection. Hence, most applications of inclusion complexation in liquid chromatography employ and will continue to employ immobilized ligands. While the commercial availability of the cyclodextrin, macrocyclic antibiotics and crown ether phases has no doubt contributed to their widespread exploitation, the calixarene phases may become more useful in the future as their properties become better understood. Certainly, the calixarene structure is more amenable to intelligent design than the naturally derived macrocyclic antibiotics or cyclodextrins. Inclusion complexation technology has been most extensively used in the area of chiral separations. Derivatization of macrocyclic compounds, such as cyclodextrins, macrocyclic antibiotics, crown ethers and calix[*n*]arenes has further enhanced their chromatographic utility.

Table 3 Applications of macrocyclic antibiotic-bonded phase

Compound	Structure	<i>k</i> (1st enantiomer)	α	Mobile phase	pH
Warfarin		1.98 2.27	1.70 1.44	10% ACN/ 90% buffer	7.0 4.1
Temazepam		1.17	1.06	10% ACN/90% buffer	7.0
Aminoglutethimide		0.79	1.15	10% ACN/90% buffer	7.0

The buffer is 1% triethylammonium acetate. The column used was a 25 cm \times 4.6 mm i.d. vancomycin stationary phase.

IN-DEPTH DISTRIBUTION IN QUANTITATIVE TLC

I. Vovk and M. Prošek, National Institute of Chemistry, Ljubljana, Slovenia

Copyright © 2000 Academic Press

Among many techniques used for quantification of thin-layer chromatograms, slit-scanning densitometry is the most common. It gives the opportunity to choose between either reflectance or transmission mode according to the nature of the supporting material. For instance, glass-backed plates can only be used for transmission measurements above 320 nm due to absorption of the UV radiation, while aluminium-backed plates are opaque at all wavelengths.

The matrix of sample and stationary phase, which consists of small particles, is optically opaque and strongly light-scattering. Therefore, densitometric measurements of separated substances are much more difficult than equivalent photometric measurements in solution. A further problem with densitometry is the fact that it is unable to detect the vertical and radial concentration profiles of the separated substance within the spot as a result of diffusion and the chromatographic process.

Reflectance and transmission are particularly sensitive to changes in sorbent quality, thickness, spot shape and size, eluent and development conditions. To reduce the errors due to plate-to-plate variation, standards should always be applied to the same plate as the unknown samples. The errors due to migration differences as a result of edge effects, deviations in layer thickness and nonlinear solvent fronts can be further minimized using the data-pair technique introduced by Bethke and co-workers in 1974. This technique is based on an internal compensation, by pairing up the measurements of two spots on the same plate.

Most thin-layer chromatography (TLC) analysis is performed in the UV and visible spectral region by applying reflectance scanning densitometry. However, the results of reflectance measurements are restricted to the surface of the sorbent on the TLC plate and are therefore strongly dependent upon the in-depth distribution of the analysed compound inside the sorbent. Nonuniformity of the in-depth distribution of a compound inside the sorbent as a result of secondary chromatography can occur during the evaporation-drying stage. Differences in the in-depth concentration profiles of the samples and stan-

dards can cause significant errors and cannot be completely eliminated by the data-pair technique.

Theoretical Problems of Optical Scanning Densitometry

All optical methods for the quantitative evaluation of planar chromatograms are based on measuring the difference in optical response between blank regions of the stationary phase and regions with a separated substance. When monochromatic light falls on an opaque medium, some light may be reflected from the surface, some may be absorbed by the medium and converted to heat, and the remainder is diffusely reflected or transmitted by the medium. Regularly (specularly) reflected light does not give any useful information of the sample distributed within the sorbent, however, it can contribute to the noise signal in scanning densitometry as it cannot be distinguished from the diffusely reflected light. Quantification in TLC is based on measuring the diffusely reflected or transmitted light and assuming that the specularly reflected component from the sorbent is very small.

The propagation of light within an opaque medium is a very complex process that can be mathematically solved only by assuming certain simplifications. The transmission and reflectance of light in highly scattering media has been discussed by Chandrasekhar (1950) in his book on radiative transfer, where he gives the basic integro-differential radiation transport equation. As this equation has no analytical solution, all useful equations and theories have been developed by simplifying the actual case.

Continuum theories of absorption in opaque media, such as Kubelka-Munk's theory, are not appropriate for quantitative TLC. Although they describe the absorption and scattering properties of the medium, they do not take into account the interaction of light with individual particles in the layer and the very important problem of nonuniform in-depth distribution of a compound within the sorbent. Bodo, Johnson and Melamed have developed well-known discontinuum theories for the determination of absolute optical constants from the properties of individual sample particles. In 1968 Goldman and Godal published their paper on the theoretical basis of measurements by optical transmission and reflection in silica gel layers using a modified

Kubelka-Munk equation. The theoretical background of *in situ* evaluation of thin-layer chromatograms was described by Kortüm in 1969.

Theoretical studies of the problems in light scattering are important in order to reach an understanding of the measuring principle and to help the analyst to find more precise methods of evaluating the data. However, one of the main difficulties is the fact that the adsorbed substance is never homogeneously distributed over the whole sorbent which is required in theory for a relationship between reflectance and concentration of the adsorbed substance.

Multilayer Models

The effect of the concentration gradient of the substance on the intensity of the signal in reflectance and transmission measurements has been studied by a number of authors. Most have studied the theoretical aspect of this problem. Nevertheless, using different approaches, they have all come to the same conclusion. They showed that densitometric transmittance measurements and fluorescence measurements from the far (nonilluminated) side of a plate yield results which are almost independent of the in-depth distribution of the analysed material. In contrast, the densitometric reflectance and fluorescence measurements from the near (illuminated) side are strongly dependent on that distribution. They suggested using transmittance or fluorescence transmittance mode whenever there are reasons to suspect a non-homogeneous distribution of concentration or a changing coefficient of fluorescence of the separated material in the depth of the chromatogram.

However, as already pointed out, most densitometric measurements are performed in reflectance mode, and are therefore restricted only to the surface of the sorbent. It is for this reason that differences in the in-depth distribution of compounds (samples and standards) can cause erroneous results. Prošek and his co-workers have investigated the effect of the concentration gradient on the intensity of the diffusely transmitted and reflected light. They solved multilayer models using the mathematical theory of Bodo and Markov chains. In such a model a chromatographic band was placed in different sublayers (Figure 1). Although their equations do not offer any improvement from a practical point of view, they show the effect of the concentration gradient in the sorbent layer that the Kubelka-Munk theory cannot. The practical application of their theory was confirmed using the real models prepared from different kinds of layers (paper and TLC sorbents). The results obtained from these real models were in good agreement, confirming theoretical

Figure 1 Schematic presentation of a multilayer model. I , incident beam; R , reflected beam; T , transmitted beam.

results and showing that reflectance densitometric measurements do not take into account the vertical subsurface concentration distribution.

Further investigations have been made with image analysing systems, an emerging detection technique in TLC. In the case of image analysing systems, higher radiation fluxes must be taken into account as the result of the illumination of a whole plate. Compared to slit-scanning densitometry, the intensity of diffuse light inside the illuminated layer is much higher, as higher numbers of reflected beams come from all parts of the layer. The results obtained by measuring multilayer models with a charge coupled device (CCD) camera (Figure 2) showed the effect of the position of the spot inside the layer on the signal. As can be seen from Figure 3, the intensity of the signal in the reflectance measurements is highly dependent on the position of the spot inside the layer. This has confirmed that differences in the in-depth distributions of standards and samples can cause significant errors in reflectance quantitative TLC. On the other hand, the position of the spot inside the layer has almost no effect on the signal in transmittance measurements.

Secondary Chromatography

While drying a TLC plate, molecules of compounds are moving with the evaporating mobile phase in the direction of the sorbent's surface. This process is called secondary chromatography and results in inhomogeneous vertical distribution of compounds inside the sorbent. This effect is bigger for compounds having high R_F values in the solvent being evaporated.

Variations of in-depth distribution have a big impact on densitometric reflectance measurements. This

Figure 2 CCD images of a 10-layer model while measuring reflectance (R) and transmission (T) with a Camag video documentation system.

is one of the reasons for the nonlinearity of calibration curves and may lead to the erroneous interpretation of TLC chromatograms by reflectance densitometry. It is therefore very important to find drying conditions which will give TLC plates with the most homogeneous and consistent depth distribution of compounds.

Depth Profiling of TLC Plates by Photoacoustic Spectroscopy

Preliminary investigations of nondestructive depth profiling of TLC plates have been performed. The results obtained using different photothermal techniques, showed that photoacoustic spectroscopy (PAS) is most suitable for characterization of TLC

plates. Although PAS has been used previously for the qualitative and quantitative spectroscopic analysis of TLC plates, the first results of photoacoustic depth profiling of TLC plates have only recently been published.

PAS is a photothermal technique, which relies on the detection of pressure waves (sound) generated by the absorption of radiation in a periodically irradiated sample. It has the capability for *in situ* and nondestructive depth profiling of solid samples. This unique feature is due to the fact that the magnitude of the induced photothermal effect depends on the concentration and on the thermal diffusivity of a compound. The plot of the dependence of the photoacoustic (PA) signal on the modulation frequency provides information about the depth profile of the analysed compound.

Figure 3 The effect of the spot position in the 10-layer model on the reflectance (circles) and transmission (squares) measurements with a Camag video documentation system.

Copyright Research Institute for Medicinal Plants in cooperation with Springer Hungarica.)

The PA signals were analysed using the theory for a two-layer model consisting of the sorbent and the glass as the supporting material. Thermal diffusivity values (α) of the spots on TLC plates were obtained by curve fitting of normalized phase lags of PA signals. Different thicknesses of sample, corresponding to the thermal diffusion length μ , given as $\mu = \sqrt{(\alpha/\pi f)}$, were probed by varying the frequency (f) of the laser beam modulation.

The PA signals originating from different layers of a TLC plate were calculated by subtracting the values obtained at higher modulation frequencies

from those obtained at lower frequencies. From these two modulation frequencies and the previously obtained thermal diffusivities of each spot, the depth and thickness of each layer can be determined. Depending on the available range of modulation frequencies used in the PA measurements, the thickness of the probed layers varied from 23 to 37 μm . All the results were corrected for differences in layer thickness.

In-Depth Distribution of Compounds Inside the Sorbent and Quantitative TLC

The effect of nonhomogeneous in-depth distribution of compounds on quantitative TLC has been studied on TLC and high performance TLC (HPTLC) plates using the separation of a test dye mixture (Figure 4). The results of PA investigations showed that all compounds exhibited nonhomogeneous concentration profiles in a vertical direction. Although all the investigated compounds tended to concentrate in the upper 25% of a 250 μm thick layer, secondary chromatography can lead to deviations from this behaviour. Additionally, differences in the in-depth concentration distribution of different compounds on the same TLC plate were seen (Figures 5 and 6). While the yellow dye spots concentrated in the top 31 μm layer, the highest concentration in the violet spots was observed in the region between 39 and 61 μm . This indicates that the effects of secondary chromatography depend strongly on the properties of the compounds in each spot. The situation is different in the case of HPTLC plates, where

even the violet spots tends to concentrate in the upper, 0–37 μm layer (Figure 7). Different in-depth distribution of compound inside the sorbent of TLC and HPTLC plates can be explained by 50 μm differences in the layer thickness. In the case of the thinner layer of the HPTLC plate, the evaporation of the mobile phase is faster and causes faster movement of the substance to the surface of the plate. Differences in PA signals from the same depths were observed for spots from different tracks. This

indicated that nonuniformity within one TLC plate could be the source of erroneous quantification in scanning densitometry (Figures 5–7). Additionally, when monitoring only the surface of the TLC plate, by reflectance densitometry, such irregular vertical concentration distribution can result in the nonlinearity of calibration curves (Figure 8). For the same reasons a nonlinear calibration curve is obtained by PAS, when the probed sorbent layer is too thin (top curve in Figure 9). Taking into account all the con-

siderable irregularities in vertical concentration distribution (61 μm) by PA probing of thicker sorbent layers (lower curves in Figure 9) leads to improved linearity of calibration curves compared to those obtained by reflectance densitometry.

Our investigations confirmed that in TLC not only accurate application, development and quantitative

evaluation, but also accurate drying are essential to obtain good results. Unfortunately, up to now the importance of this procedure has not been fully appreciated. The effects of drying process on the in-depth distribution of compounds inside the sorbent on HPTLC plates has therefore been investigated for drying in a dryer, in a stream of warm air

and in ambient air. The results obtained by PAS studies from different HPTLC plates were compared to those obtained by reflectance densitometry.

A comparison of the response areas was obtained for five violet dye spots from HPTLC plates dried in ambient air (A), in a stream of warm air (W) and in a dryer (D). The highest relative standard deviation (RSD) values were obtained for the plate dried in a stream of warm air (Table 1). The RSD for drying in a dryer was significantly lower than the RSD values for drying in the ambient air or in the stream of warm air. This can be explained by the nonuniform drying conditions across the HPTLC plate while drying in a stream of warm air.

The results of PA measurements are presented in Figure 7. For most of the tracks on all three HPTLC plates, the highest PA signals were detected in the top 37 μm thick layer. Significant differences in PA signals were observed under different drying conditions in the top 62 μm layer of the sorbent. Differences in the in-depth distribution of compounds due to variations of drying conditions across the same HPTLC plate are especially remarkable when the results for all five tracks from one plate (A, W or D) are compared (Figure 7). The largest variation was observed between tracks on the HPTLC plate dried in the stream of warm air. The most reasonable explanation for the large differences in PA signals observed between the plates dried in ambient air and those dried in a dryer or in the stream of warm air is the difference in radial distribution of the compound within the spots. When a TLC plate is dried in ambient air, the compound is radially distributed over a larger area as a result of diffusion. In the case of drying in the dryer and drying in a stream of warm air, the spots are shrinking due to migration of molecules in a radial direction towards the centre of the spot. This results in an increased concentration, and therefore higher PA signals (Figure 7), when the radius of the laser beam is smaller than the spot radius, as was the case. In the case of densitometric

measurements the probed area is larger than the diameter of a spot so that radial changes in concentration cannot be observed.

The magnitude of secondary chromatography, and consequently the vertical as well as the radial concentration distribution of compounds in the sorbent, depends on drying conditions. It also depends on the properties of the analytes and the type of TLC plate (TLC or HPTLC). Drying in a dryer gives the most reproducible results, while drying in a stream of warm air gives the least reproducible results.

Future Trends

We anticipate that in-depth distribution will have less effect on quantitative TLC in the future, because developments in the field of TLC plates is focused on producing thinner layers by using stationary phases with a smaller and more defined particle size. However, until this is achieved, further studies of secondary chromatography are necessary.

In addition, the wider use of image-analysing systems, mostly working in the visible part of the spectrum, will increase the number of methods using postchromatographic derivatization and quenching techniques. These procedures should also be tested by PAS to elucidate their effect on the in-depth and radial distribution of compounds on TLC plates.

INDUSTRIAL ANALYTICAL APPLICATIONS: SUPERCRITICAL FLUID EXTRACTION

M. E. P. McNally, DuPont de Nemours, Wilmington, DE, USA

Copyright © 2000 Academic Press

By the mid-1980s, routine analysis was accomplished in most industrial laboratories with the help of automated sampling and data-handling systems. The next major bottleneck caused by the burden of large sample loads that existed in many industrial environments was sample preparation and the method development time associated with it. Robots and automated systems were introduced to address these bottlenecks. Supercritical fluid extraction (SFE) was one of the automated systems introduced.

The initial introduction of SFE was unique, in that supercritical fluid chromatography (SFC) was developing at a parallel pace. Both introductions into the analytical community produced scientists who needed to learn the nuances of a totally new fluid, its capabilities, limitations, likeness to and difference from both gases and liquids.

SFE was embraced more readily in the industrial community than SFC. The reasons for this, in its utility as well as its developments, are considered in more detail in this overview.

Actual industrial applications of any analytical technology are sometimes well-guarded secrets. References can come from a variety of sources, not necessarily the published literature. Trends in the applications of SFE are no different. The most use has been in the food industry and the environmental area. Additional ap-

plications to a lesser extent are in polymer analysis, consumer products and pharmaceuticals.

Beyond the ability to conduct an analysis previously unachievable, the driving force for the adaptation of a technique into the industrial laboratory depends on a financial benefit. SFE has solved some problems that could not previously be solved. But it has mostly gained an industrial foothold by offering worthwhile cost savings over the already acceptable methodology, such as liquid extraction.

Instrumental Developments

In the development of SFE, industrial applications were the driving force to the advancement of commercial instrumentation. Initial offerings of commercial equipment involved cumbersome sample vessels with a myriad of problems. Not uncommonly, these were placed in single-vessel extraction units. At most, the instrumentation was capable of conducting SFC following the supercritical extraction. Speeds of analysis were typically measured by actual extraction time, and not overall sample handling, operator time or productivity. In this early equipment, productivity was not truly improved and industrial acceptance was slow. This equipment was only viable for those extraction methods that could not be conducted by another extraction solvent, i.e. a liquid or a gas. This led SFC, where both liquid and gas chromatography had a strong hold in the separation field, to be labelled as a niche technique. In the sample preparation field, where alternative automated extraction methods with liquids and gases were not as firmly

established, the competition was not as fierce for SFE.

Two paths were chosen. Work ensued to optimize the capabilities of supercritical fluids to encompass those compounds that might be more readily extracted by a liquid or a gas as opposed to a supercritical fluid. In addition, to compete with existing technology, albeit even classical liquid extraction, SFE needed to be able to routinely handle a larger volume of samples than was possible with these early instruments.

The first path necessitated a study of the theory and principles of supercritical fluids in terms of their solubilizing powers, matrix interactions, change with modifier or additive additions and their handling. These are generally considered academic endeavours, but much of this occurred in the industrial environment strictly out of need. Simply, it was cost-beneficial to use SFE over the classical technology. SFE was demonstrated to be a factor of 2–5 times cheaper per analysis but, more importantly, it was demonstrated to reduce classical liquid extraction method development time by 3–5 months. Reducing man-months in the process of reaching a product to market is a critical success factor in business. Not only is labour costly, but timing influences the introduction of product to market, the return of capital investiture and the ability to outpace the competition. This tremendous cost benefit resulted in industrial work on understanding some of the theoretical principles which would have otherwise been more slowly developed in academia.

Beyond the theoretical principles, the biggest single improvement, achieved through the second path, was the incorporation of the sample carousel. Easily adapted from the principle of commercial autosamplers, the carousel not only increased the total number of samples that could be analysed, but enabled unattended method development in the most labour-intensive portion of chemical analysis, the extraction step. Replicates of this have already spilled into other technologies, such as pressurized liquid extraction, but SFE was the first to utilize this feature in sample preparation.

A technique such as SFE is unlikely to survive in the industrial environment without the development of commercially available instrumentation. In the late 1980s, the market place had several key manufacturers developing and selling suitable equipment. More than a decade later, some of these have merged, some have reduced their efforts, some have retreated and concentrated on more commercially profitable areas. What remains are some well-designed pieces of instrumentation, directed at specific application areas, as in the fat analysers currently of-

fered by Leco and Isco/Suprex. In addition, there are small suppliers whose instrumentation tends to be less expensive but less amenable to adapting to large routine applications.

The development of SFE is by no means complete, nor can the technology be considered mature. Much of the theoretical questions have returned to academia, progress will be slower, but breakthroughs can still be expected. Much of the development in industrial supercritical fluids is currently in process and larger scale and analytical developments will follow these trends.

Industrial Applications

Successful applications have been readily demonstrated in some fields, specifically with environmental and food samples. Other applications have been more difficult to achieve and reproduce. The following applications outline some of the well-known uses of SFE.

Food Industry

Fat analysis Fats, lipids and oils have been extracted from a wide variety of foods from soybeans to oats, corn chips to brownies and meat to meat by-products and fish. Literature reports optimize the pressure and temperature of the extraction, the length of the extraction, the sample weight, the flow rate and the collection mode. Dynamic and static modes of extraction have also been investigated. Percentages of fat have been removed from sample matrices up to the 35% level; typically, gravimetric analysis follows the extraction procedure at these levels. Commercial manufacturers of foodstuffs are required by law to report percentage of fat on the package label. SFE has revolutionized this methodology. An American Society for Testing and Materials (ASTM) method for determining fat in certain selected foodstuffs has been accepted.

The nonpolar nature of fat, lipids and oils makes them extremely amenable to SFE. Liquid extraction of fat from foodstuffs is conducted using hexane solvent. Supercritical carbon dioxide has equivalent solubility properties, i.e. Hildebrand solubility parameter, to liquid hexane at low densities. Total fat analyses as well as the relationship of different lipid classes in foodstuffs have been determined. **Figure 1** shows the dynamic extraction profiles for the removal of triglycerides from 0.5 g of pork loin. As expected, higher densities give higher extraction efficiencies in shorter time periods. Although a time of 100 min may seem excessively long, compared to the classical techniques the time was orders of magnitude less. **Figure 2** compares SFE technology

Figure 1 Extraction profiles for different densities. Circles, 105 bar (0.45 g mL^{-1}); squares, 134 bar (0.65 g mL^{-1}); triangles, 370 bar (0.91 g mL^{-1}). Pork loin 0.5 g. Dynamic extraction with pure CO_2 . Flow rate: 2 mL min^{-1} , temperature: 50°C , trap: octadecyl-silica, trap temperature: 50°C , nozzle temperature: 55°C , rinse solvent: cyclohexane at a flow rate of 1.0 mL min^{-1} , eluted volume: 1.4 mL .

versus the two classical methods for fat analysis: SBR (Schmid, Bondzynski and Rutzlaff) and the popular Bligh & Dyer (B&D) for six different samples. A paired sample *t*-test demonstrated no significant difference at the 95% confidence level for SFE versus the classical methods.

Decaffeination Commercial decaffeination of coffee, tea and cocoa using supercritical carbon dioxide has been the object of huge industrial effort. Patents have been issued since 1974 in this area, to assignees such as General Foods and Société d'Assistance Technique pour Produits Nestlé. In Germany, there is a plant able to decaffeinate approximately 27.3 million kg of product per year.

There is a substantial effort to make sure the process works and is cost-effective. It is also the first example of a commercial scale supercritical fluid process. Without a doubt, the analytical departments of the commercial operations are examining the effectiveness of supercritical fluids in both analysis and process development, but the work is rarely talked about outside individual commercial enterprises.

Not surprisingly, then, the first example of routine SFE in analysis was in the removal of caffeine from food products. Caffeine, a moderately polar molecule, would not structurally be chosen as likely to have a high solubility in supercritical carbon dioxide. The commercial and analytical scale extraction of caffeine from coffee requires the addition of water as does the extraction of caffeine using methylene chloride. Reports have suggested that there is a chemical bonding of caffeine to the coffee bean or that the moisture instigates a swelling to free the entrapped compound. In either case, this landmark extraction process had opened up the understanding of SFE; overcoming chemical interactions and access to the matrix in total are important features in the investigation of SFE.

Environmental Analysis

Soil analysis Environmental applications of SFE have attracted the largest effort. Soil has received the most attention; it is one of the most difficult matrices and one of the most frequently analysed. Soil types vary widely in both their chemical and physical properties, depending on their geographical origin and their unique history. All extraction methods for soil show wide variability of recoveries and standard deviations of $\pm 30\%$ are not uncommon. In general, the advent of SFE, which was the first analytical

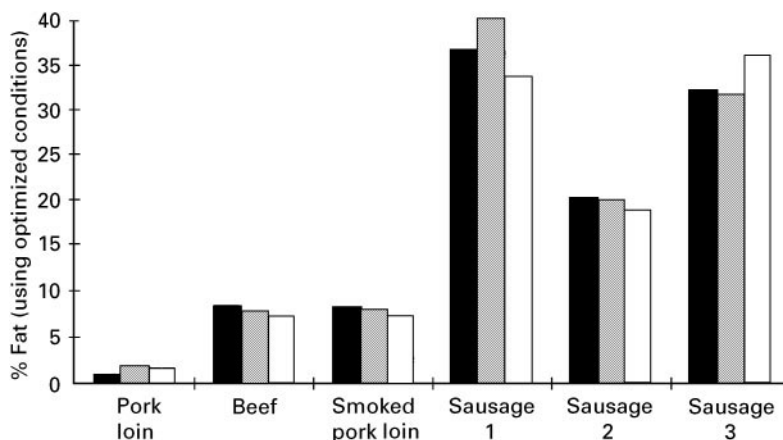

Figure 2 Comparison of total fat determination between SBR (filled columns), SFE (cross-hatched columns) and B&D (open columns). The samples were mixed with Hydromatrix (1 : 2 w/w) and 1 mL cyclohexane was added. Flow rate was 4.0 mL min^{-1} . 8% ethanol was used as modifier; the analytes were collected directly in vials; the rinse solvent pump was operated at 2 mL min^{-1} ; other conditions as outlined for Figure 1.

technology for automated soil extraction, reduced this variability to 10–20% within individual soil types. This reduced variability makes differences in extraction from different soils more apparent and gives rise to an understanding of the individual soil parameters controlling extraction.

Analytes of different polarities have been extracted with a wide range of supercritical fluid polarities. Unmodified carbon dioxide showed the best extraction reproducibility, while modified carbon dioxide demonstrated the ability to overcome active sites in the matrix or contribute to desirable matrix swelling. Additives, which show drastic effects in chromatographic retention, also show effects in SFE.

As with other extraction technologies, analytes in spiked samples are easier to recover than are real residues. Bound residues still exist with SFE, but with tighter precision a greater understanding of bound versus available residues has been obtained.

In terms of applications, wide variety of analytes from very nonpolar polychlorinated biphenyls (PCBs) to very polar herbicides have been extracted successfully. Again, optimized conditions show the wide range of polarizability that can be obtained with modified carbon dioxide mobile phases. **Table 1** gives a small example of the wide range of compounds that have been extracted from soils and the pertinent conditions. Multi-analyte methods are the norm, and coupled with liquid, gas and SFC, the methods are rugged.

Water analysis Aqueous samples have been extracted using supercritical fluids in several distinct methods. The first method is to place the liquid in the extraction vessel. The supercritical fluid either percolates through the matrix from a bottom entry port to a top exit or, in an opposite fashion, is introduced through the top of the vessel, contacting the sample for a specified period of time before it exits. Sulfonyleureas have been extracted from aqueous matrices using a system with a bottom entry and top exit. Flavour components of orange and lemon juice have used the top entry bottom exit format. Alternatively, some workers have passed the liquid either through a filter, pre-coated disc, or a separation cartridge. These trapping materials are then placed separately into extraction cartridges before introduction of the supercritical fluid. Success has been reported with all these techniques for a wide variety of environmental samples.

Agricultural products In this application area, matrices are complex and varied, detection levels are frequently at the parts per billion (p.p.b.) and parts per trillion (p.p.t.) level, and analyte similarity to the matrix is likely. All of these features lead to complex sample preparation and time-consuming method development. Food safety, environmental fate and product stewardship are major concerns for a competitive, consolidating industry. Successful extraction technologies need to demonstrate ease of use on

Table 1 Range of analytes successfully extracted by SFE from soils

Analyte	Soil	Supercritical fluid	Temperature	Pressure	Multi-residue method?
Total petroleum hydrocarbons (TPHs)	Diesel and gas contaminated	CO ₂	80°C	340 atm	Yes
Sulfonyleurea herbicides	All types	Methanol and water-modified CO ₂	60°C	300 atm	Yes
Ureas	All types	Methanol-modified CO ₂	100°C	300 atm	No
Organotin	Marine sediment, clay, topsoil	Methanol-modified CO ₂	60°C	450 atm	Yes
Polychlorinated biphenyls (PCBs) and polycyclic aromatic hydrocarbons (PAHs)	Railroad bed, storage dumpster soils and sediment	CO ₂	150°C	400 atm	Yes
Nitroaromatic and polycyclic aromatic hydrocarbons (PAHs)	Polluted industrial site and former ammunition plant soils	CO ₂ modified with triethylamine and trifluoroacetic acid in toluene	90°C	395 atm	Yes
Nonylphenol polyethoxylates (nonionic surfactants) and carboxylic acid metabolites	Sediment and sewage treatment plant sludge	Water-modified CO ₂	80°C	340 atm	Yes

a routine basis, ruggedness, reproducibility, accuracy and commercial availability of equipment. In addition, the current regulatory environment is insistent on advances in multi-residue analysis. These requirements and directives suggest that SFE is an obvious choice.

Herbicide, insecticide and fungicide extraction from soils by SFE has been demonstrated widely; conditions for some of these analytes are listed in Table 1. In addition to the work conducted on soils, plant and raw agricultural commodities have been routinely analysed. Most of the agrochemical classes have been extracted: organophosphates, phthalimides, organochlorines, phenols, carbamates, nitroanilines, oxazolidine, benzimidazoles, triazoles, sulfite esters, pyrethroids, imidazolines and sulfonfylureas.

Frequently, sample pretreatment or processing must occur before sample extraction. Although this is time-consuming, this typically also occurs in most classical extraction methodologies. Grains and seeds are ground or milled into powders to expose the internal surface area to the extractant fluid; fruits and vegetables are chopped or diced; straws and hays may be cut or shred; oils may be treated as liquids or deposited on adsorbent surfaces. For some high water content species, drying agents such as Celite 545, Hydromatrix[®], magnesium sulfate and molecular sieves have been used to lower the overall water content. They have been added to the extraction vessel before extraction or mixed with the sample during preparation. For very low moisture samples, the opposite sample preparation scheme has been pursued. As in the analysis of coffee beans described above, water has been added to dry samples such as wheat straw to swell the matrix and provide access to interstitial regions.

TCP, 3,5,6-trichloro-2-pyridinal, the major product of chlorpyrifos and chlorpyrifos methyl insecticides and trichlopyr herbicide, has been extracted from soil using SFE followed by detection via immunoassay. Effects of modifiers and additives with this extraction were dramatic, as seen in Table 2.

Pharmaceutical Applications

Some of the first reports of the use of analytical scale SFE were in the pharmaceutical industry. Specifically, benzoquinones, known as ubiquinones or co-enzyme Q (with a number which represents the number of side chain isoprenoid groups that are present, e.g. Q-6 has six side chains), were extracted from bacterial cell extracts. They have physical properties analogous to synthetic nonionic detergents, in that there is a polar aromatic end-group and a nonpolar oligomeric side chain. Because of the nature of these

Table 2 Effect of a co-solvent on the recovery of TCP from soil with SC-CO₂^a

Additive	Recovery (%)
None	15.4
Methanol	57.4
Methanol and ion-pairing reagent ^b	80.0

^a1 mL min⁻¹ CO₂ flow rate; 383 bar; 40°C; 30 min extraction; 1 mL methanol, 0.5 mL ion-pairing reagent.

^bIon-pairing reagent: 0.1 mol L⁻¹ methanolic solution of R-10 camphorsulfonic acid ammonium salt (Aldrich).

molecules, their solubility range is large; they are soluble in aqueous and hydrocarbon solvents. This property makes them easily amenable to extraction with either pure carbon dioxide or carbon dioxide systems.

As an example, an experimental human immunodeficiency virus (HIV) protease inhibitor drug (Figure 3), has been extracted from animal feed. Figure 4 shows the effects of extraction temperature and percent ethanol modifier on recovery, while Figure 5 illustrates the high performance liquid chromatography (HPLC) chromatograms of the animal feed extracts. These chromatograms illustrate the relatively clean background that can be obtained with SF extractions.

Workers from Agriculture and Agri-Food Canada gave an excellent example of a multi-residue methodology in the extraction of 22 organochlorine pesticides from eggs with a programme to screen routinely for these compounds. Figure 6 shows recoveries of the pesticides using CO₂ with and without methanol. Both solvents yielded adequate extraction results as well as drastic improvements in extraction time and solvent consumption over the existing Soxhlet extraction method. Background was significantly reduced with pure carbon dioxide.

Literature references show that fat- and water-soluble vitamins have been extracted from pharmaceutical formulations as well as food matrices. Traditionally, fat-soluble vitamin analyses require saponification followed by extraction with an organic

Figure 3 Structure of experimental drug SC-52151 extracted from animal feed using SFE.

Figure 4 Extraction recoveries for SC-52151 from animal feed spiked at the 0.05% level. (A) 5%; (B) 10% ethanol modifier.

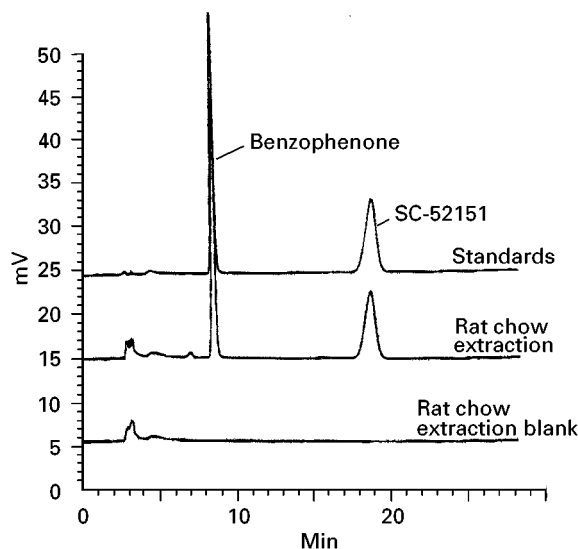

Figure 5 Reversed-phase HPLC traces of SFE animal feed extracts. Chromatographic conditions: column, Supelco C-8 DB (250 × 4.6 mm i.d.; 5 μm particle size); mobile-phase flow rate, 1.0 mL min⁻¹; injection volume, 10 μL, detection wavelength, 205 nm; mobile phase, 0.04 mol L⁻¹ sodium pentanesulfonate.

solvent. Solvent reduction and clean-up are generally also needed. SFE eliminates these steps. The water-soluble vitamins are more readily extracted with

modified carbon dioxide and minimal clean-up is required. Vitamins A₁, B₆, C, D₂, D₃ and K have all been successfully extracted using SFE.

Figure 6 Recoveries of organochlorine pesticides from eggs using SFE with (filled columns) and without methanol (open columns) as modifier. Hatched columns represent spiked blanks. Error bars represent standard deviation of five replicates for methanol-modified extractions at three levels 3, 5 and 10% where concentration showed no significant difference. Organochlorine no. 1, hexachlorobenzene; 2, α -hexachlorobenzene; 3, lindane; 4, heptachlor; 5, aldrin; 6, ronnel; 7, β -hexachlorocyclohexane; 8, chlorpyrifos; 9, dicofol; 10, oxychlorodane; 11, heptachlor epoxide; 12, α -endosulfan, 13, *trans*-chlordane; 14, *cis*-chlordane; 15, *p,p'*-DDE, 16, dieldrin; 17, endrin; 18, α,p' -DDT; 19, *p,p'*-tetrachlorodiphenylethane; 20, *p,p'* DDT; 21, mirex; 22, methoxychlor.

Herbal medicines have been characterized for industrial marketing in Japan using online SFE/SFC. A typical example is the case for atractylon, a characteristic component of *Atractylodes rhizome*. Rapid oxidation and degradation in UV light make manual methods difficult to execute with acceptable precision. The speed of the analysis by SFE coupled online with SFC make unstable, thermally labile and light-sensitive compounds easier to analyse.

Polymer Applications

The uses of supercritical fluids in industrial polymerization processes are many and varied. They include polymer fibre spinning, polymer-organic solvent-phase separation, fractionation, extraction of low molecular weight oligomers from polymers, high pressure polyethylene polymerization and fractionation and monomer purification. Backbone structure and slight differences in molecular weight can cause changes in polymer solubility properties. These differences are present in commercially prepared polymers and enable fractionation or extraction to be conducted on a large scale.

On the analytical scale, process monitoring of purity, oligomer content, oligomer and antioxidant extraction, additive concentration and removal of impurities have been conducted by SFE. Under supercritical conditions, the polymer matrix has been found to swell, in the same manner as has been described for soils. This has enabled SFE to accomplish analyses that were not previously possible by liquid extraction methods.

The most frequently reported area of SFE applications for polymers is the analysis of additives. Additives influence the physical nature of the polymer and come from a wide variety of classes. They can be low molecular weight and volatile or greater than 1 kDa with solubility in only some liquid solvents. Their analysis generally requires long, tedious multi-step procedures, which may include sample preprocessing, Soxhlet extraction, concentration and clean-up. The low viscosity and high solute diffusivity of supercritical fluids aids in the reduction and, in some cases, the elimination of these steps. The ability to determine the distribution of the additives within the polymeric grid has been demonstrated by several reports along with routine quantitative analysis. Commercial competitive product analysis is standard in industry and SFE has aided in the speed, ease and accuracy of this type of analysis.

The use of supercritical fluids in the polymer industry has opened up an area of knowledge that was previously closed; work continues to be actively conducted.

Additional Industrial Applications

In the fuel industry, stripping organics from minerals and shale rock has been conducted by SFE. Frequently, these methods used classical extraction methods that required several days. Equivalent results have been obtained in rapid extraction times of 15–30 min. Aromatic and aliphatic hydrocarbons (C_{10} – C_{35}), as well as naphthalene and asphaltene, are typical analytes that have been removed.

In the fibre industry, treatments with UV-stabilizers, removal and quantitation of residual dye components, and characterization of coatings, binders and adhesives have been conducted with the aid of SFE. Subsequent quantitative analysis either with SFC, LC, GC or mass spectrometry have all been successfully reported. The suggested procedures appear to be rugged enough to use for routine sample analysis.

Future Developments

The amount of research on SFE in the industrial environment is cyclical. Currently more work is being conducted on a larger scale in the areas of high temperature reactions, heterogeneous catalysis, reaction/separation schemes, antisolvent recrystallization and microencapsulation. However, research at the analytical scale continues. Without a doubt success with larger scale industrial processing leads to process monitoring and analysis. Analysis schemes, of necessity, frequently mimic the larger scale. This is one of the areas where SFE, and most likely supercritical chromatography, will continue to evolve with the pace controlled by need and economics. SFE, though novel in some locations, is no longer a new technology.

Low waste generation in SFE was originally touted as a huge payoff for exploiting the technique. Reduction in waste has been achieved with all automated sample preparation technologies, although the analytical laboratory has not been pushed to reduce solvent waste to the point that large scale processes have. The ability of a supercritical fluid to conduct the extraction of an analyte and leave no organic waste is a feature that can be exploited. The potential that it can be cleaned and recycled with minimum energy input makes it still more desirable. This is an area which could force the acceptance of supercritical technologies, including extraction, where it has been slow to take off.

INKS: FORENSIC ANALYSIS BY THIN-LAYER (PLANAR) CHROMATOGRAPHY

L. W. Pagano, M. J. Surrency and A. A. Cantu,
US Secret Service, Washington DC, USA

Copyright © 2000 Academic Press

Introduction

Because of the immense number of documents written, printed and copied each year, suspect documents generated by these methods have become common subjects for forensic examinations.

The forensic analysis of inks is performed to determine if inks are similar or different; to establish the authenticity of a document; to establish whether a document could have been produced on the purported date; or to determine the origin of a document. Although the chromatographic analysis of writing and stamp pad inks have been extensively documented, little has been written on the analysis of ink jet inks (jet inks) or photocopier/laser printer/LED printer toners, despite the volumes of such evidential documents under investigation.

All inks are composed of colorants in a vehicle. Today's inks include: writing, typewriting, stamp, printing, printer, jet and toner. The consistency of the vehicle ranges from liquids, such as those used in writing and jet inks; to paste, characteristic of some printing inks; to solids, such as those used in typewriting ribbons and toner.

This article only deals with inks whose colorants are separable by thin-layer chromatography (TLC). Such colorants include dyes and pigments that have some solubility in the extraction solvent. Since most printing inks use insoluble pigments as colorants, and therefore are not analysable by TLC, such inks are not considered here. Additionally, the jet inks and

toner under consideration are those used in full colour systems (YMCK).

The TLC separation of soluble inks involves six steps: sampling, extraction, spotting, developing, visualization/detection and interpretation.

A TLC method successfully used for the comparison of writing inks has translated well for the analysis of today's modern imaging media – jet ink and toner. Although colour toners are very different from classically defined 'ink', they are made up of separable dyes and TLC has proved useful in their analysis.

TLC is not an identification method unless used for comparison with a complete collection of standards. TLC is used in conjunction with a reference specimen library to match the manufacturer of an ink. These reference collections must contain samples of all inks manufactured throughout the world. Deficiencies in the library weaken the interpretation of a match and increase the number of nonmatches.

The most important criterion in the application of TLC to matching inks with library standard inks is that the inks under investigation and library inks be chromatographed under identical conditions using identical methods. A match becomes an identity only if the match is known to be unique and/or the library is complete.

Described in this article are procedures for analysing inks. The first step in an ink analysis is the identification of the ink type. This is best determined microscopically (Figures 1–5). This determination is critical because different chromatographic methods are used for different inks.

Once an ink is identified, the manufacturer may provide crucial information regarding the ink's formulation, earliest possible production date, and distribution.

Figure 1 (See Colour Plate 88). Offset lithography photographed at 25 ×.

Jet Ink

Ink Jet Technology

Surprisingly, ink jet technology has been around for over 35 years, but only recently has it gained widespread use, most notably in desktop computer printers. This digital printing technology directs small droplets of ink to the substrate surface. Although there are several methods for accomplishing this, the two most common methods are continuous jets and drop-on-demand. Continuous jets create a stream of uniformly sized and spaced drops, which are deflected to produce an image. Drop-on-demand generates only the drops needed for image creation.

Fluid Jet Ink Chemistry

Most copiers/printers, which use ink jet technology, utilize a fluid, water-based ink. During the developmental stages of ink jet technology, researchers initially used fountain pen inks. These fountain pen inks caused corrosion on the print head surfaces, clogged

Figure 2 (See Colour Plate 89). Full colour toner photographed at 25 ×.

Figure 3 (See Colour Plate 90). Full colour ink jet photographed at 25 ×.

jet orifices, and had long drying times and excessive ink bleeding. Although these inks provided a starting point, it became apparent that this new technology would require specially formulated inks.

The early dyes were borrowed from the textile industry, then reworked and purified. Most of the organic dye counterions were replaced with larger ions, decreasing the activity and pH to a more suitable level and improving solubility, thus minimizing corrosion and crusting of the jet orifices. Along with the direct dyes, acid dyes and basic dyes used in textiles and food dyes were also adapted for ink jet systems. Organic dyes generally consist of three-dimensional compounds with ring structures having electron configurations that interact with incident radiation in the visible light range. Although these dyes must be soluble in water, they must be water-fast enough on the printed substrate to be used in an office environment. Amines and carboxylic functional groups were added to improve the binding of the dyes to the paper, and thus increase water-fastness.

Figure 4 (See Colour Plate 91). Letterpress ink photographed at 25 ×.

Figure 5 (See Colour Plate 92). Writing ink photographed at 25 ×.

Today, the majority of commercially available jet inks are specifically formulated by the manufacturers of the print-head and delivery systems, to several performance and aesthetic requirements. In addition, the ink must be chemically compatible with the components used to construct the ink reservoir and delivery and head assemblies; it must have sufficient relative density and surface tension to remain in the nozzle without leaking out of the orifice; and when ejected it must produce the desired drop shape and radius. The ink also needs to have good wetting properties, while maintaining rapid drying times, and must have chroma, hue and optical density suitable for producing colours pleasing to the end user. In addition, the ink must be nontoxic and environmentally safe.

Dyes are the most useful colorants for jet inks; however, pigments also have properties valuable to these systems. Pigments, which are insoluble and must be suspended in the ink, have many advantages over dyes, including optical density, light- and water-fastness and stability. The main disadvantage is the lack of commercially available pigments with particle sizes less than 1 μm; most pigments are simply too large for use in ink jet systems. Advances in micropigments are producing more suitable pigments for use in ink jet systems.

To enhance ink performance, additives are incorporated. Often a low vapour pressure solvent, such as polyethylene glycol, is added to inhibit crusting. Other additives aid in buffering the solution, stabilizing the dyes (i.e. pyrrolidone), and wetting the paper (i.e. glycols, butyl ethers). To inhibit organic growth, biocides and fungicides are carefully selected and added to the formula. Like other water-based ink systems, bacteria and fungus thrive in jet inks.

The ink solution is a dynamic environment. Upon entering the delivery system or cartridge, the ink reacts with the polymers, foams and metals of the

container. Therefore, the ink in the printer or cartridge is no longer in its original state. The ink also changes composition, depending on its location in the cartridge and what materials are used. In systems that use low vapour pressure solvent(s) for crusting prevention, the actual chemical composition of the ink changes near the orifice as the solvent(s) evaporate.

Ink–Paper Interaction

In addition to the critical compatibility of the ink and print system, ink and substrate compatibility also plays a crucial role in print quality. The print quality is partially determined by the surface tension, viscosity, delivery angle and velocity of the ink and the sizing, surface energy and topography of the substrate. When paper is used as the substrate, print problems such as spread (dot-gain), absorption (bleed through the paper) and paper curl are quite apparent. Initially these problems were addressed by developing special paper coatings to control these factors, as well as to enhance contrast and to improve the colour gamut, optical density and water-fastness. Many of these coatings contain silica and starch and have a large surface pore volume to absorb large quantities of ink quickly. Other ink jet papers include multilayer configurations and polymerized coatings, designed to interact with the dyes, to adjust and render them insoluble in water and adjusting for the pH of the ink.

Analysing Jet Ink

Extraction solvent The solubility of the jet inks in their sampled state determines the solvent used for their extraction. Since the ink to be forensically examined is almost always on a document, the primary focus is the solubility of the ink in its dried state on a particular substrate. The most useful method is classical solubility testing by sampling and determining solubility in pure solvents, then binary combinations, in dimple plates. Once the best extraction solution has been determined, the solvents used should be chromatographic grade to avoid contamination. For jet inks an extraction solution of ethanol/water (1 : 1) has been found to be the most successful.

Solvent (mobile phase)/stationary phase Because of the complexity of the jet inks, the colorants generally cannot be separated using a single solvent. Therefore, solvent mixtures must be used. Chromatographically these solvents are chosen for their selectivity and strength. Additionally, the solvent should be made just before chromatographing. If the mobile phase is not made fresh, the concentrations will change as the higher vapour pressure solvents escape into the gas-

Table 1 Ink solvent system I

<i>Solvent</i>	<i>Eluotropic value (ϵ°) solvent strength on silica gel</i>	<i>Snyder group (selectivity)</i>	<i>Parts</i>

Water	10.2	VIII	30

eous portion of the container. One solvent system, widely used for examining writing inks, has been found useful in the analysis of jet inks; this is solvent system I (Table 1). Additionally, solvent system V (Table 2) has been found to be another successful system.

The stationary phase, which is as important as the mobile phase, dictates the interactions between itself and the sample and solvent. Although there are several different stationary phases available (e.g. diol, reversed-phase, etc.) silica gel has proved to be most useful. Since some dyes have fluorescent characteristics, fluorescent indicators should be absent from the plate. It is highly advisable to clean the plates to remove any contaminants. This is performed by running the plate in the chosen solvent for the length of the plate and drying prior to spotting.

Sample preparation The substrate from which the inks are sampled is critical. Inks sampled from coated papers, which chemically and/or physically bind the ink, will chromatograph differently from the same ink printed on noncoated paper. Further, samples of ink taken directly from the cartridge versus drying the ink on a neutral substrate may also affect the chromatograms. Therefore, it may not be possible to analyse reliably documents produced on certain substrates by TLC.

Using a scalpel, ink should be removed from the uppermost layer of paper containing the ink. This method not only increases the ink-to-paper ratio, but also reduces potential contamination from ink on the reverse of the document. Samples must contain all of the imaging colours on the document, preferably in

Table 2 Ink solvent system V

<i>Solvent</i>	<i>Eluotropic value (ϵ°) solvent strength on silica gel</i>	<i>Snyder group (selectivity)</i>	<i>Parts</i>
Water	10.2	VIII	32
Acetic acid	6.0	IV	17
<i>N</i> -Butanol	3.9	II	41
Butyl acetate	–	–	10

equal amounts. If the document does not contain all four of the process colours, changes to the library comparison and confirmation test methods are performed with only those colours found in the sample in question. Additionally, samples of plain areas of the paper must also be taken to identify any components contributed by the paper. Depending upon the subject of the document, little if no plain areas may exist for a proper substrate blank. This is often the case when the background of the original is not white. The scalpel method should help to minimize paper influence.

Extraction/spotting/development The amount of ethanol/water is dependent on the size of the sample. The concentration of the samples should be within the relative range of the library specimens. The extract is spotted using a Camag Nanomat with 1.0 μ L micropipettes at 1 cm from the bottom of a Whatman polyester silica gel plate. Once spotted, the plate is placed in a 95°C oven for 3 min to remove the extraction solvent. The plate is cooled to room temperature, then placed in a saturated vertical chamber containing solvent system I. The plate is allowed to develop to 4 cm from the origin, removed and dried.

Comparison/interpretation The developed plate is then compared with the chromatograms within the jet ink library and a list of possible matches is recorded. The possible library specimens are then sampled using the above mentioned method. The questioned ink and library specimens are spotted on a precleaned Whatman HPKF silica gel 60 plate. The plate is developed in a Camag saturated horizontal chamber containing solvent system I. After developing, the plate is dried. Once dry, the plate is interpreted under both UV and visible light (Figure 6).

**Figure 6** (See Colour Plate 96). Thin-layer chromatogram of full colour jet inks, solvent system I.

Figure 7 (See Colour Plate 97). Thin-layer chromatogram of full colour jet inks, solvent system V.

It should be noted that the interpretation of jet ink chromatograms is very different from interpretation of standard writing inks such as ball-point ink. Writing ink is eliminated if the relative dye concentrations are different between the questioned ink and a library specimen. This elimination is based on the fixed dye ratios within a writing ink, which is as characteristic as the dye composition itself. In ink jet systems, the concentrations of each of the four process colours varies according to the colour being reproduced; the relative concentrations of the dyes within the chromatograms will therefore also vary. As a result, relative concentration differences are not grounds for eliminating a jet ink specimen for consideration, as in the case of writing inks.

To confirm any matches to the library, a second plate with both the questioned sample and the matching library specimen is chromatographed using a Whatman HPLC silica gel 60 plate in solvent system V (Table 2). The match is then confirmed by interpreting the plate under both UV and visible light (Figure 7; see also Table 3).

If no matches are found, there may be deficiencies within the library or this may be caused by the use of

post-market inks, i.e. inks made to refill original cartridges. In the case of such inks, a new range of reactions take place. Even though post-market inks may be well represented in the library, when they are added to existing cartridges the interaction with the original ink and container components may alter their chromatograms to the extent that they do not resemble either the original ink or the post-market ink. For example, the post-market ink will initially force the original ink to the print-head. Farther back in the cartridge the old and new inks mix, forming gradients. The changes that occur are often greater than the sum of the components.

Writing Ink

Writing Ink Chemistry

All writing inks consists of colorants and a vehicle containing solvents and resin binders (ballpoint). Writing inks can generally be placed into two categories: ballpoint (Figure 8) and non-ballpoint inks (Figures 9 and 10). Non-ballpoint inks can be further subdivided into inks that are water-based (i.e. fountain pens, felt-tip markers, roller-ball) and those that are solvent-based ('permanent' markers). For ballpoint inks, the vehicle is commonly a mixture of glycol(s) (i.e. 2,3-butanediol, 1,2-propanediol), alcohols with low relative molecular mass (i.e. 2-phenoxy-ethanol, benzyl alcohol) and resin binders, which result in a paste-like consistency.

Most writing inks contain complex mixtures of mostly soluble dyes and occasionally suspended pigments (carbon or inorganic pigment), which result in unique formulations. Some of the more popular dyes and pigments are phthalocyanine blue, rhodamine, nigrosine and methyl violet.

Analysing Writing Ink

Extraction solvent The method for choosing an extraction solvent for writing ink is the same as that used for jet inks. For writing inks, extraction solvents

Table 3 Thin-layer chromatography of full colour jet inks as shown in Figures 6 and 7

Spot	Post-market Co.	Manufacturer	Model	Colours

Figure 8 (See Colour Plate 93). Ballpoint writing ink photographed at 25 \times .

include ethanol/water for water-based and some solvent-based inks and pyridine for ballpoint and most solvent-based inks.

Solvent (mobile phase)/stationary phase Writing inks are complex mixtures and generally cannot be separated using a single solvent. Therefore, solvent mixtures are used to enhance separation of the colorants. Several different systems have been developed and tried. Solvent systems I and II (Table 1 and Table 4) are the most successful. Other solvent systems such as III and IV (Tables 5 and 6) can be more effective when inks are highly polar or contain Nigrosine.

Silica gel is the most useful stationary phase. The dyes and pigments used in writing inks may have fluorescent characteristics that are very helpful in their examination; fluorescent indicators should therefore be absent from the plate. Once again, the plates should be cleaned to remove any contaminants.

Figure 9 (See Colour Plate 94). Non-ballpoint writing ink (solvent-based) photographed at 25 \times .

Figure 10 (See Colour Plate 95). Non-ballpoint writing ink (fountain pen) photographed at 25 \times .

Sample preparation Sampling is often accomplished by removal of the ink by use of a scalpel, a blunted 16–20 gauge hypodermic needle, or a commercially available forensic document sampling punch. If a scalpel is used, approximately 1 cm of an ink line is removed and placed into a vial. If the hypodermic needle or sampling device is used approximately ten plugs of ink (~ 0.1 μg of ink) are removed from the document and transferred to a vial. As with ink jet analysis, samples of paper/substrate should be taken and examined to identify its contribution to the ink sample extract.

Extraction/spotting/development The ink is extracted by adding a minimum of appropriate extraction solvent and spotted onto the plate with 1.0 μL micropipettes at 1 cm from the bottom of a Whatman polyester silica gel plate. Once spotted, the plate is placed in a 95 $^{\circ}\text{C}$ oven for 3 min to remove the extraction solvent. The plate is cooled to room temperature, then placed in a saturated vertical chamber containing solvent system I. The plate is allowed to develop to 4 cm from the origin. The plate is removed and allowed to dry by evaporation.

Comparison/interpretation The developed plate is then compared with the chromatograms within the writing ink library and a list of possible matches is

Table 4 Ink solvent system II

<i>Solvent</i>	<i>Eluotropic value (ϵ°) solvent strength on silica gel</i>	<i>Snyder group (selectivity)</i>	<i>Parts</i>
N-Butanol	3.9	II	41
Absolute ethanol	4.3	II	35
Water	10.2	VIII	32

Table 5 Ink solvent system III

Solvent	Eluotropic value (ϵ°) solvent strength on silica gel	Snyder group (selectivity)	Parts
Cyclohexane	0.04	VII	10
Chlorobenzene	0.3	–	2
Absolute ethanol	4.3	II	1

recorded. The possible matches are sampled using the above mentioned method. The questioned ink and possible matching standards are then spotted on a precleaned Whatman HPKF silica gel 60 plate. The plate is developed in a horizontal chamber containing solvent system I. After developing, the plate is dried by evaporation and interpreted under both UV and visible light (Figure 11).

Unlike ink jet ink interpretation, the concentrations of the dye components from nonrefillable cartridge pens will not vary between the questioned document and the library samples. Therefore, relative concentration differences are grounds for eliminating an ink specimen.

To confirm any matches to the library, a second plate with both the questioned sample and the matching library specimen is chromatographed on a precleaned HPKF plate in solvent system II (Table 4). The match is then confirmed by interpreting the plate under both UV and visible light (Figure 12; see also Table 7).

Toner

Toner Technology

Electrophotography dates back to 1938 and has become the most widely used plateless printing technology. Electrophotography is a process that consists of a photoreceptive drum that is charged in darkness with a corona discharge and exposed to an original document through an optics system. The light reflected from the original image discharges the photoconductor where the light strikes it, creating a latent image on the drum corresponding to the dark areas on the original. This latent charged image is de-

Table 6 Ink solvent system IV (modified)

veloped with oppositely charged toner. The toner is transferred to a substrate and fixed. Today's digital electrophotographic machines use lasers or light emitting diodes (LED) driven by digital data to create the latent image on the photoreceptive drum.

Dry Toner Chemistry

Toners are electrostatically transferred to the paper or print substrate and are fused by heat, pressure or a combination of both. As with other inks, toners must meet certain print parameters, such as water- and light-fastness, but because of their unique way of imaging they must also meet a unique set of chemical and physical parameters, such as triboelectric properties.

Dry toners are very fine powders consisting primarily of a polymer resin binder and colorants. These colorants, pigments and dyes, are chosen primarily for their chroma, hue and colour purity. The most common pigments and dyes are carbon black,

**Figure 12** (See Colour Plate 99). Thin-layer chromatogram of ballpoint inks, solvent system II.

Extraction solvent: pyridine.
Whatman HPKF Silica Gel 60.

nigrosines, copper phthalocyanines, azo-pigments and quinacridone.

The polymer or copolymer resin binder is chosen for its thermal characteristics such as glass transition temperature and flow viscosity. Polystyrene acrylates and epoxy polymers are used for hot roll and flash fusing. Small chain homologue polymers, e.g. polyethylene and polypropylene, and vinyl acetates are used for cold pressure and roll fusing. Polyester is used primarily for radiant fusing. Often additives are incorporated into the toners to alter physical properties: pigments and dyes are added for colour; magnetite salts are added to enhance control of the toner; ammonium salts are used for positive charge control; acidified carbon black and metal complexes are added for negative charge control; silica and zinc stearate are added as a lubricant and flow enhancement; and silicone oils and low weight polyethyl and polypropyl waxes are used as release agents to prevent the toner from adhering to the fusing roller.

Analysing Toner

Extraction solvent The method for choosing an extraction solvent for toner is the same as that used for jet and writing inks. It must first be determined in which solvent(s) the toner is soluble, then whether mixtures of solvents are needed to enhance solubility. Pure chloroform was found to be the most successful.

Solvent (mobile phase)/stationary phase Like jet and writing ink, toners generally cannot be separated using a single solvent. Therefore, solvent mixtures must be used to accomplish separation of the colorants. The most successful solvent system for toners are solvent systems I (Table 1) and modified IV (Table 6).

Silica gel is the most useful stationary phase. The dyes and pigments used in toners often have fluorescent characteristics that are very helpful in their examination, hence fluorescent indicators should be absent from the plate. Once again, the plates should be cleaned to remove any contaminants.

Sample preparation Sampling toner documents has advantages over jet ink documents. Although, as with ink jet documents, toner documents may have little or no clean paper areas, this is of little concern with toner sampling because the toner is removed from the document thermally. To remove the sample, a clean scanning electron microscope (SEM) aluminium stub placed over the sampling area is heated with a soldering iron. The heat causes some of the toner to be transferred to the stub. Since this method removes only the toner, paper interactions are avoided. Again, as with jet inks, all of the process colours should be sampled from the document in equal proportions. If the document does not contain all four of the process colours, changes to the library comparison and conformation test methods are performed with only those colours found in the sample.

Extraction/spotting/development The toner is washed from the stub with chloroform into a sampling vial. The toner wash is spotted onto the plate using 2.0 μ L micropipettes at 1 cm from the bottom of a Whatman polyester silica gel plate. Once spotted, the plate is placed in a 95°C oven for 3 min to remove the extraction solvent. The plate is cooled to room temperature, then placed in a saturated vertical chamber containing solvent system I. The plate is allowed to develop to 4 cm from the origin, removed and allowed to dry by evaporation (Figure 13).

Comparison/interpretation The developed plate is then compared with the chromatograms within the toner library and a list of possible matches is recorded. The possible library specimens are sampled using the abovementioned method. The questioned toner and library specimens are then spotted on a precleaned Merck silica gel 60 plate. The plate is

Figure 13 (See Colour Plate 100). Thin-layer chromatogram of full colour toner, solvent system I.

Figure 14 (See Colour Plate 101). Thin-layer chromatogram of full colour toner, solvent system IV.

developed in a Camag saturated horizontal chamber containing solvent system I. After developing, the plate is dried by evaporation. Once dry, the plate is interpreted under both UV and visible light.

As with jet ink interpretation, the concentrations of the dye components will vary owing to the varying concentrations of the four process colours between the questioned document and the library samples. Therefore, relative concentration differences are not grounds for eliminating a toner specimen, as in the case of writing inks.

To confirm any matches to the library, a second plate with both the sample and the matching library specimen is chromatographed using a Merck silica gel 60 plate, without fluorescent indicator, in modified solvent system IV (Table 6). The match is then confirmed by interpreting the plate under both UV and visible light (Figure 14; see also Table 8).

Conclusions

Through the use of colorant separation by TLC in conjunction with comparison libraries, the various original manufactures' inks can generally be distinguished from each other. At the time of this article,

Table 8 Thin-layer chromatography of full colour toner as shown in Figures 13 and 14

Spot	Manufacturer	Model	Colours

Merck Silica Gel 60.

total distinguishability is obtained for full colour jet inks and toners. The comparison of the colour components has proved to be more discriminating than the comparison of other components, such as resins within ballpoint inks and toner. The ability to discriminate inks, coupled with the low cost, ease and multiple samples per run, make TLC a powerful forensic tool for the analysis of modern documents produced by traditional and new inks.

See Colour Plates 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, 98, 99, 100, 101.

Developments in insecticide analysis have been closely linked to developments in gas chromatography (GC). Indeed, the invention of the electron-capture detector led to the discovery of residues of the persistent organochlorine insecticides in dead birds and this in turn raised concerns regarding pesticide residues in food and the environment. The range of applications of GC to insecticide analysis is very wide and the choice of technique must be appropriate for the intended purpose. The first requirement is to detect the compounds of interest; most GC detectors have some use in insecticide analysis. Different types of column are needed for different applications and the choice of injection technique is related to the analyte and the type of column. The ability to obtain a chromatogram from a solution of insecticides is just a starting point. The insecticides have to be extracted from a variety of samples and separated from many other co-extracted compounds which can interfere with the separation or degrade the column. There are four major classes of insecticides, each of which has its particular analytical requirements.

Applications of GC in Insecticide Analysis

Insecticides are biologically active compounds used principally in agriculture but also in public health applications. There is public concern over their production and use, their presence in food and their persistence in the environment. The requirement for insecticide analysis is wide-ranging. GC is better suited to residue analysis than measuring the high concentrations encountered in formulations. For GC analysis, the insecticides must be sufficiently volatile and thermally stable.

A manufacturer may be interested in a particular compound together with its metabolites and degradation products in biological systems and the environment. In cases of animal poisoning by an insecticide, the identification of the poison is the main task. Foods are monitored for many different insecticides and some degradation products; small residues around statutory limits must be identified and measured accurately in a wide variety of foods, each of which poses particular analytical challenges. Residues in water and air are even smaller and must be trapped and concentrated prior to measurement.

With such a variety of applications, it is essential that the analytical method is fit for its purpose.

Detectors for GC of Insecticides

A list of detectors and their application to insecticide analysis is shown in Table 1.

Columns and Injection Ports for GC of Insecticides

Packed Columns

GC of insecticides began with packed columns that gave low resolution and were limited by the temperature at which the nonbonded stationary phase began to bleed. To achieve sufficient resolution for identification and to obtain good peak shapes, a wide range of stationary phases was needed. Packed columns are not well suited to temperature programming and the sample is usually introduced by vaporization of a solution in a heated injection port. This is unsuitable for the thermally labile carbamates which have to be converted to more stable derivatives.

Capillary Columns

The introduction of fused silica capillary columns and bonded stationary phases brought higher resolution GC to routine analysis of insecticides. Higher

Table 1 Detectors used in the gas chromatography of insecticides

<i>Detector</i>	<i>Species detected</i>	<i>Insecticide classes</i>	<i>Comments</i>
FID (flame ionization) PID (photoionization)	Carbon compounds	All	With these detectors, difficult to identify the insecticides amongst the peaks from co-extracted compounds in residue analysis
ECD (electron capture)	Halogens and other electron-capturing species	Organochlorines, most pyrethroids, some OPs	Sensitive but not highly selective. Responds to some nonhalogenated compounds. Response affected by co-extractives
Electrolytic conductivity	Chlorine or sulfur or others	Organochlorines	More selective than ECD but less sensitive. Less robust. Requires more maintenance
NPD (nitrogen phosphorus)	Nitrogen and phosphorus	Organophosphates, carbamates	Responds to both elements. Slightly 'tunable'. Response changes slowly as salt bead ages. Response affected by co-extractives
Chemiluminescence	Nitrogen	Carbamates	Rarely used to date
FPD (flame photometric)	Phosphorus (with 526 nm filter)	Organophosphates some have phosphorus and sulfur	Very selective for phosphorus but large amounts of sulfur compounds may interfere
	Sulfur (394 nm)	Others with sulfur	Nonlinear response. Affected by bleed
AED (atomic emission)	Carbon, chlorine, nitrogen, sulfur, phosphorus, oxygen (not all at once)	All (but selective for chosen elements)	Versatile selective multielement detector but not as sensitive as some and costs more to buy and run
FTIR (Fourier transform infrared)	Functional groups that absorb infrared	Various, but only at high levels	Not sensitive enough for residue analysis
MS (mass spectrometry)			
Total ion chromatogram	All that ionize in MS	All	Same disadvantages as FID (above), but other modes are selective (below)
Selected ion(s)	Selected ions	All chosen compounds	Selective for compounds producing the chosen ions
Full spectrum	Mass spectrum	Identification of peak	Good identification if sufficiently sensitive
Negative-ion CI	Halogens (as ECD)	OCs, pyrethroids	Limited application
MS-MS	Fragmentation of ion	Co-eluting compounds or sparse spectrum	Aids identification in these difficult situations

OPs, organophosphates; OCs, organochlorines; CI, chemical ionization.

resolution, less active sites, temperature programming, cool on-column injection and the development of sensitive mass spectrometric detectors enabled many insecticides, including some that are thermally labile, to be analysed on a low polarity stationary phase (dimethyl polysiloxane, DB-1 or methylphenyl polysiloxane, DB-5, DB-17, etc.)

For fast analyses or for thermally labile compounds, a short wide-bore column (10 m × 0.53 mm i.d. with a 1 µm stationary phase thickness) works well in combination with semi-selective detectors (electron-capture, nitrogen-phosphorus and flame photometric detectors). If the analyte is sufficiently stable, a packed column injector can be converted for direct injection into a 0.53 mm capillary column by the addition of a liner with a volume of

about 1 mL and an appropriate reducing adapter. For cool on-column injection, a purpose-built port is necessary. A carrier gas (nitrogen or preferably helium or hydrogen) flow of about 5 mL min⁻¹ and a temperature gradient from 50 or 100°C at 5°C min⁻¹ to 250°C will be suitable for the analysis of most insecticides.

For higher resolution, a smaller bore (e.g. 0.25 mm internal diameter) and/or longer column is needed. Also, if the detector is a mass spectrometer, a low carrier flow around 1 mL min⁻¹ is preferred. Concentrated sample solutions are best analysed with a split injection technique where only a small proportion of the injected extract goes on to the column. For most insecticide analysis, splitless injection is used together with an initial column temperature low enough to

cold-trap the analytes and to condense the solvent if the solvent effect is to be employed.

Cool on-column injection is ideal for compounds that start to decompose in a hot injection port, but nonvolatile co-extracted solutes remaining in sample extracts will rapidly contaminate the column. A wide-bore retention gap will trap nonvolatiles and allow injection with a conventional syringe needle (instead of needing a fragile thin needle to inject directly into a small-bore column). Some carbamate insecticides can be analysed without derivatization on a nonpolar column with on-column injection.

Large volume injection is becoming popular for the analysis of low concentrations of insecticides in water samples. Volumes in excess of 100 μL of extract are injected into packing in an injection port liner from which the solvent is evaporated. The solutes are thermally desorbed on to the column where they are cold-trapped prior to the start of temperature-programmed GC analysis.

A thermal desorption and cold-trapping technique is also used for analysis of air samples from which contaminants have been trapped by passage through a tube of adsorbent.

Volatile insecticides used as fumigants in grain and other stored commodities may be analysed by head-space analysis; the volatile compounds are sampled from the air above the samples and passed in a gas stream to be trapped on the top of the GC column.

Analysis for Insecticides in Biological and Environmental Samples

Before insecticide residues can be analysed by GC, they have to be extracted from the samples containing them. These extracts contain many other co-extractives in addition to the insecticides and require a clean-up.

Extraction

The simple – and usual – way to check whether an analytical procedure will extract compounds of interest is to add a solution of the compounds to the exposed surfaces of sample (whole, chopped up or finely ground), allow the solvent to evaporate fully, then apply the analytical procedure. Residues that have been acquired by a plant or animal by systemic processes (transport via a plant's vascular system or the processes through gut and internal organs following ingestion by an animal) may be more difficult to extract than surface residues. Studies using radiolabelled compounds may be needed to determine whether such residues are extractable or bound.

Extracts are usually obtained by cutting the sample very finely (blending, homogenizing, milling, grinding, etc.) and extracting with an organic solvent. Extraction may be a one- or two-stage process aided by agitation (shaking, ultrasonication, homogenizing) followed by filtration or centrifugation (to separate solid and liquid). It may be continuous as in liquid-liquid extraction (for liquid samples) or in Soxhlet extraction, accelerated solvent extraction or supercritical fluid extraction (for solid samples).

Clean-up

The effects of co-extractives on GC include:

1. visible additional peaks on the chromatogram, perhaps unresolved from the analyte peak;
2. volatile substances that, although not themselves showing a detector response, elute with the analyte and affect the chromatography or the response of the detector to the analyte;
3. nonvolatile solutes deposited on injection, coating the injection liner and top of the column, changing the characteristics of the stationary phase in that region.

A clean-up from which a wide range of insecticides can be recovered will also recover many other co-extracted compounds. Some analysts use extracts with little or no clean-up, and selective detection such as GC-mass spectrometry (GC-MS). They compensate for chromatographic effects from co-extractives by the use of carefully chosen internal standards or prepare matrix-matched external standards in extracts of analyte-free sample material. An instrument used in this way will require frequent maintenance, but the overall result may be cost-effective.

Clean-up is a source of potential loss of analyte and adds extra time to analyses (but in recent years equipment for partial automation of this process has been introduced).

Gel permeation chromatography (GPC) is a technique that delays small molecules such as insecticides as they flow in and out of pores in the gel while larger molecules flow past in the solvent stream. The large molecules mainly form the nonvolatile material deposited at the GC injection port, so GPC is potentially a useful clean-up for insecticides in a wide range of sample matrices. The disadvantage of traditional GPC is that it uses large quantities of solvents (hundreds of millilitres) which have to be removed by evaporation. High performance GPC works on a smaller scale and can be automated, but the columns are expensive compared to analytical high performance liquid chromatography columns.

Column adsorption chromatography using quantities of between 1 g and 50 g of materials such as alumina, silica gel and Florisil was the traditional method for clean-up of extracts containing insecticides. These traditional columns have been largely superseded by small particle size materials in quantities from 100 mg to 1 g in cartridges, usually requiring a small pressure or vacuum to give a suitable flow rate. Cartridges of this type, including those with reversed-phase (C_{18}) and ion exchange packings, are now known as solid-phase extraction (SPE) cartridges. Equipment for automated operation of these cartridges is widely available.

Partition between two immiscible solvents, such as water and hexane, may be used to separate polar co-extractives from insecticides that are generally of low polarity. Originally separating funnels were used, but there are now cartridges of inert material that will absorb an aqueous solution but still allow efficient partition of insecticides into a water-immiscible solvent poured through the cartridge. A partition mechanism also operates with SPE cartridges containing bonded C_{18} packing material. Insecticides in aqueous solution are extracted by a partition process into the C_{18} and then eluted selectively from the cartridge by organic solvent mixtures of appropriate polarity.

There are other clean-up techniques developed for specific purposes. Sweep co-distillation is a process analogous to steam distillation, in which insecticides and other volatile materials are distilled out of heated liquid fat samples. Some of the organochlorine insecticides are resistant to chemical attack, so reaction of interfering compounds with strong acids or oxidizing agents has been used as a clean-up for these compounds.

The extraction and clean-up methods to be employed depend on the insecticide(s) to be analysed and the nature of the sample material. The analyst should consult the literature for a particular application, but if no suitable technique is described, some experimentation will be necessary.

Determination of Insecticides by GC

The requirements for GC determination depend on the purpose of the analysis. Generally, GC determination with a semi-selective detector or a single ion on a mass spectrometer requires additional confirmation, by an alternative technique or by measurement of other ions.

Organochlorines

Most of the insecticides of this type have been withdrawn from use in many countries, but residues per-

sist in the environment. Organochlorine insecticides are of several different chemical types but all contain chlorine atoms and are fat-soluble (non-polar). Lindane (hexachlorocyclohexane (γ isomer), γ -HCH), dichlorodiphenyltrichloroethane (DDT) and dieldrin are examples (Figure 1). They are very slightly soluble in water, but are readily extractable into hexane from water or homogenized water-containing samples. Diethyl ether or ethyl acetate will also extract them from dry materials on which they are adsorbed. An alternative is to use a water-miscible solvent such as acetone to extract from water-containing samples; this is followed by partition between water and hexane. Supercritical fluid extraction with carbon dioxide as solvent and a C_{18} trap has also been used to extract organochlorine insecticides from relatively dry commodities. For clean-up of hexane extracts of fatty samples, chromatography on deactivated alumina or Florisil with further hexane elution recovers most of the organochlorines while leaving most co-extractives behind. GPC and sweep co-distillation are sometimes used to clean up extracts containing organochlorines. Although these insecticides are solids, care must be taken when evaporating extracts as, for example, γ -HCH is easily lost if a solution is evaporated to dryness.

All the organochlorine insecticides chromatograph well on dimethyl silicone stationary phases (DB-1, OV-1, etc.). Endrin and 1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane (p,p' -DDT) may break down or

adsorb strongly if the injection liner and top of column become dirty or active. Splitless injection is usually used for residue analysis. A 20 m long, 0.53 mm i.d. column gives satisfactory resolution with a temperature programme from 100°C to 225°C . A chlorine-selective detector such as the very sensitive electron-capture detector or the less sensitive but more selective atomic emission detector may be used. For certainty of identification, a bench-top mass spectrometer is used to obtain a full mass spectrum; the chromatogram is monitored for selected ions at particular retention times to locate any organochlorine peaks (Figure 2). A capillary column has to be used to suit the maximum gas flow requirements of the mass spectrometer. For some of the organochlorines, negative-ion chemical ionization mass spectrometry is a successful detection technique.

Synthetic Pyrethroids

Synthetic pyrethroid insecticides have certain structural features in common. Permethrin, bifenthrin and fenvalerate are typical examples (Figure 3). They are only slightly more polar than the organochlorines and may be extracted in a similar way. Mixtures of, for example, hexane and ether will elute pyrethroids from Florisil clean-up columns or cartridges. Those synthetic pyrethroids that do not contain chlorine atoms contain other halogens or chemical groups that are electron-capturing. Retention times are longer than for the organochlorine compounds, so the temperature programme has to rise to 275°C (Figure 4). However, resolution of the isomers of some pyreth-

roids (e.g. cypermethrin) requires a higher resolution column (e.g. $30 \text{ m} \times 0.25 \text{ mm}$ i.d.).

Carbamates

The carbamate insecticides are of two types, esters of *N*-methyl (or *N,N*-dimethyl) carbamic acid with

Figure 3 Synthetic pyrethroid insecticides.

Figure 4 Chromatogram of six synthetic pyrethroids in honey bee extract. Chromatogram of cleaned-up supercritical fluid extract of honey bees spiked before extraction with six pyrethroids, each at 0.1 mg kg^{-1} . 1, Bifenthrin; 2, λ -cyhalothrin; 3, permethrin; 4, cypermethrin; 5, fenvalerate; 6, deltamethrin. $1 \mu\text{L}$ direct injection at 175°C on to $30 \text{ m} \times 0.53 \text{ mm}$ i.d., DB-1 column ($1.5 \mu\text{m}$ film thickness). either a phenol or an oxime. Carbaryl and pirimicarb are examples of the phenolic type. Aldicarb and methomyl are examples of the oxime type (Figure 5). They are extractable with diethyl ether, dichloro-

Carbamate insecticide: general structure

Carbaryl

Pirimicarb (an *N,N*-dimethyl carbamate)

Aldicarb (an *N*-methyl oxime carbamate)

methane, ethyl acetate or acetone. Supercritical fluid extraction with carbon dioxide as extractant and a C_{18} trap is effective for dry or easily dried samples. Extracts containing carbamates may be cleaned up on columns or cartridges of silica gel, Florisil or very deactivated alumina eluted with hexane–diethyl ether mixtures or hexane with small additions of acetone. Gel permeation is an alternative clean-up technique that is useful for multiclass analyses.

The carbamate insecticides in general, and the oxime carbamates in particular, break down when heated. Before fused silica capillary GC columns and cool on-column injection became available, the carbamates were usually chromatographed as derivatives. A widely used derivatization procedure involved hydrolysis with hot aqueous sodium hydroxide solution, reaction of the phenol with 1-fluoro-2,4-dinitrobenzene and analysis on a dimethyl silicone packed column with electron-capture detection. Another procedure formed derivatives from intact carbamates and trifluoroacetic anhydride prior to GC analysis. Aldicarb, an oxime carbamate, and its toxic breakdown products may all be oxidized to aldicarb sulfone using peracetic acid or potassium permanganate. Aldicarb sulfone is chromatographed on a nonpolar column with a nitrogen-phosphorus detector (NPD), but with an injection port packed with glass wool at a temperature of 300°C where the carbamate breaks down and forms a nitrile from the oxime part of the molecule.

Carbamates of the phenolic type may be analysed successfully by using a nonpolar column of moderate length ($10\text{--}15 \text{ m} \times 0.53 \text{ mm}$ i.d.) together with cool

Figure 5 Carbamate insecticides.

Gradient from 50°C (0.5 min) at $20^\circ\text{C min}^{-1}$ to 235°C (4 min). Helium carrier gas. Hewlett Packard 5890 GC with NPD. Note: Pirimicarb has four nitrogen atoms, so gives a larger response than the others.

on-column injection, a gentle temperature gradient and NPD (**Figure 6**). For analysis by GC-MS, small bore capillaries are used, coupled with a 0.53 mm i.d. retention gap. GC of most oxime carbamates is unsuccessful unless they are converted to derivatives. For oxime carbamates, and perhaps for many phenol carbamates, the preferred method of analysis is by liquid chromatography-MS (LC-MS) or by liquid chromatography with post-column conversion to a fluorescent derivative.

Organophosphates

The organophosphorus insecticides are esters of phosphoric acid (or its sulfur analogues) and are therefore often referred to as organophosphates to distinguish them from compounds with a C-P bond. There are several groups of chemically related organophosphates. Dichlorvos, malathion and parathion are examples (**Figure 7**). Organophosphates cover a wide polarity range from persistent and fat-soluble compounds such as carbophenothion to water-soluble and easily hydrolysed compounds such as mevinphos. Most are extractable from dried samples with dichloromethane, diethyl ether or ethyl acetate. As with carbamates, supercritical fluid extraction with carbon dioxide and a C_{18} trap will extract most of them from dry samples (or from samples that can be dried with sufficient drying agent). Clean-up depends on the compounds being analysed and the nature of the sample material. Silica

Gradient from 140°C (0.5 min) at $10^\circ\text{C min}^{-1}$ to 180°C then at 6°C min^{-1} to 270°C (10.5 min). Helium carrier gas. AI Cambridge Ai93 GC with Tracor FPD.

gel does not give a very effective multiresidue clean-up from fatty materials as many organophosphates are eluted with co-extractives. Active alumina will break down some organophosphates. Gel permeation is probably the best choice when analysing organophosphates covering a wide range of polarities.

Residue-level GC may be carried out using splitless or cool on-column injection with detection by mass spectrometry, flame photometric or atomic emission detector or NPD (of these, NPD is the least selective). Medium polarity columns (such as 50% phenyl) give good separation and peak shapes, but a more polar phase such as cyanopropyl is sometimes useful (avoid using it with an NPD). As for column length and diameter, although a $15 \text{ m} \times 0.53 \text{ mm i.d.}$ column will separate many organophosphates over a long slow temperature gradient, there are so many compounds of this type that some are bound to co-elute whatever the resolving power of the column (Figure 8).

Future Trends in the Analysis of Insecticides by GC

Capillary columns have largely replaced packed columns and precise electronic control of temperatures and gas pressures are standard features of modern gas chromatographs. The bench-top mass spectrometer is

now firmly established as the detector of choice for most applications. As computers increase in power, software for interpreting chromatograms and spectra and selecting results of interest will continue to develop and will become integrated with laboratory information management systems. The atomic emission detector may gradually displace the well-established element-selective detectors in a role complementary to GC-MS-MS in the larger analytical laboratories. The move away from GC for the thermally less stable compounds will continue as LC-MS is now sufficiently sensitive and robust for routine residue analysis. Large volume injection is becoming established as a standard technique in water analysis. The slow trend towards the analysis of smaller and smaller residues in food and environmental samples may take a step forward when large volume injection is used together with improved cartridge clean-up methods. For some sample types, solid-phase microextraction will routinely provide rapid transfer of analyte to the GC.

Automation of extraction and clean-up operations has been predicted as a major area of advance for the past 15 years. The laboratory robot has not taken over all laboratory work and the trend is towards laboratory instruments with added versatility and capacity for automation.

Supercritical fluid extraction is making slow progress, probably because of its high cost compared to traditional extraction methods. Perhaps eventually the gas chromatograph will control the extraction and clean-up of its own samples, recording all steps with a thorough audit trail. Trends in insecticide analysis will also depend on what new classes of compounds are approaching commercial use. Element-selective detectors may not be suitable, but GC-MS-MS and LC-MS-MS should be able to cope with just about anything.

Introduction

Synthetic insecticides represent an almost universal environmental pollutant. Chemical structures of insecticides are very diverse, but major groups include organochlorine and organophosphorus compounds, methylcarbamates, and synthetic pyrethroids.

Organochlorine insecticides have been largely phased out of general use because of their toxicities and especially their persistence and accumulation in food chains. The structures of several common organochlorine insecticides are shown in **Figure 1**.

Organophosphorus insecticides have largely replaced organochlorine insecticides, because organophosphorus compounds readily undergo biodegradation and do not bioaccumulate. The structural formulas of some common organophosphorus insecticides are shown in **Figure 2**.

Carbamate insecticides are widely used for crop protection. Methylcarbamates are of environmental concern because of their high acute toxicity. **Figure 3** depicts the structures of several common carbamate insecticides.

Synthetic pyrethroids have been widely produced as insecticides during recent years. They have several advantages over organochlorine and organophos-

phorus insecticides, including greater photostability, enhanced insecticidal activity, and relatively low toxicity. The structures of common pyrethroids are shown in **Figure 4**.

As a result of their toxicity and carcinogenicity, insecticides are hazardous to human health and life. The major route of human exposure to insecticides is the gastrointestinal system. Besides regular use of polluted water, humans eat large amounts of food in which these pollutants have been accumulated, e.g., milk and dairy products, fish, poultry and meat, and fruits and vegetables.

Prior to 1960, an individual analytical procedure was used for almost every insecticide. As the number of insecticides in use increased, it became impractical to apply a large number of individual methods for all the insecticides that may be present. This has led to the development of multiresidue methods for the analysis of environmental samples. Ideally, multiresidue methods should provide rapid identification and quantification of as many different insecticides as possible at the required detection level.

The concentrations of insecticides in the environment are very low, typically in the parts-per-trillion to the parts-per-billion range. Furthermore, the sample matrices in which insecticides are usually determined are very complex in most cases. Consequently, extensive sample extraction, clean-up, and preconcentration are often required prior to the analysis.

Figure 1 Structures of common organochlorine insecticides.

Comparison of Methods of Extraction for Insecticides

The most difficult and time-consuming step in the determination of insecticides in environmental samples is the extraction of the analytes from the matrix. Several methods are used to accomplish this task, including liquid-liquid extraction (LLE), solid-phase extraction (SPE), solid-phase microextraction (SPME), and supercritical fluid extraction (SFE).

Semivolatile compounds, such as insecticides, have been traditionally extracted by LLE using an organic solvent, such as methylene chloride. The main advantages of LLE are its simplicity and inexpensive equipment used. The procedure suffers from a number of disadvantages, including the use of large volumes of organic solvent which must be very pure (pesticide-grade), tediousness, difficulty with automation, and the formation of emulsions which are difficult to break. Also, the LLE is a multi-step procedure and is therefore prone to loss of analytes and/or contamination.

There is no doubt that solid-phase extraction has now become the method of choice for the extraction, clean-up, and preconcentration of insecticides from environmental, food, or biological samples. SPE drastically reduces amounts of organic solvents used and is not as time-consuming. It enables field sampling and does not suffer from emulsion problems. Other reasons for the growing number of procedures using SPE are the large choice of sorbents, including new polar sorbents capable of retaining more polar insecticides, the introduction of apparatus for automated SPE, which reduces time of analysis and increases sample throughput, and the possibility of automation of analytical procedures. However, SPE is not completely free from problems such as column overloading by passing samples with high content of contaminants, or early breakthrough caused by clogging of the pores by solids present in a sample. The cost of disposable SPE cartridges or discs may be significant in the case of a large number of analyses. Also, the interaction between sample matrix and analytes may result in low recoveries. SPE can carry contaminants into the final sample producing a high background.

Solid-phase microextraction is a new and simple extraction method which uses fused silica fibres coated with a polymeric liquid phase, such as polydimethylsiloxane, or a solid adsorbent, to extract analytes from gaseous, liquid or solid samples. The SPME process has only two steps: (1) partitioning of analytes between the fibre coating and the sample matrix, followed by (2) desorption of extracts into an analytical instrument: gas chromatograph or high-performance liquid chromatograph. SPME is different from SPE in that SPE isolates the majority of the analyte (> 90%) from a sample but only a small fraction of the sample (1-2%) is analysed, while SPME isolates only 2-20% of the analyte, but all of that sample is used in the analysis. SPME is solvent-free and it requires small amounts of samples. The SPME devices enable simple and direct introduction of concentrated samples into the analytical instruments. These devices are commercially available and the technique has been automated. The SPME technique has a wide linear dynamic range and low detection limits. Since SPME is usually used in the equilibrium rather than exhaustive extraction mode, recoveries are not 100%, but the precision and accuracy of the analytical methods using SPME are similar to those using other extraction procedures. The current limitation of SPME is a limited choice of available fibres, especially for the extraction of the more polar insecticides.

In the last six years, supercritical fluid extraction has proved to be an appropriate replacement for the

Figure 2 Structures of typical organophosphorus insecticides.

solvent extraction of insecticides from solid samples. SFE has gained acceptance in environmental analyses because it is a rapid, nonorganic solvent extraction technique that gives recoveries equal to, or even better than, traditional extraction procedures. SFE can be used directly or it can be coupled with solid-phase extraction (SPE-SFE). Direct SFE is mostly used for solid matrices (soil, sediment, food), while the tandem SPE-SFE is usually used for the extraction of insecticides from aqueous samples. The disadvantages of SFE include high costs associated with high-pressure fluid delivery system and high-purity gas source, both of which are heavy equipment that make field analysis difficult. However, the combination of solid-phase extraction and supercritical fluid extraction enables the performance of SPE directly in the field, using SPE sorbents, and carrying out the SFE step in the laboratory, thus eliminating the need for transporting the SFE equipment to the field.

In the near future, further improvements are to be expected with SPME, SPE, SFE and their combination (SPE-SFE). This should lead to the development of more standard methods for the determination of insecticides using these extraction techniques.

Application of SPE and SPME to Extraction and Preconcentration of Insecticides

Air Analysis

Increasing concern over the presence of insecticides in ambient and indoor air has led to the development of specific extraction methods for these pollutants. As a result of very low concentrations of insecticides in air (ng m^{-3} to $\mu\text{g m}^{-3}$), air sampling methods call for large sample volumes, ranging from about 1 m^3 to close to 1000 m^3 . In order to achieve those sample volumes in reasonable time, high sampling rates are required. Consequently, the sorbents used for air sampling should have low pneumatic resistance. The most typical extraction procedure makes use of polyurethane foam (PUF) as a lightweight, easy-to-use sampling material for these semivolatile compounds. Cylindrical PUF plugs effectively trap insecticides without creating excessive back pressure. Thus, high sampling rates are possible, which allows shorter sampling times and ensures more representative samples. These high sampling rates may also be required

Figure 3 Structures of commonly used carbamate insecticides.

to attain needed detection limits. PUF plugs are sometimes used with an additional sorbent, such as Tenax TA or XAD-2 resin, to collect more volatile analytes. The air sample is usually first filtered through a microfibre filter, which traps aerosols and particulates. Then the air is drawn through the PUF cartridge. Following sample collection, the PUF sorbent is extracted by Soxhlet extraction with 5% diethyl ether in hexane and the insecticides are determined by gas chromatography with selective detection. For some insecticides, high performance liquid chromatography (HPLC) with an ultraviolet (UV) detector or electrochemical detector may also be the method of choice. If necessary, the extract may be cleaned up by SPE using Florisil or alumina and concentrated using a Kuderna-Danish apparatus. The above procedure can be applied to the multiresidue analysis of insecticides.

Applications using PUF to extract insecticides from air samples include a number of standard methods, including EPA Method IP-8, Method TO-4A and TO-10A. **Table 1** summarizes SPE conditions used for the extraction of insecticides from air samples.

XAD and Tenax resins have also been used for the isolation and analysis of insecticides from air samples. A method based on a high volume sampler with an XAD-2 resin trap was used to monitor 39 pesticides in ambient air. The volume of air sampled was 700 m³. After the extraction, pesticides were separately extracted with methylene chloride from the filter and XAD-2 resin. Extracts were concentrated and cleaned up by silica gel column chromatography and analysed by capillary gas chromatography/mass spectrometry with selected ion monitoring (cGC-MS-SIM). Organophosphorus and carbamate insecticides were detected at the 10 ng m⁻³ level.

Figure 4 Structures of common pyrethroid insecticides.

An improved sampling method using SPE was developed for the multiresidue determination of pesticides in indoor air. The method involves adsorption of the pesticides in 1 m³ of air onto Tenax TA via an air-sampling pump, desorption with acetone, and determination by GC-MS. Limits of detection for the 23 pesticides studied (including organophosphorus insecticides) were on the order of ng m⁻³.

Recoveries of insecticides from XAD and Tenax resins can be improved by using supercritical fluid extraction to elute the analytes.

Water Analysis

The determination of insecticides in water samples is carried out by gas chromatography, liquid chromatography, or thin-layer chromatography. These chromatographic techniques require efficient isolation and concentration procedures, such as solid-phase extraction and solid-phase microextraction. Generally, the major role of SPE in water analysis is for trace enrichment of insecticides. The usual sample volume for trace enrichment varies from 100 mL to 1 L, although large-volume analysis by SPE is also possible. In the latter case, 10 to 100 L of water is passed through a column containing 1 to 10 L of XAD resin. This approach has been used to isolate and determine DDT from natural waters and the detection limit was in the order of pg L⁻¹.

The mechanism of sorption in trace enrichment is typically reversed phase, and the commonly used sorbents are C-18, C-8 or styrene-divinylbenzene (SDB) porous polymer. Trace enrichment using SPE can be accomplished in two modes: cartridge or disc. Both modes can be automated and be performed

Table 1 SPE conditions used in extraction of insecticides from air

Sample	Air (0.9 m ³) at 1–5 L min ⁻¹ for 4–24 h (low volume sampling (LVS)). Air (> 300 m ³) at 0.225 m ³ min ⁻¹ for 24 h (high volume sampling (HVS)).
Analytes	Organochlorine (OC), organophosphorus (OP), methylcarbamates (MC), pyrethroids (PY). Concentration: 0.001–50 µg m ⁻³ .
Sorbent	7.6 cm × 22 mm ID. PUF plug (density 0.0225 g mL ⁻¹) (LVS). 2.5 cm × 65 mm ID. PUF plug (HVS).
Sorbent preparation	Using Soxhlet extractor, wash plug with acetone for 16 h, followed by ether–hexane (5 : 95) for 16 h. Vacuum dry 2–4 h at room temperature. Place in glass sampling cartridge and seal until sample collection.
Elution of analytes	Using Soxhlet apparatus, extract plug with 300 mL of ether–hexane (5 : 95) for 16 h. Concentrate the extract to 5.0 mL using a Kuderna–Danish apparatus.
Extract clean-up	For OC analysis, remove OP and MC with alumina. Use Florisil to achieve class separation.
Determination	OC cGC/ECD OP cGC/FPD or NPD MC cGC/NPD or reversed-phase HPLC Multiresidue GC-MS

Table 2 SPE conditions used in extraction of organochlorine insecticides from water

Sample	River water (100 mL) with 1% methanol added
Analytes	28 organochlorine insecticides and their metabolites
Sorbent	500 mg C-18 cartridges
Sorbent preparation	Precondition with 5 mL each of acetone, methanol, and distilled water
Elution of analytes	Rinse the cartridge with 3 mL water, apply vacuum to remove water, and elute the analytes with 3 mL acetone
Determination	GC/ECD

either online or offline. The major advantage of discs over cartridges is that the former can use higher sample flow rates, which reduces the time necessary for extraction. On the other hand, the advantage of cartridges over discs is that the cartridges require a smaller volume of solvent to elute the analytes, which simplifies subsequent steps in the analytical procedure.

A typical SPE sequence using a C-18 cartridge consists of four steps. First, the SPE column is prepared to receive a water sample, by wetting with an organic solvent and by conditioning with water. Then, the aqueous sample is applied, and often the insecticides of interest are retained together with interferences from the sample matrix. Some of these interferences can then be removed by application of a washing solution. In the last step, the concentrated insecticides are desorbed with a small volume of organic solvent, which can then be partially evaporated to increase the enrichment factor. An example of such a procedure used for the extraction of organochlorine insecticides from water is shown in **Table 2**.

The US EPA has a number of standard methods for the analysis of organic pollutants in water, including insecticides, which make use of SPE. In Method 525.1, for example, analytes are extracted from a 1 L water sample using a C-18 SPE cartridge or disc. Next, the analytes are eluted from the cartridge or disc with a small quantity of methylene chloride, and concentrated further by evaporation of some of the solvent. The analytes are then quantified using GC-MS.

The US EPA has also approved various methods based on SPE discs containing either C-18 silica or styrene-divinylbenzene sorbent for the determination of organonitrogen and organophosphorus pesticides (Method 507) and of organochlorine insecticides (Method 508.1) in drinking and source waters. The use of SPE discs is particularly easy. The disc is placed in a filtration apparatus attached to a water-aspirator

vacuum source. Next, it is conditioned with 10 mL of methanol and 10 mL of distilled water, and the water sample is filtered through it. Then the extraction funnel and frit assembly is transferred to a second vacuum filtration flask containing a test tube. Three 5 mL aliquots of the eluting organic solvent are then drawn through the disc. The combined eluates are concentrated by evaporation and analysed by GC or HPLC.

There are many choices for eluting solvents in trace enrichment by C-18 solid-phase extraction. One of the most common solvents, removing the majority of hydrophobic insecticides sorbed on the resin, is ethyl acetate. If this eluent is followed by methanol, then this combination is compatible with both GC-MS and HPLC analysis. For very hydrophobic analytes, such as dichlorodiphenyltrichloroethane (DDT), a mixture of ethyl acetate–methylene chloride (1 : 1) is more effective than ethyl acetate alone.

Reversed-phase SPE is best suited for the extraction of nonpolar insecticides, such as organochlorine compounds. For polar pesticides, such as methylcarbamates or some organophosphorus compounds, different sorbents are preferred. Of those, two types are most common: graphitized carbon blacks (GCB) and styrene-divinylbenzene resins. Graphitized carbon black was successfully used to isolate carbamate and organophosphorus insecticides from water. Multi-residue methods have been developed for both polar and nonpolar insecticides in water for subsequent analysis by HPLC. Detection limits of 0.003 to 0.007 $\mu\text{g L}^{-1}$ were reported for a number of the analytes. A typical procedure for insecticide extraction from drinking water using a GCB sorbent is shown in **Table 3**. Usually, the preferred eluting solvent is a mixture of methylene chloride–methanol (80 : 20).

Table 3 SPE conditions used in extraction of carbamates and organophosphorus insecticides from water

Sample	Drinking water (100 mL to 1 L)
Analytes	Carbamates and organophosphorus insecticides
Sorbent	0.25 g ENVI-Carb
Sorbent preparation	Precondition with 5 mL methylene chloride–methanol (80 : 20), 1 mL methanol, and 10 mL 2% acetic acid in water
Elution of analytes	Elute the analytes with 0.8–1 mL methanol, followed by 2 \times 3.5 mL methylene chloride–methanol (80 : 20). Dry eluate to 400–500 μL . Reconstitute samples to 1 mL with methanol
Determination	HPLC with UV, DAD, or MS detection

DAD, diode array detector.

New polymeric sorbents, based on styrene-divinylbenzene copolymer, have proved their usefulness in the isolation of polar insecticides from water. These polymers (SDB from International Sorbent Technology or the Oasis HLB from Waters) have some hydrophilic nature to improve their wetting characteristics for good mass transfer, but they still have high capacities for polar analytes. The Oasis sorbent was used to isolate organophosphorus insecticides from tap water. Recoveries of the analytes ranged from 87 to 112%.

SPE clean-up and trace enrichment methods can be automated. In semiautomated methods, some operator intervention is required. In fully automated procedures, the entire SPE operation is carried out without user intervention, including online analysis by gas chromatography (GC) and HPLC. Automated online methods using SPE for the determination of carbamates and organophosphorus insecticides in water coupled with HPLC or GC have been developed. The methods offer all the inherent advantages of automatic methods, i.e. low sample and reagent consumption, minimal manipulation and contact with the reagents, accurate and reproducible results, and high throughput. The detection limits for the automated procedures were in the ng L^{-1} range for organophosphorus insecticides and between 0.01 and $1 \mu\text{g L}^{-1}$ for carbamates.

The majority of environmental applications of solid-phase microextraction have dealt with the isolation and determination of organic analytes in water samples. SPME has been successfully used for the determination of carbamates, as well as organochlorine and organophosphorus insecticides, in aqueous matrices. Usually, poly(dimethylsiloxane) (PDMS) fibres are used in the analysis of organochlorine insecticides; for organophosphorus insecticides, polyacrylate (PA) fibres are preferred, whereas for carbamates, either PDMS or PDMS/divinylbenzene (DVB) fibres are applied. A multiresidue procedure for the simultaneous determination of 60 pesticides in water has been developed. Either a PDMS-coated or a PA-coated fibre may be used to achieve detection limits in the low $\mu\text{g L}^{-1}$ range. The method had adequate precision and good linearity over the range 0.1–100 $\mu\text{g L}^{-1}$.

SPME is characterized by its simplicity, low cost, rapidity and sensitivity. An example of SPME procedure for the determination of organochlorine insecticides in water is shown in Table 4.

The compact nature of the SPME device and the simplicity of the procedure allow this method to be readily automated. The automated SPME instrument is available from Varian. Two online methods of determination using SPME have been described: one

Table 4 SPME conditions used in extraction of insecticides from water

Sample	4 mL water
Analytes	Organochlorine insecticides
Sorbent	100 μm polydimethylsiloxane fibre
Sorbent conditioning	Expose the fibre to the hot GC injection port (250°C) for at least 3 h
Extraction	Immerse the fibre into the sample for 15 minutes, stir rapidly
Elution of analytes	After extraction, insert the fibre into the GC injector port held at 260°C for five minutes
Determination	GC with ECD detection

for organochlorine insecticides and the other for organophosphorus insecticides. The former method used GC with electron-capture detector (ECD), while the latter method employed GC with nitrogen-phosphorus detector (NPD).

Soil and Sediment Analysis

Soils and sediments have much more complex matrices than air or groundwater. Consequently, the analysis of soil making use of SPE must be preceded by the extraction of the insecticides from a soil sample by an organic solvent or a mixture of solvents. A methanol/water mixture is often used for this purpose. Alternatively, accelerated solvent extraction can be used for the extraction of soils and sediments. Recently, however, supercritical fluid extraction has also been tried and found to be superior to liquid extraction in terms of reproducibility. The use of microwave-assisted solvent extraction (MASE) for the extraction of organochlorine insecticides from soil samples has been investigated. Compared to a conventional liquid extraction method, MASE yielded better or equal recoveries and superior repeatability. Extraction of insecticides from soil and sludge samples can also be accomplished by using subcritical water. Subcritical water is an excellent solvent to quantitatively extract both polar and nonpolar analytes from soils. Furthermore, subcritical water extractions can be highly selective and can be coupled with both SPE and SPME.

Following the extraction of insecticides from soils or sediments, SPE is used for both clean-up of the extract and for trace enrichment of the analytes. The procedures employed will be different for clean-up compared to those of trace enrichment. Two strategies are possible. The first is to remove interfering compounds by trapping them on the SPE cartridge and allowing the insecticides to pass through the cartridge for direct analysis or further enrichment (SPE clean-up). The second approach is to isolate the insecticides directly by SPE and elute them free

from the interferences or to wash the interferences off the SPE sorbent prior to elution (trace enrichment).

Polar sorbents are usually used to accomplish SPE clean-up of soil extracts. The most common sorbent is Florisil, which has been used widely for clean-up of soil extracts for the determination of various insecticides. Silica gel has also been used for this purpose, mostly in the determination of nonpolar analytes, such as organochlorine insecticides or pyrethroids. Alumina has been used less often, and only for the determination of organochlorine analytes. The clean-up step can also use SPE cartridges packed with silica gel modified with polar aminopropyl groups. This procedure has been applied to the determination of N-methylcarbamates in soils.

Clean-up of soil extracts can also be based on size-exclusion chromatography (SEC), which separates species by size rather than polarity. Clean-up by sorbents such as Florisil does not remove interferences of high molecular mass and polarity similar to that of the insecticides. In contrast, SEC removes materials of high molecular mass, such as humic substances from soil extracts. Currently, polystyrene columns are the most often used SEC sorbents. They are eluted with a number of different solvents, such as cyclohexane or cyclohexane-ethyl acetate.

When nonpolar sorbents, such as C-18 or C-8, are used, the clean-up of soil extracts can be incorporated in the SPE sequence just before the insecticide desorption. In this strategy, the soil extract is passed through the SPE cartridge or disc. Next, the sorbent is rinsed with a small volume of water containing an organic modifier, usually methanol. The interferences are removed, but the insecticides are retained. This step can only remove interferences that are more polar than the analytes, so the method can only be applied for the determination of nonpolar insecticides. Following the clean-up step, the insecticides are eluted from the SPE cartridge or disc using a small volume of an organic solvent, typically ethyl acetate, and this extract is further preconcentrated or directly analysed.

Table 5 summarizes SPE conditions used for the extraction of insecticides from soils and sediments.

When using polar sorbents, such as silica gel, alumina, Florisil, or silica gel with chemically bonded aminopropyl groups, SPE procedures can combine trace enrichment of insecticides and removal of interferences in soil extracts. In this strategy, the soil extract in a nonpolar solvent is passed through a column or cartridge containing a polar sorbent. Next, the analytes are eluted from the sorbent in a series of fractions using solvents of increasing polarity. For example, the effectiveness of Florisil, silica gel and alumina for the clean-up and trace enrichment of soil extracts containing organochlorine and organophosphorus insecticides has been compared. The results showed that silica gel was the best adsorbent. Nonpolar interferences were removed by a rinse with cyclohexane. An elution with ethyl acetate-hexane (5 : 95) followed by ethyl acetate resulted in the separation of the two classes of insecticides. The organochlorine insecticides were present in the first fraction, and the organophosphorus insecticides in the second fraction.

SPME has been used for the extraction of organochlorine insecticides from soil samples and soil solutions. The fibre was coated with polydimethylsiloxane. The method linearity and detection limits were tested in the 0.1–20.0 ng g⁻¹ range. SPME was found to be useful for screening of insecticides in contaminated soil samples, offering a simple alternative to established methods of analysis of insecticides in soil.

Analysis of Biological Materials

Biological matrices consist of body fluids, such as urine or plasma, and tissues. Biological fluids are viscous and may require pre-treatment, e.g. centrifugation, dilution or buffer addition, before SPE can be applied. Prior to extraction, tissue samples generally need to be blended or ground in order to disrupt the general architecture of the sample. Because of the complexity of matrices, SPE may have to

Table 5 SPE conditions used in extraction of insecticides from soil and sediment

Sample	Soil or sediment (20 g)
Analytes	Organochlorine (OC), organophosphorus (OP), methylcarbamates (MC), pyrethroids (PY)
Extractant	Water-methanol (10 : 90), water-acetone (50 : 50), hexane-acetone (90 : 10). Extract twice using Soxhlet, heated vial or accelerated solvent extractor. Dilute with distilled water and then process by SPE
Sorbent	360 mg of C-18 in a cartridge or 47 mm C-8 discs
Sorbent preparation	Precondition with 2 mL each of methanol, ethyl acetate, methanol, and distilled water
Elution of analytes	After sample addition, remove water from the sorbent by air, and elute with 2 mL of ethyl acetate
Determination	OC cGC/ECD or GC/MS OP cGC/FPD or NPD or GC/MS MC cGC/NPD or reversed phase HPLC Multiresidue GC-MS

be used for clean-up of sample extracts, as well as for trace enrichment.

Reversed-phase sorbents, such as C-18, are most commonly used for SPE of biological samples. The determination of insecticides in fluids does not require such extensive sample preparation as the analysis of insecticides in tissues. For example, in SPE methods for isolation and clean-up of organochlorine insecticides or synthetic pyrethroids from human urine or plasma, the samples only needed to be diluted prior to extraction, and the eluent did not require any further clean-up prior to gas chromatographic determination (see Table 6 for details). High recoveries, ranging from 90–102% for urine and 81–93% for plasma, were obtained.

The extraction of insecticides from tissue samples requires large volumes of organic solvents (100–500 mL), and extensive extract clean-up. The procedure is also very time-consuming. A novel procedure, so-called matrix solid-phase dispersion (MSPD), can reduce solvent use by 98% and increase sample throughput by 90%. This process involves the grinding of biological samples with bulk C-18 sorbent. The MSPD method consists of adding 0.5 g of sample to 2.0 g of C-18 packing and grinding the sample until a nearly homogeneous blend of sample components adsorbed onto the SPE material is obtained. The packing material is then transferred into a syringe barrel plugged with a filter paper disc. The column head is covered with a second disc and the contents are compressed with a plunger to a volume of 4.5 mL. The column may then be eluted with a solvent or a series of solvents for the analytes of interest. This procedure was used for the isolation of organochlorine and organophosphorus insecticides from a number of animal tissues. The analytes were eluted from the MSPD column with 8.0 mL of acetonitrile or acetonitrile–methanol (9 : 1) through a Florisil co-column. The resulting eluate was analysed directly by GC. The recoveries of the analytes

ranged from 60–114% for the concentrations examined.

Food and Natural Product Analysis

The determination of insecticides in food and natural products requires extracting the analytes from a complex matrix, either liquid or solid. Solids, such as food, must be homogenized and extracted with organic solvents or aqueous buffers before SPE. Interferences from the food products must be removed either during extraction or during SPE isolation. Homogenization can be carried out by grinding followed by solvent extraction and filtration, or by grinding and Soxhlet extraction. A recent improvement is accelerated solvent extraction (ASE), in which high temperature and pressure are used to push an organic solvent through a solid sample and to collect the eluate in a vial. Automated instrumentation capable of running 30 samples at once is available commercially. One sample is processed in 15 minutes with extraction efficiency equal to that produced by Soxhlet extraction in 12 h. Supercritical fluids can also be used for extraction of food. In this procedure, supercritical carbon dioxide is used to remove analytes from food without dissolving the matrix. Methanol is often added as a modifier to the supercritical CO₂ to enhance the solubility of analytes. Microwave-assisted solvent extraction and matrix solid-phase dispersion, fast and safe alternatives to traditional solvent extraction, can also be applied to food analysis.

The solvent used to extract insecticides should be compatible with the SPE method being used. In addition, it should not co-extract interferences. For samples with high content of nonpolar components (such as fats or oils), a nonpolar solvent such as hexane should be chosen. This, in turn, determines normal-phase SPE with Florisil, silica, alumina or a cyano (CN) sorbent. Samples with high water content are best extracted with polar solvents such as methanol, acetone, or acetonitrile. In this case, reversed-phase SPE (C-18 or C-8) is preferable.

A multiresidue method for the determination of 43 organophosphorus, 17 organochlorine, and 11 N-methyl carbamate insecticides in 10 g of plant or animal tissues has been developed. The insecticides are extracted with 5% ethanol in ethyl acetate. Samples with high lipid content are cleaned up by automated gel permeation chromatography with a 30% ethyl acetate in hexane eluent and inline silica gel minicolumns. Highly pigmented samples are cleaned up with class-specific SPE columns: Florisil for organochlorine insecticides, and aminopropyl for N-methyl carbamates. No further clean-up of

Table 6 SPE conditions used in extraction of insecticides from biological fluids

Sample	Human urine or plasma diluted with water (OP) or with 70% methanol (pyrethroids)	
Analytes	Pyrethroids, organophosphorus (OP)	
Sorbent	C-18 cartridges	
Sorbent preparation	Precondition with 2 mL each of methanol, ethyl acetate, methanol, and distilled water	
Elution of analytes	2 mL chloroform (pyrethroids) or chloroform–isopropanol (9 : 1) (OP).	
Determination	Pyrethroids	cGC/FID
	OP	cGC/FID

organophosphorus insecticide was necessary. Recovery of 71 insecticides ranged from 77 to 113%. The concentrated extracts were analysed by GC or liquid chromatography (LC) with specific detection.

Many multiresidue methods use acetonitrile extraction of the homogenized sample, reversed-phase SPE extraction of the analytes, and clean-up with an aminopropyl cartridge. In other cases, SPE is used for clean-up only. In this case, preparation of samples involves extraction with acetone and partitioning into methylene chloride–petroleum ether. This extract is cleaned up with an SPE aminopropyl column. The latter procedure has been automated by Gilson (Automated SPE clean-up (ASPEC)).

MSPD with C-18 silica has been used in multiresidue insecticide analysis in fruits and vegetables. The procedure is simple, inexpensive and rapid. Low detection limits (in the ppb range) and high recoveries (67–105%) were found for the investigated analytes.

In addition to using reversed-phase and normal-phase SPE for the clean-up and isolation of insecticides from foods and natural products, graphitized carbon black has also proved an excellent sorbent for this purpose. Table 7 shows SPE conditions for a rapid multiresidue clean-up and analysis of over 200 organochlorine, organophosphorus and

methylcarbamate insecticides in fruits and vegetables. Recoveries of the analytes ranged from 65 to 99.3%.

Future Developments

It is reasonable to expect continued development of the methods of isolation and preconcentration of insecticides based on SPE and SPME. The future for the latter technique looks particularly interesting, because simplification and increasing automation of preliminary analytical operations, particularly the extraction steps, is one of the modern trends in analytical chemistry. The analytical procedures using SPME have only two steps, can be easily automated, are rapid, simple, inexpensive, sensitive, and suitable for field analysis. New fibre coatings, more suitable for polar analytes, including those containing in-fibre derivatization reagents, should further extend the applicability of this technique.

In the extraction of insecticides from solid samples, such as food or biological materials, more procedures using MSPD are expected.

Future developments in solid-phase extraction will involve miniaturization of SPE procedures and considerably more online use of GC and HPLC. Sample handling will be minimized with automated systems. The use of automation will result in fast, easy, and reliable methods for SPE. To this end, syringe barrel designs and 96-well SPE plates will be used more extensively. Also, disposable pipette tips holding an extraction disc in the tip end, which are robotics compatible, will become more popular.

New SPE phases taking advantage of specific interactions will be introduced more widely. These include affinity SPE with antibodies bound to a solid substrate (immunosorbents) and the molecular-imprinted polymers.

Other uses of SPE, such as derivatization on SPE sorbents, will become more widely used. Also, the use of supercritical fluid extraction and subcritical water extraction for the elution of insecticides from sorbents will be given more attention. Compared to conventional solvents, SPE will enable more selective removal of interferences and more selective extractions of insecticides from matrix, and will minimize preparation of some complex samples (e.g. biological tissues) with the potential for developing completely automated SFE-SPE-SFE methods.

Table 7 SPE conditions used in extraction of insecticides from fruits and vegetables

1. Homogenize 50 g of chopped sample with 100 mL of acetonitrile
2. Add 10 g of NaCl. Homogenize for 5 minutes. Discard the lower aqueous layer
3. Condition C-18 tube with 5 mL of acetonitrile
4. Add 2 mL of acetonitrile extract from the sample; discard
5. Pass 13 mL of acetonitrile sample extract through the tube; collect
6. Add enough Na₂SO₄ to C-18 extracted sample to reach 15-mL mark. Cap the tube, shake well, and centrifuge for 5 minutes
7. Evaporate 10 mL of centrifuged sample to 0.5 mL
8. Add 1 cm Na₂SO₄ to the top of an ENVI-Carb (graphitized carbon black) tube
9. Condition the ENVI-Carb and LC-NH₂ tubes separately with 5 mL acetonitrile–toluene (3 : 1)
10. Connect the LC-NH₂ tube to the outlet of the ENVI-Carb tube
11. Condition with 5 mL of acetonitrile–toluene (3 : 1)
12. Add 0.5 mL of C-18 cleaned sample; allow to drain through both tubes by gravity; collect
13. Rinse the tubes with 1 mL acetonitrile–toluene (3 : 1). Continue eluting with 5 mL of solvent mixture
14. Rotoevaporate to approximately 2 mL. Add 10 mL of acetone. Evaporate again. Reconstitute to the desired volume
15. Organochlorine and organophosphorus insecticides are determined by GC/MS. Carbamates are determined by HPLC/postcolumn derivatization/fluorescence detection.

ION ANALYSIS

Capillary Electrophoresis

M. Macka and P. R. Haddad, University of Tasmania, Hobart, Tasmania, Australia

Introduction and Scope

Before the advent of capillary electrophoresis (CE), some impressive separations of inorganic species had been achieved by other electrophoretic methods, such as the separation of lanthanoids by paper electrophoresis using complexation with 2-hydroxyisobutyric acid (HIBA). With the introduction of capillary electrophoresis in 1981 by Jorgenson and Lukacs, separations of inorganic anions and cations started to appear quite early, but only sporadically until the late-1980s. There were several reasons for this. First, CE was a very new analytical technique

and some time was needed for the theoretical background and instrumentation to mature. The second factor was competition with alternative analytical techniques, mainly spectroscopic methods (atomic absorption spectrometry, inductively coupled plasma spectrometry), in the area of determinations of metals, and ion chromatography in the area of separation of inorganic anions. Third, the main potential of CE was seen to be in the separation of biopolymers and biologically active compounds including drugs, with inorganic analysis being regarded as a relatively minor application area of CE. Although the last two factors remain valid, CE has matured to the stage where applications are sought in all areas of analysis, including inorganic analysis. This development has been characterized by more research oriented towards solving the practical requirements of inorganic analysis. The important developments in inorganic analysis by CE are summarized in **Table 1**.

Anions and cations migrate in opposite directions when placed in an electric field. Typical commercial

Table 1 Some important developments in inorganic analysis by CE

Time	Development
1967	First separation of cations (Br^{3+} Cu^{2+}) by free solution electrophoresis (0.1 mol L^{-1} lactate) in a 3 mm axially rotating tube
1974	Separation of alkali metal cations in 200–500 mm Pyrex capillaries with potentiometric detection
1979	Separation of inorganic anions using 200 mm PTFE capillary and conductometric detection
1983	Separation of Cu^{2+} , Fe^{3+} using a simple acetic acid electrolyte and direct photometric detection at 254 nm
1987	Indirect detection of anions
1989	Use of pre-capillary formed PAR complexes for separation of Co^{II} , Cr^{III} , Ni^{II} , Fe^{III} MEC (electrolyte containing SDS, pH 8, 0.1 mmol L^{-1} PAR) and using direct detection in visible
1990	Indirect photometric detection of anions using chromate electrolyte at pH 8 and reversed EOF
1990	Separation of rare earths metals and Li, Na, K, Mg using HIBA and indirect UV detection using an electrolyte of 0.03 mol L^{-1} creatinine-HAc pH 4.8, 4 mmol L^{-1} HIBA
1995	Hyphenation with ICP-MS: separation and detection of Sr, Cu, Fe^{III} , Fe^{II} , Cr, As, Sn^{II} , Sn^{IV}
1997	ITP-CE online: separation of Fe^{III} as pre-capillary formed EDTA complex; BGE: 25 mmol L^{-1} MES + 10 mmol L^{-1} bis-tris-propane, pH 6.6; leading: 10 mmol L^{-1} HCl + 20 mmol L^{-1} L-histidine + 0.1% HPMC, pH 6.0; terminating: 5 mmol L^{-1} MES

MEC, micellar electrochromatography

CE instruments have one point of sample introduction and one point of detection, so the choice must be made as to the polarity of the electrodes placed at the injection and detection ends of the capillary in order to establish the direction of movement of ions. Further, the electroosmotic flow (EOF) caused by the application of the separation potential will sweep the ions either towards or away from the detector, according to the polarity of the electrodes and the surface charge on the capillary. While it is theoretically possible to design a CE system in which a high EOF flowing towards the detector is established, causing both anions and cations to flow towards the detector, the electrophoretic mobilities of most inorganic anions and cations are too high to allow this approach to be applied. It is therefore more common for inorganic anions and cations to be analysed separately and for their electrophoretic movement to be in the same direction as the EOF (i.e. towards the detector). This is termed 'co-electroosmotic' separation.

Separation of Inorganic Anions

Separation Strategy

The electrophoretic mobilities of inorganic anions are quite large in comparison to those of most organic anions (Figure 1). Consequently, the normal instrumental arrangement is to assign the negative side of the separation voltage to the electrode at the injection end (so that the electrophoretic migration of the analyte anions is towards the positive electrode at the detection end). Moreover, since the normal flow of EOF in a fused silica capillary is towards the cathode (i.e. in the direction opposite to the electrophoretic migration of anions in the above case), it is normally

necessary to suppress or reverse the EOF to give a rapid co-electroosmotic separation. Such EOF reversal can be achieved by dynamic modification of the fused silica capillary inner wall by adsorption of cationic compounds or by permanent (covalent bonding) of cationic groups onto the fused silica capillary inner wall to provide an overall positive charge on the wall. The dynamic modification method is used most commonly and can be achieved by adsorption of suitable cationic surfactants (such as C_{12} to C_{16} alkyltrimethylammonium salts) or of large molecules such as cationic polymers (e.g. polybrene, poly(N,N,N',N'-tetramethyl-N-trimethylenehexamethylenediammonium dibromide) by adding these to the background electrolyte (BGE) or by flushing the capillary between the runs. This is illustrated schematically in Figure 2.

After introduction of the sample into the capillary and application of the separation voltage, the anions migrate towards the cathode at the detection end in the order of their effective electrophoretic mobilities, which means that the anions migrating fastest will be detected first. The flow of the bulk BGE driven by the EOF towards the detector (co-EOF separation) allows anions of low electrophoretic mobility to be carried to the detector point more rapidly than would occur based only on their electrophoretic mobility in case of a suppressed-EOF separation. Therefore typical co-EOF separations of anions are characterized by rapid analysis times, as illustrated in Figure 3.

Separation Selectivity

The electrophoretic mobilities of inorganic anions cover a wide range from about $30 \times 10^{-9} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ to over $100 \times 10^{-9} \text{ m}^2 \text{ V}^{-1} \text{ s}^{-1}$ (Figure 1). Inspection

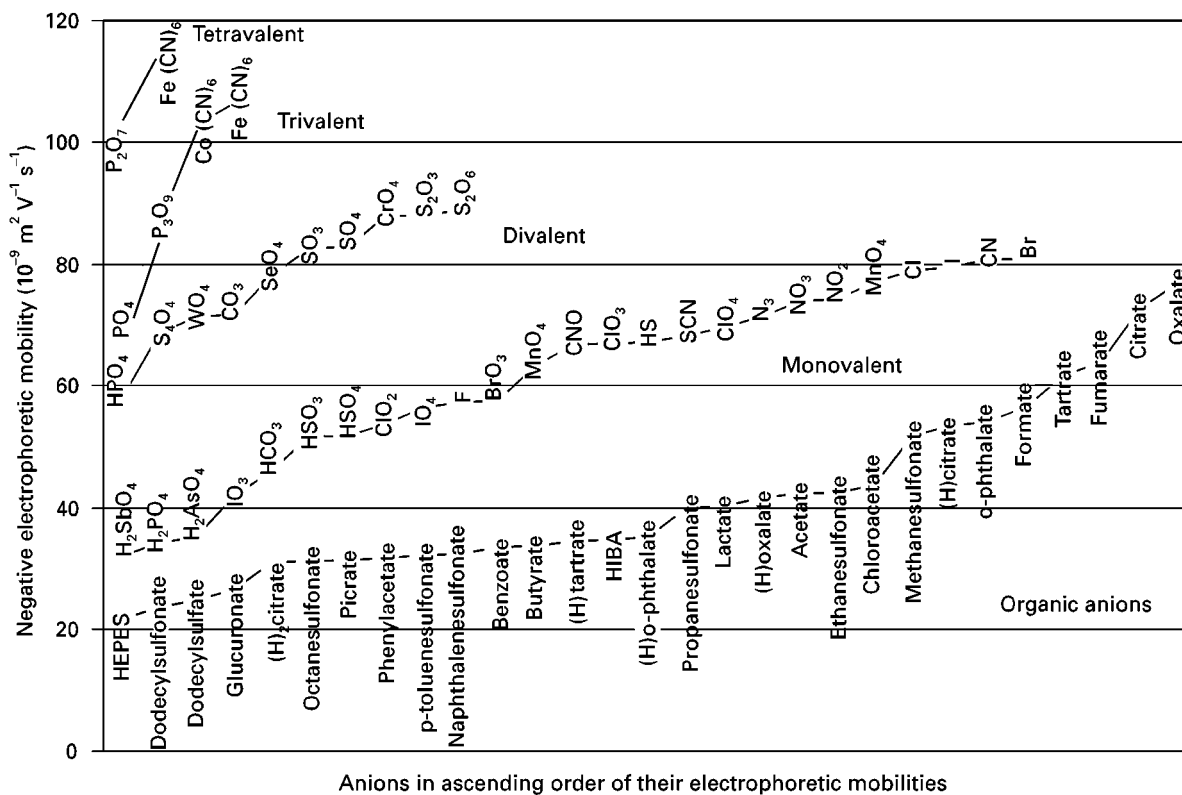

Figure 1 Electrophoretic mobilities of inorganic and some organic anions in ascending order of their mobilities. Key: (H), protonated form; (H)₂, diprotonated form, charges left out for simplicity. Electrophoretic mobilities were calculated from tabulated ionic conductances or taken from published values.

of Figure 1 shows that most inorganic anions have a unique value of electrophoretic mobility and should be straightforward to separate without the need to optimize the separation selectivity. However, in some cases electrophoretic mobilities of ions are similar

and steps need to be taken to manipulate selectivity in order to achieve a separation. The approaches available to achieve this goal are summarized in Table 2.

Probably the most universal tool for manipulating selectivity is to alter the solvation of the analyte anion

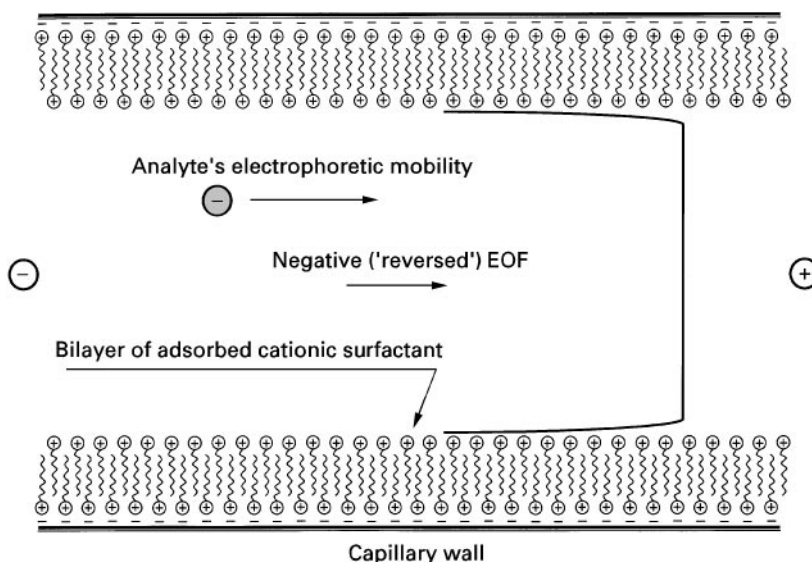

Figure 2 Schematic representation of co-electroosmotic separation of anions using EOF reversal.

Figure 3 Separation of 30 anions using chromate BGE. Conditions: capillary, fused silica 75 μm i.d., 0.600 m length, 0.527 m to detector; BGE, 5 mmol L^{-1} chromate, 0.5 mmol L^{-1} tetradecyltrimethylammonium bromide (TTAB), pH 8.0; separation voltage, -30 kV; detection, indirect at 254 nm; injection, electrokinetic at 1 kV for 15 s; sample, 0.3–1.7 ppm of each anion. Peak identification: 1, thiosulfate; 2, bromide; 3, chloride; 4, sulfate; 5, nitrite; 6, nitrate; 7, molybdate; 8, azide; 9, tungstate; 10, monofluorophosphate; 11, chlorate; 12, citrate; 13, fluoride; 14, formate; 15, phosphate; 16, phosphite; 17, chlorite; 18, galactarate; 19, carbonate; 20, acetate; 21, ethanesulfonate; 22, propionate; 23, propanesulfonate; 24, butyrate; 25, butanesulfonate; 26, valerate; 27, benzoate; 28, L-glutamate; 29, pentanesulfonate; 30, D-glucanate. (Reproduced with permission from Jones WR and Jandik P (1991) Controlled changes of selectivity in the separation of ions by capillary electrophoresis. *Journal of Chromatography* 546: 445–458.)

by adding organic solvents. For those anions that exhibit protonation equilibria in the pH range used in CE, substantial selectivity changes can be achieved by pH variations. The effective mobility of the analyte is defined as the weighted average of all the

mobilities of each of the forms, which for an acid H_nA undergoing protonation equilibria is

$$\bar{\mu}_A = \sum_{i=0}^n \mu_i \alpha_i \quad [1]$$

Table 2 Equilibria utilized for governing the separation selectivity

Anions/cations	Source of separation selectivity	Examples of BGE additives
Anions	Changes of effective mobility by utilizing protonation equilibria Changes of effective mobility by changes in solvation of the anions Ion association of anions capable of hydrophobic interactions (e.g. I^- , SCN^-), with amphiphilic cations Ion exchange interactions with polycationic molecules	pH optimization Organic solvents Hexadecyltrimethylammonium Polybrene, polyethyleneimine
Cations	Complexation with an auxiliary ligand in partial complexation mode Influence of the metal on the $\text{p}K_a$ of a ligand group (total complexation mode) Dissociation of bound water molecules to mixed hydroxo–ligand–metal complexes (total complexation mode) Ion association of anionic complexes with amphiphilic cations, e.g. TBA^+ or hexamethonium (total complexation mode) IEEC (ion exchange electrochromatography), e.g. with poly(diallyldimethylammonium chloride), (total complexation mode) Changes of effective mobility by changes in solvation of the cations	HIBA, lactate, etc. PAR EDTA, CDTA and analogues DHABS, CN^- EDTA, Quin2 Organic solvents

HIBA, 2-hydroxyisobutyric acid; PAR, pyridylazoresorcinol; EDTA, ethylenediaminetetraacetic acid; CDTA, trans-1,2-diaminocyclohexane-N,N',N'-tetraacetic acid; DHABS, 2,2'-dihydroxyazobenzene-5,5'-disulfonate; Quin, 2,8-amino-2-[(2-aminomethylphenoxy)methyl]-6-methoxyquinoline-N,N',N'-tetraacetic acid.

where μ_i is mobility and α_i is the fraction of the anion ion existing in form i .

For this approach to be successful, the BGE must be well buffered to avoid pH inhomogeneity within the migrating sample zone. Finally, ion exchange-type interactions between the analyte anions and some cationic water-soluble polymers may also be used to manipulate separation selectivity.

Detection of Anions

Direct and indirect photometric detection Most commercial CE instruments are equipped with a photometric detector and therefore direct and indirect photometric detection are the most commonly used detection methods in CE. Probably the most simple and robust detection technique in terms of baseline stability and lack of system peaks is direct photometric detection. Unfortunately this can be applied only to a few inorganic anions, such as iodate, bromide, thiocyanate, nitrate, nitrite, and some others.

Indirect detection has the prime advantage of being universal in its applicability and is the most frequently applied detection mode for CE separations of both inorganic anions and cations. An absorbing co-ion (commonly referred to as the probe ion) is added to the BGE and the detector monitors a suitable absorbing wavelength of the probe. Migrating bands of analytes displace the probe from the BGE and indirect detection is possible due to the resulting decrease in absorbance. The limit of detection (LOD) of a nonabsorbing analyte ion when detected by this process is given by:

$$c_{\text{LOD}} = \frac{c_{\text{P}}}{R \times D} = \frac{c_{\text{P}} \times N_{\text{BL}}}{R \times A} = \frac{N_{\text{BL}}}{R \times \varepsilon \times l} \quad [2]$$

where c_{LOD} is the concentration LOD, c_{P} is concentration of the probe co-ion in the BGE, R is the transfer (or displacement) ratio (that is, the average number of

probe co-ions displaced by one analyte ion), D is the dynamic reserve (the ratio of absorbance caused by the probe in the BGE to baseline noise), N_{BL} is the baseline noise, A is the absorbance caused by the probe in the BGE, ε is the molar absorptivity of the probe, and l is the effective pathlength.

The factors influencing detection sensitivity in indirect photometric detection are summarized in Table 3. As a general rule, the BGE should be well buffered to ensure optimal reproducibility, but at the same time the buffer must not add any competing co-ions to the BGE so that the probe ion is the only species displaced by the analyte (maximizing R) and detection sensitivity is therefore maximized. For indirect detection of anions it has been shown that this can be achieved either by using a buffering counter ion (i.e. one having the opposite charge sign to the probe) or by using buffering species of extremely low mobility, such as buffering ampholytes employed at a pH close to their pI . A further consideration in maximizing detection sensitivity is to ensure that the probe and the analyte have similar mobilities. Figure 4 shows the electrophoretic mobilities of some inorganic anions and some anionic probes. Typical concentration detection limits for indirect detection are in the low $\mu\text{mol L}^{-1}$ region, although sub- $\mu\text{mol L}^{-1}$ detection limits have been achieved by using highly absorbing dyes as probes.

Other detection methods Electrochemical detection methods, such as conductometric, amperometric and potentiometric detection methods, can be used in CE of inorganic anions with the first being the most successful. End-capillary detection, in which the detection electrodes are placed at the capillary outlet, has proved to be the optimal configuration. Commercial instrumentation for end-capillary conductometric detection has been introduced and is a useful approach for highly conductive analyte ions separated in a low conductivity BGE, such as 2-(N-

Table 3 Factors influencing sensitivity of indirect photometric detection

<i>Factor</i>	<i>Methods of achievement</i>
Minimal analyte peak width	Matching the mobilities of the analyte and the probe co-ion(s); minimizing solute-wall interactions
Maximal transfer ratio (R)	Matching the mobilities of analyte and probe co-ion(s); choice of BGEs without further co-ions which can compete with the probe (especially of similar mobilities)
Minimal baseline noise (N_{BL})	Minimal detector noise (usually by ensuring that the background absorbance is not too high); minimal 'chemical noise' (i.e. minimal solute-wall interactions of the analytes and/or probe)
Maximal absorptivity (ε) of the probe	Correct choice of the probe
Maximal effective pathlength (l)	Use of larger rather than smaller i.d. capillaries, use of extended pathlength capillary or z-cell

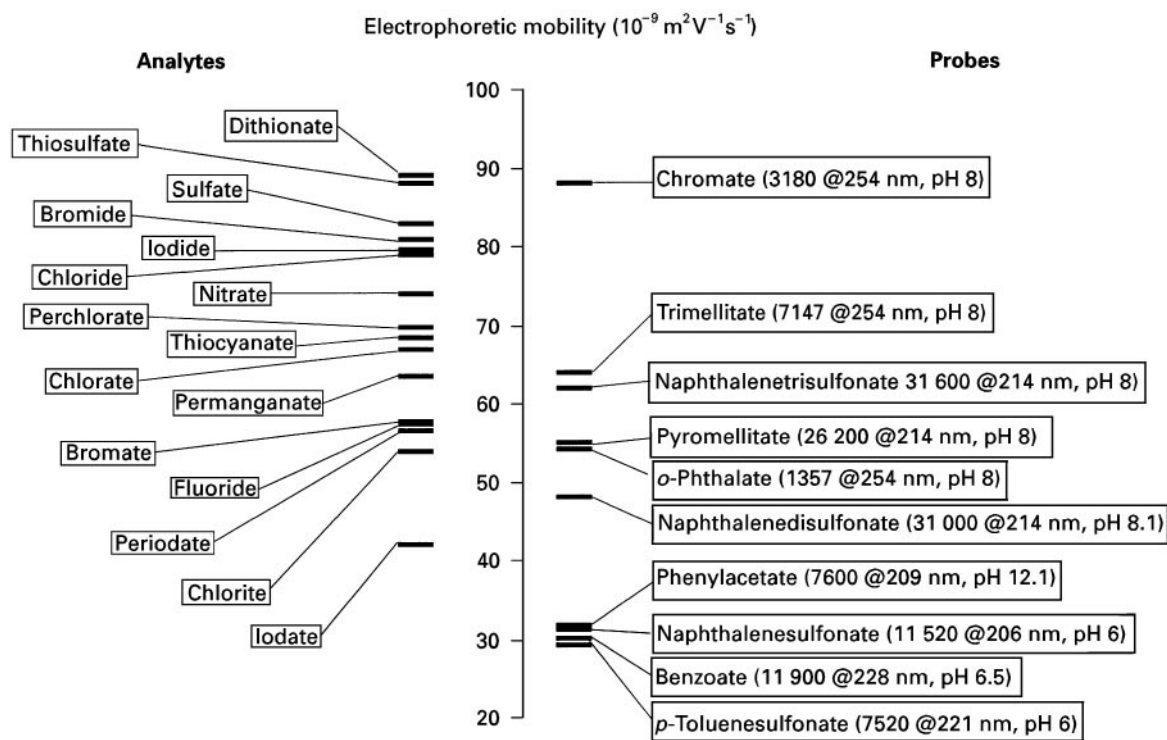

Figure 4 Matching of electrophoretic mobilities of some inorganic anionic analytes and probes. Given in brackets are molar absorptivity ($\text{L mol}^{-1} \text{cm}^{-1}$) at a wavelength (nm), and optionally a pH. (Data taken from Doble P and Haddad PR (1998) Indirect photometric detection of anions in capillary electrophoresis. *Journal of Chromatography A* 834: 189–212.)

cyclohexylamino)ethanesulfonic acid (CHES) buffer. The detection sensitivity is best for the most mobile anions and typical LODs are in the low $\mu\text{mol L}^{-1}$ range. End-capillary amperometric detection based on oxidation of anions such as nitrite, iodide, thiocyanate, azide or sulfite on gold, platinum or carbon fibre electrodes has been applied, with LODs down to the low nmol L^{-1} region. Finally, potentiometric detection using liquid membrane, solid-state coated wire or metallic copper electrodes has been applied to a range of anions. Concentration detection limits in the $\mu\text{mol L}^{-1}$ range have been achieved.

The use of information-rich detection techniques, such as mass spectrometry (MS), provides additional information that can be of advantage for analyte identification or to enhance the separation selectivity. The intriguing task of coupling CE to ICP-MS has been solved with the design of special nebulizers, such as the direct injection nebulizer, which introduces 100% of the sample to the plasma and does not cause any detectable peak broadening. Despite the disadvantages of high running costs and equipment complexity, CE interfaced to inductively coupled plasma mass spectrometry (CE-ICP-MS) has been successfully applied to speciation studies, such as of inorganic and organic species of selenium or arsenic,

for which LODs in the low ppt range have been reported.

Method Optimization

An important factor in the attainment of a robust CE method, delivering reproducible migration times and possessing some matrix tolerance, is correct buffering of BGEs. **Figure 5** shows the difference in tolerance towards an alkaline sample matrix for a buffered BGE and an unbuffered BGE, from which it can be seen that buffering is essential in the analysis of samples of this type.

With appropriate knowledge of the underlying principles of CE, such as methods for governing the separation selectivity or maximizing the sensitivity of indirect detection, methods for the separation of a limited number of analytes can often be developed without use of computer-based optimization procedures. In the case of inorganic anions the most frequently used BGE is sodium chromate (pH 8.0) containing a low concentration of a cationic surfactant such as tetradecyltrimethylammonium bromide for reversal of the EOF. The chromate ion acts as the probe for indirect photometric detection and has an electrophoretic mobility that is similar to those of many inorganic anions. Sensitive indirect

Figure 5 Tolerance to alkaline matrix illustrated using buffered (A), and unbuffered (B) chromate electrolytes. Conditions: capillary, fused silica 75 μm i.d., 0.600 m length, 0.500 m to detector; BGE, 5 mmol L^{-1} chromic trioxide, 20 mmol L^{-1} Tris, 0.5 mmol L^{-1} TTAB, pH 8.5 (a) or 5 mmol L^{-1} sodium chromate, 0.5 mmol L^{-1} TTAB, pH 8.5 (b); separation voltage, -20 kV; detection, indirect at 254 nm; injection, hydrostatic at 100 mm for 10 s; temperature, 25°C; sample, 0.1 mmol L^{-1} of each anion in 50 mmol L^{-1} sodium hydroxide. Peak identification: 1, chloride; 2, sulfate; 3, nitrate; 4, chlorate; 5, phosphate; 6, carbonate. (Reproduced with permission from Doble P, Macka M, Andersson P and Haddad PR (1997) Buffered chromate electrolytes for separation and indirect absorbance detection of inorganic anions in capillary electrophoresis. *Analytical Communications* 34: 351–353.)

photometric detection at 254 nm can be achieved. Recently, buffered chromate electrolytes have been introduced using counterionic (cationic) buffers such as Tris or diethanolamine (Figure 5).

Sample Introduction and Sample Pretreatment

Sample introduction by electromigration methods is known to be matrix-dependent, therefore hydrostatic/hydrodynamic sample introduction is typically used. If electromigration injection is to be employed, matrix effects should be examined and standard addition rather than an external standard method should be used for calibration. Field-amplified stacking effects can be used for samples of lower ionic strength than the BGE, leading to lower concentration detection limits.

Real samples often require the application of simple procedures such as extraction, filtration to remove particular matter, or dilution, prior to the CE step and an online or at-line combination of such procedure(s) with CE is desirable. A dialysis/flow-

injection analysis (FIA) sample clean-up system coupled online to a CE allowed analysis of a number of anions in a variety of samples with complex matrixes such as milk, juice, slurries or liquors from the pulp and paper industry. In some cases, matrix removal (sample clean-up) combined with preconcentration of the analyte(s) may be necessary. Online isotachopheresis (ITP)-CE systems are capable of analysing anionic analytes in complex matrixes, but commercial instrumentation is not available widely. A general rule for the applicability of CITP-CE for sample clean-up is that the mobility of the analyte(s) should differ from the matrix ion(s) to be removed.

Figure 6 Separation of inorganic and anions and carboxylic acids in a beer sample using simultaneous nonsuppressed conductivity and indirect conductivity detection. Conditions: capillary, fused silica 50 μm i.d., 0.600 m length to end-capillary conductivity detector, 0.480 m to photometric detector; BGE, 7.5 mmol L^{-1} 4-aminobenzoic acid, 0.12 mmol L^{-1} TTAB, pH 5.75; separation voltage, -30 kV; detection, indirect at 254 nm; injection, hydrodynamic at 25 mbar for 12 s; sample, 10 \times diluted stout. (Reproduced with permission from Klampfl CW and Katzmayr MU (1998) Determination of low-molecular-mass anionic compounds in beverage samples using capillary zone electrophoresis with simultaneous indirect ultra-violet and conductivity detection. *Journal of Chromatography A* 822: 117–123.)

Applications

A high proportion of the real samples analysed for inorganic anions by CE have been water samples (drinking water, mineral water, river water, ground water, well water, etc.), with fruit juices and beverages being another common type of sample. The fact that CE is not tolerant to high ionic strength samples is reflected in the infrequent application of CE to samples such as seawater, unless considerable dilution of the sample is undertaken. **Figure 6** shows a successful application of CE to the determination of inorganic anions using simultaneous indirect photometric and conductometric detection. This example also illustrates the fact that real samples usually require separation of inorganic anions from organic anions.

Cations

Separation Strategy

As for inorganic anions, most inorganic cations have electrophoretic mobilities that are too high to permit counter-EOF separation, so these species are usually separated co-electroosmotically. In this case the electrode with positive polarity is placed at the injection

side and when a bare fused silica capillary is used, the EOF is towards the detection side (cathode). Under these conditions the migration order is such that the analyte with the highest positive electrophoretic mobility migrates first and the analyte having the lowest positive mobility migrates last.

In contrast to the case for inorganic anions, many inorganic cations exhibit very similar mobilities, such as the whole group of rare earth metals or numerous transition metal ions (**Figure 7**). Therefore additional sources of separation selectivity to those available for anions are needed in order to separate these species. The main approach used is the addition of an auxiliary ligand to the BGE in order partially to complex the analyte cations (**Figure 8**). Provided the degree of complexation is different for each analyte cation, the effective charge and hence the effective mobility of each analyte will be unique and separation should be possible. These auxiliary ligands can be divided qualitatively into two groups according to the thermodynamic stability of the complexes formed with the analyte cations. **Table 4** summarizes the important characteristics of CE separation of metal ions using either weakly or strongly complexing auxiliary ligands.

Weakly complexing auxiliary ligands (such as HIBA or 19-crown-6) usually serve the sole purpose

Figure 7 Electrophoretic mobilities of metal ions and some organic cations in ascending order to their mobilities. Ammonium was included with the alkaline metals because of its frequent importance in analysis of metal ions. Charges of metal cations have been left out for simplicity; transition metal ions divalent apart from monovalent Ag and Tl; organic cations all bear a charge of + 1.

Figure 8 Separation of 27 alkali, alkaline earth, transition and rare earth metal ions in a single run using lactate as auxiliary ligand. Conditions: capillary, fused silica 75 μm i.d., 0.600 m length, 0.527 m to detector; BGE, 15 mmol L^{-1} lactic acid, 8 mmol L^{-1} 4-methylbenzylamine, 5% methanol, pH 4.25; separation voltage, 30 kV; detection, indirect at 214 nm; injection, hydrostatic at 100 nm for 30 s; sample, 1–5 ppm or each metal. Peak identification: 1, K^+ ; 2, Ba^{2+} ; 3, Sr^{2+} ; 4, Na^+ ; 5, Ca^{2+} ; 6, Mg^{2+} ; 7, Mn^{2+} ; 8, Cd^{2+} ; 9, Li^+ ; 10, Co^{2+} ; 11, Pb^{2+} ; 12, Ni^{2+} ; 13, Zn^{2+} ; 14, La^{3+} ; 15, Ce^{3+} ; 16, Pr^{3+} ; 17, Nd^{3+} ; 18, Sm^{3+} ; 19, Gd^{3+} ; 20, Cu^{2+} ; 21, Tb^{3+} ; 22, Dy^{3+} ; 23, Ho^{3+} ; 24, Er^{3+} ; 25, Tm^{3+} ; 26, Yb^{3+} ; 27, Lu^{3+} . (Reproduced with permission from Shi YC and Fritz JS (1993) Separation of metal ions by capillary electrophoresis with a complexing electrolyte. *Journal of Chromatography* 640: 473–479.)

of manipulating the separation selectivity and normally form part of the BGE into which samples containing free metal ions are injected. That is, *on-capillary complexation* is utilized (Figure 8). Since a substantial part of the metal exists as an uncomplexed cation, indirect absorption detection using a cationic absorbing probe contained within the BGE

is normally applied. Rapid complexation equilibria are necessary to enable manipulation of the selectivity of separation by varying parameters of the BGE such as the concentration of the auxiliary ligand and pH (Figure 8).

A completely different strategy is to use ligands forming stable, typically anionic complexes,

Table 4 Typical method properties according to the stability of the complex formed between the auxiliary ligand and the metal ion analyte

<i>Thermodynamic stability of the metal complex with the auxiliary ligand</i>	<i>Low</i>	<i>High</i>
Typical examples of the auxiliary ligand	HIBA, citric acid, lactic acid	CN^- , polydentate ligands such as EDTA and its analogues, metallochromic ligands
Degree of metal ion complexation	Partial	Total
Method of complex formation	On-capillary	Pre-capillary, often with on-capillary also used
Method of photometric detection	Indirect	Direct
Ease of selectivity manipulation	Straightforward	More difficult
Polarity of separation voltage on injection side	+	+, -

which are then separated as anions using the same approaches discussed earlier. Auxiliary ligands such as ethylenediaminetetraacetic acid (EDTA) or 2-pyridylazoresorcinol (PAR) may be used for this purpose and are usually added to the sample (that is, *precapillary complexation* is used). Often the BGE also contains a low concentration of the ligand in order to prevent the decomposition of less stable complexes. Most (or all) of the metal is complexed, so that detection using direct photometry is usually applicable. The complexation equilibria can be slow, but this then makes it difficult to alter the selectivity of separation and to retain good peak shapes. These separations are carried out in bare fused silica capillaries, fused silica capillaries with reversed EOF, or using other capillary wall chemistries. Depending on the charge of the metal complexes, the separation can be performed in either the co- or counter-electroosmotic modes, with either positive or negative separation potential applied on the injection side.

Metal ions are known to adsorb onto the surface of silica particles through interaction with silanol groups. In the case of polyvalent metal cations, this adsorption can be considered to be irreversible. Although the surface density of silanols on fused silica is lower by approximately an order of magnitude than for porous silica, it is well documented in CE using bare fused silica capillaries that metal ions present in the BGE (even as an impurity) can adsorb onto the capillary wall. The extent of adsorption is often reflected in changes to the EOF, with both suppression and reversal of EOF having been demonstrated. Despite these facts, coated capillaries have found relatively little use in separations of metal ions. In bare fused silica capillaries, the risk of adsorption of metal ions is counteracted by typically weakly acidic and complexing electrolytes.

Separation Selectivity

The most powerful and straightforward tool governing separation selectivity is control of the degree of complexation with the auxiliary ligand. For a metal ion present in several forms that are in equilibrium with rapid kinetics of interchange between the forms, the effective mobility of the analyte is given by the weighted average of the mobilities of each of the forms. For a metal ion M migrating in a BGE containing a ligand L forming complexes ML , ML_2 , ..., ML_n , the effective mobility of the metal can then be expressed as:

$$\bar{\mu}_M = \sum_{i=0}^n \mu_i \alpha_i = \frac{\sum_{i=0}^n \mu_i [ML_i]}{\sum_{i=0}^n [ML_i]} = \frac{\sum_{i=0}^n \mu_i \beta_i [L]^i}{\sum_{i=0}^n \beta_i [L]^i} \quad [3]$$

where μ_i is mobility and α_i is the fraction of metal ion existing in form i , $[ML_i]$ is the concentration of the complex ML_i , $[L]$ is the concentration of the form of ligand forming the complex and β is the overall stability constant ($ML_0 = M$, $\beta_0 = 1$).

A different situation occurs when utilizing auxiliary complexing ligands that form strong complexes with the metal ions. Since most of the metal ion is complexed under all BGE conditions, the complex formation/dissociation cannot be used to govern the separation selectivity as in the case of weakly complexing ligands. Apart from minor factors influencing the selectivity, such as solvation changes in various media, there are very few means to bring about a change in the charge/mass value of the analytes (and consequently a substantial change in selectivity). These include: (1) dissociation of functional groups on the ligand exhibiting protonation equilibria; (2) exchange of the remaining water molecules on the metal ion coordination sites not saturated by the ligand; and (3) ion association or ion exchange equilibria in the BGE solution (Table 4). The separation selectivity therefore varies considerably with the nature of the ligand used.

Detection

Direct and indirect photometric detection As with inorganic anions, direct and indirect photometric detection are the most commonly used detection methods in the separation of metal ions, being employed in about 85% of publications. Since most hydrated metal ions do not absorb at all, or have only weak absorption bands in the UV region above 185 nm, direct detection is normally possible only when the metal ions are complexed with an auxiliary ligand. Thus the auxiliary ligand, which in earlier discussion has been shown to play a crucial role in the separation of metal ions, also enhances the detectability of these species. Metallochromic ligands form highly absorbing ($\epsilon \sim 10^5 \text{ L mol}^{-1} \text{ cm}^{-1}$) coloured complexes with metal ions. When these complexes are stable and the separation results in well-shaped peaks, very good detection sensitivity can be obtained. For example, determination of transition metals in the form of complexes with PAR achieved concentration LODs in the order of $10^{-7} \text{ mol L}^{-1}$ or absolute LODs at fmol levels. Even lower LODs (80 nmol L^{-1} or 0.5 fmol for Zn) have been obtained for porphinate complexes ($\epsilon \sim 10^5 \text{ L mol}^{-1} \text{ cm}^{-1}$), but the detection method is less universal because different metal ions exhibit a range of absorption maxima and absorptivities.

The underlying principles for indirect photometric detection of inorganic cations are the same as for

inorganic anions (see above). Figure 9 illustrates matching of electrophoretic mobilities of some metal cations as analytes with some cationic probes.

Other detection methods Conductometric, amperometric and potentiometric detection methods can be utilized for inorganic cations and the same principles discussed apply. End-capillary conductometric detection has been used for a range of cations using low-conductive histidine-MES BGEs with similar success to anion analysis (LODs are in low $\mu\text{mol L}^{-1}$ range). End-capillary amperometric detection utilizing reduction of metal ions such as thallium, lead, cadmium, etc., and inorganic and organic mercury compounds on gold, platinum or mercury films, has been applied with low nmol L^{-1} range LODs. Potentiometric detection can also be used for metal ions and, as for anions, the solid-state electrodes show greatest promise.

CE coupled with electrospray mass spectrometry has achieved detection of about 30 metal ions by positive ion MS. Although chemical noise does not allow detection below ppb levels, LODs are generally

below those obtained for indirect photometric detection. Impressive LODs have been obtained by CE-ICP-MS, e.g. of 0.06 ppb for Sr^{II} (8 fg or 90 amol).

Method Optimization

The separation of up to 30 metal ions in one run using weakly complexing auxiliary ligands is a challenging analytical task and optimization of the BGE composition often requires the use of computer methods based on thermodynamic complexation models or the use of artificial neural networks. The BGEs used most frequently for metal ion analysis would normally utilize indirect photometric detection and a typical BGE contains a weakly complexing auxiliary ligand (such as HIBA) for governing separation selectivity for most transition metal ions and rare earth metals. It often also contains a crown-ether as a second auxiliary ligand to separate ammonium from potassium (see Figure 7) and an indirect detection cationic probe (such as imidazole, benzylamine, or creatinine) at $\text{pH} \sim 4.5-5$.

While most authors have demonstrated the application of their developed separation to a real

Figure 9 Matching of electrophoretic mobilities of some metal ion analytes and probes. Given in brackets are molar absorptivity ($\text{L mol}^{-1} \text{cm}^{-1}$) at a wavelength (nm), and optionally a pH. (Source of data: Beck W and Engelhardt H (1992) *Chromatographia* 313; Chen M and Cassidy RM (1993) Separation of metal ions by capillary electrophoresis. *Journal of Chromatography* 640: 425-431.)

sample of some kind, there have been relatively few studies on aspects of method validation, such as precision and accuracy. Typical precision for migration times, peak areas and peak heights show a relative standard deviation ranging from 3 to 10%.

Sample Introduction and Sample Pretreatment

In addition to the principles discussed earlier for anions, stacking effects can be achieved in the separation of metal ions using on-capillary complex formation in which oppositely migrating metal cations and ligand anions converge and react at the boundary between the injected sample plug and the BGE. A necessary condition to utilize the stacking by on-capillary complexation is fast complex formation. This approach was first demonstrated for four divalent metal complexes with PAR in which a plug of 1 mmol L^{-1} PAR was first injected into the capillary and then electromigration injection from a sample without added ligand was performed. This method with an optimized stacking procedure gave detection limits in the range of 10 nmol L^{-1} .

Ion exchange and chelating resins may be used to preconcentrate metal ions prior to CE determination in an offline configuration. Ion exchange materials are less successful for the selective preconcentration of heavy metals than chelating (iminodiacetate or dithiocarbamate) resins, or by the formation of metal chelates with an excess of the reagent, followed by adsorption of the chelate on a hydrophobic column.

Applications

As with anions, many of the real samples analysed have been various water samples, fruit juices and beverages and food. An example of an unusual application of CE to the analysis of high salinity samples is shown in Figure 10.

Simultaneous Separations of Anions and Cations

Despite the potential advantages of reduced analysis time and costs that arise from analysing both anions and cations in one run, separate analysis of both groups is still much easier and more robust. The simple fact that anions and cations migrate in opposite directions in an electric field means that a simultaneous analysis cannot be realized with one point of sample introduction and one point of detection.

However, there are two approaches that have proved successful. The first uses a sample injection simultaneously in two capillaries operated with the same BGE, with both capillaries equipped with independent detectors located near their ends. A relatively

Figure 10 Separation of metal ions in a mixture of salt water and formation water using indirect photometric detection. Conditions: capillary, fused silica $75 \mu\text{m}$ i.d., 0.600 m length, 0.520 m to detector; BGE, 6.5 mmol L^{-1} HIBA, 5 mmol L^{-1} UVCAT-1 (Waters), 6.2 mmol L^{-1} 18-crown-6, 25% (v/v) methanol, apparent pH 4.8; separation voltage, 20 kV ; detection, indirect at 185 nm ; injection, hydrodynamic at 98 mm for 20 s ; sample, diluted by a factor of 125. (Reproduced with permission from Tangen A, Lund W and Frederiksen RB (1997) Determination of sodium, potassium, magnesium and calcium ions in mixtures of sea water and formation water by capillary electrophoresis. *Journal of Chromatography A* 767: 311–317.)

easier approach uses just one capillary, but sample is injected at both ends and the detector is located approximately in the middle of the capillary. This approach has been applied to the analysis of a range of real samples; an example is given in Figure 11.

It should be noted that when applying indirect detection using both an anionic and a cationic probe, the probes should be mixed in their free acid and free base forms to avoid the presence of competing ions in the BGE.

Future Developments

Control of the separation selectivity will be an area of development in CE of inorganic species. Utilization of ion exchange-type interactions with pseudostationary phases, and particles of sub- μm size, can introduce new selectivity into a CE separation. It is instructive to examine the separation selectivities achieved by ion chromatography and CE under standard conditions, as revealed by the elution or migration order of common analytes. In the case of IC, anions are eluted in the following order of retention times: $\text{F}^- < \text{Cl}^- < \text{NO}_2^- < \text{Br}^- < \text{NO}_3^- < \text{PO}_4^{3-} < \text{SO}_4^{2-} < \text{I}^-$. However, the migration times of these species in co-EOF CE are $\text{Br}^- < \text{Cl}^- < \text{SO}_4^{2-} < \text{NO}_2^- < \text{I}^- < \text{NO}_3^- < \text{F}^- < \text{PO}_4^{3-}$. A similar pattern emerges when the same comparison is made for inorganic cations, for which the IC retention times follow the order: $\text{Li}^+ < \text{Na}^+ < \text{NH}_4^+ < \text{K}^+ < \text{Mg}^{2+} < \text{Ca}^{2+} < \text{Sr}^{2+} < \text{Ba}^{2+}$, while migration times for co-EOF CE are

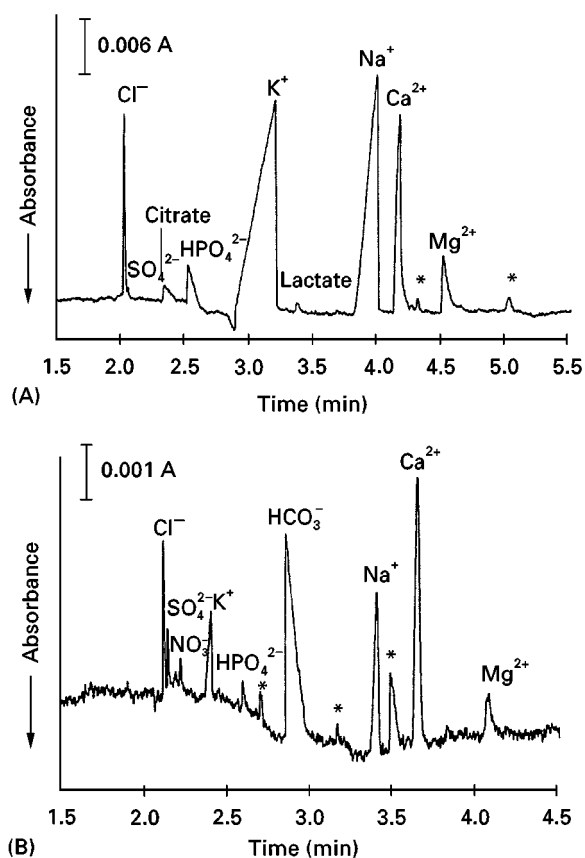

Figure 11 Simultaneous determination of inorganic anions and cations in milk (A) and mud (B) after offline dialysis. Conditions: capillary, fused silica 50 μm i.d., 0.500 m total length, 0.200 m to detection window from the anodic end; BGE, 6 mmol L^{-1} 4-aminopyridine, 2.7 mmol L^{-1} H_2CrO_4 , 30 $\mu\text{mol L}^{-1}$ CTAB, 2 mmol L^{-1} 18-crown-6, pH 8; separation voltage, 20 kV; detection, indirect at 262 nm; injection, hydrostatic at 50 mm for 10 s (cathode end) and 50 mm for 10 s (anode end) (A) or at 50 mm for 20 s (cathode end) and 100 mm for 40 s (anode end) (B); time between the injections, 60 s (A) or 30 s (B). (Reproduced with permission from Kuban P and Karlberg B (1998) Simultaneous determination of small cations and anions by capillary electrophoresis. *Analytical Chemistry* 70: 360–365.)

$\text{NH}_4^+ < \text{K}^+ < \text{Ba}^{2+} < \text{Sr}^{2+} < \text{Ca}^{2+} < \text{Na}^+ < \text{Mg}^{2+} < \text{Li}^+$. Complementary selectivities are again apparent. These selectivities suggest that a mixed-mode separation system in which the movement of analytes is influenced both by electromigration effects and ion exchange interactions might provide a means to manipulate selectivity in order to solve existing separation problems.

New developments can also be expected in the area of detection techniques. For instance, the use of highly absorbing cationic probes in carefully formulated BGEs that avoid competitive displacement has the potential to increase the sensitivity using indirect photometric detection. Further development

of other detection techniques can be anticipated, especially those compatible with the capillary dimensions and suitable for on- or end-capillary use and which do not necessitate elaborate changes to the capillary.

Finally, more advances in the area of online sample treatment and/or preconcentration techniques are likely to occur as CE becomes more of a routine tool for the determination of inorganic species in complex samples.

High-Speed Countercurrent Chromatography

E. Kitazume, Iwate University, Morioka, Iwate, Japan

Copyright © 2000 Academic Press

High-speed countercurrent chromatography (HSCCC), developed by Ito, is a useful method of separating many organic materials, such as biologically active substances, natural and synthetic peptides and various plant hormones. Like other countercurrent chromatography (CCC) methods, it is also free from problems based on solid supports, such as adsorption or irreversible binding and contamination of the sample.

HSCCC has been applied to preconcentration and separation of inorganic elements since the late 1980s and since then, inorganic elements, including rare earth elements, have been separated by HSCCC. Also the preconcentration and separation of inorganics from geological samples have been studied. The liquid systems for inorganics are more complicated than those for separation of organics, because they usually contain significant amounts of an extracting agent, which influences kinetic properties and viscosities of the whole two-phase system.

In order to achieve high sensitivity for analysing trace inorganic elements in a solution using atomic absorption spectrometry (AAS) or inductively coupled plasma atomic emission spectrometry (ICP-AES), conventional preconcentration methods such as evaporation, ion exchange and solvent extraction have been used. However, there are several problems in these methods for the determination of ultra trace elements, for example, peak broadening for ion exchange and a small enrichment factor for solvent extraction. It is difficult to achieve under 0.5 mL concentrated sample solutions by conventional methods. If there were effective methods to concentrate traces into 0.1 mL volume or less, absolute detection limits for trace analysis such as AAS, ICP-AES and ICP-mass spectrometry (ICP-MS) would be

greatly decreased, and matrix effects would be eliminated.

Recently, pH-zone refining CCC, which is a unique technique based on the neutralization reaction between the mobile and stationary phase, has been developed for the separation and enrichment of organic acids, basic derivatives of amino acids and acidic peptide derivatives. It can initiate chemical reactions in quite a limited thin area, the interface between the organic and aqueous phase. Therefore, if there is a reversible pH area between the mobile and stationary phase, the pH in the column can be continuously controlled. This means that another flow rate, concerned with pH and different from real flow rate, can be realized in the column. Impurities in sample solutions can be concentrated in the pH boundary in the column. As it can be successfully applied to the enrichment of inorganic trace elements in solution, it has great potential for on-line enrichment and subsequent analysis, when HSCCC is combined with instruments such as AAS, ICP-AES and ICP-MS.

Mechanism of Two-phase Separation in HSCCC

In HSCCC, a stationary sun gear is mounted around the central stationary axis of the centrifuge to prevent the flow tubes twisting. This gear arrangement gives a planetary motion of the column holder – one rotation about its own axis for one revolution around the central stationary axis of the centrifuge in the same direction.

Figure 1 shows a schematic diagram of two-phase separation in an HSCCC column. The heavier mobile phase (black) is introduced into the column from the right side (column head). The upper stationary phase (grey) is retained in the column by a rotational force field and Archimedean screw effect (ASE), in spite of being pushed to the column end by the mobile phase. For separation and enrichment of inorganic elements, the stationary phase commonly contains one or more extracting reagents, such as di(2-ethylhexyl)phosphoric acid (DEHPA), dissolved in the appropriate stationary organic phase. The mobile phase is commonly composed of inorganic acids and their salts. Water-soluble complexing reagents forming

Figure 1 Schematic diagram of two-phase separation in HSCCC column. r , Rotation radius; R , revolution radius.

stable compounds with specified elements in the sample can also be used as an aqueous mobile phase. The column is revolved in the radius R and rotated with the radius r at the same time. When the coil column is facing the axis of revolution (top left in Figure 1), the two phases are vigorously mixed because of the weak force field. In contrast, when facing the outer side of the column, the mobile phase is clearly separated by a stronger force field than that at the inner side. The inner quarter turn of the coil is the most vigorous mixing area. As one phase usually occupies the column head by an Archimedean screw effect, another phase can be introduced as an eluent. After being introduced from the column head, the heavier mobile phase emerges from the end of the column (bottom left in Figure 1). When the column makes one revolution around the axis, it rotates once on the orbital of revolution. Therefore, as a specific point in the column, one turn in the coil proceeds towards the column head per revolution. At the same time, one cycle of each mixing and separation process at the specific point occurs in the column. As the HSCCC column rotates at over several hundred rpm, this is a rapid process. For example, there are 13 processes per second taking place at 800 rpm, giving efficient separation and mixing in the column.

Extracting Reagent for Separation of Inorganic Elements

As mentioned above, the existence of extracting reagent in the mobile phase is an essential factor in the separation of inorganic elements. It complicates the determination of several important factors, such as distribution coefficients, peak resolution and separation efficiency. Research reveals that the kinetic properties of a specific system used in HSCCC affect the separation efficiency. The mass transfer rate into the organic stationary phase is responsible for using either stepwise or isocratic elution. In addition, the value of the distribution coefficients, determined by batch extraction measurements on systems, are sometimes considerably different from the dynamic distribution coefficients calculated from the elution curve. Further theoretical and basic investigations are necessarily concerned with extraction kinetics, as well as the hydrodynamic behaviour of the two phases in the HSCCC column.

In Table 1, typical extracting reagents used for separation and enrichment of inorganic elements are summarized. Organophosphorus extractants are often used because of their solubility properties.

Table 1 Typical extracting reagents for separation and enrichment of inorganic elements using high-speed countercurrent chromatography

Extracting reagent	Two-phase system	Inorganic element
Di(2-ethylhexyl)phosphoric acid (DEHPA)	HCl, organic acid–heptane	Rare earth, heavy metals
2-Ethylhexylphosphonic acid mono-2-ethylhexyl ester (EHPA)	Carboxylic acid–toluene	Rare earth
Dinonyltin dichloride	HCl, HNO ₃ ⁻ Methylisobutylketone (MIBK)	Ortho- and pyrophosphate
Cobalt dicarbonyl	HNO ₃ -nitrobenzene	Cs and Sr
Tetraoctylethylenediamine (TOEDA)	HCl, HNO ₃ , organic acid–chloroform	Alkali, alkaline earth, rare earth, heavy metals, Hf, Zr, Nb, Ta

Figure 2 Extraction equilibrium in HSCCC column using di (2-ethylhexyl) phosphoric acid (DEHPA) as an extracting reagent for trivalent metal ion (M^{3+}). $(HX)_2$, dimer of DEHPA.

Figure 2 shows the equilibrium for extraction of trivalent metal ions, such as lanthanide, using the extracting reagent (DEHPA). DEHPA is commonly applied in industrial separation due to its high extractability and high separation factors between many inorganic elements, especially for rare earth elements. Trivalent metal ions (M^{3+}) are extracted as shown in Figure 2 in PTFE tubing of 0.3–1.6 mm in diameter. The long thin rectangles in Figure 2 show the wall of the PTFE tubing. $(HX)_2$ is a dimer of DEHPA. Metal ions in the aqueous phase are extracted into organic phase as $M(HX_2)_3$.

Mutual Separation of Inorganic Elements

Figure 3 shows a typical flow diagram of the instrumentation assembly for the separation of rare earth elements and other inorganic elements by HSCCC. In this case, the spectrophotometer is used as a detector for each element. If an alternative measurement system such as AAS, ICP-AES or ICP-MS is used, all the equipment depicted after the splitter is not required. Each separation is usually initiated by filling the en-

tire column with the stationary nonaqueous phase, followed by injection of an appropriate volume of the sample solution through the sampling port. Then, the mobile phase is eluted through the column at a flow rate of 0.1–5 mL min^{-1} while the apparatus is rotated at several hundred rpm. In Figure 3, continuous detection of the inorganic elements is effected by means of a post-column reaction with an appropriate compound such as arsenazo III, and the elution curve is obtained by monitoring the effluent with a spectrophotometer. The effluent is divided into two streams with a tee adapter and a low-dead-volume pump (pump II). Pump II delivers a portion of the effluent at the required flow rate to the spectrophotometer and pump III adds reagent for post-column reaction to the effluent stream. The resulting stream first passed through a narrow mixing coil and then leads through an analytical flow cell in a spectrophotometer. The other effluent stream through the tee adapter is either collected or discarded.

Figure 4 shows a one-step separation of all 14 lanthanides (except for promethium) performed by applying an exponential gradient of hydrochloric acid in the mobile phase. The main problem in gradient elution is that the optimum range of the ligand concentration in the stationary phase is substantially different between the lighter and heavier groups of the rare earth elements. Because the separation of the heavy lanthanide elements, including thulium, ytterbium and lutetium, is more difficult, a ligand concentration of 0.003 mol L^{-1} was selected for best resolution. With an isocratic separation mode, using a constant eluent concentration, even heavy lanthanide elements such as Tm, Yb and La are well separated.

Figure 5 shows a typical chromatogram of Ni(II), Co(II), Mg(II) and Cu(II) obtained by eluting with

Group Separation of Inorganic Elements

There are numerous methods, such as X-ray fluorescence (XRF), spectroscopy, AAS, AES and ICP-MS, for the determination of trace inorganics including rare earth elements. Of these methods, ICP-AES is one of the most popular for the determination of metals such as Ta, Zr, Hf, etc., including rare earth elements. However, there may be problems with spectral interference because of the many spectral lines. To ensure sufficient precision and accuracy,

especially for the determination of trace elements, separation of matrix elements, which interfere with the determination, must be undertaken. HSCCC has great potential as a separation technique which pre-concentrates trace elements before determination.

Figure 6 shows an example of the quantitative group separation of the rare earth elements from the constituents of rocks, which interfere with the determination of trace elements by ICP-AES. A 0.5 mol L⁻¹ solution of DEHPA in decane was used as the stationary phase. Alkaline, alkaline earth elements and iron(II) were separated from the total amount of rare earth elements at the first stage of the eluent concentration with 0.1 mol L⁻¹ hydrochloric acid. Then the total amount of rare earth elements, including yttrium, was eluted from the stationary

Figure 6 Example of quantitative group separation of the rare earth elements from the constituents of rocks. Apparatus: HSCCC centrifuge with 14.0 cm revolution radius; column: one monolayer coil, 1.13 m \times 1.5 mm i.d., 20 mL capacity; stationary phase: 0.5 mol L⁻¹ DEHPA in decane Kr: 30%; mobile phase: 1–0.1 mol L⁻¹ HCl, 2–3 mol L⁻¹ HCl, 3–5 mol L⁻¹ HCl; sample: Mn 0.3, Fe 6.4, Ca 8.2, Na 4.2, K 4.1 (%) and Ba 440, La 1350, Ce 2290, Nd 760, Pr 239, Sm 97, Eu 18.3, Gd 120, Tb 15, Dy 139, Ho 29, Er 88, Tm 12.5, Yb 71, Lu 8.6, Y 716, Cs 2.6, Sr 307, U 682, Th 940 (p.p.m.); speed: 350 rpm; flow rate: 2.0 mL min⁻¹. Kr, the retained stationary phase volume relative to the total column volume.

phase with 3 mol L⁻¹ hydrochloric acid. To elute other elements, including iron(III), from the stationary phase, 5 mol L⁻¹ hydrochloric acid was introduced into the column. Separation of the mixture was performed within 40 min at a pumping rate of the mobile phase of 2 mL min⁻¹.

Enrichment of Inorganic Elements

Large-scale Enrichment of Inorganics

HSCCC has great potential as an enrichment technique for trace elements before determination. Enrichment prior to determination can overcome problems such as interference, toxic or radioactive samples.

The p.p.b. level of metal ions in a 500 mL of the mobile phase was continuously concentrated into a small volume of the stationary phase retained in the column. Concentrated metal ions were simultaneously eluted with nitric acid and determined by a plasma atomic emission spectrometer. The recoveries of Ca, Cd, Mg, Mn, Pb and Zn were over 88% at the 10 p.p.b. level in 500 mL of the sample solution. The versatility of this method has been further demonstrated by the determination of trace metals in tap water and deionized water.

Rare earth elements have been enriched in a stationary phase of toluene: 2-ethylhexylphosphonic acid mono-2-ethylhexyl ester (EHPA) from a litre of aqueous solution, and eluted with a stepwise pH gradient.

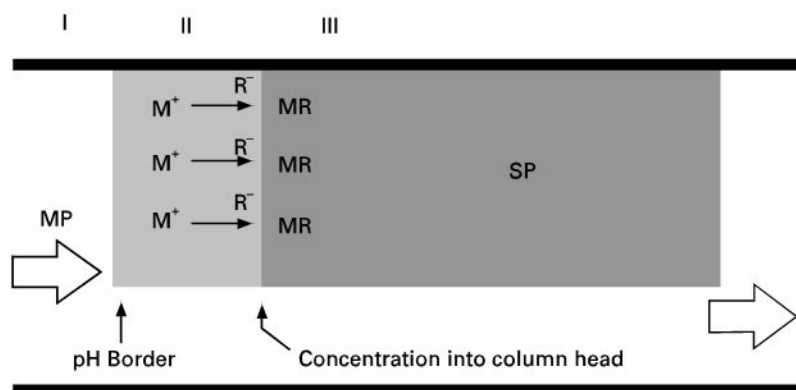

Figure 7 Concentration procedure just after revolving the HSCCC column. I, Mobile phase (MP) with HCl; II, sample with NH_3 ; III, stationary phase (SP) with NH_3 .

Large-scale enrichment is very useful to determine extremely low levels of metals in solution, when a large amount of sample is available.

Enrichment Using the pH-zone Refining Technique

Even if a large volume of sample is not available, enrichment techniques that concentrate trace metals in microlitre samples are sometimes quite useful because modern instrumental methods do not need a large sample size. Moreover, if trace metals separated from their major matrices can be concentrated in an extremely small area of the polytetrafluoroethylene (PTFE) tube in HSCCC, this would be ideal for flow-injection analysis. From this point of view, the recently developed pH-zone refining technique has great potential for enrichment of trace inorganic elements.

In pH-zone refining, a basic organic solution containing a complex-forming reagent such as DEHPA as

a stationary phase is used. After sample introduction into the column, metal ions stay close to the sharp pH border region in the small-bore PTFE tube. Then the trace inorganic ions in the sample are moved by the acid effluent (dilute HCl or HNO_3) to the tail of the column while concentrating in the sharp-moving pH interface, and finally eluted as small fractions containing concentrated inorganic ions.

This concentration procedure is shown in Figures 7 and 8. In Figure 7, sample ion is concentrated into the column head soon after the concentration procedure is started. After the stationary phase and the sample are introduced into the system, HSCCC is started at an appropriate revolution rate, followed by the mobile-phase pump. Metal or inorganic ions (M^+) are concentrated into the column head as MR. Zone III shows the stationary phase, which includes DEHPA and ammonia in an organic solvent such as ether or heptane. Zone II shows a sample phase with the pH adjusted by ammonia. When the column revolution is started, as the organic stationary phase is lighter than

Figure 8 Concentration procedure at the pH interface in the HSCCC column. I, Mobile phase (MP) with HCl; II, stationary phase after neutralization with HCl; III, stationary phase with NH_3 .

the mobile phase (diluted acid solution), it moves to the head of the column by ASE. The driving force based on ASE increases with the revolution speed of the column. Therefore, the stationary phase can be retained in the column by selecting an appropriate speed of revolution and pump rate, even if the mobile phase is introduced from the head into the column. The retention ratio of the stationary phase to the whole column can be varied from 20 to 70%, but is stable when all conditions including pump or revolution rate are constant. So, the position of the mobile phase is stable in the column when in operation. Inorganic ions (M^+) form complexes with ligand ions (R^-) and are mainly concentrated on the column head, shown as MR in Figure 7. Hydrogen and counter ions of the ligand are not shown in the figure.

Figure 8 shows a concentration procedure in the HSCCC column after all the ions in the sample are extracted on top of the zone III in Figure 7. After Zone II in Figure 7 (sample) has completely passed through the top of the stationary phase, ammonia in the stationary phase begins to be neutralized with hydrochloric acid in the mobile phase. The neutralization area, where reaction between the acid and the base has just finished, is shown as the pH border in Figure 8. The pH border proceeds from left to right. Also the concentrated ions proceed circulating (extracting and back-extracting process in Figure 8) around the pH interface. The rectangular zone (II + III) shows the total stationary phase.

The mobile phase that includes acid solution (hydrochloric acid in Figures 7 and 8) moves at a constant flow rate from the head of the column (left) to the tail of the column (right). The three arrows labelled High show a constant stream of the mobile phase.

As the mobile phase is an acidic solution, it reacts with ammonia in the stationary phase as it proceeds to the tail of the column in Figure 8. The left area (II) in the rectangular zone shows the stationary phase that has been saturated with hydrochloric acid. In the right area (III) in the rectangular zone, ammonia is not yet neutralized with hydrochloric acid. The dark gradation zone between areas II and III shows a pH interface, where the neutralization between acid and base has just finished. As the stationary phase and the mobile phase are mixed well in the HSCCC column, there must be a pH interface in the mobile phase.

The pH interface moves to the right (the same direction as the mobile phase); however, its flow rate is lower than that of the mobile phase because of the delay based on the neutralization. So, concentrated ions shown as MR on the top left of the zone III in

Figure 7 move slowly as shown by the flow rate arrow Low in Figure 8, and circulate around the pH interface by repeating extraction and back-extraction into the stationary phase and the mobile phase, respectively. The flow rate of the pH interface in the mobile phase is shown as the Low arrow in the stationary phase in Figure 8. The flow rate of the pH interface in the mobile phase may be made the same as that in the stationary phase by vigorous mixing in HSCCC column. The pH interface in the mobile phase is shown by the dotted line at the pH border in Figure 8. When the inorganic ions combined with ligand (MR) pass through the pH interface from zone III to zone II in the stationary phase, they are back-extracted into the mobile phase. Then, as the flow rate of the mobile phase is faster than that of the pH interface, the ions (M^+) pass through the pH border (shown by the black dotted line in Figure 8) from left to right in the mobile phase. Just after passing the pH border, the pH is rapidly rising, so, the ions react with the ligand again and are extracted back into the stationary phase. By repeating this cycle, the ions are moved to the tail (right) of the column without diffusion.

In the concentration mechanisms described above, there is no diffusion process observed as in elution procedures with ion exchange or other chromatographic separation methods, such as conventional HSCCC and HPLC. If there is no basic compound such as ammonia in the stationary phase, ions move to the tail with a different flow rate as a function of the distribution ratio between the stationary phase and the mobile phase. Many ions can be separated from each other in this way but because there is no sharp pH interface in the column, concentration is not effected, but only separation with diffusion.

Figure 9 shows the typical concentration results for a 10 p.p.m. solution of cadmium, magnesium and zinc. The injected sample solution contained 50 μg of each in 5 mL of 0.1 mol L⁻¹ tartaric acid solution adjusted to pH 8.8. The mobile phase was pumped at a flow rate of 0.05 mL min⁻¹. Revolutionary speed was 950 rpm. The eluent was collected every 2 min (0.1 mL fractions). The fractions were diluted 1 : 10 with water and the emission intensity for each element was measured by direct current plasma atomic emission spectrometer. The emission intensities for each element were increased 20-fold compared to the original sample solution. The results of this study demonstrate the high performance capabilities of the pH-zone refining technique. Trace elements in the sample solution can be successfully concentrated into a small volume with enormous enrichment.

Figure 9 Typical concentration results for 10 p.p.m. solution of cadmium (continuous line), zinc (dashed line), magnesium (dotted line). Apparatus: HSCCC centrifuge with 10.0 cm revolution radius; column: one multilayer coil; sample: 5 mL of each 10 p.p.m. solution (pH 9.25) in 0.1 mol L^{-1} tartaric acid; mobile phase: 0.1 mol L^{-1} HCl saturated with ether; stationary phase: 6 mL of 0.2 mol L^{-1} DEHPA and 0.18 mol L^{-1} ammonia in ether; column: $0.5 \text{ mm i.d.} \times 32 \text{ m}$; flow rate: 0.05 mL min^{-1} ; speed: 950 rpm.

Conclusions

In contrast to HPLC, the unique feature of HSCCC is that there is no solid support in the column. As the distribution abilities including the capacity of the stationary phase are easy to control, HSCCC can be applied to the separation, enrichment and purification of inorganics over a wide range of concentration. In particular, enrichment of trace elements using pH-zone refining technique will be an ideal preconcentration method for subsequent determination by modern instrumental methods. HSCCC can be combined directly with the flow injection technique, and shows great potential for preconcentration of selected desired trace element prior to detection. On-line enrichment and subsequent analysis may thus take the place of conventional sample preparation using a beaker and separating funnel, in future investigations in this field.

Introduction

In general, inorganic ions cannot be detected using absorbance spectroscopy or electrochemistry. As a result, determinations of inorganic ions by liquid chromatography (LC) possess many characteristics distinct from determinations of organic compounds by LC. These differences are most noticeable in the detection methodologies used, but also feed back into the column design and operation. This article focuses on the distinct aspects of LC determinations of inorganic ions, and provides an introduction to approved methodologies for inorganic ion analysis. For further reading, the monograph by Haddad and Jackson and the recent special issue of *Journal of Chromatography A* (volume 789) devoted to chromatography of inorganic ions are strongly recommended.

Instrumentation for Inorganic Ion Analysis

General

Figure 1 shows a schematic diagram of a high performance liquid chromatograph (HPLC) for inorganic ion analysis. This instrument is commonly referred to as an ion chromatograph. The most distinguishing difference from a typical HPLC is the post-column reactor. Nonetheless, there are a number of other subtle differences. The pump, injector and tubing are essentially standard HPLC components. The only significant difference is that for inorganic ion analysis these components are generally constructed of metal-free materials, such as poly-

etheretherketone (PEEK). PEEK is extremely chemically inert, flexible, inexpensive and capable of withstanding high pressures.

Column

Separations of inorganic ions are performed using ion exchange. However, classical gel type (polystyrene-divinylbenzene) ion exchangers are not used. Such resins possess too high a capacity and the mass transfer is too slow to allow the low eluent strengths and high separation efficiencies required. Rather, columns for inorganic ion analysis are generally of two types. Firstly, and most commonly, the columns are packed with pellicular particles. Pellicular pickings have a solid core with ion exchange sites only on the outer surface of the particle. Alternatively, dynamic ion exchange columns can be prepared from reversed-phase packings (C_{18}) by addition of an ion pair reagent to the mobile phase. In either case the ion exchange capacity of the columns is low, typically 20–200 μeq per column.

Post-column Reactor

As stated above, the most distinguishing feature of an HPLC for inorganic ion analysis is the post-column reactor. Its purpose is to facilitate detection of the inorganic ions. The simplest post-column reaction is the formation of a coloured product which can be measured with a spectrophotometer. For example, transition and lanthanide metal ions (M) can be monitored using post-column reaction with 4-(2-pyridylazo)resorcinol (PAR):

A reagent stream of excess PAR is added to the effluent from the ion exchange column. The

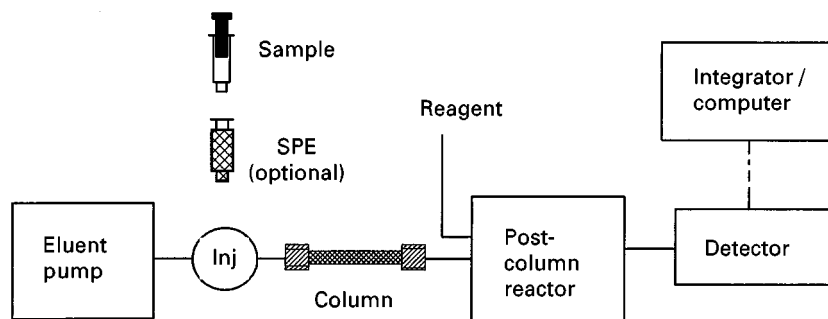

Figure 1 Schematic diagram of a high performance liquid chromatograph for analysis of inorganic ions. SPE, solid-phase extraction.

post-column reaction should ideally be instantaneous, as with PAR, allowing use of a simple T-connector as the post-column reactor. Once the colourless metal ions present are complexed by the PAR, the PAR absorbance undergoes a bathochromic shift. That is, in the absence of metal ions, the PAR reagent absorbs little light at ~ 510 nm, whereas metal-PAR complexes absorb intensely at this wavelength. This absorbance can be directly related to the metal ion concentration.

A more complex post-column reaction is suppression, which is used in conjunction with conductivity detection. All inorganic ions conduct electricity. Thus, conductivity is a universal detector for these species. However, the eluents used in ion exchange chromatography are also conducting. The function of the post-column suppressor is to eliminate (suppress) the background conductivity of the eluent, or at least reduce it to an insignificant level. Typical suppressors are membrane-based, although fibre- and column-based suppressors were used in older systems. The suppression process can be illustrated using the example of the determination of inorganic anions in a sodium carbonate eluent, as is used in Environmental Protection Agency (EPA) Method 300.0 and American Society for Testing and Materials (ASTM) Method D 4327. The membrane in a suppressor for anion chromatography is a cation exchange membrane. Eluent from the column flows on one side of the membrane, while a regenerant flows on the other side. The regenerant is typically H_2SO_4 . H^+ from the regenerant and Na^+ from the eluent freely exchange through the cation exchange membrane. Anions cannot pass through the membrane due to charge repulsion. As a result of exchange of H^+ for Na^+ in the eluent stream, the carbonate eluent is protonated, minimizing the background conductivity.

Carbonic acid is however a weak acid and does undergo some dissociation back to H^+ and HCO_3^- . However, this dissociation only results in a small residual ($\sim 15 \mu\text{S}$) background conductivity. Samples do not possess this background conductivity. Thus, a 'water dip' is observed at the dead volume of the column (0.7 min in Figure 2) when the water from the sample elutes from the column. The weak acid character of carbonic acid can also cause some nonlinearity in calibration curves for inorganic anions when suppressed conductivity detection is used.

Figure 2 Separation of standard inorganic anions using pre-concentration as per ASTM method D 5542. Peaks: 1, $5 \mu\text{g L}^{-1}$ chloride; 2, $20 \mu\text{g L}^{-1}$ nitrate; 3, $20 \mu\text{g L}^{-1}$ phosphate; 4, $20 \mu\text{g L}^{-1}$ sulfate. Special Considerations for Inorganic Ion Analysis

Water

Water used in the preparation of standards and eluents for routine determinations should be freshly distilled and deionized, and meet the specifications

for ASTM Type II water ($1 \text{ M}\Omega \cdot \text{cm}$). However, $1 \text{ M}\Omega \cdot \text{cm}$ water may contain up to 200 p.p.b. of any anion. Therefore, for trace anion analyses, ASTM Type I water ($18 \text{ M}\Omega \cdot \text{cm}$) is recommended. Modern deionization systems using nuclear-grade ion exchange resins to polish out inorganic impurities provide water of this grade which contains down to 20 p.p.t. chloride, 100 p.p.t. sodium and 50–60 p.p.t. ammonium.

Eluents

All eluents should be filtered through $0.2 \mu\text{m}$ membranes before use. Many ion chromatographic eluents are excellent growth media for algae. Therefore eluents should be stored at 4°C and not kept for longer than 1 month.

Sample Handling

Many samples possess acidic, alkaline or saline matrices which can disrupt liquid chromatographic determinations of inorganic ions. In such cases it is essential that the matrix components be removed prior to analysis. Solid-phase extraction (SPE) is a convenient means of eliminating such interferents. A SPE device is generally a small column or filter containing a chromatographic medium which fits on

to a sample syringe. Typical SPE cartridges for inorganic ion analysis contain cation exchange resin in the H^+ form to reduce sample pH, in the Ag^+ form to selectively precipitate halides and in the Ba^{2+} form to precipitate sulfate; anion exchange resin in the OH^- form to neutralize acidic samples; and hydrophobic materials such as polystyrene to remove hydrophobic matrix components. Passage of the sample through the SPE and directly into the injector provides a quick and convenient means of eliminating deleterious matrix components.

Methods for Inorganic Ion Analysis

A reliable source of methods for inorganic ion analysis is the approved regulatory methodologies. **Table 1** provides a brief summary of approved methods from the US EPA and the ASTM. Other agencies, such as the National Institute for Occupational Safety and Health (US) and the Occupational Safety and Health Administration (US), also have approved methods for determination of air-borne species such as SO_2 , Br_2 , Cl_2 , NO_x and organoarsenics by conversion into aqueous inorganic ions and determination by ion chromatography.

Another rich source of information are vendor application notes. On-line listings of these application

notes are available from a number of companies, such as Alltech Associates, Dionex Corporation, Metrohm and Waters Corporation.

Anions by Suppressed Conductivity

Many of the regulatory procedures listed in Table 1 for standard anions use suppressed conductivity ion chromatography and low capacity (20–35 µeq per column) ion exchange columns. Bicarbonate/carbonate eluents are used for the inorganic acid anions (EPA 300.0 and 300.6; ASTM D4327, D5085, D5542 A and E1787). Figure 2 shows the separation of standard anions using ASTM Method D 5542 with a bicarbonate/carbonate eluent on a Dionex AS4A column. Similar elution orders are observed with

other ion chromatographic columns. However, separation selectivities do vary with the column capacity, hydrophobicity and structure. Thus, the precise eluent concentrations and selectivities depend upon the specific column used.

Method B of the ASTM D 5542 protocol recommends the use of 5 mmol L⁻¹ sodium tetraborate, for separation of fluoride, acetate and formate. These anions are very weakly retained, and so a weak eluent is required to separate them from each other and from the water dip.

Detection limits for these regulatory methods are listed in Table 2. Using a 50 µL injection loop, low parts per billion (p.p.b., µg L⁻¹) are achieved using suppressed conductivity. This equates to less than

$1 \mu\text{mol L}^{-1}$ concentration in solution, or to less than 1 ng of anion injected. Much lower concentration detection limits can be achieved by preconcentrating the sample onto a small low capacity pre-column. In ASTM Method D5542 (Figure 2), 10 mL of high purity water is concentrated onto a pre-column. Such preconcentration can yield sub-p.p.b. detection limits. At such levels, proper handling of ultra pure water samples is essential to avoid contamination. Appropriate handling procedures are covered in ASTM Method D4453.

Anions by Direct Conductivity

Suppressed conductivity is the most common means of monitoring inorganic anions. However, approved methods also exist which do not use suppression. Rather these procedures measure the conductivity of the column effluent directly. EPA Method A-1000 has been approved for the determination of chloride and sulfate in drinking water. Figure 3A shows the separation achieved using a Waters IC-Pak anion column with a pH 8.5 borate/gluconate eluent.

Detection limits for direct conductivity detection are given in Table 2. In the analysis of drinking waters or other environmental samples with this direct conductivity method, high levels of carbonate, interfering metals (e.g. magnesium and calcium) and excess base may cause baseline disturbances. These interferences can be eliminated using an H^+ form SPE system.

Anions by Absorbance Detection

Anions by direct absorbance detection A number of inorganic anions absorb light in the low UV ($205\text{--}215 \text{ nm}$) range. In such cases it is possible to analyse these anions using a standard high performance liquid chromatograph possessing a UV detector. EPA Method B-1011 describes the analysis of nitrite and nitrate in water using absorbance detection at 214 nm . The molar absorptivity of these ions is quite strong (e.g. $9000 \text{ M}^{-1} \text{ cm}^{-1}$ for nitrate at 210 nm), yielding detection limits of 0.003 and 0.0003 mg L^{-1} for nitrite and nitrate respectively. UV detection provides comparable precision and

Figure 3 Separation and detection of standard inorganic anions using: (A) direct conductivity detection; (B) direct absorbance detection at 214 nm . Peaks: 1, $1 \mu\text{g L}^{-1}$ fluoride; 2, unknown concentration of bicarbonate (due to contamination by CO_2 in air); 3, $2 \mu\text{g L}^{-1}$ chloride; 4, $4 \mu\text{g L}^{-1}$ nitrite; 5, $4 \mu\text{g L}^{-1}$ bromide; 6, $4 \mu\text{g L}^{-1}$ nitrate; 7, $6 \mu\text{g L}^{-1}$ phosphate; 8, $4 \mu\text{g L}^{-1}$ sulfate. Experimental conditions: column, Waters IC-Pak A HR ($75 \times 4.6 \text{ mm}$; $6 \mu\text{m}$); eluent, borate-gluconate (pH 8.5); flow rate, 1.0 mL min^{-1} ; detection, direct absorbance at 214 nm followed in series by direct conductivity at 35°C ; injection, $100 \mu\text{L}$. (Courtesy of Waters.)

accuracy to suppressed conductivity for nitrate. Other anions such as F^- , Cl^- , ClO_4^- , HPO_4^{2-} and SO_4^{2-} do not absorb significantly above 195 nm, and so do not interfere, as can be seen in Figure 3B.

Other ions which absorb in the UV include Br^- (214 nm; 50 p.p.b. detection limit); BrO_3^- (210 nm; 50 p.p.b.); CrO_4^{2-} ($1600 M^{-1} cm^{-1}$ at 365 nm; < 1 p.p.b.); I^- (226 nm; 50 p.p.b.); and IO_3^- (210 nm; 50 p.p.b.). However, there are no approved methods using UV absorbance detection for these ions.

Anions by indirect absorbance detection Indirect UV absorbance may also be used to detect inorganic anions. In indirect detection, the eluent is a strongly absorbing anion such as phthalate. Within the eluting peak, the analyte anion displaces an equivalent amount of the absorbing eluent anion. Thus, the absorbance decreases as each analyte elutes from the column. Often the leads on the detector are reversed when performing indirect detection, such that the peaks appear positive. Standard anions can be determined in 15 min with low p.p.b. detection limits using $0.8 mmol L^{-1}$ phthalate at pH 6.8 as eluent and indirect detection at 265 nm.

Post-column reaction detection In EPA Method 218.6 and ASTM Method D5257, hexavalent chro-

mium Cr(VI) is separated from Cr(III) and other reactive metal ions by anion exchange chromatography. Detection is by absorbance at 520 nm after post-column reaction with diphenylcarbohydrazide. This procedure is suitable for monitoring Cr(VI) from 1 to 1000 p.p.b.

Dasgupta has provided an exhaustive review of other methods for post-column reaction detection of anions.

Cations by suppressed conductivity EPA Method 300.7 is currently the only approved procedure for determination of inorganic cations using ion chromatography. This procedure was developed to determine monovalent and divalent cations in precipitation using ion chromatography with suppressed conductivity detection. As indicated in Table 2, detection limits for this procedure are in the low p.p.b. ($\mu g L^{-1}$) range. Cation exchange with suppressed conductivity is not limited to metal ions. **Figure 4** shows a separation of alkali metals, alkaline earth metals and some volatile amines.

Cations by Direct Conductivity

Alkali metals and alkaline earth metals can be detected using nonsuppressed conductivity detection. Using a

Figure 4 Separation of group I and II cations and volatile amines. Column: 25 cm \times 4 mm, 8–9 μm IonPac CS12A; mobile phase, step gradient of $16 mmol L^{-1}$ sulfuric acid–4% acetonitrile to $28 mmol L^{-1}$ sulfuric acid–4% acetonitrile to $50 mmol L^{-1}$ sulfuric acid–5% acetonitrile; flow rate, $1.0 mL min^{-1}$; detection, conductivity with suppression from a CSRS-II autosuppressor unit; temperature, $40^\circ C$. Sample: 1, lithium (0.5 p.p.m.); 2, sodium (2.0 p.p.m.); 3, ammonium (2.5 p.p.m.); 4, potassium (5.0 p.p.m.); 5, morpholine (10.0 p.p.m.); 6, 2-diethylaminoethanol (10.0 p.p.m.); 7, magnesium (2.5 p.p.m.); 8, calcium (5.0 p.p.m.); 9, cyclohexylamine (15.0 p.p.m.). (Courtesy of Dionex.)

3 mmol L⁻¹ HNO₃/0.1 mmol L⁻¹ ethylenediaminetetraacetic acid (EDTA) eluent on a Waters IC-Pak cation M/D column, linear response is observed down to 0.05 p.p.m. for Li⁺, Na⁺, NH₄⁺, K⁺, Mg²⁺ and Ca²⁺ in a 15 min separation. Other alkali metals, alkaline earth metals and amines can also be detected in this fashion.

Inorganic Cations by Absorbance Detection

Cations by direct and indirect absorbance detection

Simple inorganic cations generally cannot be effectively monitored by direct UV absorbance due to their low molar absorptivities. However, metal complexes with complexing ligands such as dithiocarbamates provide high molar absorptivities which yield low p.p.b. detection limits. Furthermore, these hydrophobic complexes can be separated using conventional reversed-phase columns. For instance, pre-derivatization of Ru³⁺, Pt²⁺, Pd²⁺ and Rh³⁺ with diethyldithiocarbamate enables their separation on a standard C₁₈ reversed-phase column with a methanol-water eluent and sensitive (p.p.b.) detection at 260 nm. This approach is most attractive when a post-column reaction detection system cannot be used and for the analysis of precious metals.

Indirect absorbance detection of alkali metals can be performed using eluents such as 4-methylbenzylamine (262 nm) and Cu²⁺ (252 nm). However, the detection limits are inferior to those obtained with suppressed conductivity.

Inorganic cations by post-column reaction detection

The most common means of separating the first row transition metals by LC is on reversed-phase

(C₁₈) columns dynamically coated with C₈SO₃⁻ or low capacity ion exchangers. Complexing eluents such as tartrate and pyridine-2,6-dicarboxylate (PDCA) are used. Post-column reaction detection with PAR can be used for a wide range of metal ions including Pb²⁺, Fe³⁺, Cu²⁺, Ni²⁺, Zn²⁺, Co²⁺, Cd²⁺, Mn²⁺, Fe²⁺ and Hg²⁺ with detection limits in the low p.p.b. range for typical injection volumes. This is more than 100 times the sensitivity achievable with conductivity. Figure 5 shows a typical separation of transition metals by HPLC. A number of species (Fe³⁺, Cr³⁺, Sn⁴⁺) elute at the void volume (1.6 min in Figure 5) and so cannot be quantified. Degradation of the peak shape for copper is observed if trace organic acids are present in the water used to prepare the eluent.

High efficiency lanthanide separations are achieved using reversed-phase C₁₈ columns dynamically coated with C₈SO₃⁻ with gradient elution by α -hydroxyisobutyric acid. Elution is in the order of decreasing atomic mass (Lu → La). Post-column reaction detection with Arsenazo III with detection at 658 nm yields 1–5 p.p.b. detection limits using a 20 μ L injection.

Simultaneous separation of transition and lanthanide metals has been achieved based on the charge of the metal-PDCA complexes. Transition metals form monovalent or divalent anionic complexes with PDCA and so can be separated with a PDCA eluent on a Dionex CS5 column. Once all of the transition metals have eluted, the lanthanides, which form strongly retained trivalent anionic complexes with PDCA, are eluted with an oxalate-diglycolate eluent. Detection limits of 20–40 p.p.b. are observed for post-column reaction detection with PAR.

Figure 5 Separation of transition metals with post-column reaction detection. Experimental conditions: column, Waters Delta Pak C₁₈ (10 nm, 5 μ m); eluent, 2 mmol L⁻¹ sodium octanesulfonate, 35 mmol L⁻¹ sodium tartrate, 5% acetonitrile adjusted to pH 3.65 with NaOH; flow rate, 0.8 mL min⁻¹; detection, 500 nm after post-column addition of 0.5 mL min⁻¹ of 0.2 mmol L⁻¹ 4-(2-pyridylazo) resorcinol (PAR), 1 mol L⁻¹ acetic acid, 3 mol L⁻¹ ammonium hydroxide. (Courtesy of Waters.)

Thin-Layer (Planar) Chromatography

Introduction

Thin-layer chromatography (TLC) is a subdivision of liquid chromatography in which the mobile phase (a liquid) migrates through the stationary phase (thin layer of porous sorbent on a flat inert surface) by capillary action. In 1938, two Russian workers, Izmailov and Schraiber, separated certain medicinal compounds on binder-free horizontal thin layers of alumina spread on a glass plate. Since the development was carried out by placing solvent drops on the glass plate containing sample and sorbent, their method was called drop chromatography. This method remained unnoticed for 10 years until two American chemists, Meinhard and Hall, used a mixture of aluminium oxide (adsorbent) and celite (binder) in a layer on a microscope slide to separate Fe^{2+} from Zn^{2+} . They called this technique surface chromatography and this was the first application of planar chromatography to the separation of inorganic ions. The real impetus for advancement of TLC started in 1951 with the work of Kirchner and his associates. Stahl introduced the term thin-layer chromatography in 1958 and standardized procedures, materials and nomenclature. The rapid growth of TLC slowed down during the 1970s with the rise in popularity of high performance liquid chromatography (HPLC) and ion chromatography (IC). However, recent improvements in TLC have removed many of its limitations.

High performance TLC (HPTLC) layers, being thinner and made of more uniform particle size sorbents, provide faster separations, reduced zone diffusion, lower detection limits, less solvent consumption and better separation efficiency. The distinct advantages of TLC over HPLC have been identified as low solvent consumption, low operational cost, easier sample preparation, more rapid throughput, greater detection possibilities and the use of disposable plates. TLC permits the simultaneous analysis of many samples in the same time required for one HPLC analysis and samples and standards are analysed by TLC under exactly the same conditions rather than serially, as in HPLC. Typically, 18–36 samples can be run on a single HPTLC plate with a development time of 3–20 min over a migration distance of 2–7 cm. However, the influence of environmental conditions on the reproducibility of R_F values and poor separation efficiency have been major disadvantages of TLC compared with HPLC and gas chromatography (GC).

TLC can be used for *qualitative* analysis, to identify the presence or absence of a particular substance in a mixture; *quantitative* analysis, to determine precisely and accurately the amount of a particular substance in a sample mixture; and *preparative* analysis, to purify and isolate a particular substance for subsequent use. All three applications require the common procedures of sample application, chromatographic separation and component visualization. However, analytical TLC differs from preparative TLC in that volumes and/or weights of samples are applied to thicker layers in the latter case.

Inorganic TLC

Though the first published reports on TLC described the separation of inorganic species, the importance of inorganic TLC did not receive recognition until the beginning of the 1960s when Seiler separated inorganic substances. After the work of Seiler, TLC of metal ions received a great impetus. Some of the major fields in which inorganic TLC has found applications include the analysis of biological, food, geological, industrial, pharmaceutical, soil, water and industrial waste water samples. The purpose of this article is to present briefly the current state-of-the-art procedures of TLC/HPTLC as applied to the analysis of inorganic ions.

Procedure

TLC is an offline process in which various steps are carried out independently (Figure 1). The basic TLC procedure involves the spotting of sample mixture (5–10 μL for conventional TLC and 1–2 μL for HPTLC) at about 1.5–2 cm above the lower edge of the layer, drying the spot completely at room temperature or at an elevated temperature, development of the plate, usually by one-dimensional ascending technique in a closed chamber (cylindrical or rectangular) to a distance of 8–10 cm, removing the plate from the developing chamber, removal of mobile phase from the layer by drying, detection of spots on the plate using a suitable detection reagent/procedure, measurement of R_F values of resolved spots and determination of the separated analyte. The differential migration of components in a mixture is due to varying degrees of affinity of the components for the stationary and mobile phases.

Sample Preparation

The sample solution to be analysed must be sufficiently concentrated to provide clear detection and/or be pure enough so that it can be separated as a discrete and compact zone. For low concentrations of analyte in a complex sample, preconcentration and clean-up procedures must frequently precede TLC.

Metal solutions are generally prepared by dissolving their corresponding salts in distilled water or 0.1 mol L^{-1} HCl (or HNO_3) to a final metal concentration of 0.1–0.2 mol L^{-1} . Rare earth oxide solutions are prepared by fusion followed by dissolution in 0.5–6 mol L^{-1} HNO_3 and anion solutions in distilled water, dilute acid or alkali are prepared from sodium, potassium and ammonium salts of the corresponding acids. Metal complexes are used as freshly

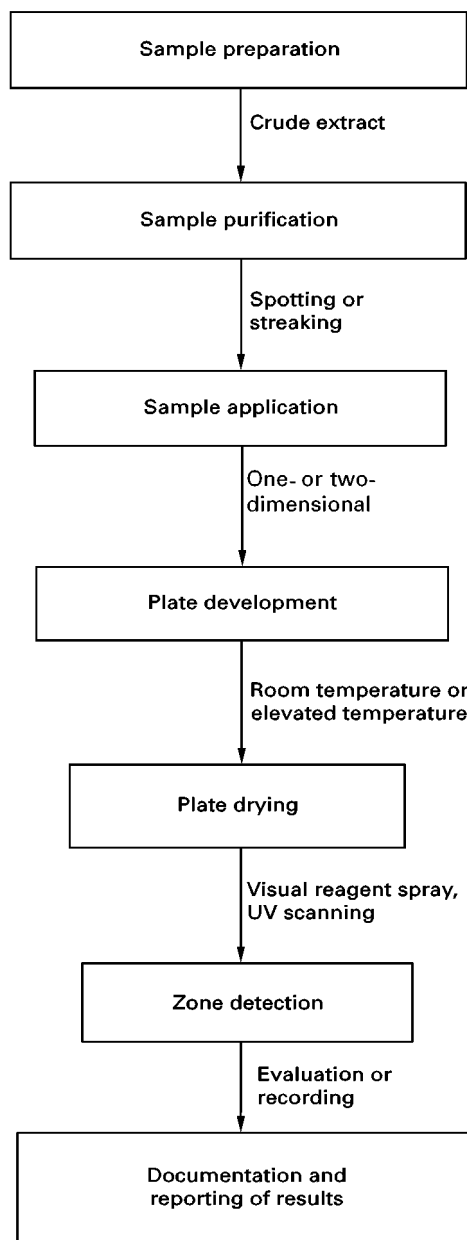

Figure 1 Schematic diagram showing the steps involved in a TLC process.

prepared solutions in ethanol, acetone, chloroform or distilled water. Specific standard methods are followed for sample preparation to identify and determine metal ions in biological, environmental, alloys, plants, foods, textile and geological samples.

TLC Plate Preparation

The current trend is to use commercially available pre-coated plates. The manual preparation of layers involves the coating of a slurry of the adsorbent (silica

gel, alumina, etc.) on to glass, aluminium or plastic sheets (20 × 20 or 20 × 10 cm) with the help of an applicator. The thickness of the dried layer of analytical purposes is kept to 0.1–0.3 mm. A binder (starch, gypsum, dextrin, polyvinyl alcohol) is usually added to the adsorbent to provide better adhesion, mechanical stability and durability. The addition of a fluorescent indicator compound is optional. Compared to conventional TLC, HPTLC layers are produced from sorbents of smaller and more uniform particle size (5–10 μm instead of 10–20 μm).

Sample Application

Definite volumes of samples are applied as spots or streaks using a micropipette, microsyringe or glass capillaries. A number of automatic spotters of various designs are available for sample application. The nano-applicator (Nanomat) is an example of a micrometer-controlled syringe which has a dynamic volume range of 50–230 nL. Another applicator (Linomat) allows sample application in narrow bands by a spray-on technique. The application of a sample as a streak or band provides more efficient separations because the efficiency of the separation on a TLC plate depends on the diameter of the spot along the direction of development. Thus, the best efficiency is achieved with the smallest diameter spot. Alternatively, the use of TLC plates with concentration zones converts the sample from the original spot into a band or streak. These plates consist of a bottom layer (2–2.5 cm) of a chromatographically inactive adsorbent (e.g. Kieselguhr) followed by the layer of an active adsorbent (silica or bonded silica). The advantages of sample application as a streak and the use of TLC plates with concentration zones are illustrated in Figure 2. The general aspects

of a sample application have been reviewed by Jaenchen.

Development Techniques

The migration of the mobile phases through the stationary phase (or sorbent layer) to effect separation of samples is called development. One-dimensional ascending development is the most commonly used mode in inorganic TLC. Other development techniques, such as multiple, stepwise, circular and two-dimensional development, have also been used to a limited extent. The migration distance for the mobile phase is kept to 10–12 cm for conventional TLC and 2–6 cm for HPTLC. Dzido has described the variants of the development techniques.

Chromatographic Systems

A combination of stationary and mobile phases constitutes a chromatographic system. The proper selection of stationary and mobile-phase conditions determines the effectiveness of a separation.

Stationary Phase (Layer Sorbent)

Many materials have been used as stationary phase in inorganic TLC but silica gel, an amorphous and porous adsorbent, has been the most favoured material, followed by alumina and cellulose. Thin layers of silica gel G (gypsum binder) and S (starch binder) with or without fluorescent indicator are frequently used. Silica gel is slightly acidic in nature and the silanol groups (Si–OH) can interact with solute molecules. On the other hand, alumina (aluminium oxide) is basic and more reactive than silica gel. Adsorption is the separation mechanism with both alumina

Figure 2 (A) Resolution of a two-component mixture on a TLC plate; (B) improved efficiency due to streaking; and (C) utility of concentration zone as a promoter of efficiency.

and silica gel. Cellulose, an organic material, is used as a sorbent to perform separations with increased sensitivity of detection and decreased development time compared to paper chromatography. The various layer materials may be broadly classified as:

1. nonsurface-modified or untreated sorbents;
2. impregnated or treated sorbents (organic and inorganic impregnants);
3. bonded or chemically modified sorbents (hydrophobic modified or reversed-phase and hydrophilic modified);
4. inorganic ion exchangers;
5. mixed sorbents.

More detailed information on pre-coated layers and sorbents that are commonly used in TLC is available elsewhere (see Further Reading).

The selective application of these different types of layer materials in inorganic TLC is summarized below.

Anions Silica gel, silica gel silica impregnated with fluorescein or inorganic salts, silica gel + antimonic acid/alumina/hydrous antimony(V) oxide/Zr(IV) molybdate, Sephadex, microcrystalline cellulose, surface-modified cellulose, cellulose + Kieselguhr/alumina, Kieselguhr, alumina, kaolin, hydrated stannic oxide and polyamide have all been used for the separation of anions.

Metal ions and rare earth elements The various layer materials used for the separation of metal ions, metal complexes and rare earth elements (REE) may, broadly, be classified as follows.

Nonsurface modified or untreated sorbents These include silica gel, alumina, cellulose, polyamide, polyacrylonitrile, Sephadex and Kieselguhr. Layers of chitin and its deacetylated derivative chitosan have been used to separate metal ions.

Impregnated or treated sorbents In general, silica gel impregnated with aqueous salt solutions, high molecular weight amines, organophosphorous compounds and organic chelating agents has been widely used for the separation of metal ions and REE. Metal complexes have been separated on silica gel impregnated with chlorobenzene, *p*-toluidine or surfactants and on layers of egg shell powder impregnated with Triton X-100.

Bonded or chemically modified sorbents Lipophilic C₁₈-bonded silica gel for REE and metal complexes, aminopropyl silica gel (NH₂) and octadecyl silica gel

(C₁₈) for lanthanide complexes of tetraphenyl porphine and surface-modified cellulose as well as cellulose derivatives for several metal ions have been used.

Mixed sorbents Combinations of silica gel and microcrystalline cellulose for noble metal ions and transition metal chlorosulfates, silica gel and microcrystalline cellulose containing ammonium nitrate for REE and silica gel and inorganic ion exchange gel mixtures for transition metal ions have been used.

Other sorbents Synthetic inorganic ion exchangers, porous glass sheets, soil and soil-flyash mixture, polychrome A, carbamide-formaldehyde copolymer and immobilized analogue of dibenzo-18-crown-6 on silica support for metal ions and diatomite for REE have also been used, but to a lesser extent.

The adsorbents in different forms (untreated, impregnated, chemically modified or mixed) preferred in the analysis of inorganic ions since 1973 are shown in Table 1.

Anions Silica gel > cellulose > alumina > inorganic ion exchangers > Kieselguhr > polyamide.

Cations/metal ions Silica gel > cellulose > inorganic ion exchangers > alumina > chitin and chitosan > diatomite > soil.

Metal complexes Silica gel > alumina > cellulose > polyacrylonitrile > Sephadex = polyamide.

The salting-out efficiency of mixed aminocarboxylato Co(III) complexes obtained on different adsorbents shows the sorbent precipitation in the order (with small discrepancies) polyacrylonitrile > cellulose > silica gel. Polyacrylonitrile is the most suitable sorbent for the separation of complexes. The HPTLC results of rare earth-tetraphenylporphine complexes show an increase in *R_F* values in the order of the atomic number on NH₂-bonded silica plates and a reverse trend, i.e. decrease in *R_F* values, with an

Table 1 Number of publications (%) on some sorbent layers appearing from 1973 to 1996

Layer material	Per cent publications		
	Metal ions	Metal complexes	Anions
Silica gel	49.6	75.6	50.5
Alumina	6.4	10.7	9.3
Cellulose	29.3	4.8	29.3
Inorganic ion exchanger	10.0		4.0
Chitin and chitosan	2.0		
Polyacrylonitrile		4.8	
Polyamide		~1.0	1.3

increase in atomic number is obtained on C₁₈-bonded silica layers.

Mobile Phase (Solvent System)

With a particular sorbent layer, the separation possibility of a complex mixture is greatly improved by the proper selection of the mobile phase. Mixtures of organic solvents containing an aqueous acid, base or a buffer are, in general, well suited for the separation of ionic species whereas anhydrous organic solvents are more useful for separating nonionic species. The following mobile phases have been used for inorganic TLC.

Inorganic solvents This includes solutions of mineral acids, bases, salts and mixtures of acids, bases and/or their salts.

Organic solvents This includes acids, bases, hydrocarbons, alcohols, amines, ketones, aldehydes, esters, phosphates and their mixtures in different proportions.

Mixed aqueous-organic solvents This includes organic solvents mixed with water, mineral acids, inorganic bases or dimethyl sulfoxide and buffered salt solutions.

Complexing solvents Solutions of surfactants (sodium dodecyl sulphate (SDS), cetyltrimethylammonium bromide (CTAB), Triton X-100) and ethylenediaminetetraacetic acid.

TLC with mobile phases of lower volatility gives better reproducibility compared to volatile mobile phases, although the latter have the advantage of quick evaporation from the sorbent layer after development.

Visualization

For the visualization of separated zones, physical, chemical or biological detection methods are commonly used. The physical detection methods are based on substance-specific properties and the most commonly employed methods of this group include the absorption or emission spectrophotometry, autoradiography and X-ray fluorescence. The chemical methods of detection involve spraying reagents capable of forming coloured compounds with the separated species on the plate or exposing the plate to vapour. Alternatively, the reagent can be incorporated in the mobile phase or in the adsorbent. In some cases, detection is completed by inspecting the TLC plate under ultraviolet light, after spraying with

a suitable reagent, or by exposing the plate to ammonia vapour. Bioautographic analysis, reprint methods and enzymatic tests can also be applied for detection purposes. Immunostaining and flame ionization detection methods have also been reported.

The detection methods and reagents used in inorganic TLC are summarized below.

Metal Ions

In addition to using conventional detection reagents such as dithizone, dimethylglyoxime, potassium ferrocyanide and 8-hydroxyquinoline, for cations, new reagents such as sulfochlorophenol azorhodamine, phenolazotriaminorhodamine and benzolazobenzol-azorhodamine have been proposed for selective detection of toxic heavy metals at nanogram levels. Radiometry is used to detect Pr(III), Pr(IV) and Tb(III). An elegant fluorescent method for the detection of Mg, Al, Ca, V, Cu, Zn, Ge, Y, Zr, Mo, Ag, Cd, In, La, Ce, Eu, Tb, Tl, Pb, and Bi at $3-3 \times 10^{-6}$ μmol levels has been reported whereby these cations are detected as coloured fluorescent zones generated simply on heating the chromatograms on porous glass sheets at 100–700°C for 15 min. Typical representative fluorescence spectra are shown in Figure 3.

Anions

For the detection of anions, saturated silver nitrate solution in methanol, 0.2–0.5% diphenylamine solution in 4 mol L⁻¹ H₂SO₄, 1% aqueous solution of potassium ferrocyanide, 0.5% alcoholic solution of pyrogallol, 10% FeCl₃ solution in 2 mol L⁻¹ HCl, 1% KI in 1.0 mol L⁻¹ HCl and mixture of aqueous KSCN and SnCl₂ in 1.0 mol L⁻¹ HCl, ammoniacal AgNO₃, aqueous bromocresol green, FeSO₄ + FeCl₃, alizarin, alizarin-zirconium lake, benzidine solution, (NH₄)₂ MoO₄ + SnCl₂ and 0.1% bromocresol purple containing dil. NH₄OH have been used. Autoradiography, scintillation counting and radiometric detection methods have also been applied. Several anions are detected on the basis of quenching effects: dark spots of the anions appeared on the bright greenish fluorescent background when the chromatograms are sprayed with aluminium(III)-morin fluorescent complex (prepared by dissolving 5 mg AlCl₃ and 5 mg of 2',3,4',5,7-pentahydroxyflavone (morin) in a mixture of 10 mL 30% CH₃COOH, 20 mL 98% ethanol and 20 mL water). The detected anions are IO₃⁻, IO₄⁻, CrO₄²⁻, PO₄³⁻, Cr₂O₇²⁻, NO₂⁻, NO₃⁻, SO₄²⁻, SO₃²⁻, Fe(CN)₆³⁻, Fe(CN)₆⁴⁻, and BrO₃⁻ (strong violet spots), F⁻, Cl⁻, Br⁻, I⁻, S²⁻, S₂O₃²⁻, VO₃⁻, VO₄³⁻, and MoO₄²⁻ (medium blue spots) and ClO₂⁻, ClO₃⁻, ClO₄⁻, SCN⁻ and WO₄²⁻ (weak yellow spots). Several anions producing intense blue colour with

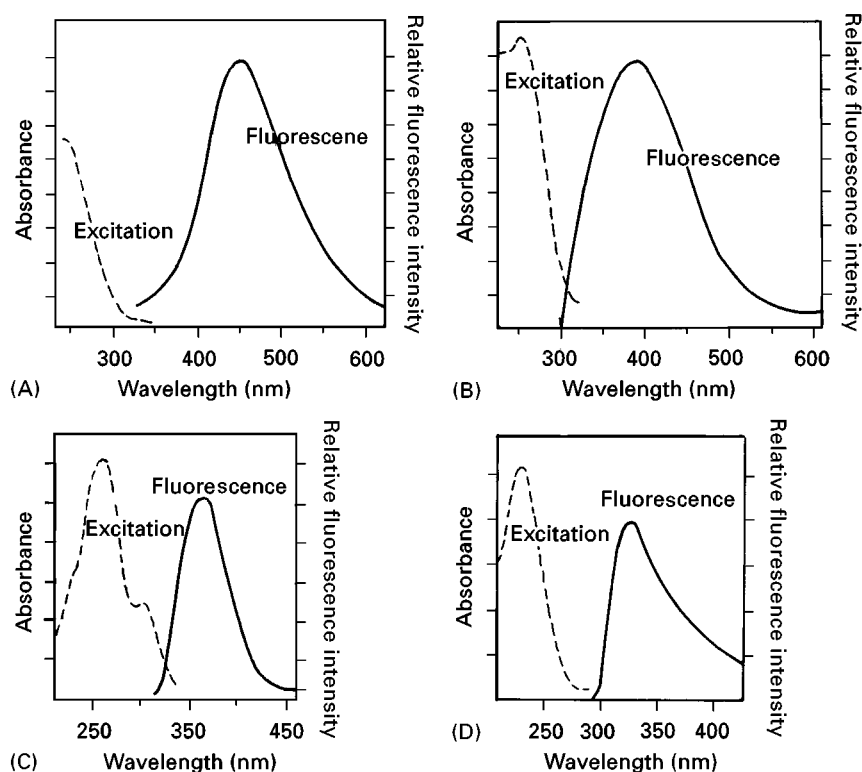

Figure 3 Fluorescence spectra of (A) copper, (B) lead, (C) cerium and (D) thallium ions heated on porous glass sheet. (Reproduced with permission from Yoshioka M *et al.* (1992) Fluorescence reactions of inorganic cations heated on a porous glass sheet for thin-layer chromatography. *Journal of Chromatography* 603: 223–229.)

0.2% Ph₂NH in H₂SO₄ are detected down to 0.1 µg on silufol layers. Halides have been detected with alizarin-zirconium lake and AgNO₃.

Rare Earth Elements

The REEs have been detected by first, spraying the plate with 0.1% arsenazo(III) solution and then with aqueous ammonia followed by gentle heating; second, heating at 70°C for 10 min after spraying with 0.02% chlorophosphonazo solution; and third, exposure of the plate to NH₃ after spraying with tribromo-chlorophosphonazo or xylenol orange solution. Saturated ethanolic solution of alizarin and dilute solutions (0.2–1%) of tribromoarsenazo have been used to detect REE.

Metal Complexes

Most of the complexes being coloured are visible without further treatment, e.g. Fe(phen)₃²⁺; Fe(bpy)₃²⁺; metal glyoxaldithiosemicarbazone; thiocarbonate complexes of Cu, Ni and Co; anil complexes of Cu, Mn, Fe and Zn; metal chelates of V, Co, Cr, Ni and Mn with 2,2'-dihydroxy-5,5'-dimethylazobenzene; trifluoroacetylacetonates of rare

earths; metal xanthates; metal chelates of 1-hydroxyphenazine; metal diethyldithiocarbamate complexes; metal dithizonates; transition metal monothio-β-diketonates; dithioacetylacetone; metal acetothioacetanilide. Metal oxinates, some geometrical isomeric complexes of Rh, Pt and Co, methylbenzylidithiocarbonate metal chelates, Cu(II) carboxylates and Co (gly) are self-coloured but located under ultraviolet light. Trisethylenediamine Co(III) complexes are detected with sodium sulfide solution. β-Diketonates of Fe, Cr and Co, organotin compounds, alkali metal xanthates and piperidine dithiocarbamate complexes can be detected with iodine vapour. A fluorometric method has been used for the detection of heavy metal complexes with pyrene-substituted *N*-acylthiourea. Sometimes spots are detected by spraying coloured reagents such as pyrocatechol violet and copper sulfate as well as by immersing the TLC plates in a dilute solution of phenylfluorone reagent. *N,N*-diethyl-*N'*-benzoylthiourea-metal chelates have been detected by graphite furnace atomic absorption spectrometry and by UV detection. These techniques permit the sensitive detection of enriched platinum metals with detection limits in the nano- and picogram range (Table 2).

Table 2 Absolute detection limits for *N,N*-di ethyl-*N'*-benzoylthiourea chelates in chromatography

Qualitative Analysis

Identification

In TLC the identification of separated compounds is primarily based on their mobility in a suitable solvent which is described by the R_F value of each compound, where:

$$R_F = \frac{\text{distance of spot migration from the origin}}{\text{distance of solvent front from origin}}$$

The factors which influence the magnitude of the R_F include the nature of the sorbent, layer thickness, activation temperature, chamber saturation, nature of the mobile phase, pH of the medium, room temperature, sample volume, relative humidity and mode of development. Another term, R_M , which is the logarithmic function of the R_F value, i.e. $R_M = \log(1/R_F - 1)$, is more useful as it bears a linear relationship to some TLC parameters or structural elements of the analyte. However, in cases of continuous and multiple development, where the solvent front is not measured, the term R_X :

$$R_X = \frac{\text{distance travelled by solute}}{\text{distance travelled by standard}}$$

is used.

If the retention data (R_F , R_M , or R_X values) of the compound to be identified are identical with those of the reference substance in three different solvent systems but on the same stationary phase or with the same solvent but on three different types of stationary phases, the two compounds can be regarded as identical with a good probability. However, for correct identification the chromatographic retention data are not enough and at least one spectroscopic method is necessary.

Table 3 hR_F ($R_F \times 100$) values, standard deviation (SD) of R_F values of metal ions present in industrial wastewater and dilution limits of metal ions in standard spiked water

Metal ion	hR_F value	SD of R_F value	Detection limit (μg)
Pb ²⁺	00	34×10^{-4}	7.78
Cd ²⁺	62	44×10^{-4}	6.00
Zn ²⁺	70	12.2×10^{-3}	0.46
Cu ²⁺	97	26×10^{-4}	5.23
Co ²⁺	97	12.4×10^{-3}	7.40
Ni ²⁺	97	58×10^{-4}	3.22

Stationary phase: silica gel G; mobile phase: 1.0 mol L⁻¹ sodium formate + 1.0 mol L⁻¹ KI (1 + 9). (Reproduced with permission from Mohammad A (1995) Identification, quantitative separation and recovery of copper from spiked water and industrial wastewater by TLC-atomic absorption and TLC-titrimetry. *Journal of Planar Chromatography – Modern TLC* 8: 463–466.)

Separation

The separated components of a mixture are detected and their R_F values recorded from the values of R_L (R_F of leading front) and R_T (R_F of trailing front). Some of the basic requirements for a good separation are (a) each spot should be compact ($R_L - R_T \leq 0.3$), (b) the difference in R_F values of two adjacent spots should be at least 0.1, (c) no complexation should occur between/among separable species and (d) chromatography of reference compounds and the

Table 4 Separation of thorium from uranium in presence of common anions

Anions	ΔR_F	K_{Th}	α	R_S
I ⁻	0.50	1.22	24.40	2.56
IO ₃ ⁻	0.41	0.96	10.60	2.34
Br ⁻	0.51	1.27	25.40	2.62
BrO ₃ ⁻	0.40	1.00	9.09	2.22
NO ₃ ⁻	0.40	1.00	9.09	2.00
Cl ⁻	0.48	1.38	27.60	2.74
SCN ⁻	0.25	0.54	4.91	1.25
S ²⁻	0.30	0.66	6.00	1.20

ΔR_F = Difference in the R_F values of UO₂²⁺ and Th⁴⁺. K_{Th} = Capacity factor of Th⁴⁺ [$K_{Th} = (1 - R_F)/R_F$ for thorium]. α = Separation factor ($\alpha = K_{Th}/K_{UO_2}$). R_S = Resolution for the separation of Th⁴⁺ from UO₂²⁺. [$R_S = D/0.5(d_1 + d_2)$]: D = distance between the centres of separated spots of Th⁴⁺ and UO₂²⁺ whereas d_1 and d_2 are their respective diameters. Stationary phase: silica gel; mobile phase: dimethylamine–acetone–formic acid (2 + 6 + 2, v/v). Reproduced with permission from Mohammad A and Fatima N (1988) A new solvent system for the separation of Th⁴⁺, UO₂²⁺ and Zr⁴⁺ in the presence of common anions by thin layer chromatography. *Chromatographia* 25: 536–538.

Table 5 Separation of Zn–Cd–Hg mixture in spiked environmental samples

Metal ion	R_F values of separated ions			
	Seawater	Industrial wastewater	River water	Soil
Cd^{2+}	0.79	0.81	0.81	0.80
Hg^{2+}	0.96	0.90	0.96	0.98
Zn^{2+}	0.10	0.11	0.11	0.12

Stationary phase: silica gel G impregnated with 0.1% thorium nitrate; mobile phase: 1.0 mol L⁻¹ aqueous solution of sodium formate (pH 7.65). The presence of pesticides (malathion, carbaryl, carbofuran, bavistin and 2,4-dichlorophenoxy acetic acid) and anions (Cl⁻, Br⁻, I⁻, SCN⁻, MoO₄²⁻ and CrO₄²⁻) did not hamper the separation of Zn²⁺ from Hg²⁺ and Cd²⁺. Reproduced with permission from Mohammad A and Majid Khan MA (1992) *Proceedings of National Conference on Clean Environment Strategies, Planning and Management*. Lucknow, India, pp. 191–193. Lucknow: Legend India Environment Protection Pvt. Ltd.

mixture should be performed under identical experimental conditions. Selected examples of TLC/HPTLC separation of inorganic ions are given in Tables 3–5 and Figures 4–10. Bonded silica C₁₈ reversed-phase layers in combination with a methanol–lactate medium as mobile phase have been found to be most suitable for the separation of adjacent rare earths of middle atomic weight group (Figure 4). Carbamide–formaldehyde polymer (amino-

Figure 6 Separation of a mixture of diantipyrilmethane (DAM) salts. Mobile phase: acetone–chloroform (3 : 1 v/v). Reagents: (A) DAM; (B) MDAM (C) HDAM; (D) PDAM. Anions: 1, SO_4^{2-} ; 2, Cl^- ; 3, Br^- ; 4, NO_3^- ; 5, SCN^- ; 6, I^- ; 7, ClO_4^- ; 8, reagent. (Reproduced with permission from Shadrin O, Zhivopistsev V and Timerbaev A (1993) Thin-layer chromatographic determination of inorganic anions as counter-ions of metal diantipyrilmethane cationic complexes and diantipyrilmethane cations. *Chromatographia* 35: 667–670.)

common anions in the form of metal diantipyrilmethane (DAM) complexes and salts of protonated DAM. The separation takes place on silica gel plates with elution by organic solvent–mineral acid or bi-

Figure 7 Sector of the radial thin-layer chromatogram of the mixture of diantipyrilmethane (DAM) salts. (Reproduced with permission from Shadrin O, Zhivopistsev V and Timerbaev A (1993) Thin-layer chromatographic determination of inorganic anions as counter-ions of metal diantipyrilmethane cationic complexes and diantipyrilmethane cations. *Chromatographia* 35: 667–670.)

Figure 8 Separation of the mixture of diantipyrilmethanates of rare earth elements. TLC plate: silufol; mobile phase: *n*-propanol–0.7 mol L^{-1} HCl (9 : 2). (Reproduced with permission from Timerbaev A, Shadrin O and Zhivopistsev V (1990) Diantipyrilmethane as complex-forming reagents in the thin-layer chromatographic determination of metals. *Chromatographia* 30: 436–441.)

nary organic solvent mixtures using ascending or radial development. Being highly coloured (iron complexes) or fluorescent under ultraviolet light (terbium complexes), chromatographic zones can easily be detected. Mixtures of REEs as diantipyrilmethanates are well resolved on silufol plates (Figure 8). A four-component mixture consisting of 4-methyl-2-pentanone, tetrahydrofuran, nitric acid and mono-2-ethylhexyl ester of 2-ethylhexylphosphoric acid (P 507) has been used for HPTLC resolution of 10 rare earths (Figure 9). HPTLC allows fast and effective separation of platinum group metals with *N,N*-diethyl-*N'*-4-(1-pyrene)butyrylthiourea (DE Py BuT) on silica gel layers using toluene as the mobile phase (Figure 10).

Quantitative Analysis

Methods for the quantitative evaluation of thin-layer chromatograms may be divided into two main categories: quantitation after elution from the layer and *in situ* quantitation on the layer. In the first, quantitation is performed after scraping off the separated analyte zone, collecting the sorbent and recovery of the substance by elution from the sorbent. Thereafter, the eluates are analysed by applying any suitable method of analysis, such as GC,

Figure 9 Chromatogram of the 10 rare earths using optimum mobile-phase conditions: 4-methyl-2-pentanone-THF-HNO₃-P 507 (3 : 1.5 : 0.46 : 0.46). (Reproduced with permission from Wang QS and Fan DP (1991) Optimization of separation of rare earths in high-performance thin-layer chromatography. *Journal of Chromatography* 587: 359-363.)

spectrophotometry or titrimetry. In the second, solutes are assayed directly on the layer with the help of visual, manual or instrumental measurement methods.

Figure 10 HPTLC separation of platinum group metals with DEP_γ BuT. Eluent: toluene; relative humidity 5.0%, separation distance, 6 cm (Reproduced with permission from Schuster M and Unterreitmaier E (1993) Fluorometric detection of heavy metals with pyrene substituted *N*-acylthioureas. *Fresenius Journal of Analytical Chemistry* 346: 630-633.)

Figure 11 HPTLC determination of Pd in a synthesis solution. Ligand: *N,N*-di-*n*-hexyl-*N'*-benzoylthiourea. Stationary phase: silica gel 60, mobile phase: chloroform, relative humidity: 20%, separation distance: 3 cm detection: reflectance at 280 nm. (Reproduced with permission from Schuster M (1992) Selective complexing agents for the trace enrichment of platinum metals. *Fresenius Journal of Analytical Chemistry* 342: 791-794.)

In situ densitometry, a preferred technique for quantitative TLC, involves the measurement of visible or ultraviolet absorbance, fluorescence or fluorescence quenching directly on the layer. The measurements are made either through the plates (transmission), by reflection from the plate, or by reflection and transmission simultaneously, using either single-beam, double-beam, or single-beam-dual-wavelength

Figure 12 Densitogram of a mixture of rare earth element complexes. Stationary phase: silufol, mobile phase: *n*-propanol-0.7 mol L⁻¹ HCl (9 : 2); spraying reagent: 0.1% arsenazo III; wavelength: 590 nm. (Reproduced with permission from Timerbaev A, Shadrin O and Zhivopistsev V (1990) Diantipyrilmethane as complex-forming reagents in the thin-layer chromatographic determination of metals. *Chromatographia* 30: 436-441.)

Table 6 Quantitative and semiquantitative determination methods for inorganic ions

Method	Species determined
TLC-densitometry	B, Pb, Fe, Cu, Mn, Co, Ni, Mg, Zr, Mo, Ba, La, Ce, Sr, Se, Ti, Hg, phosphates, selenocyanate, U, Cd, Y, NO ₂ ⁻ , NO ₃ ⁻ , Fe(CN) ₆ ³⁻ , SCN ⁻ , rare earth elements, Co(III)-1-(2-pyridylazo)-2-naphthol complex and bis carboxy ethyl germanium sesquioxide
TLC-spectrophotometry	Pb, Zn, Ni, Cu, Co, Zr, Pd, Mo, U, Hg(II), metal complexes, SCN ⁻ , La, Ce, Pr, Nd, Cr(III), Fe(II), Cr ₂ O ₇ ²⁻ and Fe(CN) ₆ ³⁻
TLC-UV spectroscopy	Hg(II), Cu, Cd
TLC-titrimetry	Cu, SCN ⁻
TLC-atomic absorption spectroscopy (AAS)	Cu, Zn, Fe, Ni, Pb, Mn
ICP-TLC-atomic emission spectroscopy (AES)	Rare earth elements, heavy metals
Neutron activation-circular TLC	Rare earth elements
Square wave-stripping voltammetry-TLC	Pb, Cd, Zn, Cu
TLC-photoacoustic measurement	Cobalt complex of 1-(2-pyridylazo)-2-naphthol
TLC-emission spectrometry	Alkaline earth metals
Visual colorimetry and peak spot-area measurement	Ti, Ni, Cu, Cr, Pb, Ag, Th, Tl(I), Al, Co, Zr, Fe(II), Fe(III), V, U, Cd, Zn, Ce, Hg, IO ₄ ⁻ , Br ⁻ , I ⁻ , NO ₂ ⁻ , Cl ⁻ , NO ₃ ⁻ , SCN ⁻ , SO ₄ ²⁻ , BrO ₃ ⁻

scanning instruments. Modern optical densitometric scanners are linked to a computer and are capable of automated peak location, multiple wavelength scanning and spectral comparison of fractions in several operating modes (reflectance, absorption, transmission and fluorescence). Representative examples of HPTLC determination and densitometry are shown in **Figures 11** and **12**.

The combination of TLC with other analytical techniques has proved useful for the analysis of complex samples. Spectrophotometry, HPLC, inductively

coupled plasma–mass spectrometry and voltammetry in conjugation with TLC are the most commonly used techniques. However, infrared, thermal analysis and mass spectrometry have also been used.

For semiquantitative analysis, visual comparison and spot-size measurement methods are used. A definite volume of sample is chromatographed alongside standards containing the analyte. After detection, the amount of analyte in the sample is estimated by visual comparison of the size and intensity of the sample zone with the standards. This method works

Table 7 TLC results of the determination of Ti, Zr, Hf, La and Tb in various samples

Technique	Sample	Analyte	Determination results	
			Amount found (mean and SD)	Known amount (concentration)
Spot-area measurement method	Sulfite-cellulose liquor	Ti	31 ± 4 p.p.m.	35 p.p.m.
	High speed steel	Ti	25 ± 3 mg g ⁻¹	29.3 mg g ⁻¹
TLC-spectrophotometry	Synthetic mixture (Zr + Hf)	Zr	10.4 ± 0.3 µg	10 µg
		Hf	9.7 ± 0.2 µg	10 µg
	Mg–Al–Zr–Hf	Zr	1.1 ± 0.2 mg g ⁻¹	1.1 mg g ⁻¹
TLC-densitometry	Synthetic mixture	La	1.1 ± 0.1 µg	1.2 µg
		Tb	1.4 ± 0.1 µg	1.6 µg
	Lanthanum glass	La	179 ± 5 mg g ⁻¹	174 mg
		Tb		
	Monazite	La	4.0 ± 0.2 mg g ⁻¹	4.3 mg g ⁻¹
	Tb	1.1 ± 0.2 mg g ⁻¹	1.2 mg g ⁻¹

Table 8 Comparison of results of anions in water samples by TLC and ion chromatography (IC)

Sample	Technique	Determination results (p.p.m.)		
		SO ₄ ²⁻	Cl ⁻	NO ₃ ⁻
Ground water	TLC	34 ± 5	ND	10 ± 2
	IC	38.3	ND	12.8
Lake water	TLC	25 ± 4	29 ± 5	ND
	IC	27.2	28.0	ND
River water	TLC	9.8 ± 1.6	6.3 ± 1.2	ND
	IC	9.3	7.0	2.9

ND, not detected. Reproduced with permission from Shadrin O, Zhivopistsev V and Timerbaev A (1993) Thin-layer chromatographic determination of inorganic anions as counter-ions of metal-diantipyrilmethane cationic complexes and diantipyrilmethane cations. *Chromatographia* 35: 667–670.

well if the applied amounts of sample are kept close to the detection limit and the sample is accurately bracketed with standards. The shape and size of the spot produced are significantly influenced by the amount of analyte. A linear relationship between the size of the spot and the amount of analyte has been observed. This method has been used for semiquantitative estimation of titanium in steel and inorganic anions in water.

TLC techniques used and the species determined are listed in **Table 6**. TLC results of determination of certain species in real samples are shown in **Tables 7 and 8**, which indicate the versatility and accuracy of TLC.

Application

Some applications of inorganic TLC have been covered above. **Tables 9–11** list representative applications of TLC as used for the analysis of anionic, cationic and metal complex mixtures. In **Table 12** selective TLC applications related to the analysis of real samples (biological, food, geological, industrial, pharmaceutical, soil, water, wastewater and irradiated products) have been given.

Further Developments

Looking to the future, it is reasonable to expect increasing use of TLC and HPTLC for more application-oriented research in several fields (pharmaceutical, environmental, geological, forensic, agrochemical, textile, cosmetic and food sciences) because of the continued development of computer and microprocessor-based instrumental TLC. Layers with immobilized phases of wider range of selectivity, automation of sample application, hybrid mobile phases with improved chromatographic performance, online

Table 9 Stationary and mobile phases used in the analysis of certain anionic species

Anions	Stationary phase	Mobile phase
Hexacyanoferrate (II) and (III)	Silica gel G, alumina G	Polyhydric alcohols, formamide, DMF, methylamine, pyridine, water, ketones, esters and their mixtures in various ratios
Sulfur oxyanions	Silufol UV 254	Ethanol-dioxane-water-NH ₄ OH (30 + 60 + 50 + 25)
Oxyanions	Cellulose, microcrystalline cellulose containing fluorescent indicator	28% Aqueous ammonia-acetone- <i>n</i> -butanol (6 + 13 + 3), 28% aqueous ammonia-acetone (2 + 3), dioxane-water (3 + 2), acetone-acetic acid-water (20 + 1 + 20)
Halogen anions	Silica gel G, zirconium(IV) molybdate, cellulose	Basic and polar solvent systems, various alcohols mixed with aqueous ammonia
Phosphorous anions	Cellulose	Water-ethanol-2-methylpropanol-2-propanol-aqueous ammonia-trichloroacetic acid (150 + 175 + 75 + 107 + 2 + 25)
Arsenate, arsenite	Aluminium oxide	Aqueous solutions of KNO ₃ , Na ₂ CO ₃ , NaOAc, HOAc, K ₂ SO ₄ , K ₃ PO ₄ , NaF, acids and bases and buffer solutions
Oxyanions, chromate, dichromate, oxalate	Silica gel G impregnated with 0.1% aq. solutions of CuSO ₄ , ZnSO ₄ , NiCl ₂ , CoCl ₂ , Co(NH ₃) ₆ Cl	Acetone-DMSO or formic acid, acetone-DMSO-formic acid and acetone-mineral acid mixtures

DMF, dimethylformamide; DMSO, dimethylsulfoxide.

Table 10 Stationary and mobile phases used in the analysis of some cationic species

<i>Metal ions</i>	<i>Stationary phase</i>	<i>Mobile phase</i>
Alkali and alkaline metals	Microcrystalline cellulose, cellulose (MN-300) microcrystalline cellulose Lk, zinc ferrocyanide, tin(IV) arsenosilicate and arsenophosphate	Methanol–conc.HCl–water (8 + 1 + 1, 7 + 1 + 2), dioxane–2-propanol–conc. HCl–H ₂ O (7 + 7 + 5 + 8). HNO ₃ –methanol mixtures, buffered EDTA solutions, aqueous ammonium nitrate
Transition metals	Silica gel G, DEAE cellulose in chloride form, chitosan, chitin, silica gel impregnated with high molecular weight amines, cellulose	Aqueous solutions of HCl (1–5 mol L ⁻¹), LiCl (1–9 mol L ⁻¹), MgCl ₂ (2.5 mol L ⁻¹), CaCl ₂ (2.5 mol L ⁻¹) and saturated NaCl, Me ₂ CO–EtOAc–C ₆ H ₆ (7 + 1 + 3), 0.03 mol L ⁻¹ citric acid, HNO ₃ at different concentrations
Light rare earth metals	Mixture of silica gel, starch and NH ₄ NO ₃ ; silica gel–NH ₄ NO ₃ –CM cellulose (5 : 0.64 : 0.16, w/w)	P ₂₀₄ –dioxane–EtOAc–HNO ₃ (1.1 + 2 + 2.4 + 4) tributylphosphate–THF–diethyl ether–HNO ₃ (1 + 9 + 9 + 1.5), trialkylmethyl ammonium chloride– <i>n</i> -octyl alcohol–petroleum ether–conc. HNO ₃ (60 + 7 + 25 + 1)
Heavy rare earth metals	Silica gel–NH ₄ NO ₃ –CM–cellulose (5.0 + 0.64 + 0.16, w/w); silica gel–starch–ammonium rhodanate (2.8 + 0.15 + 0.5, w/w)	Et ₂ O–THF–bis (2-ethylhexyl)phosphate–HNO ₃ , trimethylammonium chloride– <i>n</i> -octyl alcohol–petroleum ether–HCl (2 + 10 + 30 + 1, 2 + 6 + 30 + 1.2 and 2 + 7 + 30 + 1), bis (2 + ethylhexyl)phosphate–diisopropyl ether–diethyl ether–nitric acid (1 + 10 + 6 + 1.1), mono(2-ethylhexyl) phosphate–isopropyl ether–diethyl ether–nitric acid (1 + 8 + 8 + 1.1)
Lanthanides	Silanized silica gel (Merck) and polygram plate, silica gel impregnated with different concentrations of mono (2-ethyl hexyl) phosphate	3 mol L ⁻¹ Tributyl phosphate in HNO ₃ –isooctane (2 + 8); THF–paraldehyde–HNO ₃ (2 + 7 + 1); 0.3 mol L ⁻¹ triphenylphosphine oxide in paraldehyde–HNO ₃ (9 + 1); di-isopropyl ether–THF–HNO ₃ (10 + 6 + 1); HNO ₃ (0.05–3.0 mol L ⁻¹)
Radionuclides ⁹⁰ Sr, ⁹⁰ Y, ¹⁴⁰ Ba, ¹⁴⁰ La	Silica gel (with and without gypsum binder)	Aqueous solutions of NaCl, KCl, NH ₄ Cl, CaCl ₂ , SrCl ₂ , and BaCl ₂
High valence metal ions	Silica gel impregnated with crystalline antimon(V) acid- <i>p</i> -sulfochlorophosphanazo	Potassium pyrophosphate solution
Mn(II), Mn(III)	Silica gel G	Eleven organic mobile phases consisting of hydrocarbons and their derivatives in different ratios
Transition metals	1,10-Phenanthroline (1%), DMG (1%), EDTA (2%) or β -naphthol (0.1%) impregnated silica gel	Pyridine–benzene–HOAc–H ₂ O (6 + 5 + 8 + 4), BuOH–benzene–formic acid (5 + 10 + 9), pyridine–benzene–HOAc–H ₂ O (5 + 5 + 4 + 1)

DEAE, diethylaminoethyl; THF, tetrahydrofuran; DMG, dimethylglyoxime; EDTA, ethylenediaminetetraacetic acid.

coupling of TLC with other sensitive techniques, better approaches in method development and application of detection reagents and greater use of instrumental densitometry can be expected. It is

hoped that the forced-flow layer methods with increased automation will be developed in the near future for faster separation of inorganic ions in real samples.

Table 11 Stationary and mobile phases used in the analysis of certain metal complexes

<i>Metal complexes</i>	<i>Stationary phase</i>	<i>Mobile phase</i>
Diethylthiocarbamates of Bi, Cu, Co, Ni	Silica gel G	Dichloromethane–petroleum ether (5 + 3)
Sulfate complexes of Pt, Pd, Rh, Ir	Commercial silufol plates (Kavalier, CSSR), silica gel KSK, silica gel	0.1, 1.0 and 6.0 NH ₄ SO ₄ , 0.2 or 0.5 mol L ⁻¹ tetraoctylamine in benzene
β-Diketonates of Fe, Cr and Co	Silica gel (Merck)	CCl ₄ , toluene, benzene, dichloromethane, diethyl ether
Xanthates of Cu, Ni, Co, Mo, Bi, Pb, Zn	Silica gel G	CCl ₄ –CHCl ₃ (10 + 1), toluene–benzene (10 + 1)
Anil complexes of Mn, Fe, Cu, Zn	Silica gel–starch (19 : 1)	Acetonitrile, methanol, ethanol, butanol, acetic acid or butanol–acetic acid (4 + 1, 3 + 2, 2 + 3, 1 + 4)
Metal oxinates (OX), (HOX), Cu (OX) ₂ , Zn (OX) ₂ , Al(OX) ₃ , Ga(OX) ₃ , In (OX) ₃	Styragel 60A (polystyrene–divinylbenzene copolymers), Merckogel OR-PVA 2000	CHCl ₃ , <i>p</i> -dioxane, benzene, 10 ⁻³ –10 ⁻¹ mol L ⁻¹ HOX in CHCl ₃ , 10 ⁻² mol L ⁻¹ HOX in dioxane, 10 ⁻¹ mol L ⁻¹ pyridine in CHCl ₃
Mn, Co, Ni, Zn, Rh, Pd, Pt, Chelates of dithioacetyl-acetone	Silica gel	CCl ₄ , 1,1,1-trichloroethane
Mixed amino carboxylato cobalt(III) complexes	Polyacrylonitrile	Aqueous ammonium sulfate solutions (1.1–3.48 mol dm ⁻³)
Chlorosulfate complexes of transition metals and rare earths	Silica gel G–cellulose (2 : 1)	Sodium formate (1 mol L ⁻¹) and ammonium sulfate (1 mol L ⁻¹)
Mercapto-4-methyl-5-phenylazopyrimidine complexes of Co, Ni, Pb, Cd, Cu	Surfactant-impregnated silica gel plate	Acetonitrile–xylene (70 : 30)

Table 12 Application of TLC to the analysis of real samples

<i>Species</i>	<i>Sample</i>	<i>Remark</i>
Se	Biological (tissues, blood, serum) environmental (drinking and surface water) and food stuffs	Isolation of Se from matrix, derivatization, extraction of Se-containing complex, TLC separation and fluorimetric determination. Detection limit 250 fg Se per spot
Cu, Fe	Serum	TLC separation and densitometric determination of Fe ²⁺ , Fe ³⁺ and Cu ²⁺ complexed with 2-[(5-bromo-2-pyridinyl)azo]-5-(diethylamino) phenol in serum
Cd, Hg, Pb	Urine, blood	Separation on silica gel layer prior to spectrophotometric determination of Cd ²⁺ , Pb ²⁺ and Hg ²⁺ in blood and urine samples
Heavy metals	Urine, blood, excrement	A sensitive detection of Zn ²⁺ , Hg ²⁺ , Cu ²⁺ , Co ²⁺ , Pb ²⁺ , Ni ²⁺ , Ag ⁺ and Bi ³⁺ on silica gel layers (sensitivity 10 ⁻³ g L ⁻¹) as dithizonates in biological samples
Hg	Animal, fish and plant tissues	Quantitative determination of mercury species (inorganic and methyl mercury) after extraction from tissues
Cu, Mg, Zn, Fe, Mn	Human faeces	Detection of metal–EDTA complexes on silica gel and cellulose layers
BrO ₃ ⁻	Food stuff	Extraction and purification using alumina column, separation on silica gel layer and densitometric determination of BrO ₃ ⁻ in bread and flour dough. Detection limit of BrO ₃ ⁻ was 0.1 μg g ⁻¹ of bread
Fe, Mn, Co	Human milk	Extraction of metals from human milk with isobutyl methyl ketone–amyl acetate (2 : 1) and identification on cellulose layer

Table 12 Continued

Species	Sample	Remark
Polyphosphoric acids	Cheese, milk	Extraction with 25% trichloroacetic acid, separation and identification on polyamide layer developed with <i>n</i> -butanol–formic acid (1 : 1)
Polyphosphates	Soft drinks	Separation and determination of ortho- and polyphosphates in soft drinks using two-dimensional TLC and ion-exchange column chromatography
Si	Edible oils	Detection with rhodanine on silica gel layers developed with light petroleum–diethyl ether (98 : 2)
Rare earth metals	Rocks, monazite sand, ores, irradiated nuclear fuels	Determination by neutron activation analysis (determination limits 0.05–10 $\mu\text{g g}^{-1}$ for 10–30 mg sample) after preconcentration by circular TLC on Fixion 50 \times 8. Use of ICP-AES for determination of rare earths in concentrates obtained by means of TLC. Densitometric determination in monazite sand (linear range 0.015–0.60 μg of individual rare earth) after TLC separation. The limits of detection for rare earths were 9–12 ng
Fe, Mn, Cu	Cotton materials	Detection of metal ions on microcrystalline cellulose plates developed with acetone–HCl–H ₂ O (8 : 1 : 2). TLC-spectrophotometry for determination of Mn traces in textile materials
NO_3^- , Fe (CN) ₆ ³⁻	Molasses	TLC separation on silufol 254 plates developed with propanol–ammonia solution (2 : 1), detection with acidified diphenylamine and densitometric determination
La, Y	Alloys	Circular TLC with trioctylamine-treated cellulose layers as stationary phase and aqueous HCl as mobile phase for separation and spectrophotometric determination of La and Y (0.01–1.0%) in Mo-based alloys
Co	White wine	Fixation of Co ²⁺ as 1-(2-pyridylazo)-2-naphthol complex on membrane filter followed by densitometric determination (concentration range in white wine 2.5–4.5 $\mu\text{g L}^{-1}$) by reflection absorbance of the complex
Fe(II)	Pharmaceuticals	Separation on microcrystalline cellulose layers, detection by 1,10-phenanthroline and determination by spectrophotometry
Mercury salts	Homeopathic drugs	Identification of chloride, nitrate, cyanide, sulfate and sulfide of Hg on silica gel G plates developed with acetone–chloroform–conc. HNO ₃ (4 : 5 : 1)
Mn	Pharmaceuticals	TLC separation and photodensitometric determination of Mn in vitamins and pharmaceuticals as PAN complex
Cr	Na ₂ ⁵¹ CrO ₄ injection	Determination of radiochemical purity of Na ₂ ⁵¹ CrO ₄ injections and γ -scintillation for quantitation of Cr-containing zones
NO_3^-	Feeds	Separation on alumina layer and spectrophotometric determination at 430 nm after extracting the coloured product formed with 3,4-xylenol
Rare earths and fission products	Irradiated nuclear fuels	Two-dimensional TLC separation and enrichment followed by quantification by γ -spectroscopy

Table 12 Continued

Species	Sample	Remark
Co, Fe(III)	Cosmic dust	TLC separation and semiquantitative determination on the basis of spot size and colour intensity or by reflectance densitometry
⁸⁹ Sr, ⁹⁰ Sr	Soil	Extraction of strontium from soil with dicyclohexano-18-crown-6 in chloroform and TLC separation using circular procedure with silufol layer
Ta	Molybdenum-based alloys	TLC-AES for determination of Ta ($\geq 0.5\%$) in molybdenum alloys
Zn, Pb, Cu, Cd, Hg (organic and inorganic)	Plants	Detection (10–500 ng) using azo rhodanines as detector and nanogram determination by visual sorption-photometric method
Hg (organic and inorganic)	Water	HPTLC separation on silica gel layers and densitometric determination as dithizonates
Al, Be, Cr, Bi, Cu, Hg	Water	Extraction, TLC separation, detection (as Bi, Cu, Hg dithizonates, detection limit, 0.5 p.p.m.) and determination fluorimetrically (Al and Be as oxinates) and photometrically (Cr as diphenylcarbamide complex)
CuSO ₄ , CdSO ₄ , HgCl ₂ , AgNO ₃	Fresh and seawater	Evaporation, precipitation, micro-TLC separation and enzymatic detection

ION EXCHANGE RESINS: CHARACTERIZATION OF

L. S. Golden, Purolite International Ltd, Pontyclun, Mid-Glamorgan, Wales, UK

Copyright © 2000 Academic Press

Introduction

An ion exchange resin is an insoluble polymer matrix containing labile ions which are capable of exchanging with ions in the surrounding medium without any major physical change taking place in its structure. They are of two basic types, cation and anion exchangers. So-called cation exchange resins are in fact polymeric anions to which the labile cation is bound, and it is this cation which exchanges with other cations in solution. Likewise, anion exchange resins are polymeric cations with a labile, exchangeable anion.

The first synthetic ion exchange resins were developed by Adams and Holmes in 1935, based on a phenol-formaldehyde structure. The next most important development was the introduction of commercial ion exchange resins based on a cross-linked polystyrene matrix, and these resin types today still represent about 90% of the commercial resin market. More recently, polyacrylic resins have been introduced which have widened the scope and versatility of the synthetic ion exchange resins, and these represent most of the remaining 10% of the commercial market.

The development of synthetic polystyrene and polyacrylic resins has enabled these ion exchangers to be produced in spherical bead form, unlike the irregular-shaped particles of the phenol-formaldehyde types. In the majority of applications, the most effi-

cient treatment of a solution is obtained by passing this solution through a bed of ion exchange resin. A spherical bead shape offers optimum contact with the percolating solution without undue pressure drop across the bed, requiring only minimal inlet pressures.

The first polystyrene resins, introduced in 1947, were of what is now known as a *gel* type. Exchange takes place by diffusion of the ions through the resin structure to and from the ion exchange sites. The polymer chains are only separated by molecular distances, and the ease of penetration of the ions is very much influenced by the amount by which the resin structure can be swelled by the contacting solution. In 1956, Mikes and co-workers discovered a means of introducing pores (or holes) into the resin structure, which led to the introduction of *macroporous* resins, which further increased the scope of ion exchange techniques. These resins comprise a continuous polymer matrix interspersed with a continuous pore matrix.

Synthesis

Polymerization

Generally speaking, the synthesis of a modern ion exchange resin is a two-step process. In the first step, the spherical bead is produced by polymerization of styrene (or an acrylic monomer, usually methyl acrylate) plus a cross-linking agent (usually divinylbenzene, DVB) in an aqueous suspension. This technique of suspension polymerization is used extensively in the production of pearl (or bead) polymers, not specifically to make ion exchange resins, and is

dependent on the fact that the monomer is essentially insoluble in water. Thus, when stirred with water, the monomer will disperse into spherical droplets. Small quantities of various stabilizing ingredients are added to the water to make this dispersion more permanent.

An initiator is added to the monomer mixture which, on the application of heat, produces free radicals. These start a chain reaction with the monomer in which monomer units are progressively added to the growing polymer chains. Styrene contains just one double bond capable of reacting into the polymer chain. As a consequence, a polymer produced from styrene alone will comprise a large number of unconnected chains, and this hydrophobic polymer will be soluble in organic solvents such as aromatic hydrocarbons. Cross-linking agents, such as DVB, contain two or more reactive double bonds, each of which is capable of reacting in a separate polymer chain, ultimately leading to an 'infinite' single polymer chain network. Solvents will still be absorbed by the polymer chain and swell the polymer, but will not be able to dissolve it. The extent of the swelling is dependent on the proportion of DVB in the monomer: the more DVB, the less the polymer will swell.

The invention of macroporous resins has been briefly mentioned. The continuous pore structure within the resin matrix is produced by polymerizing the monomers in the presence of an inert diluent which is miscible with the monomers but essentially immiscible with the growing polymer chains. As the polymerization progresses, the mixture separates into two phases, one phase being the growing polymer, the other being the diluent plus a continuously decreasing amount of monomer. At the end of the polymerization, the diluent, which has not actually polymerized into the structure, is removed by distillation or washing, leaving the interconnecting network of pores.

Activation

The second stage of synthesis is to add a functional group to the polymer, which will contain the labile ion capable of exchange with ions in solution. The effect of this functional group is to make the polymer structure hydrophilic. The resin will now be swollen by water, but again cannot dissolve due to the polymer chain structure. The extent of this swelling by water is an important characteristic of an ion exchange resin, and controls its behaviour in many applications.

The sulfonic acid group of the strong acid cation resins is added by reaction of the polystyrene polymer with sulfuric acid at temperatures between 90 and

140°C. The amino group of the strong and weak base resins is added in two stages, firstly a chloromethylation to add a chloromethyl group to the polystyrene chain followed by addition of an amine to give the final quaternary or tertiary amino functionality. The choice of amine affects the resin properties, which will be discussed shortly.

Polyacrylic resins are produced as either weak acid cation resins with a carboxylic acid functional group (to which there is no polystyrene resin equivalent), or as strong or weak base anion resin whose properties are similar, but not identical, to those produced from polystyrene.

Classification of Ion Exchange Resins

Both cation and anion resins are available with strong and weak functional groups. The strong functional groups are ionized species within which the ionized labile ion can be replaced with an ion in solution. These resins will therefore easily exchange ions with dissolved salts. On the other hand, the weak functional groups are themselves nonionized and will therefore have very little ability to exchange with salts. Weakly functional anion resins will however readily remove anions from acidic solutions, and weakly acidic resins will readily remove calcium and magnesium from solutions of carbonates and bicarbonates.

Strongly basic resins are further subdivided into three categories. The most commonly encountered of these is the *strong base anion Type I* resin (often abbreviated to SBA I). The second most common category is the *strong base anion Type II* (SBA II), which is a weaker base than the Type I but still not weakly basic enough to be categorized as a weakly basic resin. The third category, *strong base anion Type III* (SBA III), is actually intermediate between these two types, and, although not as yet widely used, is being shown to combine useful characteristics of both.

In more recent years, a number of resins with special functional groups have been produced commercially. These are designed for removal of specific ions for special applications. One particular application is the use of a polystyrene resin with an aminophosphonic chelating group—this resin, in the sodium form, is used to remove calcium and other divalent ions from brine prior to the production of caustic soda by the membrane cell process. A conventional cation resin would be completely unable to remove these alkaline earths from concentrated salt solutions.

Resins in each category can be produced in both gel and macroporous forms.

Fundamental Ion Exchange Resin Characteristics

Irrespective of the resin type, there are certain fundamental parameters which characterize ion exchange resins, and determine how that resin will perform in its applications.

Moisture Retention

As mentioned earlier, an ion exchange resin is swollen by water but will not dissolve in it. The extent of this swelling is one factor which controls how the resin will perform in specific applications. A resin will absorb a certain amount of water, depending on the functional group, the ionic form and the amount of cross-linking. For a given resin type in a given ionic form, the swelling is entirely dependent on the amount of cross-linking.

Moisture retention is defined as the amount of water which is in equilibrium with the dry resin matrix. This water can be removed by hot air drying, but will be reabsorbed when the resin is put back in contact with excess water. The value of the moisture retention is easily determined by measuring the loss in weight of a fully swollen resin on drying, and expressing the moisture loss as a percentage of the total wet weight.

The importance of moisture retention in the performance of a resin should be fairly obvious. For the resin to operate, the ions in solution must have access to the active sites throughout the polymer structure, just as the ions which are displaced from these sites must be able to pass out of the resin back into solution. The more open the structure (i.e. the higher the moisture retention), the easier this will be.

The labile ion which is attached to the resin influences the hydrophilic nature of the structure, and so the moisture retention. For instance, at a given amount of cross-linking, a strong acid cation resin in the sodium form (i.e. with a Na^+ group attached to each sulfonic acid site on the structure) will have a significantly lower moisture retention than the same resin in the hydrogen form. Therefore, the ionic form must be stated along with the moisture retention.

Resin Capacity

The ability of an ion exchange resin to exchange ions is a function of the number of active groups that have been placed on the resin during the activation process. The overall term for this is the *capacity* of the resin, but this can be expressed and determined in a number of ways.

Dry weight capacity This measures the proportion of active sites in the dry resin matrix, and is expressed as equivalents per kilogram (or milliequivalents per gram, as some workers prefer). It is easily determined by weighing a dry sample of resin, rewetting it and displacing completely from the resin an ion which can be titrated in solution. This gives the total equivalents of sites on the dry resin, and is a direct measure of the extent of activation of the base polymer. For most applications, the figure obtained does not have any direct significance, since the resin is rarely used in its dry state except in certain specialized applications.

Total volume capacity Since resins are normally supplied and used wet (i.e. fully swollen in water), the capacity based on a volume of wet resin is more useful. It is, however, more difficult to measure a wet resin volume as accurately as dry resin weight, but essentially the test method is the same apart from measuring a known volume of resin rather than weight. The data is expressed in terms of equivalents per litre (or milliequivalents per millilitre).

Although the test value can now be related to the volume of resin installed in the resin treatment plant, it will still not tell the plant designer or user the capacity achievable when the unit is in practical operation.

Operating capacity This is the true practical parameter, but unfortunately it cannot be determined by a straightforward laboratory test. Since the operating capacity of a resin depends on many factors, such as the dimensions of the unit, the flow rate and quality of the liquid to be treated, the quality required of the effluent from the unit, the regenerant quantity and the operating temperature, etc., this capacity can only be calculated from data obtained by extensive laboratory testing of a resin type under simulated operating conditions. This data is usually provided in brochures supplied by the resin manufacturers, and more recently a number of these manufacturers have computer programs available to make these calculations quickly on data stored within the software.

Particle Size Distribution

As already described, modern ion exchange resins are in the form of spherical beads. The suspension polymerization technique does not produce beads of a uniform particle size, rather a distribution of sizes to give a resin within the range 0.3–1.2 mm. Most ion exchange applications have been developed around resins of this particle size range, but some special

applications do require the particles to be of a more specific size.

In the majority of applications, the ion exchange resin is contained in a vessel which is designed to allow the solution to be treated to pass through the resin bed and subsequently emerge from the unit. The resin has therefore to be retained within this unit by a suitable means, usually nozzles or slats of such an aperture that the solution can freely pass. Depending upon engineering design, these apertures will normally be about 0.2 mm wide, but in some designs can be as large as 0.4 mm. It is therefore essential that the ion exchange resin does not contain beads close to or less than this aperture size.

A number of resin applications require two resins to operate mixed together in the same unit. For regeneration, it is essential that these resins are separated. Strong acid cation resins have a density of about 1.25–1.30 g g⁻¹, whereas anion resins have a density of 1.07–1.10 g g⁻¹. Therefore, by applying backwash to lift and expand the resin bed, the cation resin beads will sink below the anion resin beads. A complete separation is readily achieved if the cation resin contains less coarse beads than the anion resin less fine beads.

Ions obviously have a greater path length to travel to the centre of a large bead compared to that of a small bead. This decreases the efficiency with which a larger bead can complete the ion exchange process. A number of applications have developed today in which beads of a more uniform size distribution, normally in the range 0.4–0.8 mm, are used, thereby eliminating the most coarse beads of the 'standard' size range.

For these reasons, measurement of particle size distribution of resins is important. The classical method is to use standard sieves, but due to limitations of sieve accuracy and availability, they are not best suited to measuring resins with narrower size distributions. Most resin manufacturers and larger users now use an instrumental technique based on a light extinction principle, such as the OMEGA (Fortress Dynamics, UK) or HIAC (Hiac-Rogco, USA).

Resin Volume Change

It was observed earlier that a given ion exchange resin will be in equilibrium with a different volume of water depending on its ionic form. Consequently, when the resin is treating the feed solution, the bed of resin will slowly swell or shrink as the ions are being exchanged. It is important for the plant design engineer to know the extent of this volume change in order to allow sufficient space for any increase in vol-

ume to be accommodated. It has been known for poorly designed plants to smash a resin, or even for the plant itself to be damaged, if this swelling factor has not been properly accounted for.

Other Resin Characteristics

There are a number of other parameters which have to be taken into account when designing an ion exchange plant, such as pH range and operating temperature. All resins of a given type will have virtually identical limitations on these parameters. The recommendations given by the resin manufacturers should be followed. It is worthy of note that SBA Type II resins are less thermally stable than their Type I counterparts, and that polyacrylic anion resins are less thermally stable than polystyrene ones with the same functionality.

Macroporous versus Gel Resins

In appearance, gel resin beads are usually transparent. Light entering the bead will pass through the homogeneous structure without being diffracted, therefore being visible from the other side of the bead. With a macroporous bead, there are numerous phase boundaries within the bead between the pores and resin matrix, at each of which the entering light will be refracted. Consequently, little or no light will emerge, giving the resin bead an opaque appearance.

Gel resins were in extensive use in ion exchange for many years before the invention of macroporous resins. These macroporous resins were found to have two main advantages over their gel counterparts – they were less susceptible to osmotic shock and less liable to organic fouling.

As just discussed, a resin will change in volume as it changes its ionic form. Moreover its volume will contract when it is in contact with strong electrolyte solutions which it will encounter during regeneration, and will rapidly swell again when this regenerant solution is washed off. These volume changes exert an osmotic stress across the boundary between resin and solution, which in the case of a gel resin is the resin bead boundary itself. These forces can weaken or even smash the resin bead. Although fragments of resin are still just as good as a whole bead in the exchange process, they will certainly impede the flow of liquid through the bed, increasing the pressure drop and decreasing the flow. Also, the small fragments can block the strainers of the unit, and even contaminate the treated solution.

A macroporous resin, by nature of its structure of interconnecting pores and matrix, comprises very

many small resin-solute interfaces, so although the osmotic force across the bead as a whole will be the same, it will be dispersed across all these small boundaries. Therefore, the stress on the bead will be much less, and there will be very much less chance of the resin bead being weakened or broken.

Most natural waters, as well as many organic solutions which ion exchange resins are used to treat, contain large and complex organic molecules. These will slowly penetrate a resin bead, particularly if the organic molecule itself contains an ionic charge. Because of their size, these molecules become entangled with the resin structure, and are not easily removed when the resin is regenerated. Consequently, these molecules build up within the resin, blocking access of the ions in solution to the exchange sites, with a resulting drop in resin capacity. This is known as *organic fouling*. The pore structure of macroporous resins allows greater freedom of passage of these organic molecules, so they are more freely released during regeneration. Anion resins based on an acrylic matrix, due to the nature of this matrix, are also less susceptible to organic fouling.

Unfortunately, macroporous resins also have a major disadvantage. Part of the resin bead, the pores, is purely water with no ion exchange properties. In order that the overall number of ion exchange sites within a given volume of resin is similar to a gel resin, the resin matrix itself has to contain less water – it will be more highly cross-linked. With such a matrix having a lower amount of water associated with the structure, ions will be able to move less freely, so causing the resin to exchange ions more slowly. In practical terms, this results in either reducing the rate at which the solution to be treated can be fed to the resin, or reducing the efficiency of the ion exchange process.

Since optimum efficiency of ion exchange (known as ion exchange *kinetics*) is an important factor in the design and operation of a treatment plant, gel resins will normally be preferred except in circumstances where the advantages of macroporous resins outweigh this major disadvantage.

Resin Regeneration

In most resin applications, the resin is used over many treatment cycles. Once the resin has become exhausted (in other words, when it is no longer removing the ions from solution at the threshold level required by the user), it is then regenerated with suitable chemicals to once again attach to the active group the mobile ion which will subsequently be released into the treated solution. In the case of cation resins in demineralization processes, this will be a mineral acid

and in the case of anion resins, an alkali, usually sodium hydroxide.

Not only do resins swell in water to a different extent when different ions are attached, they have a different affinity for the various ions, and in the case of treatment of solutions containing a mixture of ions, the resin sites will compete at different rates for the different ions. This is known as *selectivity*. Likewise, if an ion for which the resin has a higher selectivity is already attached to an active group, it will be much more difficult for an ion of a lower selectivity to displace it from the resin.

Consider a solution containing a cation B, and a cation resin in which all the sites are occupied by cation A. As a B ion penetrates through the bead, it will attach to an active site displacing an A ion in the process (Figure 1). Initially, since the resin contains only B ions, this released A ion can do nothing but emerge from the resin back into solution. However, as more and more sites within the bead take up B ions, there is a chance that the released A ion could displace another B ion which had already been taken up on a different site. The ease with which this would occur depends on the relative selectivity of ions A and B to the resin – if the resin is significantly more selective for the B ion, then this is less likely than if the resin were more selective for the A ion.

Figure 1 Ion exchange equilibrium.

Figure 2 Typical regeneration curve. Dotted line, optimal; continuous line, practical.

When a resin is being regenerated, the more regenerant which is passed, the more completely will the resin be regenerated. However, because of this interchange of ions within the resin, the percentage of resin regenerated is not a linear function of the amount of regenerant (Figure 2). In other words, doubling the amount of regenerant used will not necessarily double the number of sites regenerated. Since the operational cost of an ion exchange resin plant is heavily influenced by the regenerant cost, it is

not usually practicable to regenerate a resin fully, rather to balance the percentage regeneration to the most economic use of the regenerant. Consequently, a quantity of regenerant much more than the point at which the regeneration curve loses linearity is unlikely to be used.

The shape of this regeneration curve will vary with different resins, depending not only on the nature of the active group and the moisture retention, but also on the structure of the resin matrix itself.

Figure 3 Comparison of regeneration (squares) and volume capacities (crosses) (on the same resin samples). SBA Type I gel resins regenerated with 65 g NaOH per litre resin.

Table 1 Typical regeneration efficiencies of different resin types

Resin	Regeneration efficiency (%)
SAC gel	50–60
SAC MP	45–55
WAC gel/MP	80–95
SBA I gel	35–45
SBA I MP	30–35
SBA II gel	60–70
SBA II MP	55–65
SBA III MP	45–55
WBA MP	80–95

Even two resins of the same functionality and total exchange capacity might regenerate differently.

Strongly acidic or strongly basic resins readily exchange ions from neutral salts. The exchange process is therefore an equilibrium, and the ion displaced from a resin site will be capable of exchanging with the ion on another site. In the case of a weakly functional resin, the exchange is more of neutralization reaction, and there is little chance of the released ion exchanging with another site on the resin. For this reason, the regenerability of a resin increases as its acidity or basicity decreases.

Regeneration capacity

In this test, a known volume of fully exhausted resin is put in a column, and a fixed amount of regenerant passed through. The type and quantity of regenerant would be appropriate to the application under consideration. The equivalents of ions displaced or adsorbed by the resin are determined, and the regeneration capacity can be expressed in terms of equivalents per litre of resin, or as a percentage of the total volume capacity of the resin (known as *regeneration efficiency*), which can conveniently be determined on the same measured volume of resin.

Figure 3 clearly shows the significance of moisture retention on the kinetic performance of a resin. As discussed earlier, a gel resin of a given type with a lower moisture retention will have a higher total capacity, but this higher capacity is not reflected by the regeneration capacity, and under many conditions the operating capacity, of the resin.

For the reasons discussed earlier, macroporous resins will generally have a lower regeneration efficiency than their gel counterparts. Table 1 gives an approximate indication of the regeneration efficiencies of the different categories of resin, using typical regeneration amounts of 60–80 g regenerant per litre of resin.

Conclusions

The main characteristics of ion exchange resins are summarized in Table 2.

Most current developments in ion exchange resin manufacture have been based on modifying production techniques to give more uniform bead distributions at lower production costs. One exception has been the introduction of a range of highly porous Macronet adsorbent resins which are finding applications in the removal of trace levels of organic contaminants in aqueous, and even gaseous, feed stocks, as well as replacing activated carbon in the removal of coloured bodies from sugar syrups.

There are some new developments of resins as pharmaceutical products or in the extraction of precious metals from spent ores. Newer and more exotic applications are continually being found for ion exchange resins outside the conventional water treatment field, but these generally use existing resin types or only slight modifications thereof.

Introduction

Sebba published a paper in 1959 in which he discussed a new method (ion flotation) for recovering solute from dilute solutions by adding surfactant, with subsequent adsorption of the solute onto bubbles. The principles of the process and the characteristics of the solute-surfactant product formed in solution were discussed in his monograph on ion flotation published in 1962. The method rapidly became popular and researchers in several countries have studied various aspects of the separation of metallic ions, trace elements, molecules, inorganic anions and organic matter from aqueous solutions. Many laboratory-scale studies have been carried out, most of them aimed at development, analytical applications, water purification, resource recycling, removing radionuclides from solutions, and recovering metals from sea water.

A comprehensive development of all aspects of the subject was presented in a monograph on adsorptive bubble separation techniques, edited by Lemlich in 1972, in which details and applications of ion and precipitate flotation methods were reported by Pinfold.

The research group directed by Grieves made an important contribution to the theoretical and applied aspects of ion and precipitate flotation during the 1960s, particularly on wastewater treatment. They showed that flotation efficiency of long-chain surfactants was the result of physicochemical aspects of particle growth and dispersion. But the adsorption of surfactant onto the solid and gas phases was identified as a factor limiting bubble-particles attachment in some cases of ion flotation.

The adsorption of the surface-active solutes to the gas-liquid interface was studied by Rubin. An analysis based on the Gibbs and Langmuir isotherm and on an originally developed approach of long-chain ion adsorption in a solution containing several surface-active species was used to determine the effect of their concentrations on the ratio of distribution coefficients. This author also described the kinetic parameters for ion and precipitate flotation.

A detailed review of the precipitate and adsorbing colloid flotation technique with a comprehensive literature review appears in the monograph published in 1983 by Clarke and Wilson.

Golman has given a qualitative description of the chemical and kinetic aspects of ion flotation and some industrial applications, including the removal of molybdenum from solutions of hydrometallurgical flow-sheets. He has also given methods for treating foam products and purifying process residual solutions.

measured from samples of single and dual-phase materials, operated in a pressure-driven mode, plotted as a function of inverse temperature. This figure is intended to give some appreciation of the fluxes that are attainable; however, they are not normalized to a given partial pressure gradient or thickness of membrane, and thus the fluxes are not directly comparable. Taking a value of between 10 and $100 \text{ L m}^{-2} \text{ min}^{-1}$ as the level of oxygen flux needed for practical applications, it can be seen that the cobalt-containing single-phase materials give appreciable oxygen fluxes above about 900°C . It is interesting to note on this figure that the dual-phase material, fabricated from $(\text{Bi}_2\text{O}_3)_{0.75}(\text{Y}_2\text{O}_3)_{0.25}\text{-Ag}$ (35 v/v), approaches the lower bound of the practical fluxes at temperatures of 800°C .

It is not sensible to put data for electrical driven COGs on the same figure, given the restrictions mentioned above, however, some comparable figures are interesting. An equivalent flux of $15.8 \text{ L m}^{-2} \text{ min}^{-1}$ is

readily achievable with planar COG stack based on zirconia and operating at 1000°C . Similar performance has been reported for a system based on a CGO-operating temperature of 800°C .

Introduction

Ion exclusion chromatography (IEC) is a relatively old separation technique, attributed to Wheaton and Bauman, which is now staging an impressive comeback for the simultaneous determination of ionic species. IEC provides a useful technique for the separation of ionic and nonionic substances using an ion exchange stationary phase in which ionic substances are rejected by the resin while nonionic or partially ionized substances are retained and separated by partition between the liquid inside the resin particles and the liquid outside the particles. The ionic substances therefore pass quickly through the column, but nonionic (molecular) or partially ionized substances are held up and are eluted more slowly.

IEC is also referred to by several other names, including ion exclusion partition chromatography, ion chromatography-exclusion mode, and Donnan exclusion chromatography. In this article we use the term ion exclusion chromatography.

Generally, anions (usually anions of weak acids) are separated on a strongly acidic cation exchange resin in the hydrogen form and are eluted as the corresponding fully or partially protonated acids, while cations (usually protonated bases) are separated on a strongly basic anion exchange resin in the hydroxide form and are eluted as the corresponding bases. The eluents used are usually water, water/organic solvent mixtures, dilute (high conductivity) aqueous solutions of a strong acid, or dilute (low conductivity) aqueous solutions of a weak acid. A conductivity detector is commonly used to monitor the column effluent and, when the eluent conductivity is extremely high, a suitable suppressor system is generally used. UV-visible detection is also used as a selective detector in the determination of some aliphatic and aromatic carboxylic acids and some inorganic anions, such as nitrite and hydrogen sulfide. Using IEC, it is possible to separate weakly ionized anions such as fluoride, phosphate, nitrite, aliphatic carboxylic acids, aromatic carboxylic acids, bicarbonate, borate, aliphatic alcohols, sugars, amino acids, water, and others, as well as ammonium, amines, and others, based on a combination of the separation mechanisms of ion-exclusion, adsorption, and/or size-exclusion. Further discussion of these mechanisms may be found elsewhere in the encyclopedia.

More recently, a new concept in IEC has been developed in which a combination of a weakly acidic cation exchange resin and a weak-acid eluent is used for the separation of strong acid anions (such as sulfate, chloride and nitrate) and weak acid anions by an ion exclusion mechanism, together with the simultaneous separation of mono- and divalent cations by a cation exchange mechanism. The application of this method is described in this article.

Comprehensive reviews of IEC may be found in the texts of Haddad and Jackson, and of Gjerde and Fritz (see Further Reading). The goal of the present article is to explain the fundamental theory and some selected applications of IEC and to focus on some recent developments.

Background

Separation Mechanism

In conventional IEC of ionic and nonionic substances, a poly(styrene-divinylbenzene) (PS-DVB) based strongly acidic cation exchange resin in the hydrogen form is used exclusively as the separation column. The resin bed can be considered to consist of three distinct components:

1. a solid resin network with charged functional groups (the membrane);
2. occluded liquid within the resin beads (the stationary phase); and
3. the mobile liquid between the resin beads (the mobile phase or eluent).

The ion exchange resin acts as a hypothetical semipermeable membrane (a Donnan membrane) separating the two liquid phases (2) and (3). This membrane is permeable only for nonionic substances. When a mixture of analytes is injected onto the ion exchange column, anionic analytes are ion-excluded from the occluded liquid phase based on the Donnan membrane equilibrium established by the fixed negative charges on the cation exchange resin and therefore pass quickly through the column. On the other hand, nonionic substances may partition between the two liquid phases (2) and (3) and therefore pass more slowly through the column. Partially ionized analytes experience a lesser degree of repulsion by the membrane and are therefore eluted at retention times intermediate between fully ionized analytes and neutral analytes. This ion exclusion effect can be seen in **Figure 1A**, which shows the separation of aliphatic carboxylic acids.

In addition to this electrostatic ion exclusion effect, the separation process taking place on the surface of the resin particle may be influenced by hydro-

phobic adsorption and size exclusion effects, depending on the nature of the solute. These effects can be seen in **Figure 1B**, which shows the separation of sugars such as mono- and disaccharides by size exclusion, and the separation of alcohols such as methanol, ethanol, propanol and butanol by hydrophobic adsorption effects (**Figure 1C**).

Cation exchange resin columns with fairly large dimensions are often used for IEC because the retention volume (V_r) of the analyte is determined by the general equation:

$$V_r = V_0 + K_d V_i \quad [1]$$

where V_0 is the interstitial volume, V_i is the volume of eluent occluded within the pores of the resin beads, and K_d is a distribution coefficient ranging from 0 to 1. A large V_i value is needed to obtain good separations because of the narrow K_d range, assuming that only the ion exclusion effect is predominant in the separation of ionic and nonionic substances. This equation is essentially the same as the general equation for size exclusion chromatography.

When the V_r values of analytes measured on a strongly acidic cation exchange resin by elution with water are plotted against pK_{a1} (first dissociation constant), the plot shown in **Figure 2** is obtained. V_r values of strong acids, which are fully ionized, are independent of pK_{a1} , showing that the strong acid anions have been completely ion-excluded by the fixed sulfonate ions of the resin. V_r values of the weak acids such as phosphoric, hydrofluoric, formic, and acetic acids increase proportionally with pK_{a1} , which shows that the weak acids have been partially ion-excluded by the fixed sulfonate ions of the resin and there has been some permeation of these analytes into the occluded liquid phase inside the resin. This permeation correlated with the pK_{a1} values of the analytes between 1.3 and 6.4. The V_r values of very weak acids such as carbonic and boric acids are independent of pK_{a1} . From **Figure 2** and eqn [1], it is clear that the V_r values of the strong acids correspond to V_0 and the difference between V_r values of the strong acids and the very weak acids corresponds to V_i .

The K_d values of strong acids, weak acids, and very weak acids calculated from eqn [1] are between 0 and 1, except for weak acids having a hydrophobic nature, such as propionic, butyric and hydrogen sulfide. For these species, an adsorption effect is evident. As an example, propionic acid is eluted at a larger retention volume than expected from consideration of its pK_{a1} value alone, with the additional retention being attributable to hydrophobic adsorption of the analyte on the unfunctionalized regions of the stationary phase.

Figure 1 IEC separation of (A) aliphatic carboxylic acids by elution with 0.5 mmol L^{-1} benzoic acid/5% acetonitrile and (B) alcohols and (C) sugars by elution with 1 mmol L^{-1} sulfuric acid/water on a PS-DVB-based strongly acidic cation exchange resin column (8 mm i.d. \times 20 cm long).

(A) Peaks: 1, sulfuric acid (V_0); 2, formic acid; 3, acetic acid; 4, propionic acid; 5, butyric acid; 6, valeric acid. (B) Peaks: 1, dip; 2, sucrose; 3, glucose; 4, fructose. (C) Peaks: 1, dip; 2, methanol; 3, ethanol; 4, propanol; 5, butanol. (Figure 1A reproduced with permission from Fritz, 1988, and Figures 1B and 1C from Tanaka and Fritz 1986.)

In addition to the use of PS-DVB-based cation exchange resin, new IEC methods on polymethacrylate-based weakly acidic cation exchange resin and hydrophilic unfunctionalized silica gel have recently been developed to separate some of the more hydrophobic carboxylic acids. Figure 3 shows the IEC separation of some hydrophobic aliphatic and aromatic carboxylic acids on PS-DVB (Figure 3A) and polymethacrylate-based cation exchange resins (Figure 3B), and on unfunctionalized silica gel (Figure 3C), using 5 mmol L^{-1} sulfuric acid as eluent.

As can be seen from Figure 3, the V_r values of hydrophobic carboxylic acids increase with increasing hydrophobicity of the stationary phase (PS-DVB > polymethacrylate > silica).

Turning now to IEC of bases (cations) performed on strong anion exchange resins in the hydroxide form, some similar retention trends to those described above can be noted. Ionic analytes such as sodium and potassium ions are completely ion-excluded from the fixed positive charged resin phase and are eluted at a retention volume of V_0 , while nonionic

Figure 2 Relationship between retention volumes and their first dissociation constants for inorganic anions, carboxylic acids and nonionic substances on a PS-DVB-based strongly acidic cation exchange resin column (8 mm i.d. \times 55 cm long) by elution with water. (Reproduced with permission from Tanaka *et al.*, 1979.)

substances will permeate into the resin phase and are eluted at a retention volume of $V_0 + V_i$. Weak bases, such as ammonia and amines, are eluted at intermediate retention volumes, depending on their pK_b values and their hydrophobicity. As a result, weakly ionized cations can be separated from strongly ionized cations by the ion exclusion mechanism.

Instrumentation, Stationary Phases and Eluents

Ion exclusion chromatographic systems consist of the same components as any high performance liquid chromatography instrument. A UV detector is often used for the sensitive and selective detection of UV-absorbing substances such as aliphatic and aromatic carboxylic acids. However, this detector is insensitive to some aliphatic carboxylic acids, sugars and alcohols. Although a refractive index detector can be used as a bulk detector, the detection response is not high and the detector is flow- and temperature-sensitive. The most popular and universal detection method for IEC is conductivity. In order to decrease or suppress the eluent background conductivity, a membrane

suppressor system can be used (normally when the eluent is highly conducting), or alternatively a weak-acid eluent (aliphatic or aromatic carboxylic acids) of low conductivity can be used.

The most common resins used in ion exclusion chromatography are high capacity PS-DVB-based strongly acidic cation exchange resins of 5 μ m particle size. As discussed earlier, polymethacrylate-based weakly acidic cation exchange resin or unfunctionalized silica gel can also be employed.

Although the IEC separation of ionic and nonionic substances may be carried out simply by using water as the eluent, dilute aqueous solutions of some mineral acids or weak carboxylic acids give greatly improved peak shape and are therefore preferred for high resolution separations. Decreasing the pH of the eluent increases the retention of weakly ionized analytes such as carboxylic acids owing to a decrease in the fraction of the ionized analyte present. Therefore, the eluent pH is a very important factor in regulating retention volumes in IEC. Organic modifiers such as methanol and acetonitrile are often used to reduce hydrophobic interactions of the analytes with the resin. A further approach that may be used

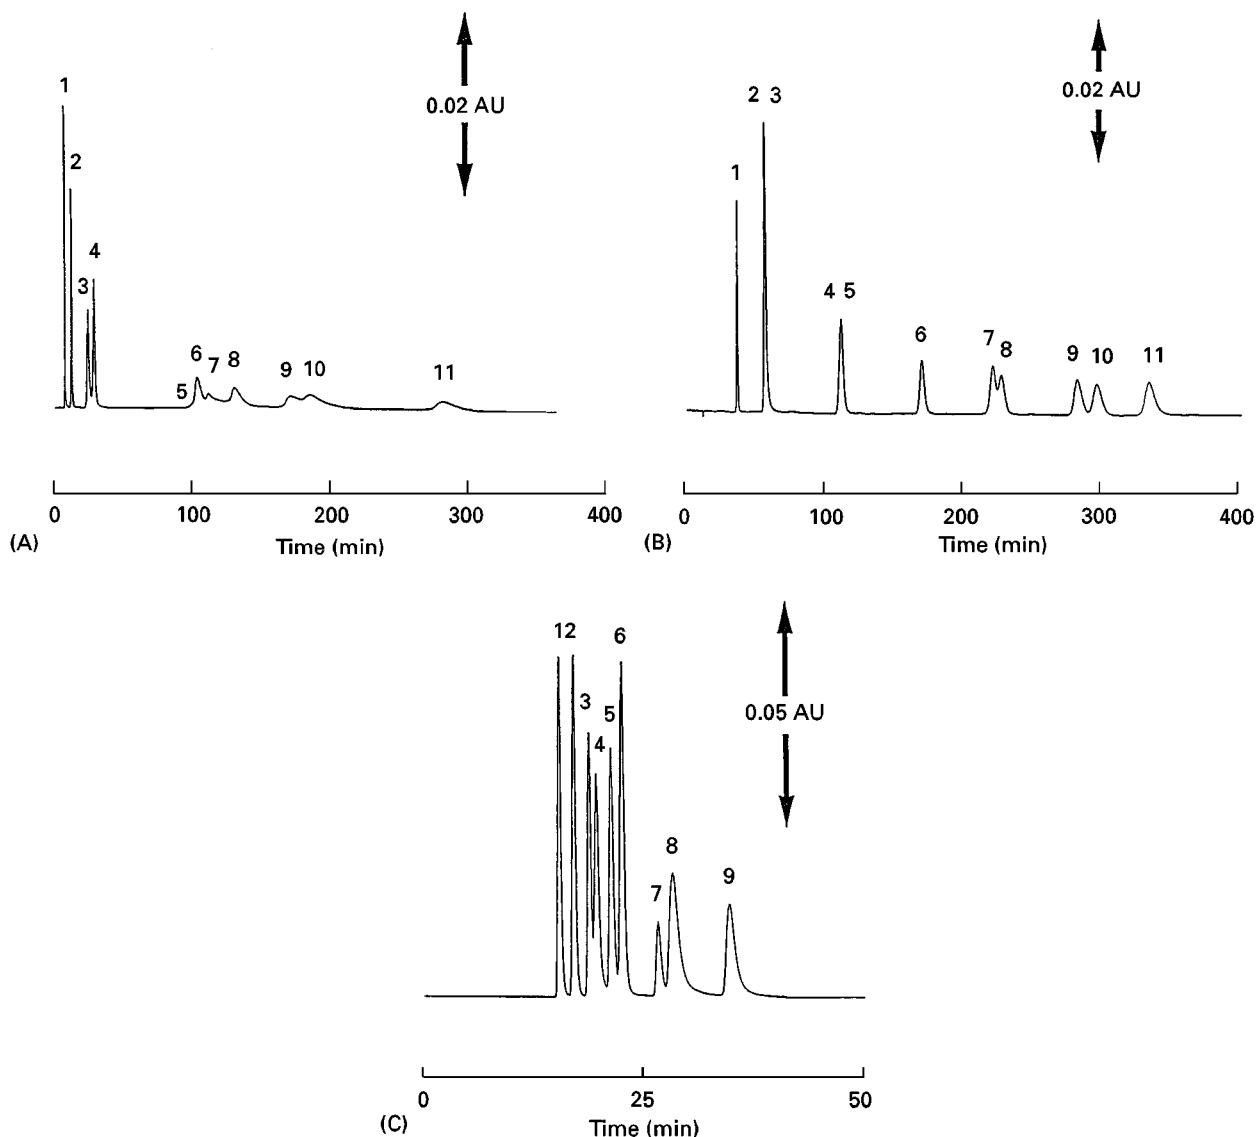

Figure 3 IEC separation of aromatic carboxylic acids on (A) PS-DVB-based strongly acidic cation exchange resin column, (B) polymethacrylate-based weakly acidic cation exchange resin, and (C) unfunctionalized silica gel by elution with 5 mmol L^{-1} sulfuric acid at 1 mL min^{-1} . (B) Peaks: 1, hemimellitic; 2, pyromellitic acid; 3, phthalic acid; 4, trimellitic acid; 5, phenol; 6, benzoic acid; 7, *m*-hydroxybenzoic acid; 8, *p*-hydroxybenzoic acid; 9, isophthalic acid; 10, salicylic acid; 12, trimesic acid. (C) Peaks: 1, pyromellitic acid; 2, trimellitic acid; 3, hemimellitic acid; 4, terephthalic acid; 5, isophthalic acid; 6, phthalic acid; 7, phenol; 8, salicylic acid; 9, benzoic acid. (Reproduced with permission from Ohta *et al.*, 1996.)

to decrease the hydrophobic adsorption of analytes onto the resin is the addition of hydrophilic species, such as sugars, polyols and polyvinyl alcohol, to the eluent.

Optimization of Ion Exclusion Chromatographic Separation

To optimize an IEC separation, careful selection of the following experimental parameters must

be made:

1. the type of matrix used as the stationary phase (PS-DVB, polymethacrylate or silica);
2. the nature of the functional group (e.g. strong or weak acid);
3. the ion exchange capacity (low or high);
4. the nature of the eluent (e.g. strong or weak acids);
5. the pH of the eluent;

6. the amount of organic modifier present in the eluent; and
7. the type of detector used (universal or selective).

Selected Applications

Carboxylic Acids

Separation of carboxylic acids is probably the most common use of IEC. Carboxylic acids such as formic, acetic, propionic, butyric, valeric, citric, tartaric, oxalic, malonic, benzoic, salicylic, and others have been determined using UV and conductivity detection. **Table 1** lists some recent applications of IEC for these analytes. These methods have been applied to a wide variety of very complex sample matrices, such as biological materials, foods, beverages, pharmaceuticals, environmental materials and others. The separation is almost always performed on a PS-DVB-based cation exchange resin in the hydrogen form; examples of such separations may be found elsewhere in the encyclopedia. As an example of the use of alternative stationary phases, the separation of aliphatic carboxylic acids on a silica gel column by elution with 5 mmol L⁻¹ sulfuric acid is shown in **Figure 4**.

Weak Inorganic Acids and Bases

IEC has found increasing use for the determination of weakly ionized inorganic anions such as fluoride, nitrite, phosphate, sulfite, arsenite, arsenate, bicarbonate, borate and cyanide. This approach is very effective for the determination of weakly ionized anions in samples containing a high concentration of

Figure 4 IEC separation of aliphatic carboxylic acids on silica gel column (7.8 mm i.d. × 30 cm long) by elution with 0.05% heptanol/0.5 mmol L⁻¹ sulfuric acid at 1 mL min⁻¹. ionic species, e.g. seawater and wastewaters. **Figure 5** shows the separation of bicarbonate in tap waters by IEC with conductimetric detection by elution with water. The monitoring of bicarbonate ion is very important for the quality control of tap water and for

the evaluation of the buffering capacity of natural waters.

Ethanolamines and ammonium ion may be successfully determined by IEC with UV or conductimetric detection on a PS-DVB-based strongly basic anion exchange resin in the hydroxide form. Industrial and environmental applications of the determination of ammonium ion are also common and include samples such as biological treatment process waters and ur-

ban river waters, as shown in Figure 6. Table 2 lists some of the recent applications of IEC in the analysis of weak inorganic acids and bases.

Strong Inorganic Acids

More recently, a simple and highly sensitive method involving simultaneous ion exclusion/cation exchange chromatography with conductimetric detection on a polymethacrylate-based weakly acidic cation exchange resin in the hydrogen form has been developed for the determination of inorganic strong acid anions such as sulfate, nitrate and chloride ions, and strong base cations such as sodium, ammonium potassium, magnesium and calcium ions commonly found in acid rainwater. Use of a weak acid eluent (such as tartrate) permits both the anions and the cations to be determined, based on a simultaneous

ion exclusion and cation exchange mechanism on the same stationary phase. The conductimetric detector responses are positive for the anions (which are separated by IEC and detected directly) and negative for

the cations (which are separated by ion exchange and are detected indirectly). The effectiveness of this method has been demonstrated in its application to acid rain, as shown in Figure 7.

Neutral Compounds

Neutral compounds such as sugars and alcohols can be separated by IEC, as shown earlier in Figure 1B and 1C. Table 3 lists some of the recent applications of IEC in this field. One of the more significant applications of IEC is its use for the determination of water. Using a short column packed with PS-DVB-based cation exchange resin in the hydrogen form and eluting with methanol containing a small amount of strong acid, a peak for water can be obtained with a spectrophotometric detector at 310 nm. This method is applicable to the determination of water in some organic solvents.

Conclusion

Despite the fact that IEC is a relatively old separation technique, new and diverse applications continue to emerge. IEC remains the method of choice for the separation of low molecular weight carboxylic acids. The separation mechanism of IEC is complicated by the fact that a wide range of processes are known to contribute to retention. At present there is no comprehensive mathematical retention model that accounts for all of the retention processes in IEC. For this reason, optimization of separations is generally performed on an empirical basis rather than through the use of computerized optimization routines such as those employed in many other forms of chromatography. However, there has been considerable recent activity in the study of retention processes in IEC and it can be expected that suitable computer optimization methods will soon appear.

ION FLOTATION

L. O. Filippov, Laboratoire Environnement et Minéralurgie, INPL-ENSG, Nancy, France

Copyright © 2000 Academic Press

Introduction

Sebba published a paper in 1959 in which he discussed a new method (ion flotation) for recovering solute from dilute solutions by adding surfactant, with subsequent adsorption of the solute onto bubbles. The principles of the process and the characteristics of the solute-surfactant product formed in solution were discussed in his monograph on ion flotation published in 1962. The method rapidly became popular and researchers in several countries have studied various aspects of the separation of metallic ions, trace elements, molecules, inorganic anions and organic matter from aqueous solutions. Many laboratory-scale studies have been carried out, most of them aimed at development, analytical applications, water purification, resource recycling, removing radionuclides from solutions, and recovering metals from sea water.

A comprehensive development of all aspects of the subject was presented in a monograph on adsorptive bubble separation techniques, edited by Lemlich in 1972, in which details and applications of ion and precipitate flotation methods were reported by Pinfold.

The research group directed by Grieves made an important contribution to the theoretical and applied aspects of ion and precipitate flotation during the 1960s, particularly on wastewater treatment. They showed that flotation efficiency of long-chain surfactants was the result of physicochemical aspects of particle growth and dispersion. But the adsorption of surfactant onto the solid and gas phases was identified as a factor limiting bubble-particles attachment in some cases of ion flotation.

The adsorption of the surface-active solutes to the gas-liquid interface was studied by Rubin. An analysis based on the Gibbs and Langmuir isotherm and on an originally developed approach of long-chain ion adsorption in a solution containing several surface-active species was used to determine the effect of their concentrations on the ratio of distribution coefficients. This author also described the kinetic parameters for ion and precipitate flotation.

A detailed review of the precipitate and adsorbing colloid flotation technique with a comprehensive literature review appears in the monograph published in 1983 by Clarke and Wilson.

Golman has given a qualitative description of the chemical and kinetic aspects of ion flotation and some industrial applications, including the removal of molybdenum from solutions of hydrometallurgical flow-sheets. He has also given methods for treating foam products and purifying process residual solutions.

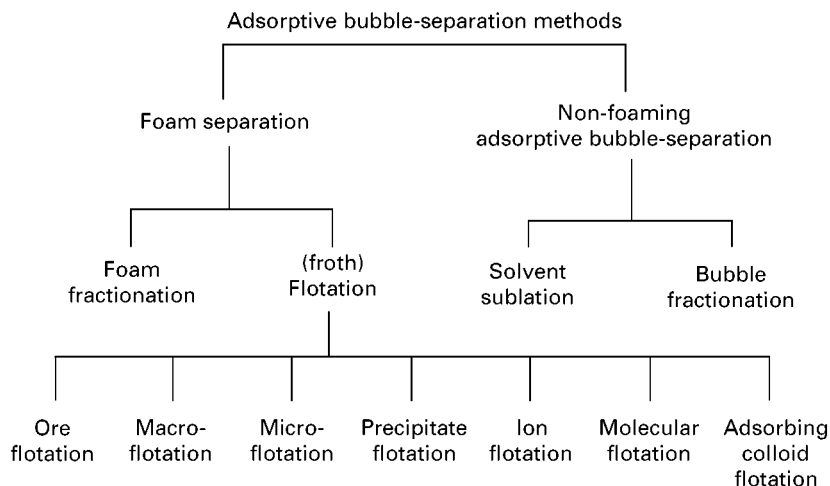

Figure 1 Schematic classification of the adsorptive bubble-separation techniques. (Reproduced with permission from R Lemlich (1972) *Adsorptive Bubble Separation Techniques*. New York: Academic Press. Copyright.)

Relatively few studies on this subject have been published recently. They focus mainly on extending the applications of the method. The progress made in column flotation techniques, especially with bubble generation systems, offers hydrodynamic conditions favourable for ion flotation. Filippov has reported on the results of recent pilot-scale studies applying this technique to precipitate and ion flotation. It was demonstrated that aggregate formation and destruction under low dissipation energy are the parameters controlling precipitate flotation. The combined use of column and bubble spargers in ion flotation provided a removal rate for metals equivalent to that of laboratory-scale trials.

Phenomenology and Classification

Separation by adsorption onto bubbles is based on the difference between the surface activities of the solute species. These species can be ionic, molecular, or colloidal, and their adsorption onto the bubble-liquid interface depends on their surface-active, adhesion or electric properties. A species that is not adsorbed onto bubbles can be made to do so by adding a surfactant to the solution.

The classification of methods based on these separation phenomena are shown in **Figure 1**. Lemlich called these processes 'adsbubble (adsorptive bubble) separation methods', while the term 'adsbubble method' was recommended by Sasaki, since the method involves both adsorption and adhesion. The classification of these techniques in **Figure 1** is based on the formation of the foam, which leads to two main groups:

- foam adsorptive separation and
- non-foaming bubble separation.

The nature of the entity is introduced later.

The Golman classification based on the phenomena at the various levels of process leads to another classification of ion recovery process (**Table 1**). This classification take into account:

- the type of phase that accumulates the floated species: foam, scum, organic or aqueous phase;
- the nature of the components to be adsorbed onto the bubble surface: ions or molecules, particles of the precipitate or carrier; and
- the collector use to modify the hydrophobic properties of the entities

Ion Flotation

Definition

Ion flotation, developed by Sebba, is a surface-inactive separation method that involves the removal of ions or molecules (*colligend*) from aqueous solution by adding surfactant, that is adsorbed onto the surface of rising bubbles. The surfactant-colligend product (*sublat*) may be formed in bulk solution or

Table 1 Classification of ion-recovery method

Flotation	Flotation			
	Froth	Foam	Solvent sublation	Bubble fractionation
Adsorptive		Without collector With collector		
Precipitate		Hydrophobic Hydrophobized		
Carrier		Hydrophobic Hydrophobized		

only at the higher concentrations produced by preferential adsorption on the bubble surface. The process is called *adsorption* ion flotation if the sublat is a soluble complex or a pair of ions. The process is *adhesion* ion flotation if the sublat forms a new phase in aqueous solution. A hydrophobic product (*scum*) is formed at the surface of the solution by destruction of the rising bubbles.

The formation of foam is not necessary for ion flotation. The hydrophobic nature of the scum makes it stable on the solution surface. A foam thin-layer phase may be needed to isolate the scum from the liquid phase and to evacuate it later to avoid it redissolving. Stable foam is a factor limiting the application of ion flotation, because it requires less foam formed or a lower gas rate. Solution entrainment also decreases the colligend concentration in the foam.

If the formation of a foam during ion flotation is undesirable or impossible (i.e. recovery of organic ions or quantitative separation), the process of *solvent sublation* is used. This method involves spreading a thin immiscible organic solvent layer on the surface of the water causing dissolution of the floating sublat.

Theory

There are several ways to describe ion flotation and to determine the quantity of surfactants required for optimal separation. One considers the bubble surface to be an ion exchanger owing to surfactant adsorption. The charge created is compensated for by the adsorption of inactive ions of opposite charge. Jorne and Rubin assumed that the radius of the hydrated ions determined the maximum approach of opposite ions to the bubble surface, based on the theory of a double electrical layer. Their theoretical calculations were confirmed experimentally. Another approach highlights the stability constants of soluble compounds (complexes and pairs of ions) formed by the surfactant with the colligend and an oppositely charged ion, according to Moore and Philipps. Some believe that a solid phase is formed (assumed to be two-dimensional) in the adsorption layer on the bubble surface. These assumptions mostly concern the adsorption mechanism of ion flotation.

Sebba and Golman used the product of the activities of the collector and colligend (L_A) to explain adhesion. The equilibrium of the system is determined by the constant of stability of sublat K_A and the solubility of its molecular form S_{AM} , when $L_A = K_A S_{AM}$. If we assume that a sublat flotation occurs as a colloid rather than molecules, the fraction P of the stoichiometric ratio Φ of collector/colligend molar concentrations is given according to

Golman by:

$$P = R + \frac{l}{m} \sqrt[m]{\frac{L_A}{f_{RX}^m f_A^l (1-R)^l C_A^{m+l}}} \quad [1]$$

where R is the rate of colligend recovery; f_{RX} , f_A are the surfactant RX and colligend A activity coefficients respectively; C_A is the colligend concentration; m and l are the stoichiometric coefficients of the reaction of sublation of A by RX.

The parameter $(L_A)_{P/R}$ calculated from this formula allows the deduction of the value of L_A that is needed to obtain a recovery R for a given Φ . This formula does not take into consideration changes in the ionic strength I with collector concentration. However, for the characteristic colligend concentrations and for Φ being practically stoichiometric the parameter I does not limit the application of this approach. This was confirmed by Golman for the ion flotation of various species.

The influence of the surface-active species concentration and solubility product P_s of sublat ($P_s = \text{constant}$ for $I = \text{constant}$) on the recovery of the colligend and the residual surfactant concentration is given in Figure 2. This confirms the experimental results. It is preferable to carry out ionic flotation in the concentration ranges of the collector so that $P = 1$ (values of Φ are stoichiometric). Colligend recovery when $P < 1$ is often reduced. The

Figure 2 Colligend recovery R (1, 2) and surfactant residual concentration $C_{(RX)r}$ (1', 2') vs. surfactant consumption for a given sublat solubility product P_s : 1, 1' - $P_s = 10^{-9}$, 2, 2' - $P_s = 10^{-10}$. Solid lines, calculated results from eqn (1); \circ , experimental results of ion flotation of ReO_4^- with laurylammonium chloride, $L_A = 3.9 \times 10^{-7}$. (Adapted from AM Golman (1982) *Ionnaya Flotatsiya*, p. 42. Moscow: Nedra.)

considerable residual concentration of collector in the bulk solution when $P > 1$ decreases the process efficiency (economic). This makes it difficult to reuse a solution without purification and/or environmental problems. The excess collector also prevents flotation because of secondary adsorption onto bubbles and sublat surfaces if the sublat is solid, as demonstrated by Grieves and Golman.

Colligend : Collector Ratio

Ion flotation operates with dilute solutions of the colligend (10^{-5} to 10^{-3} mol L⁻¹). Higher colligend concentrations require significant collector consumption, increasing the operation costs. The ratio Φ of collector and colligend molar concentrations is one of the main parameters of ion flotation. The changes in the amount of colligend removed with Φ is shown in Figure 3, which are typical of ion-flotation systems.

As noted by Pinfold, the ratio Φ required for complete flotation must be at least stoichiometric (Φ_{st}). This is true for the adhesion mechanism of ion flotation, but with adsorption, the amount of collector that can float without sublation depends on the bubble residence time in the liquid. The colligend cannot be completely removed in this case with a

Figure 3 Dependence of the flotation of various colligends on the fraction (P) of collector : colligend ratio (Φ): (1) Ge^{3+} + tetradecylammonium chloride ($\Phi_{st} = 2$); (2) ReO_4^- + laurylammonium ($\Phi_{st} = 1$); (3) Cr^{6+} with hexadecylammonium bromide ($\Phi_{st} = 1.04$); (4) Ga^{3+} + amide oxime ($\Phi_{st} = 3$). (Adapted respectively from: (1,2) AM Golman (1983) *Fiziko-khimiticheskie Aspekty Ionnoi Flotatsii*, p. 245, Moscow: Nauka; (3) *The Chemical Engineering Journal*: R Grieves Foam Separations: A Review, 93, Copyright (1975), with permission from Elsevier Science; (4) with permission from A Masuyama et al. *Industrial Engineering Chemical Research* 29: 290, Copyright (1990) American Chemical Society.)

stoichiometric Φ . The experimental results of Doyle, available in the literature, show that slightly more than stoichiometric amounts ($P = 1.1$ – 1.2) of sodium dodecyl sulfate were needed to reduce the heavy metals ion concentration to very low levels. Moreover, the curve behaviour around point $P = 1$ in Figure 3 could indicate the mechanism of ion flotation.

Role of Electrolytes and Anions

The role of electrolytes is significant during the collector-colligend and sublat–bubbles interaction. Their role must be taken into account because of their significant quantities in real industrial solutions. Electrolytes modify the ionic strength and can react with the collector. For $I = \text{constant}$, two cases are possible:

1. The opposite-charged ion forms a soluble product with the collector. The separation is more selective for higher colligend and for low opposite-charged ion concentrations. A higher collector concentration than that required by Φ also renders ion flotation more efficient.
2. The collector–colligend interaction product is insoluble. A critical concentration of the opposite ion can be defined, below which it does not react with the collector and consequently does not influence further colligend recovery.

Changing the ionic strength by adding NaCl allows the selective separation of metal oxyanions (MeO^{4-} or MeO^{2-}) with hexadecyldimethylbenzylammonium chloride as collector (Figure 4). The recovery of oxyanion flotation as a function of $p[\text{NaCl}]$ illustrates the phenomena described above.

The change in ionic strength of the medium caused by adding anions reduces the effectiveness of ion flotation. The flotation of dichromate with a quaternary amine (adhesion mechanism) is blocked in the sequence, according to Grieves: $\text{PO}_4^{3-} > \text{SO}_4^{2-} > \text{Cl}^-$. The recovery of $\text{Fe}(\text{CN})_6^{4-}$ with a cationic collector is influenced by: $\text{CN}^- > \text{NO}_3^- > \text{Cl}^- > \text{SO}_4^{2-} > \text{CO}_3^{2-} > \text{PO}_4^{3-} > \text{P}_2\text{O}_7^{4-}$. This contradiction can be explained by the process taking place in each case.

The foam flotation of dichromate is controlled by the preliminary formation of a solid phase followed by adsorption onto bubbles (similar to precipitate flotation). The adsorption of differently charged ions influences surface hydration of the bubbles and the precipitate, the importance of which is directly related to the charge of the anion. Ferricyanide flotation is by solvent sublation. As was noted by Pinfold, the smaller ionic radius of the anion, the more effective the collector competes with the colligend. The use of 2-octanol to collect the sublat on the solution

Figure 4 Effect of the negative logarithm of the sodium chloride concentration on the percentage flotation of each of five metal oxyanions. (Reprinted from *The Chemical Engineering Journal* 9: R Grieves Foam Separations: A Review, 93, Copyright (1975), with permission from Elsevier Science.)

surface can cause solvent to dissolve and become adsorbed onto the bubble surface instead of the collector. Under these conditions the lower charged anions neutralize the adsorbed collector, so that it is no longer available to float the colligend.

pH

Ion flotation is particularly sensitive to the pH because the pH determines the nature and the charge of the collector (the degree of ionization) and the colligend (hydrolysis), and causes variations in the ion-collecting mode. Pinfold also notes that the following phenomena that can take place when the pH changes:

- colligend hydroxides may form, and precipitate flotation may take place instead of ion flotation;
- extreme values of pH block flotation because the ionic strength is higher;
- the stability of scum could be affected because of sublat redispersion in the solution.

Temperature

The temperature influences all aspects of ion flotation, i.e. the collector and sublat solubility, the sublat particle size and the flotation results. Its role were confirmed by Grieves for the flotation of Cr^{6+} at $\text{pH} = 4.1$ with quaternary amine salts with hydrocarbon chains of C_{14} , C_{16} and C_{18} . The collector used acted as a precipitant, dispersing and flocculating agent depending on the temperature, determining the orientation of the collector molecules adsorbed on the sublat surface. The surfactant also acted as foaming agent because of the free collector adsorbed on the bubbles.

Optimal metal removal with C_{16} - and C_{18} -amine salts occurred with $\Phi = 1.04$ and 33 or 40°C . The abrupt drop in removal rate at higher values of Φ was explained by excess surfactant adsorbing to the particles, stabilizing them and preventing further aggregation. One of the most significant conclusions deduced from these experiments is that the particles of the precipitate $> 25 \mu\text{m}$ are completely removed from solution, while almost no particles $< 7 \mu\text{m}$ are floated.

Precipitate Flotation

According to Pinfold, precipitate flotation includes all processes in which an ionic species is precipitated in the liquid phase and is subsequently removed by attachment to the bubble surface. It is difficult to clearly distinguish between 'ion flotation' and 'precipitate flotation' when a collector is used as a precipitation agent.

If the colligend is first precipitated by a non-surface-active ion and made hydrophobic by adsorption of a surfactant, the process is termed *precipitate flotation of the first kind*. Many studies have been carried out on the removal of metal ions from aqueous solution (i.e. sea water) by this method. Heavy metals are generally precipitated with an alkali as the hydroxide and then removed by flotation with an ionic collector. The other insoluble salts (sulfide, carbonate, sulfate) can be precipitated.

The *precipitate flotation of the second kind* uses no surfactant for bubble-particle attachment because it suggests that the solid phase formed by interaction of two hydrophilic species (colligend and precipitation

agent) is hydrophobic. The following precipitants have been used for various metal ions: benzoinoxime (Mo, Cu), benzoylacetone (U), α -furyldioxime (Ni), hydroxyquinoline (Cu, Zn, U), α -nitroso- β -naphthol (Ag, Co, Pd), dodecylpyridinium with a collector (Sr, V), etc.

Kinetics

Ion flotation controlled by adhesion is a precipitate-like flotation because the sublat formed is a solid phase that can also be flocculated by adding active chemical agents or by the action of the collector. The two ionic flotation modes (adsorption and adhesion) may be distinguished at the level of particle-bubble interaction, depending on the nature of the sublat.

- The sublat formed is an ionic pair or a soluble complex (adsorption): the adsorption activity of these species on the bubbles determines the effectiveness of the process.
- The sublat is formed in the liquid phase as particles of 10^{-3} to 10^{-1} μm : the interaction of the sublat and the bubbles is controlled by the diffusion of the particles in the hydrodynamic fields of the bubbles.
- The sublat is a precipitate with micron- or millimetre-sized particle: the interaction results in sedimentation of the particles of negligible mass on the bubbles if the surface forces support the attachment of the entities.

The time necessary for 90–99% colligend recovery at colligend concentrations of 10^{-5} to 10^{-2} mol L^{-1} indicates that sublat flotation as a precipitate is kinetically preferable than flotation of the molecules (Figure 5). The flotation mechanism was concluded from independent experiments on the solubility product, microscopy, separation of the precipitated phase by centrifugation and filtration.

Few studies on the kinetics of ion flotation are published, while there are many papers on mineral particle flotation. However the kinetic parameters of the process determine the practical applications of flotation because they determine the scale-up procedure adopted.

Apparatus: Future Developments

Almost all ion flotation tests are carried out in cells (batch or continuous mode) equipped with a sintered-glass device to generate bubbles. The use of the column-type cells allows the user to: vary the introduction point of the collector and feed solution containing the colligend; vary the height of the foam;

carry out sampling and/or *in situ* measurements if radioactive ‘tracers’ are used.

The most recent bubble-generating systems make column flotation a flexible tool for ion flotation.

A study of sublat formation and its structural organization showed that a column 75 mm in diameter and 3 m high could be used for ion flotation (Cr^{6+}) and for precipitate flotation (molybdenum). The bubble diameter determined the efficiency of separation by ion and precipitate flotation because of collision probability and aggregate stability in the microturbulence created by the rising bubbles. The flotation with small bubbles as in the dissolved-gas technique increases the collision probability. However, the low feed-flow rate of the process is a limiting parameter because of the low velocity of small rising

bubbles. In addition, the flotation mechanism in this kind of technique, in which several small rising bubbles are trapped in a large precipitate floc structure, can cause transfer of the liquid present in the aggregate to the froth and reduce the separation efficiency.

Ion Flotation in a Column

The ion flotation of Cr^{6+} from sulfuric acid solutions (pH 1.5–2.0) with octadecyltrimethylammonium bromide (ODTA-Br) as collector is particularly difficult because a single chemical acts as precipitating, flocculating, dispersing and frothing agent. This is in addition to the problems of floating an element of negligible mass. It is thus nearly impossible for the precipitate to become adsorbed on bubbles because of an electrical charge of the same sign (owing to free collector) on the bubbles and precipitate particles. Several modes of ion flotation have been tested on a pilot scale (Figure 6).

In the classical mode of ion flotation (precipitation–flotation as described by Grieves), only the 200–240 μm diameter bubbles provide a low chromium recovery of 56.2–60.8%. An exceptionally stable, loaded froth with the liquid (7.0–19.0%) was carried over, which decreased the separation efficiency (Table 2). Some column/bubble generator assemblies can be used to solve the problems of bubble–precipitate electrostatic repulsion and collision. It has thus been possible to develop a new mode of ion flotation in which the chromium solution is introduced directly at the feeding point of column and the collector is introduced to the bubble generator. The strong surfactant properties of the collector caused to be adsorbed on the bubbles so that the chromium was precipitated on the gas phase. This new method gives about 81.6% Cr^{6+} removal by column flotation for a $\Phi = 1.2$ and a liquid residence time of 15–20 min. Retreatment of the solution can increase the total Cr recovery to 91.6%, with a Cr residual concentration of 4.5 mg L^{-1} , which corresponds to separation results by filtration.

Precipitate Column Flotation

The limiting conditions for molybdenum metal–organic precipitate flotation in columns are owing to aggregate stability under the turbulence created by upward movement of bubbles, which depends directly on the average bubble diameter. Pilot-scale flotation studies revealed the fundamental influence of the average bubble diameter and dissipation energy on molybdenum recovery in the form of precipitate obtained with the collector α -benzoin oxime for a molar concentration ratio of 2. It was therefore necessary to identify a bubble-size distribution and the gas hold-up in the column to ensure the flotation of low hydrophobic precipitate flocs, as they are extremely brittle with very low values of dissipated energy (0.01–0.05 W kg^{-1}). Destruction is conditioned by the aggregation mechanism (cluster–cluster type) and not only causes mean floc size to decrease from 150–350 μm to 30–50 μm , but also produces very fine particles that could elude collision with bubbles. Bubble spargers (Microcel, Flotaire, Imox) tested on a pilot scale provided the required values of these parameters for efficient column flotation (recovery up to 95%) of the precipitate for low superficial gas ($J_g = 0.22$ – 0.55 cm s^{-1}) and feed flow rates ($J_l = 0.19$ – 0.47 cm s^{-1}). An adjustment of the J_g/J_l ratio to optimal hydrodynamic conditions in counter-current pilot column corroborated laboratory-scale tests in the cell equipped with a fine porosity frit (No. 4).

Bubble Fractionation

This is the partial separation of components within a solution by the selective adsorption of surfactants, colloid or ultrafine particle species onto the bubble. The effect of separation is demonstrated by a concentration gradient along the column-like cell that allows removal of a colligend-rich solution from the top and depleted solution from the bottom of the cell. Separation efficiency clearly decreases with increasing column diameter as a result of axial diffusion of rising bubbles, which breaks up the concentration gradient.

Adsorbing Colloid Flotation or Carrier Flotation

This consists of the preliminary capture of colligend by the carrier particles (by adsorption, absorption, or co-precipitation), followed by charged-bubble flotation. Ion-exchange resin, activated charcoal, or the precipitate particles can be used as a carrier. The carrier particles can have flotation properties or be made hydrophobic by adding collector.

Molecular Flotation (Koisumi)

This is the recovery of molecules using a surfactant. The name molecular flotation is used for all flotation processes that involve the recovery of the molecular colligend or those analogous to ion flotation.

Introduction

Ceramic membranes are commonly used in separation processes involving the filtration of particulate matter from a fluid stream. This involves the use of controlled porosity ceramic materials, which essentially act as inert filters. More recently, dense ceramic membranes fabricated from ionic conductors have been proposed as active membranes for the high-temperature separation of oxygen from air for a variety of purposes.

The principle of using a dense ceramic ionic conductor to separate the ion-conducting species is, in itself, not new. The idea has been around since the turn of the century when Nernst first investigated solid electrolyte compositions for use as incandescent filaments in his glower devices. Since then ion-conducting ceramics have been used to separate a number of elements, for example oxygen, hydrogen and gallium, but mainly as a scientific curiosity and only on a laboratory scale. The current industrial interest in membrane separators was instigated by a Japanese group, who, in 1985, investigated dense oxide membranes, which were able to permeate substantial fluxes of oxygen at temperatures of 800–1000°C, with 100% selectivity. Since then there has been a rapid growth of both scientific and industrial interest in the use of these membranes for the separation of oxygen. The industrial interest has been driven by the possibility of providing compact oxygen separation plants for a number of applications including aerospace and medical, petrochemical and manufacturing industries.

This article describes a novel oxygen separation process, based on dense ion-conducting ceramic membranes. It is important to note that two different but related devices can be made from such membranes, both of which can be used in the oxygen separation process. In the first device, the driving force is supplied electrically and the membrane is made of an ionic conductor. In the second device, the driving force is supplied by a gradient in oxygen activity and the membrane consists of a mixed ionic electronic conductor. The materials used in the con-

struction of these devices and the devices themselves are described below.

Materials for Conducting Membranes

Ionic conduction in solids can be achieved in two main ways. Both require crystal structures in which there are a number of equivalent, partially occupied atomic sites. This condition of partial occupancy can occur either by the disordering of a low-temperature structure over two approximately equivalent sublattices, or by promoting large deviations from stoichiometry. Such oxygen ion-conducting materials can be further sub-divided into two groups: *electrolytes* that exhibit predominantly ionic conduction; and *mixed conductors*, materials in which there are both significant electronic and ionic contributions to the total conductivity. A useful concept to introduce at this point is the ionic transference number t_i . The ionic transference number is defined as the fractional contribution of the ionic component to the total conductivity. For a mixed conductor with both ionic (σ_i) and electronic (σ_e) conductivity, t_i is defined as:

$$t_i = \frac{\sigma_i}{\sigma_i + \sigma_e} \quad [1]$$

Clearly for solid electrolytes we require t_i to be very close to 1 and for mixed conductors $t_i < 1$.

The ionic conductivity of both types of material is thermally activated. The empirical relationship describing the ionic conductivity is given by:

$$\sigma = \frac{\sigma_0}{T} \exp\left\{\frac{-E_A}{kT}\right\} \quad [2]$$

where σ_0 is a constant pre-exponential factor, T is the absolute temperature, k the Boltzmann constant and E_A the observed activation energy for the process. Appreciable ionic conductivity for most oxygen conductors, greater than $10^{-1} \text{ S cm}^{-1}$, is only achievable at high temperatures (600–900°C) as the activation energies are always substantial ($\sim 50\text{--}100 \text{ kJ mol}^{-1}$).

Solid Electrolytes

Most practical oxide ion conductors are non-stoichiometric and are characterized by their ability

Figure 1 A half-unit cell of the fluorite structure showing a dopant cation and oxygen vacancy. ○, O²⁻-ion; ●, host cation (4⁺); □, vacancy; ◐, dopant cation (2⁺ or 3⁺).

to accommodate large departures from the ideal oxygen stoichiometry, without breakdown of the crystal structure. For example, oxides of the fluorite structure shown in **Figure 1** display high ionic conductivities when doped with lower valent cations. In one such material, gadolinia doped ceria, the trivalent gadolinium substitutes for the tetravalent cerium ion, causing a charge imbalance in the lattice. The deficit of positive charge is balanced by the formation of oxygen vacancies, which restores the charge balance (see **Figure 1**). This process can be formalized into a defect equation using Kröger–Vink notation:

Ion transport (and hence charge transport) can take place in such materials by a mechanism involving ‘hopping’ into neighbouring vacant oxygen sites, provided the ion has sufficient energy to overcome the activation barrier, E_m , associated with the ionic migration. High ionic conductivity can be achieved by ensuring an optimum level of doping. Because of the relatively stable nature of the cations used in these materials there is a negligible electronic component to the conductivity, especially at high oxygen pressures.

Of the fluorite oxides, considerable attention has been given to the cubic stabilized zirconia (ZrO₂) system for application in both the ceramic oxygen generator (COG) and a closely related device, the solid oxide fuel cell (SOFC). Zirconia with 8 mol% Y₂O₃ (8-YSZ) adopts the fluorite structure and is

a pure ionic conductor over a wide range of oxygen partial pressures; however, as mentioned above, substantial ionic conductivity is only obtained at temperatures above 900°C. Ceria-gadolinia (CGO) displays similar ionic conductivity to YSZ but at much lower temperatures (~700°C), principally owing to a lower value of the activation energy observed for the conduction process. The main concern with CGO is that its electronic conductivity becomes substantial under reducing conditions due to the reduction of Ce⁴⁺ to Ce³⁺, which renders CGO unsuitable for high temperature applications where low partial oxygen pressures occur.

Of increasing interest is a new series of solid solutions which adopt the perovskite structure (see below) based on the parent compound LaGaO₃ (lanthanum gallates). Doped gallates of the type La_{1-x}Sr_xGa_{1-y}Mg_yO_{3-δ} (LSGM) have comparable ionic conductivity to CGO and do not appear to have any appreciable electronic conductivity. **Figure 2** shows a comparison of selected fluorite and perovskite ionic conductors as a function of temperature.

Mixed Conductors

Most of the mixed conductors of technological interest adopt the perovskite (ABO₃) structure (**Figure 3**). The structure is able to accommodate the substitution of many different cations into its framework, assuming the necessary ion size constraints are met. Again, non-stoichiometry is the key to achieving high transport rates of oxygen; however, in these materials, by definition, the electronic component of the conductivity is not negligible. Taking the perovskite-structured material lanthanum cobaltate (LaCoO₃) as an example, when a divalent cation such as strontium is substituted for trivalent lanthanum on the A-site, charge compensation takes place by a dual mechanism. This involves the creation of oxygen vacancies and a change in valency of the cobalt from Co³⁺ to Co⁴⁺. As described earlier, this substitution can be expressed in a defect equation using Kröger–Vink notation of the type:

where h^{\bullet} represents an electronic hole (Co⁴⁺). In this case both electronic compensation and vacancy compensation of the substitutional occurs, and t_i is usually substantially less than one.

One problem associated with the mixed conducting perovskite and perovskite-related materials is that the dual compensation mechanism leads to changing non-stoichiometry with temperature and atmosphere,

Figure 2 Oxygen ion conductivity of selected fluorite, fluorite-related and perovskite oxides.

i.e. the balance of vacancy and electronic compensation of the dopant changes with conditions. This manifests itself in a loss or gain of oxygen from the lattice. Most notable is the loss of oxygen with tem-

perature in a constant environment, and/or the sensitivity of the materials to oxygen activity at constant temperature. This loss of oxygen causes a large effective expansion coefficient, which can cause cracking of the membranes upon heating and/or upon the imposition of an oxygen activity gradient.

Figure 3 The perovskite structure. (A) Unit cell and (B) extended structure showing the corner-sharing BO_6 octahedra. ●, cation A; ○, cation B.

Dual Phase

Finding a single phase ceramic material that has high electronic and ionic conductivity while remaining mechanically and chemically stable is not a trivial matter—in fact, these requirements are often mutually exclusive. Materials that exhibit high oxygen ion fluxes also tend to possess high thermal expansion values, which can lead to catastrophic failure in a membrane subjected to a significant oxygen partial pressure gradient, as mentioned above. A way round this problem is to construct dual-phase membranes, effectively making a mixed conductor on a macroscopic scale (Figure 4). Such dual-phase materials consist of two separate phases, one an ionic conductor (e.g. YSZ) and the other an electronic conductor (Ag), which are mixed in suitable proportions to provide connectivity for both phases. The individual components are themselves stable at high temperature and in an oxygen pressure gradient. It is not as yet clear what is the best materials combination, or how to optimize the microstructures in order to maximize the oxygen flux that the membrane can transport.

Figure 4 Schematic of a dual-phase membrane incorporating an ionic and electronic conducting phase.

Ion-Conducting Membrane Devices

Pressure Driven Devices

Pressure driven devices are perhaps the simplest form of ceramic oxygen generator. The membrane consists of a dense, gas-tight mixed ionic–electronic conductor (MIEC), which allows the transport of both oxygen ions and electronic species. The driving force for oxygen transport is a differential oxygen chemical potential applied across the membrane. This is achieved by applying a higher partial pressure of oxygen on the membrane feed side than on the permeate side (see **Figure 5**). The whole device may be operated well in excess of atmospheric pressure to achieve a pressurized permeate stream. The most practical design of such a device would be a series of thin-walled tubes. Obviously, the mechanical integrity of such a system is a major concern when very thin membranes are used, and some type of porous support would have to be employed in this case.

The device operates in the following manner. The first step is a surface reaction at the high-pressure surface of the membrane. The gaseous oxygen molecules interact with electrons at ‘active’ sites on the surface, they dissociate, become ionized and finally are incorporated into the oxide. The rate of this reaction is governed by the gas–solid surface ex-

Figure 5 Schematic of a pressure-driven ceramic oxygen generator based on a mixed conducting oxide.

change coefficient, k . The second step is the diffusion of the oxide ions through the material to the lower pressure side where the reverse process occurs and oxygen is evolved, releasing electrons. The membrane in a pressure-driven device is electrically isolated, that is, there are no external electrical current paths. Thus, the membrane material must be a good electronic conductor to provide a return path for the electrons, providing a compensatory flux of electronic species to balance that of the oxygen ions. Normally, the level of electronic conductivity ($\approx 10^2$ – 10^3 S cm $^{-1}$) in these materials is much higher than the corresponding ionic conductivity (≈ 1 – 10^{-1} S cm $^{-1}$), i.e. $t_i \ll 1$, consequently it is the oxygen transport parameters that determine the achievable oxygen fluxes.

In this case, a simplifying model can be applied which allows some insight into the operation of the membranes. The ionic current through the membrane can be described in terms of the simple equivalent circuit shown in **Figure 6**. The apparent potential η is provided by the partial pressure drop across the membrane, and is defined using the Nernst equation:

$$\eta = \frac{RT}{4F} \ln \left\{ \frac{P'_{O_2}}{P''_{O_2}} \right\} \quad [5]$$

where P'_{O_2} and P''_{O_2} refer to the partial pressure of oxygen on each side of the membrane, T is the temperature, F is Faraday’s constant, and R is the gas constant. The membrane resistance (expressed as area specific resistance R_A (ohm cm 2)) is then described in terms of two components, the resistance of the bulk of the membrane to the passage of the ionic current R_0 and the resistance of the surface of the materials caused by the oxygen exchange process. This latter term is expressed as an equivalent electrode resistance R_E , assigned equally to both high and low pressure surfaces. The chief utility of this model is that it allows an easy visualization of the processes involved and it can be applied to the electrically driven separator with a slight modification. The ionic current density, $J_{O^{2-}}$ (A cm $^{-2}$), through the membrane of thickness L and of ionic conductivity σ can be expressed as:

$$J_{O^{2-}} = \frac{\eta}{(2R_E + R_0)} \quad [6]$$

$$= \frac{\eta}{\left(2R_E + \frac{L}{\sigma} \right)} \quad [7]$$

R_E can be expanded in terms of the surface exchange coefficient for the oxygen exchange process, k ,

Figure 6 Equivalent circuit for a ceramic membrane device showing the ionic current.

and the diffusion coefficient, D :

$$J_{O^{2-}} = \frac{\eta}{\left\{ \frac{2D}{\sigma k} + \frac{L}{\sigma} \right\}} \quad [8]$$

The flux of oxygen through a pressure-driven device can be increased by making the membrane thinner (reducing R_0), but this is true only up to a certain point. The surface reaction kinetics ($\equiv R_E$) limit the ultimate flux of oxygen through a thin membrane, and beyond a certain characteristic limiting thickness, L_c , the flux remains constant. The numerical value of L_c is given by ratio D/k , which for most mixed conducting oxides of interest is approximately 100 μm , meaning that a supported thin film structure is probably required for an optimized permeation flux. A comparison of the oxygen fluxes achieved from a range of materials is discussed later.

Electrically Driven Devices

The electrically driven device consists of a solid electrolyte membrane with electrodes applied to each side to form a tri-layer structure (Figure 7). When an electrical potential is applied to the tri-layer, oxygen is reduced at the cathode, passes through the electrolyte as an O^{2-} ion and is evolved as oxygen at the anode. An external electrical connection allows the transfer of electrons from the anode to the cathode. The simple equivalent circuit used for the pressure-driven membrane is still applicable, however, R_0 now becomes the electrolyte ASR and R_E the polarization resistance of the electrodes (assumed to be identical).

The flux of oxygen produced by an electrically driven device is directly proportional to the current passing through the membrane ($1 \text{ A} \equiv 3.5 \text{ mL O}_2 \text{ min}^{-1}$), provided the ionic transference number is close to unity. Thus, the flux of oxygen for a given applied potential is governed by the resistance of the membrane (the sum of the electrolyte and electrode polarization resistances) and may be increased by either increasing the potential across the membrane or by reducing the resistance of the membrane. The extent to which the voltage can be increased depends largely on the stability of the electrolyte material. High applied potentials lead to the partial reduction of the electrolyte and the consequent increase in electronic conductivity, leading to a loss of efficiency, for example, in a material such as CGO.

The resistance of the membrane may be reduced by decreasing its thickness. Self-supporting electrolyte

Figure 7 Schematic of an electrically driven ceramic oxygen generator based on a solid electrolyte. □, Ionic conductor; ■, mixed conductor.

membranes of the order of 100 μm are available. Thinner electrolytes are not sufficiently strong to support themselves, and therefore further reduction in electrolyte thickness can be achieved by preparing a dense film of the electrolyte on the surface of a porous electrode support. The gains that can be made from switching to thin layers are limited, analogous to the pressure-driven variant. This is because the largest contribution to the resistance of a membrane is usually the polarization resistance of the electrodes, R_E , particularly at the lower temperatures of operation. These are independent of the electrolyte thickness ($\equiv R_0$) and thus again the flux of oxygen is limited by the value of R_E .

It is interesting to note that electrode compositions for the electrically driven separator are similar to compositions used as membranes in pressure-driven devices, because the requirements are identical, i.e. a high electronic conductivity and the fast transport of oxygen. Again, the limiting factor turns out to be the kinetics of the surface oxygen exchange reaction at the electrode.

The advantages of electrically driven oxygen separation devices are that large fluxes of oxygen per unit area are possible. At 800°C, an electrical potential of only 0.7 V is equivalent to an oxygen partial pressure gradient ratio of 7×10^{30} . For applications in which the volume of a device is a key constraint, such as

medical and aerospace applications, an electrically driven device would be the favoured option. An added advantage of an electrically driven COG is that the technology is closely related to that of the solid oxide fuel cell (SOFC) currently under development, and appreciable 'spin-off' is expected. The size of the device can be further reduced if a planar geometry is adopted, similar to that of the planar SOFC. Finally, an electrically driven device is also able to produce oxygen at a higher pressure than the air feed-stock, provided the applied potential across the membrane exceeds the back electromotive force due to the partial pressure gradient of oxygen.

The main disadvantage of electrically driven devices is that they are invariably complicated multi-component devices. This has implications in terms of the thermal and chemical stability, and the compatibility of the various components at the elevated temperature of operation. The need to develop a high-temperature sealant, required for the planar geometry, is an added complication for these compact devices.

Oxygen Fluxes

Having shown the principle of the devices and having discussed the materials involved, it is of interest to look at the 'state of the art' in terms of the fluxes of oxygen that can be achieved. Figure 8 shows a range of fluxes

Figure 8 Arrhenius plots of oxygen permeation for: (1) $\text{SrFeCo}_{0.5}\text{O}_{3.25-\delta}$; (2) $(\text{Bi}_2\text{O}_3)_{0.75}(\text{Y}_2\text{O}_3)_{0.25}\text{-Ag}$ (35 v/v), 90 μm ; (3) $\text{SrCo}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$; (4) $\text{La}_{0.2}\text{Sr}_{0.8}\text{Co}_{0.8}\text{Fe}_{0.2}\text{O}_{3-\delta}$; (5) $\text{La}_{0.3}\text{Sr}_{0.7}\text{CoO}_{3-\delta}$; (6) $\text{La}_{0.6}\text{Sr}_{0.4}\text{Co}_{0.2}\text{Fe}_{0.8}\text{O}_{3-\delta}$; (7) $\text{La}_{0.5}\text{Sr}_{0.5}\text{CoO}_{3-\delta}$; (8) YSZ-Pd (40 v/v), continuous Pd-phase.

measured from samples of single and dual-phase materials, operated in a pressure-driven mode, plotted as a function of inverse temperature. This figure is intended to give some appreciation of the fluxes that are attainable; however, they are not normalized to a given partial pressure gradient or thickness of membrane, and thus the fluxes are not directly comparable. Taking a value of between 10 and 100 L m⁻² min⁻¹ as the level of oxygen flux needed for practical applications, it can be seen that the cobalt-containing single-phase materials give appreciable oxygen fluxes above about 900°C. It is interesting to note on this figure that the dual-phase material, fabricated from (Bi₂O₃)_{0.75}(Y₂O₃)_{0.25}-Ag (35 v/v), approaches the lower bound of the practical fluxes at temperatures of 800°C.

It is not sensible to put data for electrical driven COGs on the same figure, given the restrictions mentioned above, however, some comparable figures are interesting. An equivalent flux of 15.8 L m⁻² min⁻¹ is

readily achievable with planar COG stack based on zirconia and operating at 1000°C. Similar performance has been reported for a system based on a CGO-operating temperature of 800°C.

Introduction

Ion exclusion chromatography (IEC) is a relatively old separation technique, attributed to Wheaton and Bauman, which is now staging an impressive comeback for the simultaneous determination of ionic species. IEC provides a useful technique for the separation of ionic and nonionic substances using an ion exchange stationary phase in which ionic substances are rejected by the resin while nonionic or partially ionized substances are retained and separated by partition between the liquid inside the resin particles and the liquid outside the particles. The ionic substances therefore pass quickly through the column, but nonionic (molecular) or partially ionized substances are held up and are eluted more slowly.

IEC is also referred to by several other names, including ion exclusion partition chromatography, ion chromatography-exclusion mode, and Donnan exclusion chromatography. In this article we use the term ion exclusion chromatography.

Generally, anions (usually anions of weak acids) are separated on a strongly acidic cation exchange resin in the hydrogen form and are eluted as the corresponding fully or partially protonated acids, while cations (usually protonated bases) are separated on a strongly basic anion exchange resin in the hydroxide form and are eluted as the corresponding bases. The eluents used are usually water, water/organic solvent mixtures, dilute (high conductivity) aqueous solutions of a strong acid, or dilute (low conductivity) aqueous solutions of a weak acid. A conductivity detector is commonly used to monitor the column effluent and, when the eluent conductivity is extremely high, a suitable suppressor system is generally used. UV-visible detection is also used as a selective detector in the determination of some aliphatic and aromatic carboxylic acids and some inorganic anions, such as nitrite and hydrogen sulfide. Using IEC, it is possible to separate weakly ionized anions such as fluoride, phosphate, nitrite, aliphatic carboxylic acids, aromatic carboxylic acids, bicarbonate, borate, aliphatic alcohols, sugars, amino acids, water, and others, as well as ammonium, amines, and others, based on a combination of the separation mechanisms of ion-exclusion, adsorption, and/or size-exclusion. Further discussion of these mechanisms may be found elsewhere in the encyclopedia.

ISOTOPE SEPARATIONS

Gas Centrifugation

Introduction

The idea that a centrifugal field might be used to separate was first suggested by Lindemann and Aston

in 1919. In 1934 Beams and others at the University of Virginia developed a convection-free centrifuge for isotope separations, shown in **Figure 1**. Two years later Beams and Haynes demonstrated practical separation of chlorine isotopes. In 1938 the Nobel prize winner Urey suggested multiplying the separating effect between axis and periphery of a rotor produced by centrifugal forces by introducing countercurrent convection (like a fractionating column) within the spinning tube. At the end of the 1930s Groth and co-workers in Germany started to construct a high speed centrifuge for uranium isotope separation with axial countercurrent flow induced

Figure 1 Schematic drawing of Beams' first successful evaporative centrifuge used to separate chlorine isotopes.

by heating the bottom of a rotor and cooling the top.

With the beginning of the Second World War in 1939, the separation of uranium isotopes became a subject of national importance. The experimental work on developing different types of gas centrifuges for uranium isotope separation was continued in Germany and was undertaken in the USA in the framework of the Manhattan Project. In that time, Dirac made fundamental contributions to the theory of the isotope separation process in a gas centrifuge, and Onsager's theory for calculation of separation efficiency in a thermal diffusion column was generalized for gas centrifuges by Cohen in 1951. They and their colleagues worked out a general mathematical model and demonstrated theoretically the ideal countercurrent flow profile to produce the maximum separation efficiency. Beginning in 1946, Steenbeck and Zippe contributed to the centrifuge development project in the USSR. Together with Russian co-workers, they developed a very elegant bearing system and adapted the scoop system of gas extraction not only to recover the gas from the rotor but also to generate the circulation flow to multiply the radial separating effect. After leaving the USSR in the mid 1950s, Zippe continued his activities in Germany and USA to reproduce the experiments that had been performed in USSR. In the USA, Zippe worked with Beams for about 2 years in the late 1950s. The Virginia short-bowl centrifuge, similar to the Russian design, was the result of their collaboration. A research and development programme for centrifugation was then pursued in the USA with the central effort located at the Department of Energy laboratories at Oak Ridge, Tennessee. In this programme, centrifuge rotors of an unprecedented length, of the order of 13 m were developed. The programme proved to be technically successful, but it was terminated in 1985 because of changes in US nuclear policies.

After the Second World War, centrifuge research programmes were initiated in several other countries: in the UK by Kronberger and Whitley; in France by Burgain and Le Manach; in Germany by Beyerle, Groth and Martin; in the Netherlands by Kistemaker and Los; in Japan by Kanagawa, Oyama and Takashima; and in Sweden by Landahl and associates.

The Soviet Union was the first country where this technology was developed on an industrial level. The first pilot plant, comprising 2500 gas centrifuges, was put into operation in 1957. The first industrial plant, which contained several tens of thousands of centrifuges, was commissioned in 1959. Soon after, USSR built an industrial plant with several hundred thou-

sand centrifuges configured in three levels and commissioned it in 1962–1964. Besides Russia, this method was commercialized at the end of the 1970s by the UK, Germany and the Netherlands collaborating and in the 1980s by Japan. At present, gas centrifugation is the most efficient, economic and reliable technology for production of enriched uranium.

Principles of Operation

The history of the development of a gas centrifuge for uranium isotope separation provides an excellent example of successfully overcoming numerous experimental and theoretical problems in the fields of physics of separation processes, gas dynamics, materials science, mechanical engineering and physical chemistry. The short-bowl centrifuge patented in 1957 by Zippe, Scheffel and Steenbeck is shown in Figure 2. The thin-walled vertical cylindrical rotor is suspended at the bottom by a low friction needle bearing and at the top by a frictionless magnetic bearing. It also uses damping bearings to resist vibrations at both ends of the rotor. In the case of the separation of uranium isotopes, uranium hexafluoride (UF_6) is introduced into the spinning rotor from a stationary central post and removed from stationary pipes called scoops located at either end of the

Figure 2 Schematic drawing of Zippe-type centrifuge.

rotor. In practice, the gas centrifuge is spun in a vacuum housing that is maintained by a Holweck-type spiral groove molecular pump. The very high peripheral speeds (for example, in the order of 600 m s^{-1}) generate centrifugal forces that compress the process gas into a thin stratified layer adjacent to the cylindrical wall of the rotor.

Separation Factor

The action of centrifugal forces causes a partial separation of isotopes along the rotor radius. If we consider the process gas to be a binary mixture of the two isotopic species $^{235}\text{UF}_6$ and $^{238}\text{UF}_6$, then the heavier molecules containing $^{238}\text{UF}_6$ will tend to be concentrated near the cylinder wall and the lighter molecules containing $^{235}\text{UF}_6$ will tend to be concentrated near the axis. Considering UF_6 as an ideal gas, a pressure gradient is developed which is governed by eqn [1]:

$$\frac{dp}{dr} = \frac{Mp}{RT}\omega^2 r \quad [1]$$

Here p is the pressure, M is the molecular weight of the gas, R is the gas constant, T is the absolute temperature, ω is the angular frequency of rotation and r is the radial coordinate. In the case of an isothermal centrifuge, the equation above is readily integrated to yield the following relation:

$$p(r) = p(0)(M\omega^2 r^2/2RT) \quad [2]$$

that gives the pressure $p(r)$ at any radial position r in terms of the pressure at the axis $p(0)$. For a mixture of two ideal gases of molecular weights, M_1 and M_2 , each gas would have a pressure governed by eqn [2] and the ratio of the two pressures gives the radial separation under equilibrium conditions (i.e. no axial gas circulation). An equilibrium separation factor between the two gases is therefore given by the expression:

$$\alpha_0 = \frac{x_1(0)/x_1(a)}{x_2(0)/x_2(a)} = \exp[(M_2 - M_1)\omega^2 a^2/2RT] \quad [3]$$

in which x_1 and x_2 are the concentrations of species 1 and 2, respectively, and a is the radius of the rotor.

The fundamental advantage of this technique over many other diffusion separation methods is that the primary isotope separation effect occurs at thermodynamic equilibrium. It should also be noted that the separation factor for the centrifuge process is a function of the absolute difference in the molecular weights of the components being separated. This is in contrast to various diffusion separation

processes where it is a function of the ratio of the molecular weights.

Separative Capacity

The stationary scoop at the top of the rotor induces a countercurrent flow by removing both mass and angular momentum, which induces pumping of the gas radially inward, forcing it to travel down near the axis and up along the cylinder wall. In order to prevent the influence of the scoop at the bottom, it is shielded by a baffle that rotates with the rotor and has holes which allow the gas to enter the scoop chamber and be removed from the centrifuge. This countercurrent flow produces a net transport of heavy isotopes to the top of the rotor and a net transport of light isotopes to the bottom, establishing a concentration gradient in the axial direction that is considerably greater than the primary (radial) isotope separation effect. Therefore, the gas removed by the bottom scoop is enriched in $^{235}\text{UF}_6$ (a product stream) and the gas removed by the top scoop is depleted in $^{235}\text{UF}_6$ (a waste stream).

As manufacturing technology has improved, higher rotational speeds have been achieved to obtain greater separation performance. At these higher speeds, shock waves develop in front of the stationary scoop, and the temperatures associated with these shock waves are high enough to cause decomposition of the process gas. It is important to note that the speed of sound in UF_6 at room temperature is approximately 90 m s^{-1} , and the peripheral speed of rotation of the process gas in modern centrifuges can be more than seven times greater than this. One design that avoids this decomposition problem is to shield the upper scoop with a rotating baffle with two concentric systems of holes. One system is located near the periphery to allow gas to enter the scoop, and the other system is located nearer the axis of rotation to induce internal circulation. Again, this internal circulation creates an axial separation factor many times that of the basic radial separation factor. The design of scoops and systems of holes in both baffles (their position and size) together with the temperature distribution on the side wall are used to control the internal circulation value and rate.

In 1941, Dirac demonstrated that a gas centrifuge, no matter how it is operated, has the maximum theoretical capacity:

$$\delta U_{\max} = \rho D \left(\frac{\Delta M \omega^2 a^2}{2RT} \right)^2 \pi Z/2 \quad [4]$$

where Z is the length of the rotor, ΔM is the difference in molecular weights, ρ is the density of the

process gas, D is the coefficient of self-diffusion, and δU is the separative capacity in moles per unit time. Maximum pressure ratio, radial separation factor and separative work at various peripheral speeds of a gas centrifuge are presented in Table 1.

Design Principles

As is evident from eqn [4], the most important parameters in centrifuge technology are peripheral rotor speed and rotor length. The peripheral speed is limited by the strength of the rotor material. Hence, gas centrifuges require materials which have a high strength to density ratio. Such materials are aluminium alloys, titanium alloys, alloy steels or fibre composites. The centrifuge rotor can be made of more than one layer; for example, aluminium alloy covered with fibre composites. The materials problems include long-term fatigue and creep at high speeds. Because uranium hexafluoride forms hydrofluoric acid even with only a little moisture, corrosion is also a challenging problem area that must be addressed in the design.

The spinning rotor has certain natural frequencies determined by the materials of construction, the rotor length to diameter ratio, and the damping characteristics of the suspension systems. Centrifuges that operate at rotational frequencies below the lowest natural flexural frequency of the rotor are called subcritical centrifuges, and those that operate at rotational frequencies above the first natural frequency are called supercritical ones. As a rule, the rotors of supercritical machines consist of sections connected by bellows that act to reduce vibrations caused by resonant frequencies at certain operating speeds.

The Dirac maximum separative capacity has been derived for the case of an ideal circulation profile in a gas centrifuge. However, this ideal profile cannot be achieved in practice. The flow patterns that actually occur within a centrifuge rotor are governed by the

equations of fluid dynamics. The theoretical solution of these equations provides a basis for the optimization of the internal flow pattern that yields the maximum separation performance of a particular gas centrifuge design.

The flow pattern in a gas centrifuge can be divided into three regions in the radial direction, each with different flow features. Near the side wall, the flow is dominated by viscosity, and a strongly rarefied gas region (a vacuum core) is located near the axis of rotation. These two regions are connected by a transition region. The transition region as a rule occupies only a few per cent of the rotor radius, and its influence on separation is negligible. The vacuum core in modern centrifuges is spread over approximately three-quarters of the rotor radius. In this region the mean free path of the gas molecules is comparable with the rotor diameter. At these low pressures, the central core of the rotor cannot contribute to the isotope separation. As a result, the separation power of a gas centrifuge at high speeds increases only as the square of the peripheral speed instead of the fourth power, as given by the Dirac equation.

Cascade of Centrifuges

The separative work output of a single gas centrifuge is generally small compared to the total desired separative work. Hence, it is necessary to combine many centrifuges into a cascade to achieve the desired separation. Each stage of a cascade may have many centrifuges connected in parallel. This arrangement of the large number of centrifuges allows for simple replacement of a faulty individual centrifuge in the cascade. The considerable advantage of the centrifuges is that they need no special compressors for pumping gas through the cascade. The pressure difference required for pumping the gas through the cascade is generated by the dragging action of the scoops on the rotating gas. The cascade contains only centrifuges and piping. Thus, gas centrifuge enrichment of uranium uses only about 1/20th to 1/30th of the electricity per unit of separative work required by the gaseous diffusion process. The reliability of modern centrifuges allows them to operate nonstop for more than 15 years with a failure rate of only a few tenths of 1% per year. Once put into operation, gas centrifuges require no special preventive maintenance through their service lives, and the machines' separation characteristics remain practically constant over time. Provided that random failures occur, the fragments of the crashed machines can be left in the cascade because they will not have much effect on the overall cascade efficiency.

Separation of Nonuranium Isotopes

New Scientific Problems
